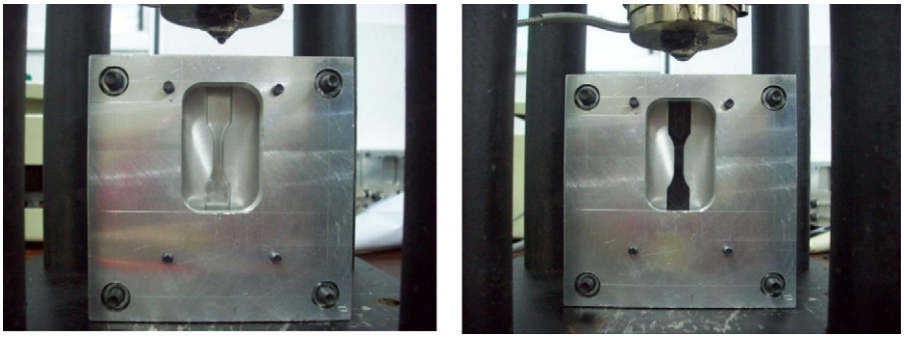
chamber is 30 mm in diameter and 50 mm in length, while outer diameter is 50 mm and covered by heater band and type *K* thermocouple for its feedback system. The thermocouple is attached to the bottom of the heater location. The maximum shot volume that can be held inside melting chamber is 2100 mm^3. The power requirement for heater band is 240 V and produces heat equivalent to 300 W. The heating rate used was 10 $^{\circ}C\,min^{-1}$. Plunger with diameter 30 mm and maximum 100 mm stroke length is connected to pneumatic piston. Compression spring mechanism is used to return melting chamber back to its original position. The compression spring has wire diameter 2.5 mm, outer diameter 22 mm, total length 93.70 mm, and number of free turn equal to 13. After testing with various loads for compression, the stiffness of this compression was 3.9.

1.15.3.2 Injection Mechanism

The plunger for injection motion was powered up by a pneumatic cylinder. The pneumatic cylinder was placed at the top plate and connected to the injection plunger through reduced size coupling. There are two ways to control injection speed: by controlling the input compressed air or by changing the pneumatic cylinder sizes which are 25, 40, and 80 mm in diameter. The movement of piston can be controlled manually by push start button on the control panel or automatically by push start timer. Using manual control, user has to press the start button for downward movement and again press release button for upward piston movement. For automatic piston controller, user is able to set the time for downward and upward piston movement. Therefore, injecting and holding time can be controlled.



1.15.3.3 Mold Design

The standard molds available in the market are unable to be used with this machine due to machine size and simplicity of the system. Therefore a mold has to be designed and fabricated to meet the specific machine requirement. The custom-made molds also have visualization capabilities which are able to track the plastic melt flow. For specific machine requirement, the maximum size of each mold in length, width, and thickness was 100 mm × 100 mm × 20 mm, respectively. The opening and closing of the mold have to be done manually with screw and nut mechanism. Definitely, it will increase the setup and opening time. The clamping forces are controlled by tightening the screw using torque wrench. The aluminum mold with polymethyl methacrylate (PMMA) transparent window allows user to see the plastic melt flow inside the mold cavity during filling phase. The term 'seeing is believing' was employed to understand the plastic melt flow behavior. Flow visualization technique is compared to quantitative data. Because human mind is designed to rapidly process an incredible amount of information with visualization. A timeline visualization method was used to track the plastic melt flow front during filling phase. Capability of this type of mold to visualize the flow behavior when plastic melts enters entire mold cavity will help user to understand more on the plastic part fabrication during injection phase. This will help in detecting molding problem through filling phase. The viewing window gives the user to capture the end of filling and starting of holding phase. But, aluminum/PMMA mold is not suitable for mass plastic parts production due to its inability to withstand the repeatable higher injection force and processing temperature in each cycle. By using a high speed video camera in-line with PMMA window, a melt flow through the mold cavity was observed. Figures 2(a) and 2(b) show aluminum mold with PMMA window before and after polypropylene (PP) was injected using the custom-made vertical injection molding machine.

1.15.4 Study of Straight, Reverse 'T' and Cross '+' Micro Channel Flow

This section will provide a detailed description of the mathematical fluid flow model and experiments of various shapes and sizes of micro channels. The section starts with the formulation of an analytical plastic flow model for fast and quick filling distance and analysis of results for various sizes of micro channel. The governing equations used in MoldFlow Part Advisor in solving plastic injection molding problems are discussed. Also, the governing equations used in ANSYS CFX software are discussed.

The investigations continue with fabrication of micro channels with straight, reverse 'T' and cross '+' shape with various mold cavity sizes. These mold cavities will be filled

(a) (b)

Figure 2 Aluminum/PMMA Mold (a) before injection and (b) after injection.

with PP using custom-made vertical injection molding machine. A study on the effect mold and melt temperatures on micro channel filling distance will be presented. The experimental objectives were to explore the flow behavior during simulation and actual injection process. Also, the effects of molding parameters on the micro channel filling distance are investigated. A MoldFlow, ANSYS CFX, and experimental results for each channel shape and sizes will be discussed thoroughly. The formation of plastic channel in different sizes with understanding the flow behavior requires specific mathematical model. Before any calculations can be done, replication of flow behavior in specific parts into mathematical model is mandatory. Mathematical modeling is an indispensable tool that gives constant demand for a better product quality. This generates interest in the analysis and the prediction of physical properties of the product.[63]

1.15.4.1 Mathematical Flow Model

As an introduction to this section, the conservation of mass principles on fluid flow modeling will be explained. The conservation of mass principle for a control volume is defined as the net mass transfer to or from a control volume during a time interval Δt. This is equal to the net change in the total mass within the control volume during finite time interval Δt. The equation is given by

$$\dot{m}_{\text{in}} - \dot{m}_{\text{out}} = \Delta m_{\text{CV}} = \frac{\mathrm{d}m_{\text{CV}}}{\mathrm{d}t} \quad [14]$$

where, $\dot{m}_{\text{in}}$ and $\dot{m}_{\text{out}}$ are the total rates of mass flow in and out of the control volume and $\frac{\mathrm{d}m_{\text{CV}}}{\mathrm{d}t}$ is the rate of change of mass within the control volume boundaries.

The mass flow rate $\dot{m}$ is the amount of mass flowing through a cross section per unit time is defined as

$$\dot{m} = \rho v_{\text{avg}} A_{\text{c}} = \rho \dot{v} = \frac{\dot{v}}{v} \quad [15]$$

where, v_{avg} is the average speed through the cross section and in integral form is

$$v_{\text{avg}} = \frac{1}{A_{\text{c}}} \int_{A_{\text{c}}} v_n \mathrm{d}A_{\text{c}} \quad [16]$$

The volume flow rate, $\dot{v}$ is the volume of fluid flowing through the cross section per unit time and expressed as

$$\dot{v} = \int_{A_{\text{c}}} V_n \mathrm{d}A_{\text{c}} = v_{\text{avg}} A_{\text{c}} = v A_{\text{c}} \quad [17]$$

The mass balance equations is applicable to control volume undergoing any fluid flow model.

$$\mathrm{d}m = \rho \mathrm{d}V \quad [18]$$

Therefore, the total mass within control volume

$$m_{\text{CV}} = \int_{\text{CV}} \rho \mathrm{d}V \quad [19]$$

For an incompressible steady flow, the $\frac{\mathrm{d}m}{\mathrm{d}t}$ term in the conservation of mass equation is equal to zero. In other words, 'What goes in must come out' or

$$\sum_{\text{outlets}} \dot{m} = \sum_{\text{inlets}} \dot{m} \quad [20]$$

As the flow is incompressible, the density is constant,

$$\dot{m} = \int_{\text{surface}} \rho V \bullet n \mathrm{d}A \quad \rho \int_{\text{surface}} V \bullet n \mathrm{d}A \quad [21]$$

The integral term of eqn [21] becomes volume flow rate, Q, therefore

$$\dot{m} = \rho Q \quad [22]$$

so the conservation of mass equation becomes:

$$\sum_{\text{outlets}} Q = \sum_{\text{inlets}} Q \quad [23]$$

Thus, $Q_{\text{out}} = VA$. Therefore, at an inlet $\dot{m}_{\text{in}} = \rho VA$ and $Q_{\text{in}} = VA$. The conservation of mass equation with simplification,

$$\sum_{\text{outlets}} \dot{m} - \sum_{\text{inlets}} \dot{m} = 0 \quad [24]$$

The formulation of eqns [14]–[24] will be used to explain the flow front position and behavior in reverse 'T' and cross '+' micro channels.

Another important parameter when working with non-Newtonian fluid is the viscosity. For clarity, the viscosity formulation is explained with an example of straight channel. The basic melt flow viscosity in a straight channel can be explained using drag flow in order to identify the shear stress τ and shear rate $\dot{\gamma}$.

Movement of plastic melt flow at each layer as shown in Figure 3 is sustained by the motion of the left side while the right side remained stationary. A force, F is required to maintain the motion while the right side moves at velocity, v.

The shear stress, τ is given by

$$\tau = \frac{F}{A} \quad [25]$$

the shear rate is proportional to the velocity gradient,

$$\dot{\gamma} = \frac{\mathrm{d}v}{\mathrm{d}x} \quad [26]$$

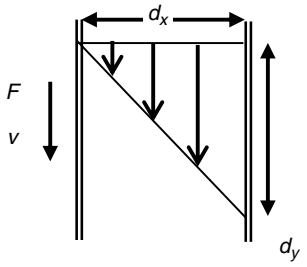


Figure 3 Plastic melt flow at each layer.

For plastic melt, assuming the shear rate proportional to the strain rate, $\tau = -\eta\dot{\gamma}$, where η is Power Law viscosity model from eqn [1].

1.15.4.1.1 MoldFlow flow model

The Moldflow Part Advisor filling simulations is to formulate from Generalized Hele-Shaw (GHS) flow model for a viscous plastic melt under non-isothermal conditions, non-Newtonian and inelastic flows as stated by Kennedy.[64] This model was used by several researchers[29,62] to simulate the plastic flow behavior in plastic injection molding. They used this approach to model polymer melt flow in the 3D thin cavities. Due to complicated 3D configurations and plastic melt rheological behavior, Su[38] simplified the flow model with the following assumptions:

1. Smaller cavity thickness compared to other dimensions.
2. Velocity component in thickness direction is zero.
3. A fully developed Hele-Shaw flows regions.

In this way, the GHS flow model significantly simplified the equations to 2D fluid flow problems. This approach also can be applied to power law fluid, Cross-Carreau and modified cross fluid flow model. It also applies to no isothermal flow in which the hot plastic melts freezes on the cold mold wall. Fluid flow problems involve solution of the equations that express conservation of mass, momentum, and energy. The conservation equations[64] are

$$\text{Mass}: \quad \frac{\partial \rho}{\partial t} + (\nabla \cdot \rho v) = 0 \qquad [27]$$

$$\text{Momentum}: \quad \rho \frac{\partial v}{\partial t} = -\nabla \rho + \left[\nabla \cdot \eta \underline{\dot{\gamma}}\right] - \rho[v \cdot \nabla v] \qquad [28]$$

$$\text{Energy}: \quad \rho c_P \left(\frac{\partial T}{\partial t} + v \cdot \nabla T\right) = \beta T \left(\frac{\partial p}{\partial t} + v \cdot \nabla T\right) + \eta\dot{\gamma}^2 + \nabla \cdot (k \nabla T) \qquad [29]$$

The viscosity of plastic is dependent on temperature, pressure and shear rate, therefore the sevent-constants cross-WLF viscosity model is used in MoldFlow simulation. The relationship of the variables is described in eqns [5] and [6]. An extra complexity in injection molding simulation is the need to incorporate a density variation as a function of temperature and pressure. The equation relates the material specific volume, pressure, and temperature are referred to as the material's pressure volume temperature (PVT) characteristic. It is complex equations and varies depending on the type of material.[64] The specific volume approach in MoldFlow is represented by the modified Tait equation.

The modified two-domain Tait PVT model has 13 constants which capture the effects of temperature and pressure on density. The modified two-domain Tait PVT model is given by the following equations:

$$V(T,P) = V_0(T)\left[1 - C\ln\left(1 + \frac{P}{B(T)}\right) + V_t(T,P)\right] \qquad [30]$$

For the upper temperature region ($T > T_t$), the V_0, $B(T)$ $V_t(T, P)$ parameters for eqn [30] can be described by following equations:

$$V_0 = b_{1m} + b_{2m}(T - b_5) \qquad [31]$$

$$B(T) = b_{3m}\exp[-b_{4m}(T - b_5)] \qquad [32]$$

$$V_t(T,P) = 0 \qquad [33]$$

For the lower temperature region ($T < T_t$), the V_0, $B(T)$, $V_t(T,P)$ parameter for eqn [30] can be described by following equations:

$$V_0 = b_{1s} + b_{2s}(T - b_5) \qquad [34]$$

$$B(T) = b_{3s}\ \exp[-b_{4s}(T - b_5)] \qquad [35]$$

$$V_t(T,P) = b_7\exp[(b_8(T - b_5)) - (b_6 P)] \qquad [36]$$

Also, the effect of T_t on pressure can be described by the equation:

$$T_t(P) = b_5 + b_6 P \qquad [37]$$

From PVT diagram in MoldFlow database for PP, the transition temperature varies between 75 and 125 °C for specific pressure and volume.

1.15.4.1.2 ANSYS CFX flow model

The ANSYS CFX software has more flexibility in modeling a plastic flow by allowing user to modify lot of flow model parameters compared to Moldflow part advisor. The software also enables user to modify or add an equation to the flow model which can give better correlation between simulation and experimental results. Even though Moldflow part advisor is better in producing faster result, ANSYS CFX is more reliable in analyzing a micro plastic flow problem. In formulating a plastic flow model using ANSYS CFX, the mold cavity is assumed to be filled by air. The plastic melts pushes the air from cavity and replaces it with plastic. Therefore, a multiphase approach or two phases flow is suitable to model this plastic flow problem.

The governing equations required to solve the plastic flow problem are multiphase continuity equation, momentum, and energy conservation equations. The governing equations are solved with rheological characteristic of the selected material. The ANSYS CFX solves the governing equations using Cartesian spatial coordinates and velocity components. The multiphase linear momentum equation is:

$$\frac{\partial}{\partial t}(r_\alpha \rho_\alpha v_\alpha) + \nabla.(r_\alpha(\rho_\alpha v_\alpha . v_\alpha)) = -r_\alpha \nabla P_\alpha + \nabla.\left(r_\alpha \mu_\alpha \left(\nabla v_\alpha + (\nabla v_\alpha)^T\right)\right) + \sum_{\beta=1}^{N_\alpha}\left(\Gamma^+_{\alpha\beta} v_\beta - \Gamma^+_{\beta\alpha} v_\alpha\right) + S_{M\alpha} + M_\alpha \qquad [38]$$

The $\left(\Gamma^{+}_{\alpha\beta}v_{\beta} - \Gamma^{+}_{\beta\alpha}v_{\alpha}\right)$ term represents momentum transfer by interphase mass transfer.

The continuity equation for multiphase problem is defined as:

$$\frac{\partial}{\partial t}(r_{\alpha}\rho_{\alpha}) + \nabla.(r_{\alpha}\rho_{\alpha}v_{\alpha}) = S_{\mathrm{MS}\alpha} + \sum_{\beta=1}^{N_{\alpha}}\Gamma_{\alpha\beta} \qquad [39]$$

A transient simulation is selected for simulating the filling process of the plastic melt. In order to generate the free surface of the plastic melt at every time step, the melt front was tracked using a volume of fluid method. The volume of fluid equation is:

$$\sum_{\alpha}\frac{1}{\rho_{\alpha}}\left(\frac{\partial}{\partial t}(r_{\alpha}\rho_{\alpha}) + \nabla.(r_{\alpha}\rho_{\alpha}v_{\alpha})\right) = \sum_{\alpha}\frac{1}{\rho_{\alpha}}\left(S_{\mathrm{MS}\alpha} + \sum_{\beta=1}^{N_{\mathrm{P}}}\Gamma_{\alpha\beta}\right) \qquad [40]$$

Instead of energy conservation equation, the thermal energy also considers the plastic melt viscous dissipation during mold filling. The thermal energy equation is:

$$\frac{\partial(\rho e)}{\partial t} + \nabla\cdot(\rho U e) = \nabla\cdot(\lambda\nabla T) - P\nabla\cdot U + \tau:\nabla v + S_{\mathrm{E}} \qquad [41]$$

The term $\tau{:}\nabla v$ is always positive and called the viscous dissipation
where

$$e = h - \frac{P}{\rho}$$

h is the internal energy.

1.15.4.1.3 Suggestion non-Newtonian viscosity model

Using ANSYS CFX simulation package, a proposed modified cross viscosity model was included in the plastic melt flow modeling. The non-Newtonian cross viscosity model used in ANSYS CFX package was

$$\eta = \frac{\eta_0}{1 + (\lambda\dot{\gamma})^{n}} \qquad [42]$$

where the η_0 is defined as

$$\eta_0 = D_1\exp\left[-\frac{A_1(T - D_2)}{A_2 + (T - D_2)}\right] \qquad [43]$$

where n, D_1, D_2, D_3, A_1 and A_2 are the constants specific for plastic material. The respective values for PP at melt temperature 240 °C were 0.275 1, 24 200 Pa, 4.66e + 012 Pa s, 263.15, 0 K Pa^{-1}, 26.12, and 51.6 K.[65] Yao and Kim[62] used eqn [13] proposed by Eringen and Okada[61] to model micro plastic flow incorporating micro functions relating size, travel length, cross section area, etc. The η_0 will be

$$\eta_0 = D_1\exp\left[\frac{-A_1(T - D_2)}{A_2 + (T - D_2)}\right] \times f_{(\mathrm{microscopic})} \qquad [44]$$

In order to identify the $f_{(\mathrm{microscopic})}$, experiments on various micro channel sizes will be conducted. Also the effect of melt and mold temperature will be considered.

1.15.4.2 Micro Channel Fabrication and Experimental Design

Many researchers investigated the effect of molding parameters on the flow behavior and filling distance. Sha *et al.*[66] fabricated various sizes of micro channels to identify injection molding factors that affect the achievable aspect ratios. The factor included barrel temperature, mold temperature, injection speed, holding pressure, the air evacuation, and the micro feature sizes. Yao and Kim[62] fabricated a micro channel to investigate the microscale phenomena on the micro channels filling process. The finding indicated that the micro channel cavities were filled almost isothermally by using microscale viscosity and wall slip effect. Young[67] also fabricated a micro channel mold to find the effect of mold temperature, injection rate, and micro channel sizes on the filling distance. A simplified flow model was developed to estimate the filling distance into the micro channels from the main channel. The filling distance increased with respect to the increment of the channel sizes, mold temperature, and injection rate.

1.15.4.2.1 Micro channels mold fabrication

An aluminum mold with visualization windows was used in this experiment. Each channel was milled using DT110 multipurpose micro machine, which was suitable for micro channel fabrication on aluminum mold. In order to understand the melt plastic flow behavior in macro, transition from macro to micro and micro size, and the channel sizes fabricated were 1.0, 0.8, 0.5, 0.4, and 0.3 mm. Three types of micro channels namely straight, reverse 'T' and cross '+' shape channel as shown in Figure 4 were studied.

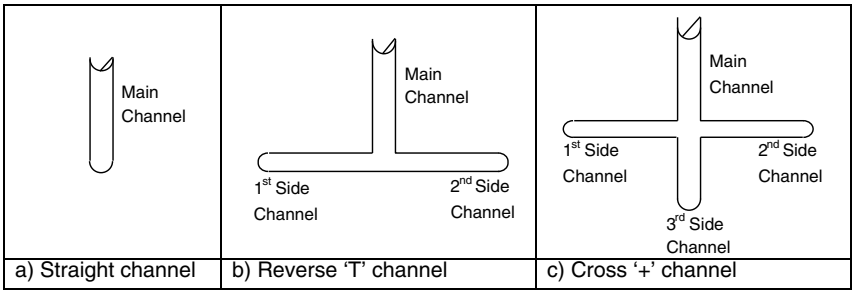

Figure 4 Shape of straight, reverse 'T' and cross '+' shape channel.

Table 1 Reverse 'T' and cross '+' shape channel size combination

			Main channel (mm)		
			1.0	*0.8*	*0.5*
Side channel (mm)	Reverse 'T'	1.0	X		
		0.8	X	X	
		0.5	X	X	X
	Cross '+'	1.0	X		
		0.8	X	X	
		0.5	X	X	X

The combination of main and side channel for reverse 'T' and cross '+' shape channel is shown in Table 1. In total, 17 molds were fabricated for straight, reverse 'T', and cross '+' shape channels.

1.15.4.2.2 Experimental design

The experiments were designed to evaluate the flow behavior and filling capabilities at different mold and melt temperatures. Then performance of software analysis simulation was compared with the actual injection process. The comparison was based on the micro channel size and shape. PP was selected as the molding material. The injection molding parameter used in this experiment was mold and melt temperatures. The custom-made vertical injection molding machine can be operated up to 0.8 MPa of compressed air input. The compressed air supply to pneumatic piston was 0.8 MPa and the piston size was 80 mm. The minimum mold temperature suggested for PP is the room temperature and maximum of 60 °C. For the experiments, three levels of mold temperature were selected, which were 25 (room temperature), 35, and 50 °C. Allowable melt temperature for PP was between 240 and 260 °C. Therefore, 240, 250, and 260 °C were chosen as melt temperature variables. A high speed video camera with capability of 210 fps was used to capture the melt flow from starting position at macro section to micro section until its solidified at some distance of travel.

Each micro channel experiment was repeated three times and the filling distance was measured using digital microscope. The same experimental procedures were applied to reverse 'T' and cross '+' micro channel shapes. The flow behavior of reverse 'T' and '+' shape micro channel with different sizes will be explained through conservation of mass and energy, then compared with visualization of flow from actual experiments. Each shape and size with various mold and melt temperature will be discussed with regard to filling capability aspects.

The experiments on the effect of mold and melt temperature on micro channel filling distance were conducted and verified with analytical, MoldFlow software, and ANSYS CFX simulation results. The increment of mold or melt temperature should increase the filling distance. This study was extended to utilize the ANSYS CFX which used governing equations with more flow constant and complex parameters including viscosity model. ANSYS CFX allowed user to include suitable equation to make the flow simulation close to experimental results. In order to predict simulation result close to experiment results, the cross viscosity model was embedded with micro function in ANSYS CFX flow model as explained in Section 1.15.4.2. The micro function used in the cross viscosity model will be developed through experimental work on various sizes of micro channel.

1.15.4.3 Experiments and Simulation for Straight Channel

This section describes the analytical, MoldFlow, ANSYS CFX, and experimental filling results of straight micro channel in various sizes. The filling time results are also presented in all the three cases. For the purpose of comparison with experimental results, only filling distance and time results will be presented. The filling distance capabilities in each straight micro channel at various combinations of mold and melt temperature will be discussed. In each straight micro channel result, an example figure of MoldFlow, ANSYS CFX, and experiment are shown to explain the cavity pressure distribution and filling capabilities. Specific η_0 value used in ANSYS CFX simulation is highlighted and used in the formulation of a modified cross viscosity model for specific straight micro channel size.

1.15.4.3.1 0.8 mm straight micro channel

Figure 5 shows filling distance and pressure distribution of MoldFlow, ANSYS CFX, and experiment when mold temperature was 35 °C and melt temperature was 240 °C. The MoldFlow filling distance prediction was less compared to ANSYS CFX and actual experiment. The maximum pressure achieved in MoldFlow analysis was 3.13 MPa and in ANCYS CFX, it was 1.433 MPa with η_0 value equal to 346.53 Pa s.

A very close filling distance was found between ANSYS CFX and experiment compared to MoldFlow prediction as shown in Figure 6. It shows that, to achieve longer filling distance, modification of temperature can be made either with mold or melt temperature. But, in experiment, there is no need to increase the melt temperature to achieve the same filling distance result when the mold temperature was 25 °C. There is an unrealistic result shown when mold was heated at 35 °C and melting temperatures were 240 and 260 °C. The percentage difference in mold filling distance recorded in ANSYS CFX when compared to experiment was 1–3%, whit it was between 10 and 15% when compared with MoldFlow results. On the other hand, MoldFlow shows much close prediction with ANSYS CFX and experiment at mold temperature 25 °C and melt temperatures of 240 and 250 °C.

1.15.4.3.2 Discussion on straight micro channel

For 1.0–0.8 mm straight micro channels, analytical, experimental, ANSYS CFX, and MoldFlow showed almost similar mold filling distance trend. For the 0.5, 0.4, and 0.3 mm straight micro channels, MoldFlow results showed inconsistent filling trend as expected, which was incremental filling distance as the mold and melt temperature increased. Figure 7 shows an average percentage difference in filling distance for various sizes of straight micro channels. The percentage difference of MoldFlow result when compare with experiments was in between 10 and 60%. The percentage difference in filling distance for analytical result was in between 5 and 22%. It is considered higher, but it was due to simplification and

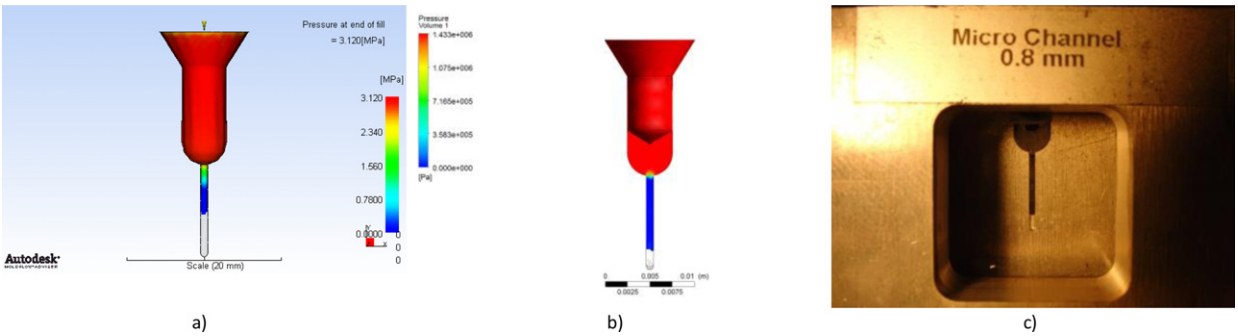

Figure 5 Example of pressure distribution and filling capability for 0.8 mm micro channel at 35 °C mold temperature and 240 °C melt temperature (a) MoldFlow, (b) ANSYS CFX, and (c) experimental.

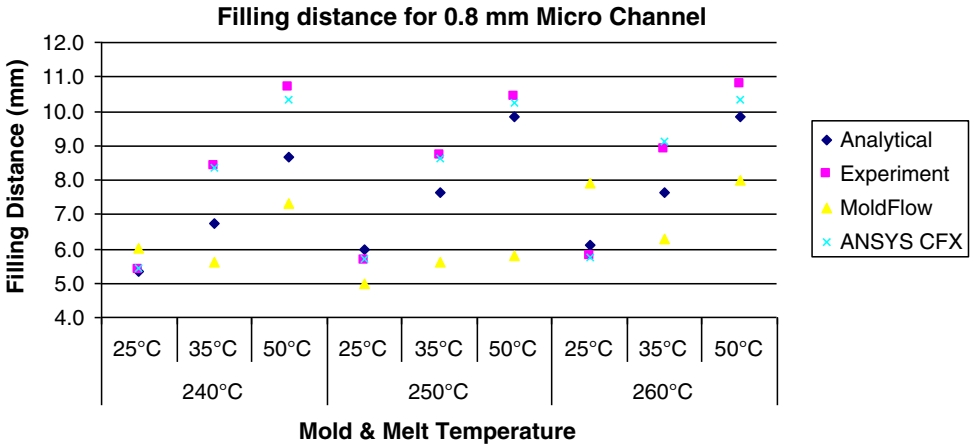

Figure 6 Filling distance for 0.8 mm micro channel with various mold and melt temperature combinations.

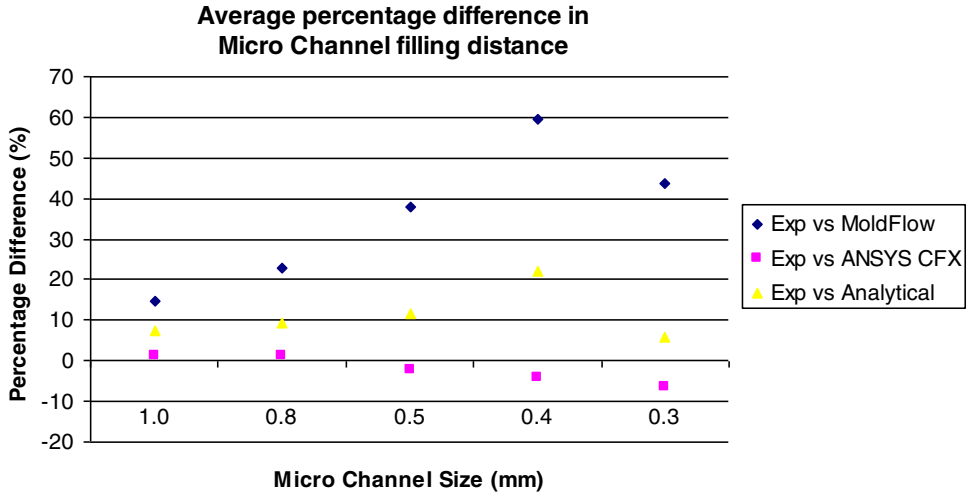

Figure 7 Average percentage differences in mold filling distance for various sizes of straight micro channel.

assumption during equations formulation. With proper modification of cross viscosity model used in ANSYS CFX, the percentage difference recorded was less than 10% for all micro channel sizes at various mold and melt temperatures.

As reported by Shen *et al.*[35,36] a mold temperature above the glass transition temperature of plastic is the most important factor for improving the replication capability of micro injection molding. Also, increment in melt temperature will

increase the filling distance. However, from analysis and experiments, it was not applicable for 0.5, 0.4, and 0.3 straight micro channels. Therefore another molding factor has to be considered for micro channel smaller than 0.5 mm.

1.15.4.3.3 Modified cross viscosity model for straight micro channels

After finalizing the average value of η_0 for each micro channel size, the suggestion for cross viscosity model is explained in this section. From eqns [42], [43], and [44], formulation of the proposed cross viscosity model is explained in Table 2. The acceptable η_0 value for each micro channel is based on maximum pressure recorded for both MoldFlow and ANSYS CFX simulation.

From Table 1, the proposed cross viscosity model formulation from the analysis of eqn [44] becomes

$$\eta_0 = D_1 \exp\left[\frac{-A_1(T-D_2)}{A_2+(T-D_2)}\right] \times C\left[\frac{\pi j^2}{2}\right] \quad [45]$$

where C is a constant between 0.7 and 0.8, except for 0.4 mm micro channel. Therefore

$$f_{(\text{microscopic})} = CA_{\text{cross section}} \quad [46]$$

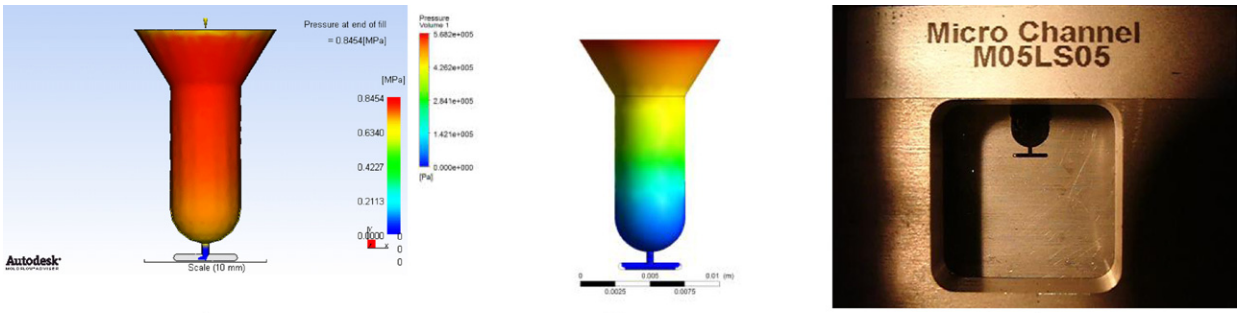
1.15.4.4 Experiments and Simulation for Reverse 'T' Shape Micro Channel

This section explains the filling capabilities of a reverse 'T' shape micro channel at various mold and melt temperature. As the side channel is symmetrical, the filling distance result is only presented at its first side channel only. Examples of filling capabilities results from MoldFlow, ANSYS CFX simulation, and experiments are presented. A suitable η_0 value for cross viscosity model was used by comparing pressure result from MoldFlow simulation. Small percentage difference between MoldFlow and ANSYS CFX pressure results is acceptable in defining the value of η_0. Each micro channel size combination will be discussed based on the filling distance under the effect of mold and melt temperatures.

Table 2 Formulation of constant, C, for various micro channel sizes

Micro channel size	*η_0 (without microscopic)*	*η_0 (with microscopic)*	*$f_{(\text{microscopic})}$*	*Cross sectional area/2*	*Constant*
1.0	1846.53	546.53	0.295 9	0.392 8	0.753 6
0.8	1846.53	346.53	0.187 6	0.251 4	0.746 6
0.5	1846.53	146.53	0.079 3	0.098 2	0.808 2
0.4	1846.53	46.53	0.025 2	0.062 9	0.400 9
0.3	1846.53	46.53	0.025 2	0.035 3	0.712 9

1.15.4.4.1 M05⊥S05 reverse 'T' micro channel



The MoldFlow, ANSYS CFX, and experiment results for M05⊥S05 with micro channel at 35 and 240 °C of mold and melt temperatures respectively are shown in Figure 8. The maximum pressure achieved in MoldFlow analysis was 0.8454 MPa and 0.5588 MPa in ANSYS CFX with η_0 value equal to 36.53 Pa s. The ANSYS CFX result shows almost similar filling capabilities as that of experiment.

The capabilities of flow front to travel at maximum side channel for M05⊥S05 micro channel at various mold and melt temperatures are shown in Figure 9. From the figure, MoldFlow result shows very small mold filling distance at various molds and melts temperature combinations. The 2.0 mm filling distance is maximum distance at each side channel. ANSYS CFX was capable to fill-up all cavities at 50 °C mold temperature and at all melt temperatures. While, the experimental result shows complete filling when melt temperature was 260 °C.

1.15.4.4.2 Discussion on reverse 'T' micro channel

With proposed η_0 for each reverse 'T' micro channel, the ANSYS CFX was able to predict more accurate result close to experimental results compared to MoldFlow simulation for M10⊥S10, M10⊥S08, and M08⊥S08 reverse 'T' micro channels. For reverse 'T' micro channel which has side channel less than 0.8 mm, the MoldFlow was unable to predict the filling distance any closer to experiments results.

With the aim to reduce viscosity in micro channel, it will not be able to help the flow front travel to the end of the cavity. It has to incorporate other factors such as surface roughness and area to travel length ratio. Longer length in the side channel will increase travel length to area ratio and it will also increase the heat loss during its travel to the end of cavity length. Figure 10 shows the average percentage difference in reverse 'T' micro channel filling

a) b) c)

Figure 8 Example of pressure distribution and filling capability for M05⊥S05 micro channel at 35 °C mold temperature and 240 °C melt temperature (a) MoldFlow, (b) ANSYS CFX, and (c) experimental.

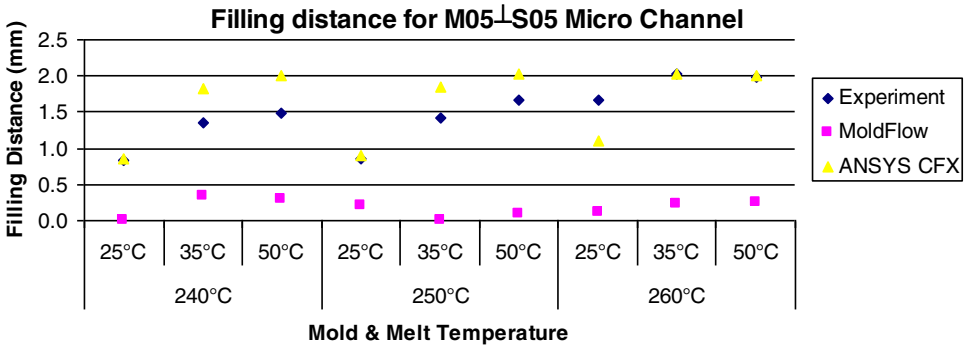


Figure 9 Filling distance for M05⊥S05 micro channel with various mold and melt temperature.

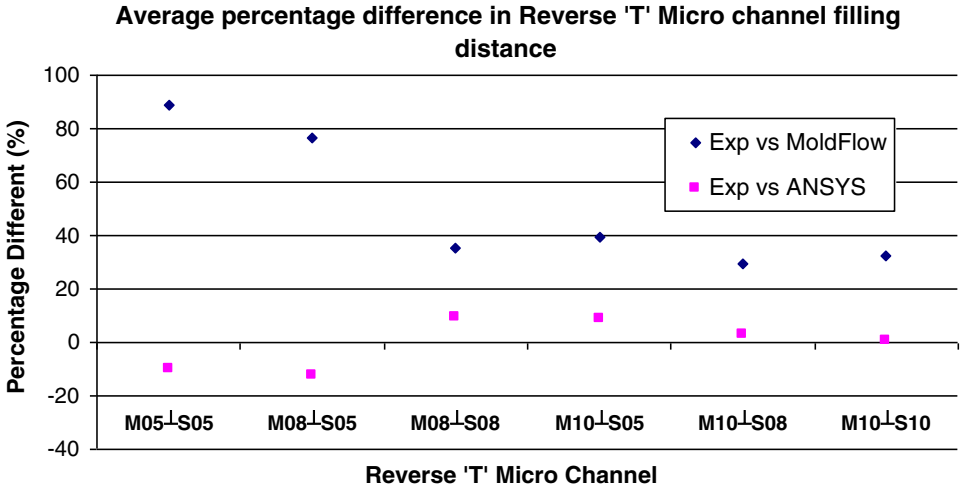

Figure 10 Average percentage differences in filling distance for various sizes combination of reverse 'T' micro channel.

distance with various sizes and combinations. Overall, the percentage difference recorded for ANSYS CFX when compared to experimental result showed a difference less than 20%. On the other hand, MoldFlow simulation showed much higher percentage difference which was between 20 and 90%.

1.15.4.4.3 Modified cross viscosity model for reverse 'T' micro channels

After finalizing the value of η_0 for each micro channel size combination with ANSYS CFX software, the suggestion for extended cross viscosity model is explained in this section. From eqns [42], [43], and [44], formulation of the analysis extended η_0 value for reverse 'T' micro channel and is shown in Table 3.

From Table 3, the proposed cross viscosity model formulation from eqn [44] becomes

$$\eta_0 = D_1 \exp\left[\frac{-A_1(T-D_2)}{A_2+(T-D_2)}\right] \times C\left[\frac{A_1+A_2+A_3}{3}\right] \quad [47]$$

where, CA_1 is the cross sectional area for main channel, CA_2 is the cross sectional area for first side channel and CA_3 is the cross sectional area for second side channel. From Table 2, C is the constant (0.1–0.3). Therefore the proposed η_0 for cross viscosity model formulation from eqn [47] becomes

$$\eta_0 = D_1 \exp\left[\frac{-A_1(T-D_2)}{A_2+(T-D_2)}\right] \times C\left[\frac{\left(\frac{\pi j_m^2}{2}\right)+\left(\frac{\pi j_1^2}{2}\right)+\left(\frac{\pi j_3^2}{2}\right)}{3}\right] \quad [48]$$

1.15.4.5 Experiments and Simulation for Cross '+' Micro Channel

This section present the experimental, MoldFlow, and ANSYS CFX results on pressure distribution and filling distance for cross '+' micro channel with various mold and melt temperature combinations. It starts with explaining the flow front position at specific location using mass flow rate, followed by cross '+' micro channel pressure distribution, and filling capability examples. Then it continues with filling distance capabilities for each micro channel size combinations. Modified cross viscosity model suitable for cross '+' micro channel was formulated through results from ANSYS CFX simulation which was based on pressure distribution results from MoldFlow analysis.

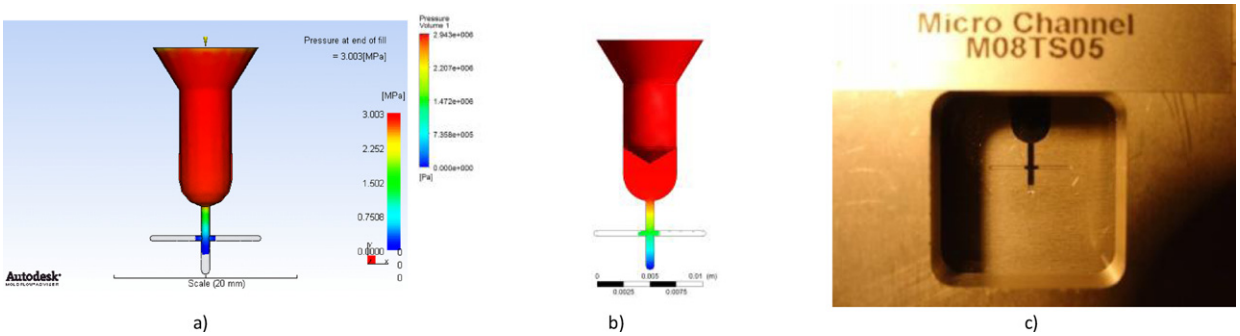

Figure 11 Example of pressure distribution and filling capability for M08 + S05 micro channel at 25 °C mold temperature and 240 °C melt temperature (a) MoldFlow, (b) ANSYS CFX, and (c) experimental.

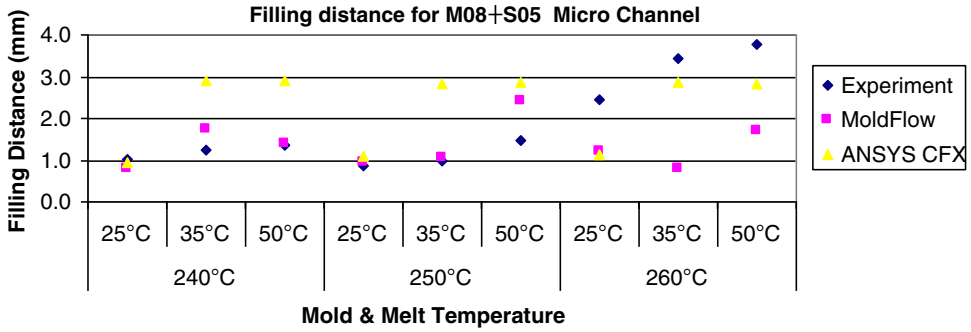

Figure 12 Filling distance for M08 + 05 micro channel with various mold and melt temperature.

1.15.4.5.1 M08+S05 cross '+' micro channel

Figure 11 shows a M08 + S05 micro channel experimental filling capabilities, MoldFlow, and ANSYS CFX pressure distribution results. Mold temperature of 25 and 240 °C melt temperature were applied during the testing. MoldFlow and experimental results showed incomplete filling in third side channel but ANSYS CFX simulation showed better filling capabilities. A 39.53 Pa s was applied for η_0 value in ANSYS CFX cross viscosity model. A 3.003 MPa of maximum pressure was recorded in MoldFlow but ANSYS CFX simulation yielded only 2.643 MPa and showed a complete filling in third side channel.

The maximum filling distance recorded for M08 + S05 micro channel with various mold and melt temperature combinations is shown in Figure 12. A 4.0 mm filling distance is considered as full filling in first and second side channel. The filling distance increased with the increase of mold and melt temperatures. When mold temperature was heated at 35 and 50 °C, ANSYS CFX simulation showed filling distance reaching 3.0 mm for all three melt temperatures. MoldFlow did not show a large filling distance increment even with increment of mold and melt temperatures. The percentage difference between experiment and ANSYS CFX was 2–5%. However the difference was 6–12% when compared with MoldFlow results.

1.15.4.5.2 Discussion on cross '+' micro channel

With suitable η_0 value used in each size and combination of cross '+'micro channel, the ANSYS CFX are capable to predict

filling distance in one of its side channel with low percentage difference when compared to actual experimental results. Filling distance recorded for M10 < S10 and M10 < S05 micro channels showed a complete cavity filling for both ANSYS CFX and experimental results when the mold was heated at 50 °C and melt temperature was set at all three levels.

There are unique flow front behavior recorded when flow was observed at each time interval for M10 + S05 and M08 + S05 micro channels. MoldFlow result showed flow front splitting into three directions when reaching a junction and the filling distance almost equal at each direction. But, experimental flow front results showed the filling distance in third side channel was much longer compared to first and second side channels. The same results were observed in ANSYS CFX simulations. The main and third channel flow direction was in vertical, while the first and second sides were in horizontal directions. As the first and second side channels were smaller than main and third side channel, the flow front traveled easily to bigger channel compared to the smaller channel. After the flow front reached the end of third side channel, the flow front was still in liquid condition. Therefore the flow front was filling more to this side channel.

For M05 + S05, ANSYS CFX result showed a complete cavity filling at third side channel identical to that produced in experiments. But, MoldFlow was unable to simulate the flow capabilities after the flow front leaving the junction. Experimental result at 50 °C mold temperature and 260 °C melt temperature gave longer filling distance in their third side compared to ANSYS CFX result.

For a cross '+' micro channel with the same main and side channel sizes, experimental result showed a better filling distance capability when compared to various filling sizes in each channel as shown in M10 + S10 and M05 + S05 results. The average percentage difference in cross '+' micro channel filling distance with various sizes and combination is shown in **Figure 13**. For the same channel size of main and side channel, there was a very small percentage of difference except for M05 + S05.

1.15.4.5.3 Modified cross viscosity model for cross '+' micro channel

After finalizing the value of η_0 for each micro channel size combination with ANSYS CFX software, the suggestion for extended cross viscosity model is explained in this section. From eqns [42]–[44], η_0 values for cross '+'micro channel is shown in **Table 4**.

From **Table 4**, the proposed cross viscosity model formulation from eqn [44] becomes

$$\eta_0 = D_1 \exp\left[\frac{-A_1(T-D_2)}{A_2+(T-D_2)}\right] \times C\left[\frac{A_1+A_2+A_3+A_4}{4}\right] \quad [49]$$

where CA_1 is the cross sectional area for main channel, CA_2 is the cross sectional area for first side channel, CA_3 is the cross sectional area for second side channel, and CA_4 is the cross sectional area for third side channel. From **Table 4**, C is the constant (0.1–0.3). Therefore the proposed η_o for cross viscosity model formulation from eqn [49] becomes

$$\eta_0 = D_1 \exp\left[\frac{-A_1(T-D_2)}{A_2+(T-D_2)}\right] \times C\left[\frac{\left(\frac{\pi j_m^2}{2}\right)+\left(\frac{\pi j_1^2}{2}\right)+\left(\frac{\pi j_3^2}{2}\right)+\left(\frac{\pi j_4^2}{2}\right)}{4}\right] \quad [50]$$

1.15.5 Study on Macro and Micro Gear Shape Molding

This section describes the case study conducted in MoldFlow, ANSYS CFX, and experiments. Gear shape was selected as a case study. Gear shape resembles various micro channel sizes and flow front splitting. A gear is a toothed wheel designed to transmit torque to another gear or toothed component. Section 1.15.5.1 will discuss on the observation of flow orientation for macro gear shape with the purpose to track the flow front direction using MoldFlow and compare to real time experiments.

a) b)

Figure 14 Gear shape cavity fabricate on aluminum mold with PMMA window. (a) Cavity with macro teeth, (b) Cavity with micro teeth.

The case study components used in this section can be analyzed by MoldFlow software, therefore there is no need to use ANSYS CFX analysis. Section 1.15.5.2 describes the capabilities of plastic melt to fill-up all cavity section in micro gear shape with various sizes of teeth. The teeth was 1.0, 0.5, and 0.3 mm. Extending from full cavity filling, the behavior of flow front direction on each teeth size also will be discussed. Various combinations of mold and melt temperature were used during experiment ranging from 25 to 50 °C and 240 to 260 °C, respectively. For the purpose of this case study, only selected figures will be discussed and explained. Modified cross viscosity models were embedded in ANSYS CFX result as obtained from Sections 1.15.4.3, 1.15.4.4, and 1.15.4.5.

1.15.5.1 Macro Gear Shape

Two gear shapes of with macro and micro structure regions were selected and replicated on the mold cavities using the EDM technique as shown in Figure 14. A Sodick-EDM machine was used to replicate the gear shape to mold cavity.

The aim of these simulation was to examine the flow of plastic melt during filling phase, and then to compare them with the actual melt flow results. The comparison was done to evaluate the capability of MoldFlow for miniature products. MoldFlow was able to generate fill time result report, showing the flow path of the plastic through the mold cavity by plotting contours, which join regions filling at the same time. The fill time result is important because it can be used to predict the flow path inside the mold cavity. Figure 15(a) shows the melt front situation of macro gear shape during the filling stage of MoldFlow simulation and actual plastic injection experimentally. The filling time predicted by MoldFlow was 0.745 5 s, while in actual injection process, the filling time was 1.828 5 s. The variation could be due to the effect of shear resistance on the cavity wall which was neglected in MoldFlow filling model.

The flow front travels as a semicircle moving away from the gate. The semicircle flow front, right from the gate enters the cavity which happens to be the first gear tooth. After filling the first tooth cavity, the melt flows downward and fills the two teeth cavities located sideways. As the melt flows further downward, its meets a circular obstacle where the flows front separates and meets each other again after the obstacle. From this point, the melts flows downward and fills the remaining teeth cavities. An identical flow behavior has been observed in actual injection process as shown in Figures 15(b), 15(d), and 15(e).

The comparison between actual injection and flow simulation by MoldFlow for the micro gear shape can be seen in Figure 16. The filling time predicted by MoldFlow simulation was 0.5266 s, while the actual injection process was 3.742 8 s. Generally, the result of melt flow front from simulation and actual injection showed a similar pattern even though the total time taken in actual injection to fill-up all cavities was large. On the other hand, plastic melt can fill the micro gear shape cavity with lower velocity due to friction of the mold cavity wall and higher melt flow viscosity. The melt front viscosity increased at the smaller cavity which reduced the melt front temperature.

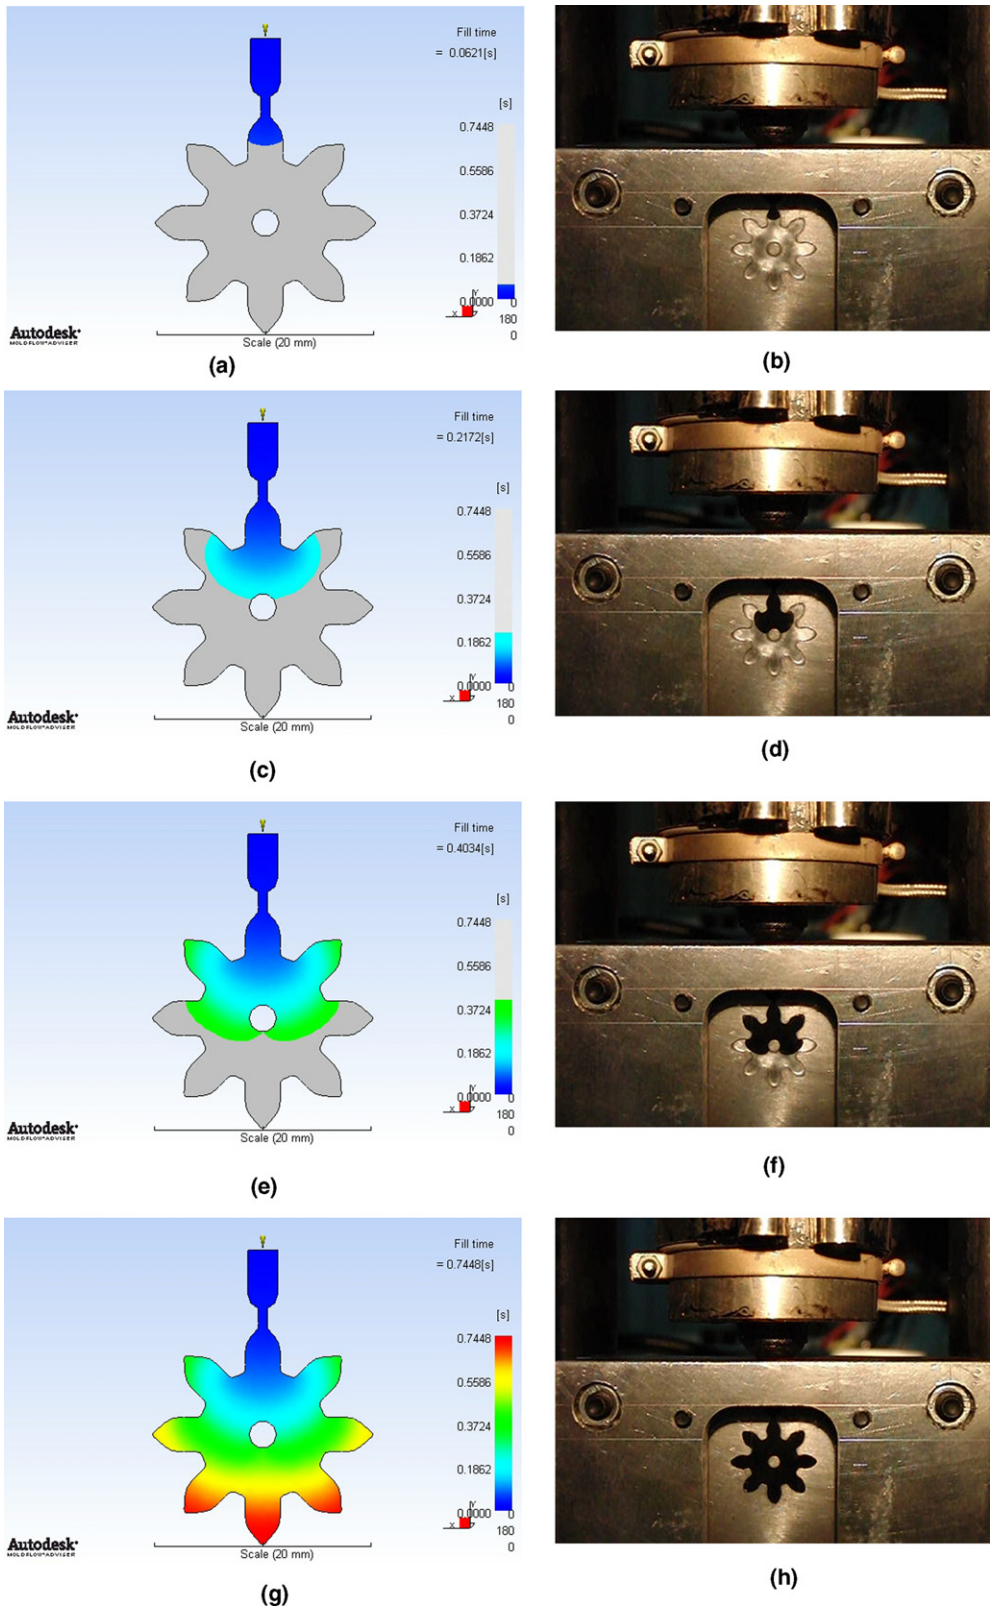

Figure 15 Result of macro plastic gear shape injection from MoldFlow simulation and actual plastic injection.

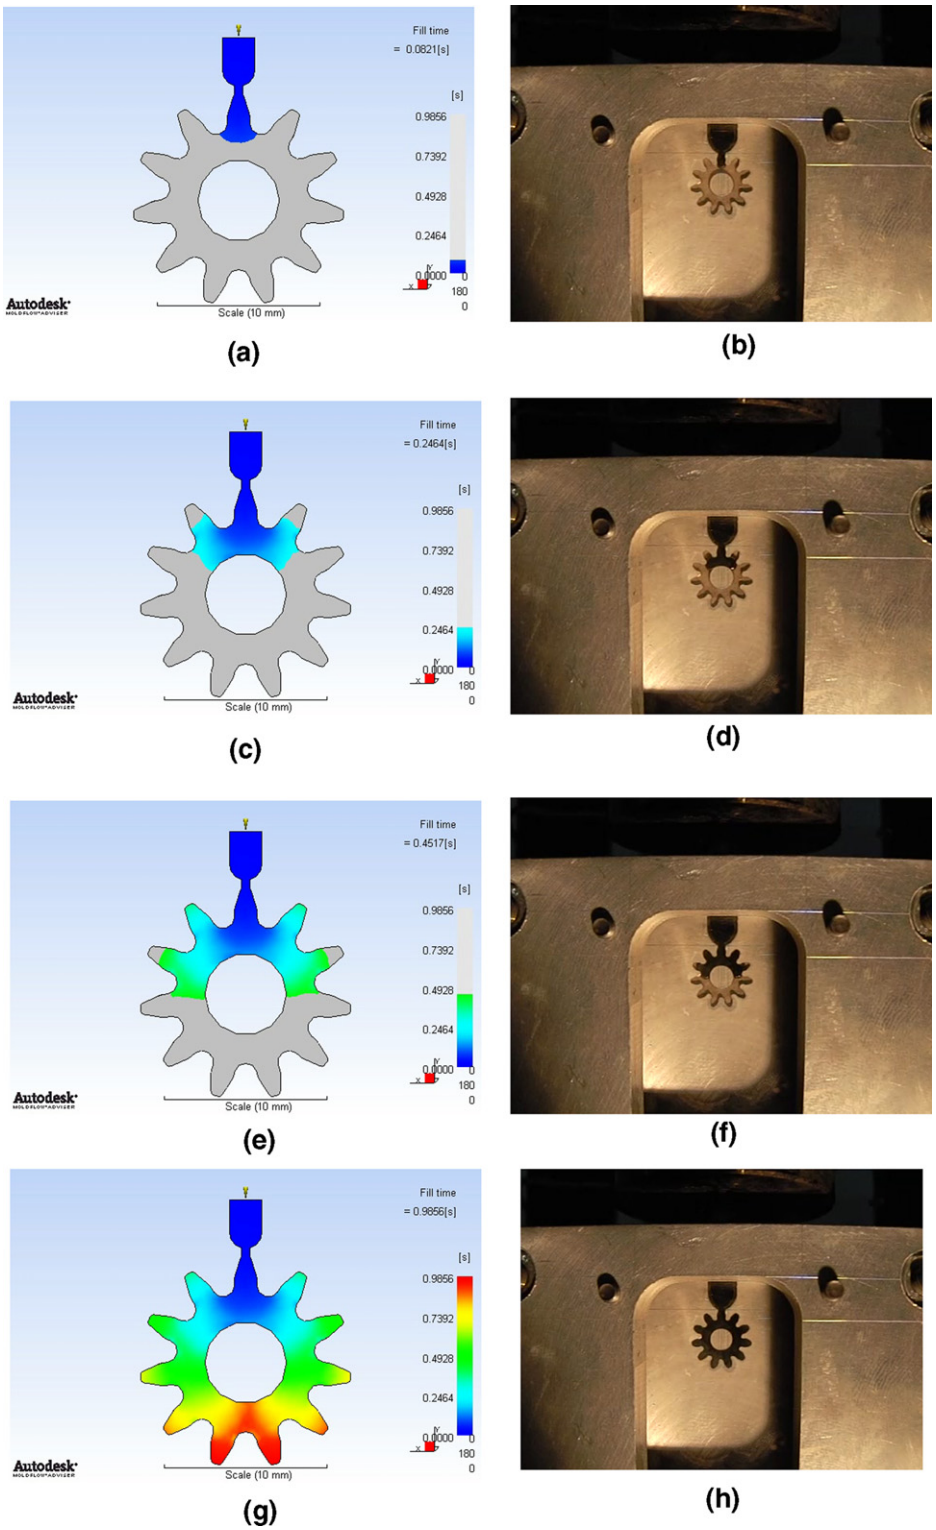

Figure 16 Result of macro and micro plastic gear shape injection from MoldFlow simulation and actual plastic injection.

The results presented here have shown that the prediction of melt flow front by MoldFlow was consistently similar with the actual injection process. But, the time taken to fill the cavities was much longer in actual plastic injection process. This can be explained by the viscosity and PVT model of the melt affecting the flow rate. The PVT model is given by eqn [30].

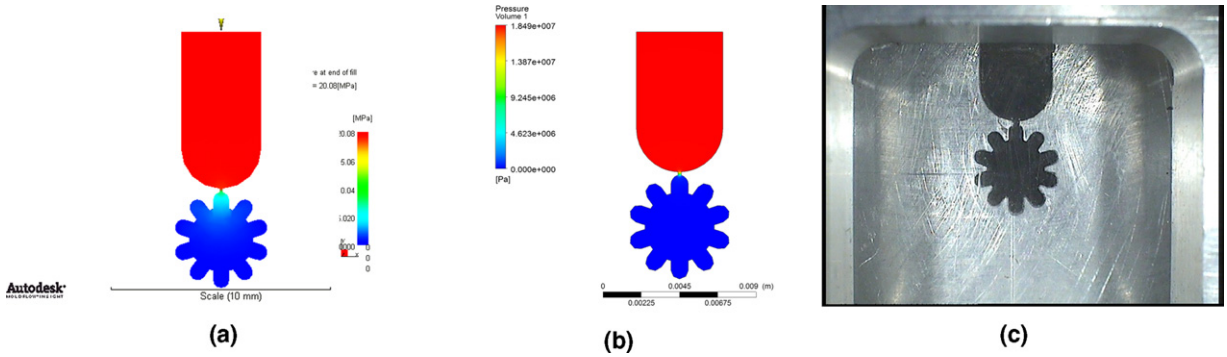

Figure 17 Pressure distribution and filling capabilities for gear shape with 1.0 mm teeth at 35 °C mold temperature and 240 °C melt temperature (a) MoldFlow, (b) ANSYS CFX, and (c) experimental.

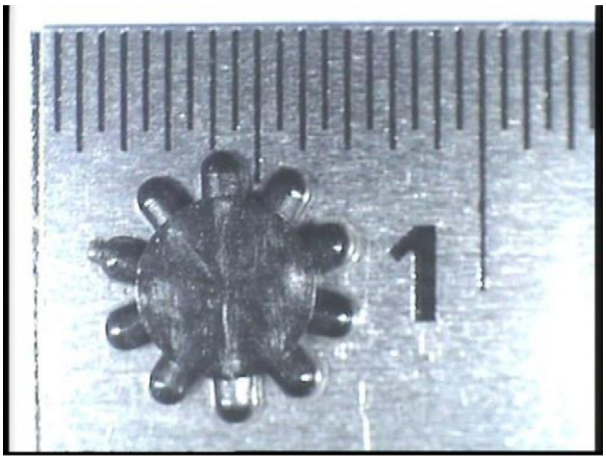

Figure 18 Gear shape with 1.0 mm teeth after solidification.

Table 5 Complete and incomplete cavity filling of gear shape with 1.0 mm teeth for various molds and melts temperature combination

		Melt temperature		
		240 °C	*250 °C*	*260 °C*
Mold temperature	25 °C	X	√	√
	35 °C	√	√	√
	50 °C	√	√	√

Higher viscosity will have higher resistance to melt flow, which will increase the total fill time. Higher viscosity of melt increases the total fill time as flow resistance increases with viscosity. The viscosity of the melt increases as the flow temperature decreases as soon as the melt comes in contact with the mold cavity wall. The fill time and flow path have been affected by viscosity and shear rate.

From this study of both macro and micro gear shapes, it can be concluded that the MoldFlow can simulate very well the filling phase. However there is a huge difference in the filling time of both simulation and actual injection. For macro cavity, the filling time for actual plastic injection increased by 145%, while for micro cavity it increased to 610%. Changes in the melt viscosity while passing through a small cross sectional area have increased the mold cavity filling time. The results also showed that the flow front starts as a semicircle moving away from the gate.

1.15.5.2 Micro Gear Shape

The capability of plastic melt to fill a gear shape cavity with various micro teeth sizes is presented in this section. Each gear shape will be analyzed using MoldFlow and ANSYS CFX simulations followed by actual experiments at various mold and melt temperatures. A suitable η_0 value obtained from study conducted in Sections 1.15.4.3, 1.15.4.4, and 1.15.4.5 will be embedded into cross viscosity model before running the ANSYS CFX analysis.

1.15.5.2.1 Gear shape with 1.0 mm teeth

The MoldFlow, ANSYS CFX and experiment results for gear shape with 1.0 mm teeth are shown in Figure 17. The mold cavity was heated at 35 °C and the melt temperature was set at 240 °C. Both MoldFlow and ANSYS CFX simulation predicted a complete cavity filling which were same as produced by experiments. The ANSYS CFX simulation used 222.53 as η_0 value in cross viscosity model. MoldFlow yielded pressure to fill the cavity equal to 20.29 MPa while that in ANSYS CFX was 18.49 MPa.

Figure 18 shows a gear shape with 1.0 mm teeth after plastic filling the cavity region was completed, solidified, and removed from mold cavity. Attach with 1 cm scale, complete gear shape solidified without any flash defects on its teeth.

Table 5 shows an incomplete and complete cavity filling for 1.0 mm teeth gear shape with various mold and melt temperature combinations. Only 240 and 25 °C of melt and mold temperature combination was not capable of full cavity filling. Others combination gave complete cavity filling.

1.15.5.2.2 Gear shape with 0.5 mm teeth

Figure 19 shows a pressure distribution and filling capabilities for gear shape with 0.5 mm teet size at 50 °C mold

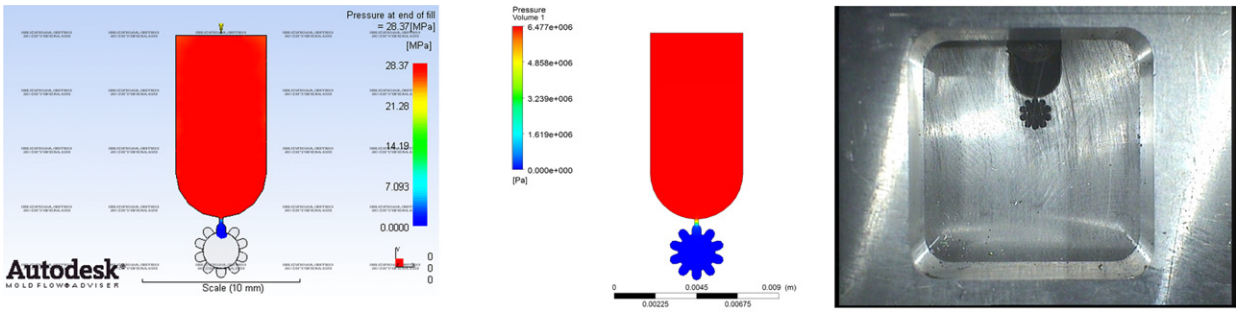

Figure 19 Pressure distribution and filling capabilities for gear shape with 0.5 mm teeth at 50 °C mold temperature and 250 °C melt temperature (a) MoldFlow, (b) ANSYS CFX, and (c) experimental.

temperature and 260 °C melt temperature. Analysis using MoldFlow showed the plastic melt filled the main channel, gate, and one gear tooth only. The remaining teeth were unfilled. However, the ANSYS CFX simulation showed a complete cavity filling same as that produced by actual experiments. This result was due to 32.53 Pa s as η_0 value used in the ANSYS CFX simulation. The maximum pressure recorded by MoldFlow was 6.2 MPa while that in ANSYS CFX was 6.5 MPa. At mold temperature 50 °C and melt temperature set at 250 °C, MoldFlow was unable to predict full cavity filling incidentally identical with experimental result. From Section 1.16.4.4, simulating the filling plastic melt into 0.5 mm micro channel was not possible using MoldFlow.

Figure 20 shows a complete plastic gear shape with 0.5 mm teeth after being removed from its cavity. The gear shape was molded without any flashing problem occurring along its teeth at 50 and 250 °C of mold and melt temperature, respectively.

At 260 °C melt temperature and 35, 50 °C of mold temperatures, the cavity filled completely as shown in Table 6. The combination of remaining melt and mold temperatures did not produce filling of the entire mold cavity.

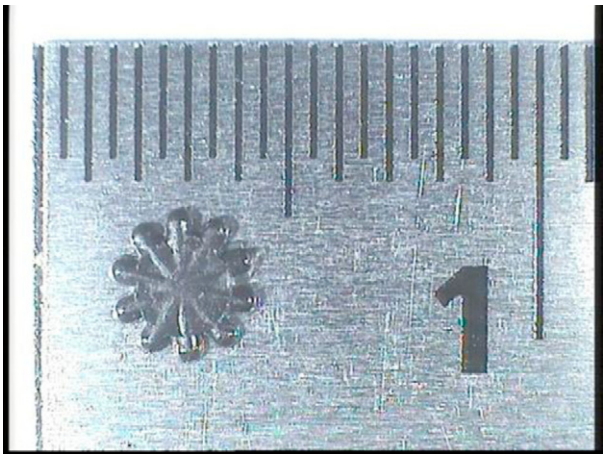

Figure 20 Gear shape with 0.5 mm teeth after solidification.

Table 6 Complete and incomplete cavity filling of gear shape with 0.5 mm teeth for various molds and melts temperature combinations

		Melt temperature		
		240 °C	*250 °C*	*260 °C*
Mold temperature	25 °C	X	X	X
	35 °C	X	X	√
	50 °C	X	√	√

1.15.5.2.3 Gear shape with 0.3 mm teeth

A simulation pressure distribution result from MoldFlow and ANSYS CFX simulations for gear shape of 0.3 mm teeth are shown in Figure 21. Also, a complete experimental injection process was done at 50 °C mold temperature and 260 °C melt temperature. Figure 21(b) shows a full cavity filling obtained from ANSYS CFX with 52.53 Pa s as η_0 value in the cross viscosity model. The maximum pressure in MoldFlow was 5.73 MPa, while ANSYS CFX recorded much higher pressure 12.72 MPa. But, ANSYS CFX was capable to simulate a complete filling compared to MoldFlow. MoldFlow showed the plastic melt filling only one teeth of gear cavity. With the combination of this mold and melt temperatures, MoldFlow was unable to simulate the plastic melt flow into the gear shape with 0.3 mm teeth. On the other hand, ANSYS CFX was capable of predicting full cavity filling identical with actual experiment.

Figure 22 shows a solidified gear shape with 0.3 mm teeth after it been removed from the mold. The gear shape had small flash problem occurring at its teeth. This was due to 50 °C of mold temperature and 260 °C melt temperature used as molding condition. At higher mold and melt temperatures, plastic melt viscosity is reduced and ability to fill micro cavity increases. There was a possibility of plastic melt filling the parting line which caused the flash problem.

Table 7 shows an incomplete and complete cavity filling for 0.3 mm teeth gear shape at various mold and melt temperature combinations. When mold was heated at 35 and 50 °C with 260 °C of melt temperature, the full cavity filling can be achieved. Others mold and melt temperature combinations gave incomplete cavity filling. As micro areas to be filled, mold and melt temperature have significant effect on the filling capability.

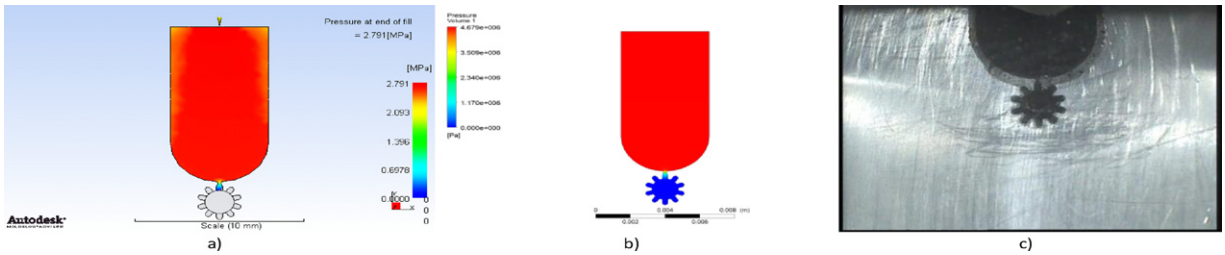

Figure 21 Pressure distribution and filling capabilities for gear shape with 0.3 mm teeth at 50 °C mold temperature and 260 °C melt temperature (a) MoldFlow, (b) ANSYS CFX, and (c) experimental.

		Melt temperature		
		240 °C	*250 °C*	*260 °C*
Mold temperature	25 °C	X	X	X
	35 °C	X	X	√
	50 °C	X	X	√

1.15.6 Conclusions

Molding of micro plastic parts require specific machine which must be capable of delivering small amount of melt plastic into micro cavity. The developed machine was embedded with controller for controlling pressure, mold, and melt temperatures during cavity filling process. Testing the machine capability with standard Tensile and Izod specimens is required for their reliability. Verification of the heat transfer behavior along flow direction with acceptable heat transfer model was an added value for the developed injection molding machine. A special mold embedded with visualization windows was developed which enables user to track the flow front position, time, and also the direction of flow. Comparison of experimental results with simulation from software showed a very good agreement for macro molding applications.

Filling of micro part or micro structure region began with exploring the filling capability of plastic melt in the micro channels with 1.0, 0.8, 0.5, 0.4, and 0.3 mm in diameter. At three levels of mold and melt temperatures applied to PP, experiments was designed to incorporate various micro straight channel sizes. Analytical straight filling capability was formulated with simple 1D direction flow for faster filling capability. Together with MoldFlow and ANSYS CFX analysis software, experiments results were compared to find the most suitable method in predicting micro straight channel filling capability. Generally, MoldFlow shows good filling capability predictions with experiments for micro channel size larger than 0.5 mm. ANSYS CFX embedded with modified cross viscosity model is able to predict filling distance compared to MoldFlow and analytical results.

Fabrications of macro gear and micro gear shape with micro teeth shows the custom-made vertical injection molding machine capabilities in delivering the plastic melt into the entire cavity without any serious molding defects. For macro gear shape fabrication, MoldFlow produced almost the same flow front direction as shown by experiments. But, filling time difference recorded for both methods was more than 100%. This was due to the simplification in equations used in MoldFlow, without considering the cavity roughness, air vent location, and dynamic viscosity due to micro size. Considering application to micro teeth cavity filling, MoldFlow is unable to predict well as produced in the actual experiments for gear shape with teeth sizes of 0.5 and 0.3 mm. Therefore, ANSYS CFX analysis with modified viscosity model was used to simulate almost similar plastic melt behavior as shown by experiments. ANSYS CFX embedded with modified cross viscosity model gives realistic plastic melt flow behavior when compared with experiments.

controlling of these parameters enhance part quality, but some are more critical.

1.16.3.2.3 Critical factors influencing part quality in IM

The choices of IMM, feedstock material selection, process condition, mold, and part design are critical factors that influence molded part quality in injection molding.[70] According to Surace *et al.*,[71] researchers investigated the optimum processing conditions for microfabrication of various parts. The following process parameters were found to affect part quality in μIM: mold temperature, melt temperature, injection speed, injection pressure, holding time, holding pressure, and cooling time. Therefore, application of optimization techniques to μIM processes will enhance molded part quality and lead to less scrap, efficient cycle times, and improved productivity.

1.16.3.3 Debinding Process

This is the process of binder removal. It is described as the most complex, difficult, expensive, and time-consuming stage, and it depends on processing conditions. In line with the formulation of the binder constituent, the minor binder components (such as plasticizers, surfactants, and lubricants) are usually removed first and the backbone binder component is removed last. In practice the debinding techniques adopted are solvent debinding,[72–73] thermal debinding,[74–75] catalytic debinding,[76] and wicking debinding,[77] respectively.

A multi-step debinding technique is now practiced, whereby the green part is processed via solvent medium (such as hexane and heptane) and then followed by thermal debinding. The multistep technique is preferred as a result of defects associated with direct thermal debinding such as cracking, slumping, porosity, and blistering.[78,79] Combining solvent and thermal debinding techniques reduces processing time; the parameters are presented in **Table 10**.

The fundamental principles of the solvent and thermal debinding techniques are discussed next.

1.16.3.3.1 Solvent debinding

This is a technique that removes the binder constituent of the feedstock using solvent. The green part is immersed in the solvent (such as water, hexane, heptain, acetone, ethanol, and other alcohols). At specified temperatures, binder constituent is dissolved in liquid at low temperatures and a network of interconnected porosity is formed in the part while being immersed in the solvent. However, most of available solvents used are dangerous to the environment if necessary precautions and measures are not observed. Meanwhile, water is identified as a safe solvent that is environmentally friendly. Solvent debinding requires a longer time to remove binder constituent relative to other techniques, such as catalytic and thermal debinding processes. Cost and environmental challenges are much lower, especially when water is used.

Table 10 Some process parameters of solvent and thermal debinding technique

Debinding technique	*Process parameters*
Thermal	Heating rate, holding temperature, holding time, cooling rate
Solvent	Immersion time, immersion temperature, dissolving medium

1.16.3.3.2 Thermal debinding

The polymeric constituent of the binder system can be eliminated by heating the green part to temperatures that cause the main polymers to decompose or degrade. The temperature could be up to 800 °C, but it strongly depends on the binder system. Meanwhile, the thermal binder burnout requires times longer than for catalytic debinding. To reduce the processing time, a combination of solvent and thermal debinding is usually adopted. Herranz *et al.*[80] used a PE-based binder system and demonstrated the successful application of the double-cycle debinding process involving solvent (heptane solvent) debinding and thermal debinding.

The use of a thermal debinding technique is widely practiced due to its high efficiency in binder burnout, but the occurrence of part defects has limited the practice as a standalone method. Therefore, the double-stage method, which involves solvent and thermal energy, is mostly practiced. The process is simple and similar to the sintering process. Therefore, it is widely accepted and used. Typically, the burnout of the polymeric constituent from the green part involves chemical and physical mechanisms.

The chemical mechanisms occur because of thermal degradation of polymers into volatile species, called pyrolysis. The physical mechanisms involve diffusion of the volatile species to the surface and changes in the polymer distribution within the green body. Depending on the material properties, such as thermal conductivity, porosity, pore size, and related features, it is possible for mass diffusion or thermal diffusion to be controlling steps. As a further complication, component heating depends on heat transfer and the reaction enthalpies associated with pyrolysis events, leading to thermal–kinetic effects that couple to the chemical–physical aspects.

1.16.3.3.3 Other debinding techniques

Apart from the solvent and thermal debinding methods, other techniques such as catalytic debinding and wicking debinding are practiced. The uses of other techniques, other solvents, and thermal debinding arise as a result of the requirements of the binder formulation or composite such as polyacetal. The polyacetal binder systems require debinding in a gaseous acid environment (usually highly concentrated nitric or oxalic acid) at a temperature of approximately 120 °C (a temperature slightly lower than that for softening the binder system). The nitric or oxalic acid used served as a catalyzer in the degradation of the polyacetal constituent of the binder system.

1.16.3.3.4 Development of master decomposition curve

The design and optimization of the debinding process are enhanced through effective investigation and development of the master decomposition curve (MDC) for the polymeric binder component of the feedstock. This is an essential tool used for the prediction of part behavior at the debinding step, a process that is viewed to be a challenging task for PIM. This is due to the fact that several researchers have reported that the process of binder removal from the green part is expensive and

time-consuming, and is sometimes viewed as a limitation for PIM processing. According to Aggarwal *et al.*,[81] the feedstock of PIM consists of multiple components that can be categorized into two groups according to their molecular weight as:

- Low-molecular-weight polymers, such as solvents and plasticizers, that can either be evaporated or are decomposed at low temperatures.
- High-molecular-weight polymers, such as polymers possessing higher thermal stability, that are pyrolyzed at relatively high temperatures.

Therefore, the need for the kinetic investigation of the binder components of the molded part during debinding is paramount and monitored through weight loss. The TGA and differential thermal analysis are used extensively for the determination of weight loss of the binder component as a function of time and temperature. **Figure 9** illustrates a typical TGA plot of the binder components at various rates in an argon atmosphere.

The concept of the master sintering curve (MSC), developed by Su and Johnson,[82] successfully extended to include binder behavior during solvent extraction and wicking process of debinding, respectively.[72] The MDC was developed for single-step and multistep burnout of the polymeric binder and is presented in the next section.

1.16.3.3.4.1 Single-step burnout process

Depolymerization of polymeric binders can be described by first-order reaction kinetics. The remaining weight fraction of a polymer, α, is expressed as[83,84]:

$$\frac{d\alpha}{dt} = -K\alpha \qquad [26]$$

where t is the time and K is the rate constant for degradation and relate to the Arrhenius eqn [27]:

$$K = K_0 \exp\left(\frac{-E}{RT}\right) \qquad [27]$$

where K_o is the specific rate constant, E is the apparent activation energy for thermal degradation, R is the gas constant, and T is the absolute temperature. Combining eqns [26] and [27] provides the following:

$$-\int_1^{\alpha} \frac{d\alpha}{\alpha} = -\ln \alpha \qquad [28]$$

$$-\ln \alpha = \int_0^t K_0 \exp\left[-\frac{E}{RT}\right] dt = K_0\Theta \qquad [29]$$

Where the decomposition (ψ) is expressed as:

$$\Theta(t, T; Q) = \int_0^t K_0 \exp\left[-\frac{E}{RT}\right] dt \qquad [30]$$

$$\alpha(\Theta; K_0) = \exp[-K_0\Theta] \qquad [31]$$

Equation [30] defines the MDC, where the decomposition curves for a given polymer with any decomposition cycle uses the concept of work of decomposition, Θ.

In addition, Enneti *et al.*[72] proposed a modification to the MSC by incorporation of the shape factor. The modified MSC is capable of estimating activation energy without further dependency on solvent extraction rate to the square of the length of the part as previously practiced. The fundamental MSC model is expressed as eqn [31], whereas the modified MSC for the prediction of activation energy during solvent extraction and wicking process is given by eqn [32].[72]

$$\Phi(\rho) = \theta(t, T) = \int_0^t \frac{1}{T} \exp\left(\frac{-E}{RT}\right) dt \qquad [32]$$

$$\Phi(\rho) = \theta(t, T) = \left(\tfrac{1}{\psi^2}\right) \int_0^t \frac{1}{T} \exp\left(\frac{-E}{RT}\right) dt \qquad [33]$$

where $\Phi(\rho)$ is the densification, ψ is the shape factor, t is the time, T is the absolute temperature, E is the apparent activation energy, and R is the universal gas constant.

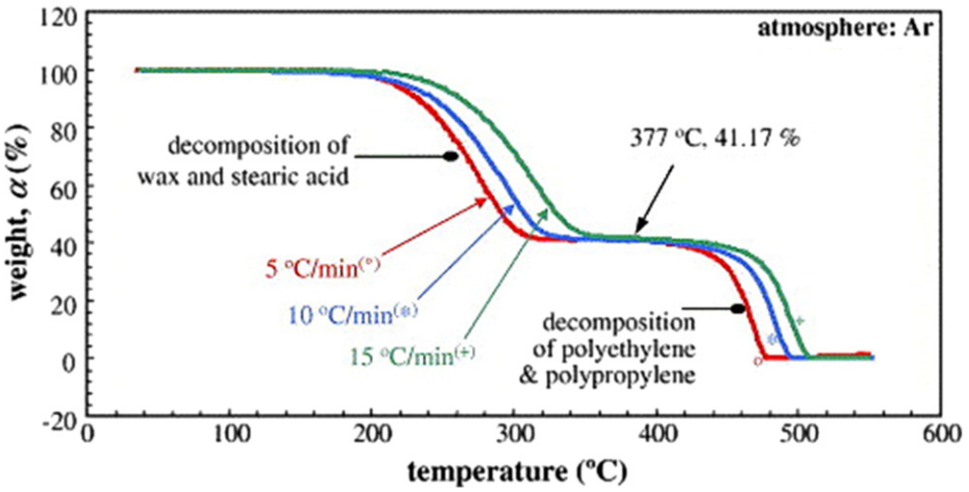

Figure 9 A typical thermogravimetric analysis plot of binder components at various rates. Aggarwal, G.; Smid, I.; Park, S. J.; German, R. M. Development of Niobium Powder Injection Molding. Part II: Debinding and Sintering. *Int. J. Refract. Metals Hard Mater.* **2007**, *35*, 226–236.

1.16.3.3.4.2 Evaluation of apparent activation energy

To evaluate the decomposition (Θ) from eqn [30], the apparent activation energy (E) needs to be determined. The activation energy for polymeric binder decomposition can be determined from TGA data using the Kissinger method. The temperature (T_{max}) at which the maximum rate of weight loss occurs at various heating rates is used for the determination as follows:

$$\frac{d}{dt}\left(-\frac{d\alpha}{dt}\right)=0 \text{ and } T=T_{max} \quad [34]$$

considering constant heating rate (r) and then

$$\frac{dT}{dt}=r \quad [35]$$

$$\frac{rE}{RT_{max}^2}=K_0 \exp\left(\frac{-E}{RT_{max}}\right) \text{ at } T=T_{max} \quad [36]$$

Equation [36] is simplified in linear form and expressed as:

$$\ln\left[\frac{r}{T_{max}^2}\right]=E\left(-\frac{1}{RT_{max}}\right)-\ln\left[\frac{E}{K_0R}\right] \text{ at } T=T_{max} \quad [37]$$

The apparent activation energy E of the reaction represents the slope from a plot of $\ln\left(\frac{r}{T_{max}^2}\right)$ and $\left(-\frac{1}{RT_{max}}\right)$, which are determined from the TGA experiments with several constant heating rates.

However, Aggarwal *et al.*[84] proposed a statistical approach for the determination of the apparent activation energy based on the MDC concept. The idea is to minimize the mean residual (MR) while varying the activation energy. MR is mathematically defined as follows:

$$MR=\sqrt{\int_t^0\left[\frac{\sum_{i=1}^{N}\left(\frac{\Theta_i}{\Theta_{avg}-1}\right)^2}{N}\right]d\alpha} \quad [38]$$

where N is the number of TGA experiments, i is the running index for the TGA experiment label, Θ_i is the work of decomposition calculated from TGA experiments with the label of i, and Θ_{avg} is the average work of decomposition calculated from all TGA experiments, respectively. This alternative method is simple because it does not attach any condition to the TGA experiments. The two methods are derived from the same fundamental equations.

1.16.3.3.4.3 Multistep burnout process

Typical TGA curves of polymer degradation follow a single sigmoidal path. However, multicomponent binder systems may have two or more sigmoids due to the different molecular weights, bonding groups, and degradation paths for each polymer constituents. Then, each sigmoid describes a rate-controlling step whose activation energy differs from those of other controlling steps. It is then important to remember that powder–binder systems in PIM often consist of several components. Typically, the binder components can be categorized into two groups based on molecular weight of the constituents: high-molecular-weight (HMW) and low-molecular-weight (LMW). The LMW ones are additives such as solvents and plasticizers, which either evaporate or decompose at low temperatures. Whereas the HMW polymers are characterized as possessing higher thermal stability and decomposing at high temperatures relative to the LMW. Therefore, the difference in molecular weight of the PIM binder system is responsible for the TGA curve with multiple sigmoids. Superposition of several sigmoids may be observed when the constituents have similar activation energy. Sigmoids typically represent a distinct reaction step with sufficiently different activation energy. A sigmoid is described by three kinetic parameters in reference to the Arrhenius equation. The frequency factor, activation energy, and reaction order are used for distinguishing each sigmoid that represents each powder. However, some powders may have catalytic effects on the pyrolysis rate; however, the shape of the pyrolysis curve with powders is similar to that without powders.

Therefore, the mathematical form of polymer pyrolysis can still be applied. Two polymers of the binder system used in this study are decomposed during the thermal debinding process:

$$\alpha=\omega\alpha_1+(1-\omega)\alpha_2 \quad [39]$$

where α is the mass ratio of the initial masses of two polymers, α_1 is the ratio of mass to initial mass of the low-molecular-weight polymer, α_2 is the ratio of mass to the initial mass of the high-molecular-weight polymer, and ω is the ratio of the initial mass of the low-molecular-weight polymer to the initial mass of the two polymers.

The mathematical form that is generally applied to the TGA curve of a polymer is modified to describe the TGA curve of organic pyrolysis with powders. In the present analysis, we assume that the kinetics are solely controlled by the temperature:

$$-\frac{1}{k_0\beta^n}d\alpha=\exp\left[-\frac{E}{RT}\left(\frac{1}{T}-\frac{1}{T_t}\right)\right]dt$$

$$\text{if } T\geq T_t(\text{or } \alpha\geq\omega),\ \alpha=\omega\alpha_1+(1-\omega),$$

$$\beta=\frac{\alpha+(\omega-1)}{\omega},\ n=n_1\ K_0=K_{01},\ E=E_1$$

$$\text{if } T>T_t(\text{or } \alpha<\omega),\ \alpha=(1-\omega)\alpha_2,$$

$$\beta=\frac{\alpha}{(1-\omega)},\ n=n_2\ K_0=K_{02},\ E=E_2 \quad [40]$$

where T_t is the transition temperature between the first and second sigmoids, and subscripts 1 and 2 that appear along with a, E, and K_0 represent the low- and high-temperature degradation, respectively. In addition, it is possible to evaluate a decomposition kinetic curve with more than two sigmoids using the concept described. Meanwhile, the Kissinger method is applied to estimate the activation energy, as described in Section 1.16.3.3.4.2.

Splitting eqn [40] and integrating each side separately is expressed as the left side of eqn [40] as a function of the mass ratio α and material properties K_0, yielding:

$$\Phi(\alpha; k_0) = \int_1^{\alpha} \frac{1}{K_0 \beta^n} \mathrm{d}\alpha \qquad [41]$$

Likewise, integrating the right side of eqn [40] is expressed as a function that depends on t, T, E, and T_t:

$$\Theta(t, T; E, T_t) = \int_0^t \exp\left[-\frac{E}{R}\left(\frac{1}{T} - \frac{1}{T_t}\right)\right] \mathrm{d}t \qquad [42]$$

where $\Phi(\alpha)$ is considered a characteristic that quantifies the effect of binder components on the decomposition kinetics. Therefore, the relationship between the mass ratio (α) and Φ (α) is defined as the MDC. MDC is unique for each powder and binder system, as described previously. **Figure 10**[84] is typical illustration of MDC developed for PIM feedstock based on intrinsic kinetics of polymer pyrolysis. In addition, Enneti *et al.*[74] presents a detailed review article on major progress of the thermal debinding process in particulate materials processing. This study includes progress made in understanding various phenomena during polymer burnout from PIM molded parts, focusing on a substantial reduction in thermal debinding time.

1.16.3.4 Sintering Process

In PIM, sintering is the fourth and final processing step. It is used to produce high-density parts with good mechanical properties. According to German,[85] sintering is a thermal treatment for bonding particles into a coherent, predominantly solid structure via mass transport events that often occur on the atomic scale. In addition, depending on the formulation and design of the binder system, the likely residues after the debinding process and pores left in the brown part are completely removed at this stage. Less attention is given to the debinding residues, which could be a serious issue for structural and/or magnetic effects of the finished part. The sintering process is identified as the processing stage that influences mechanical properties and other quality characteristics of the finished part.[77] At this stage, approximately 17–22% of shrinkage as well as other processing part defects become visible and pronounced. Therefore, it is important to handle the process with a robust design of experiment (DOE) to determine the optimum operating conditions. An optimum cooling rate of 10 °C min^{-1} was determined for both the mechanical properties and corrosion resistance of the sintered 316L stainless steel part, considering temperature, time, heating rate, and cooling rate as processing parmeters.[86] However, it is important to note that hardness and strength are the two mechanical properties commonly used to track finished part quality.

Typical processing parameters of the sintering operation are temperature, particle size, time, and pressure; the degree depends on the material properties. Although it is important to note that many materials densify as part of sintering, not all sintering involves densification. The process is characterized as pressure-assisted or pressureless sintering techniques.[85] Also, during the debinding (thermal debinding) and sintering processes, the green and brown parts are subjected to subsequent heat treatments, as depicted in **Figure 11**.[87]

The capability of PIM as a net-shaped microfabrication technique to produce parts with shiny and high surface finish values gives the technology a unique feature and makes it stand out among other microfabrication processes. This advantage is achieved through a number of factors: high density must be achieved and the metal surface must be free from reaction with sintering atmospheres to avoid the formation of oxides, nitrides, or other products. Consequently, the oxygen content or dew point in the atmosphere must be sufficiently low, and the amount of hydrogen or the degree of vacuum must be sufficiently high to reduce the metal oxides on micrometal parts surfaces. All these factors are considered to produce defect-free parts. Postprocessing of the finished part is implemented, but this strongly depends on target application. **Figure 12** illustrates tensile specimen parts at various processing stages of niobium powder injection molding, which depicts the advantages of multistep debinding techniques.

1.16.4 Optimization and Simulation of Microinjection Molding Process

Product quality is improved by the application of optimization techniques to the manufacturing processes. These optimization techniques were developed based on global search process, statistical, and mathematical approximation. A broad classification of optimization techniques applied by researchers to injection molding process is presented in **Figure 13**.

A survey of literature as depicted in **Figure 13** shows that optimization techniques applied in injection molding process are classified as: intelligent algorithms,[88–91] iterative,[88,92–95] and noniterative[96–98] methods. In addition, a simulation-based classification of optimization techniques for IM is presented in **Figure 14**.[53] This consists of two broad categories: the direct discrete optimization and metamodel-based optimization methods. The metamodel-based method is further classified as response surface methodology (RSM), radial basis function, artificial neural network (ANN), and Kriging.

However, numerical simulations are sometimes integrated with DOE as optimization techniques to enhance product quality. The DOE approach is implemented to study the impact of processing parameters on quality characteristics such as strength, surface finish, part weight, shrinkage, and warpage of the finished part. These quality characteristics have been investigated to determine the optimum processing conditions of the microinjection molding process for different materials using the DOE approach. Zhao *et al.*[10] used DOE and considered the effect of five processing parameters on the microinjection molding process and quality of microgears. Various investigations based on DOE were performed to focus on determining optimal operating conditions[99–101] and quality characteristics of molded parts.[102–104] It is important to identify and control some key parameters that influence finished part quality in injection molding processes.

1.16.4.1 Parameter Control in Injection Molding Processes

It is important to control and monitor the injection molding process. IM is a repetitive process that requires close monitoring of many variables and parameters. Production consistency and

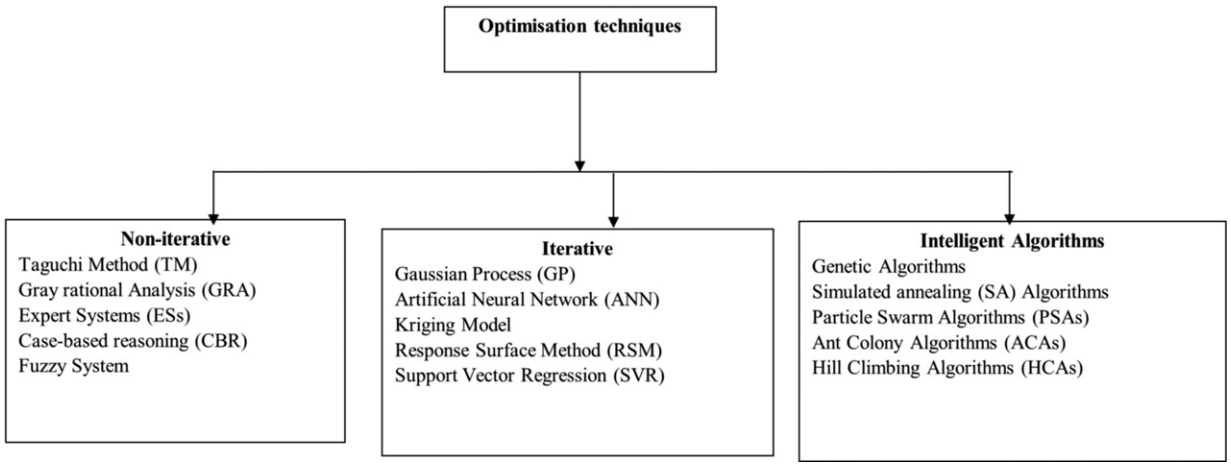

Figure 13 Optimization techniques used for IM process.

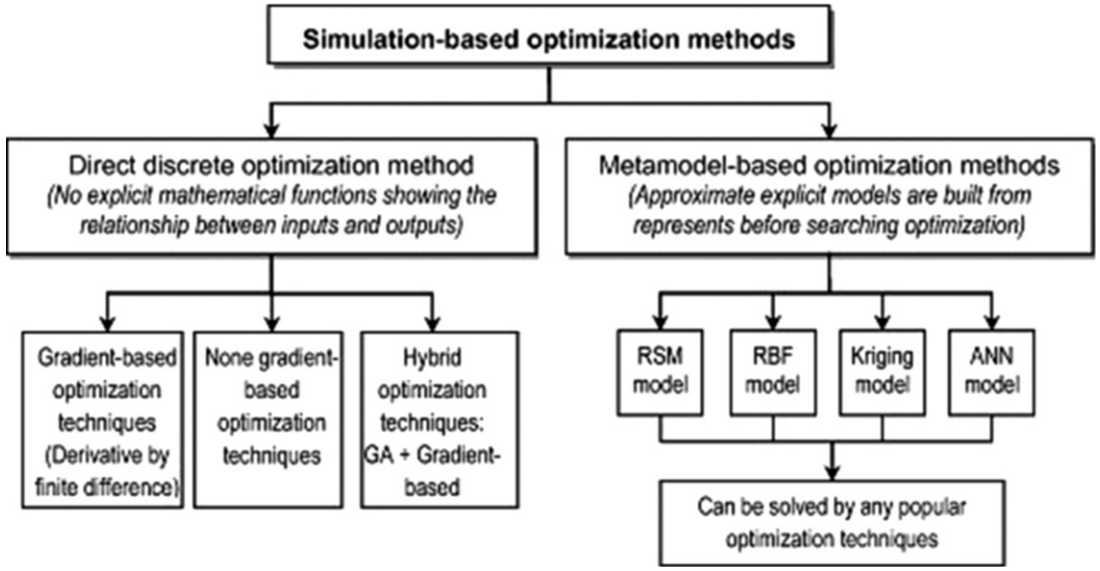

Figure 14 Simulation-based optimization techniques for IM. Dang, X.-P. General Frameworks for Optimization of Plastic Injection Molding Process Parameters. *Simul. Model. Pract. Th.* **2014**, *41*, 15–27.

part quality in IM are enhanced through control and monitoring of process parameters and conditions. IM is a very complex process that involves a high degree of interaction between feedstock material, machine, and process conditions. Therefore, the optimal performance of the IMM is characterized by production consistency and repeatability of the mold cycle. Therefore, precise control and monitoring of the processing conditions are necessary for efficient performance of IMM. However, not all parameters can be controlled and monitored at the same time. Some important parameters are linked directly to molded part quality. A typical control system in the modern injection molding process has the following main functions:

- manipulation of machine operational sequence control
- control of process and/or machine variables
- monitoring of process and performance evaluation status of the machine
- quality control of product to ensure consistency.

The sequence control ensures the molding machine operates according to the predetermined order and implements defined logic to provide target functions based on the circuit or tasks as specified in the software. This is an important function, but it does not directly influence product quality. The consistency of part quality from one production batch to another is a serious challenge in the IM process. In fact, sometimes the problem is experienced within batch production from one cycle to another, especially when manually operated or controlled. Then, process control and automation of machine operations become necessary to maintain

production consistency of parts. It is necessary to outline some important factors or key variables of the process, including process variables, material variables, and mold design variables, as presented in Table 11.

Therefore, the extent of the variability encountered by the machine output during operations is an indication of the level of inherent stability of the production. Hence, the smaller the variation, the more consistent and stable is the process.

Control and monitoring of the IM process provide continual support toward achieving a higher level of technology implementation to meet performance demands at the lowest cost. The control systems for the IM process available at present include closed loop (feedback) control, open load control, learning control, and advanced control. In addition, monitoring of the IM process is focused on statistical process control, multivariate statistics, and multiphase statistical process control. The functions of the control in injection molding are manipulation of machine sequence/mold cycle, control of machine variables, monitoring of process status and performance, and quality control of product/molded part. In addition, the control system is a useful tool for performing supervisory functions, process monitoring, and online evaluation of process variables statistically that can be used to alert the operator of any potential problems.

Table 11 Some processing variables of injection molding

Variable	*Factor/properties*	*Parameter*
Operating variables	Temperature	Melt temperatures Barrel temperature Nozzle temperature Mold temperature Cooling medium temperature
	Pressure	Injection pressure Holding/packing pressure Hydraulic back pressure Nozzle pressure Mold clamping pressure/force
	Time	Injection time Holding/packing time Pause (dwell) time Cycle time Cooling time
	Speed	Mold opening and closing mechanism speed Screw/ram speed Screw/ram recovery speed Component retraction spee
Material variables	Physical properties	Shear rate Shear stress Thermal conductivity Thermal diffusivity Specific volume Specific heat Viscosity Density
	Mechanical properties	Tensile strength Tensile modulus Elongation Compressive strength Compressive modulus Flexural strength Flexural modulus Impact strength Hardness Tensile creep Flexural creep Tensile fatigue Flexural fatigue
Mold design variables	Mold cavity measurements/ dimensions	Part dimensions and tolerances Cooling channel size Venting channel size Gate(s) location and size Runner system design

Some key variables that are often controlled in the IM process that allow optimum machine output are enumerated as temperature, pressure, injection velocity, and screw speed control. A typical experimental setup for monitoring and control of variables such as melt temperature, barrel temperature, nozzle temperature, and screw speed is illustrated in Figure 15.[105]

Figure 15 is a typical example of experimental setup of the control structure featuring SM25 IMM by Jhen-Syong Company, as reported by Lin and Lian.[105] Multiple sensors are used for data acquisition systems during operation to monitor various changes of both processing parameters and quality of the molded part. Many researchers have investigated the injection molding process by using sensors for measured variables such as injection pressure, cavity pressure, displacements and velocity of the injection pin, mold temperature, clamping, and demolding force.

1.16.4.2 Optimization Methods

The application of optimization methods in the injection molding process has become popular among researchers as they explore ways to improve quality of molded parts. The quality of molded parts is described in terms of quality characteristics, including physical and mechanical properties of dimensional conformity, surface finish, strength, hardness, and microstructure morphology. Part quality is affected by many variables and factors that are influenced by the process conditions of injection molding. This, in turn, gives rise to many processing parameters of injection molding that need to be monitored and controlled to achieve the desired molded part quality. Then, the need for selecting appropriate input variables and response factors becomes necessary. Based on this requirement, researchers applied the method of trial and error to investigate the effect of process parameters on the quality of characteristics. This involves choosing one parameter at a time and observing its effect on molded part quality characteristics of interest.

However, this technique is useful but not economical; it wastes time and materials. Due to this shortcoming, there was a shift to the DOE. The DOE technique considered the effect of more than one parameter at a time on specified quality characteristic of the molded part. This approach is widely accepted and adopted for investigation of processing parameters in microinjection molding. Table 12 presents a summary of the DOE technique as applied to microinjection molding process investigations and corresponding statements of the research findings for various materials.[101,106]

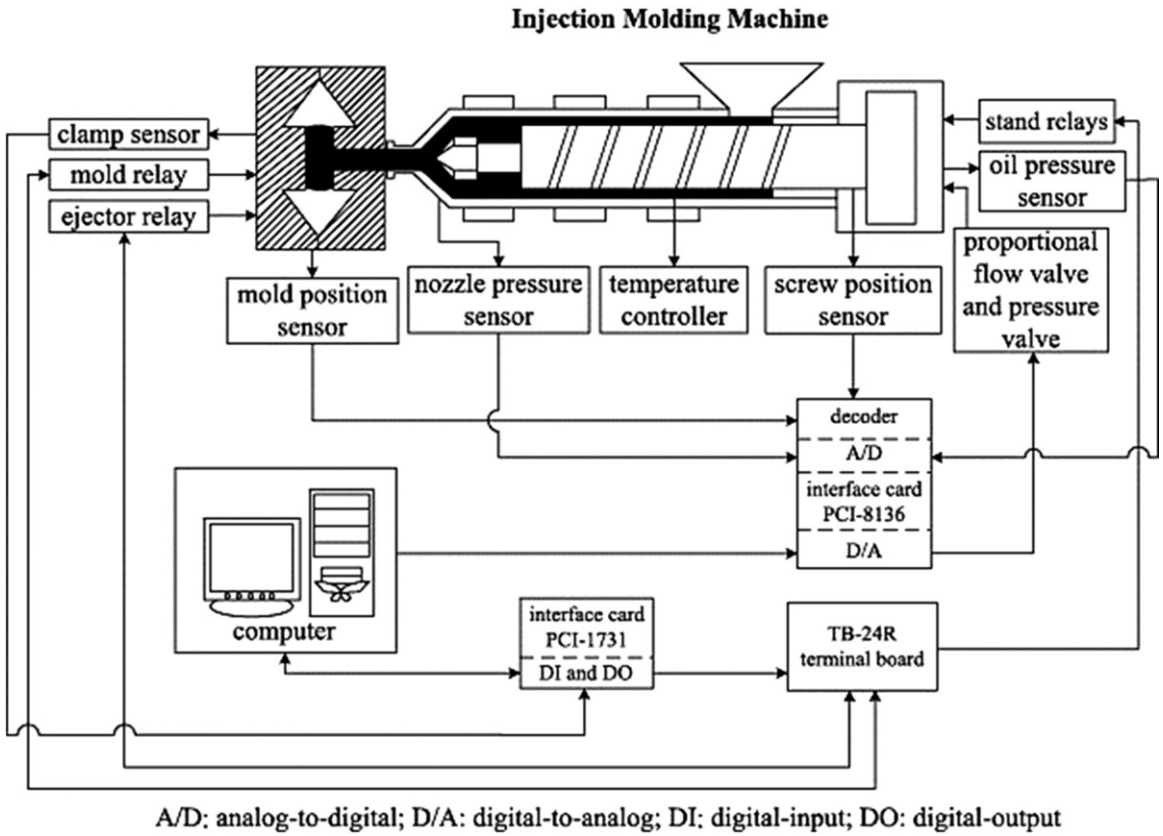

Figure 15 Experimental setup of control system for IMM. Lin, J.; Lian, R.-J. Self-Organizing Fuzzy Controller for Injection Molding Machines. *J. Process. Contr.* **2010**, *20* (5), 585–595.

The approach of DOE is most suitable for consideration of a few variables. However, as the number of variables increased, the techniques became cumbersome and the need for a more robust experiment design became required. Therefore, the method of optimization is then used for investigation of the processing conditions and the response factor(s).

The intelligent algorithms are optimization methods that are based on a global search process in a given design window. Meanwhile, long computational times are required for the simulations, which are based on black-box software. Likewise, the iterative methods are based on the approximate mathematical function obtained by a surrogate model constructed by running a simulation code. The most well-known surrogate models are the RSM, Kriging model, Gaussian process, ANN, and support vector regression. The third category is the non-iterative, with techniques that involve searching for optimum process conditions. This category includes the expert systems, gray relational analysis, fuzzy systems, case-based reasoning, and Taguchi method. In terms of product quality, the Taguchi method is widely used; therefore, some details of this method are outlined here. The Taguchi method is based on a robust design that requires the minimum cost of material and time for experiments and/or simulations.

In recent years, application of the Taguchi method has been proven to be efficient for product quality improvement.[100] However, the Taguchi method is outstanding because it centers on improvement of quality characteristics and integrates engineering and statistical methods to provide high-quality products at minimum cost. The method is based on robust DOE and is implemented by orthogonal array (OA), signal-to-noise (S/N) ratio, and analysis of variance.

The uniqueness of the Taguchi method is the design of OA. The OA responses are obtained via running the simulation code or performing corresponding experiments. OA can be divided into several classes: full level, two levels, and three levels; it is expressed as $L_n(x^y)$, where n is number of runs and x and y represent the level and number of factors considered. **Table 13** is an illustration of the OA design that features $L_9(3^4)$.

Empirical data are evaluated based on three criteria for optimized quality: the more nominal the better; the smaller the better; and the higher the better; the quality characteristics are continuous for engineering analysis. The mean-square deviation for these three quality characteristics can be expressed as:[107]

The more nominal the better:

$$\mathrm{MSD} = \frac{\bar{y}^2}{S^2} \qquad [43]$$

The smaller the better:

$$\mathrm{MSD} = \left(\frac{1}{n}\sum_{i=1}^{n} y_i^2\right) \qquad [44]$$

Table 12 Application of design of experiment for the investigation of molded part quality

Materials[a]	*Number of variables*	*Factors*		*Finding*
		Controlled	*Response*	
PC, SBS, MABS, COC, and PMMA	6	Melt temperature, injection pressure, holding pressure, injection speed, and mold temperature	Filling quality of microfeatured channels	Melt temperature and mold temperature are most significant parameters
PS, PC, and PMMA	5	Injection time, injection pressure, injection temperature, and mold temperature	3D numerical simulation of part filling	The mold temperature is the most important parameter; it must be higher than material T_g
PC and POM	6	Injection speed, holding pressure time, metering size, melt temperature, and mold temperature	Part weight and dimensions	Metering size and holding pressure are most significant; the interaction between both is also important
PS and PC	5	Injection speed, mold temperature, melt temperature, and holding pressure	Complete filling of donut-shaped parts	Injection speed and holding pressure are the most influential, whereas melt temperature and mold temperature have less influence
PP, POM, and ABS	7	Melt temperature, mold temperature, injection speed, holding pressure, air evacuation, and the size of features	Complete filling of high-aspect-ratio rods	Melt temperature and injection speed are key factors for PP and ABS; mold temperature is also significant in case of POM
PC	6	Injection speed, shot size, vacuum, holding pressure, piston diameter	Microfeature height	The diameter of the piston, shot size, injection speed, and mold temperature are significant parameters
PP, POM, and ABS	5	Melt temperature, mold temperature, injection speed, and distance between microfeatures	Complete filling of microstructures	Injection speed and melt temperature are influential in cases of POM and ABS with some side effects; mold temperature improves filling for some shapes; distance between microfeatures is not influential
PP, ABS, and PC	5	Melt temperature, mold temperature, injection speed, and surface finish	Flow length along a micro-channel into a flat cavity	The high levels of all processing parameters result in better filling; surface finish is related to level of turbulence in melt flow
PS	5	Melt temperature, mold temperature, injection speed, and holding pressure	Weld-line formation	Injection speed and mold temperature have the main effect on weld-line placement and orientation
PP	5	Injection pressure, melt temperature, mold temperature, and flow ratio	Flow length	Melt temperature and injection pressure are the most significant factors
COC	4	Holding pressure, filling flow rate, and mold temperature	Filled volume fraction of microfilters	Flow rate found to be the most important processing parameter

[a]Polycarbonate (PC); styrene-butadiene-styrene (SBS); methylmethacrylate acrylonitrile-butadiene-styrene (MABS); cyclic olefin copolymer (COC); polymethylmethacrylate (PMMA); polyoxymethylene (POM); acrylonitrile-butadiene-styrene (ABS); polypropylene (PP); polystyrene (PS).

Source: Modified from Attia, U.; Marson, S.; Alcock, J. Micro-Injection Moulding of Polymer Microfluidic Devices. *Microfluidics and Nanofluidics* **2009**, *7* (1), 1–28; From Attia, U. M.; Alcock, J. R. Optimising Process Conditions for Multiple Quality Criteria in Micro-Injection Moulding. *International Journal of Advanced Manufacturing Technology* **2010**, *50* (5–8), 533–542.

The higher the better:

$$\mathrm{MSD} = \left(\frac{1}{n}\sum_{i=1}^{n}\frac{1}{y_i^2}\right) \quad [45]$$

where $\bar{y}$ is the mean of the sample, S is the standard deviation, y_i is the response value for the specified problem in the ith test, and n is the number of replications in each test trial. Regardless of the category of the quality characteristics, a higher algebraic value of the S/N ratio corresponds to better quality characteristic, such as the smaller variance of the output characteristic around the desired (target) value. The S/N ratio for either of these mentioned criteria is evaluated using eqn [46] with a unit of dB.

$$\eta = S/N = -10\log(\text{MSD}) \quad [46]$$

Therefore, the application of the Taguchi[108,109] optimization method based on multiple quality characteristics of IM continues to emerge as the approach to minimize cost, time, and variation of production processes. This has increased performance and productivity of a given process or system, and improves part quality. Figure 16 illustrates the flow sequence of the Taguchi method.

1.16.4.3 Application of Computer Modeling in Injection Molding Processes

Simulation of the MIM process is quite complex and involves nonisothermal, non-Newtonian flow of shear-thinning of the two-phase fluid flow. The principles were adopted from early developments made in plastic injection molding simulation codes and software based on the Hele–Shaw model. These software solutions are implemented by discretization methods such as finite difference method (FDM), finite volume method (FVM), and finite element modeling (FEM) methods. Newer methods such as the mesh-free method have been developed to eliminate issues with mesh and element grids.

The process design of microinjection molding involves the determination of a number of processing parameters such as pressure (injection, holding, and melt), temperature (coolant, nozzle, barrel, melt, and mold), time (fill, holding, cooling, and cycle), clamping force, injection speed, and injection stroke. In such process, due to the irregular geometry in microscale and the complex thermo-mechanical history during the injection molding cycle, it is generally necessary to resort to numerical simulation methods to properly simulate the molding process and develop the capability of predicting the final configuration of the molded part. The target goals of adopting simulations in the injection molding process by researchers are summarized under the following heading[71, 106]:

i. Flow visualization and prediction of the mold cavity filling during injection molding process. The focus is on the material properties of the melt and tooling geometry on flow and the filling of mold cavity. The objective includes monitoring incomplete filling of the mold cavity and determination of part defects such as weld line and voids, which depend on the runners and gate location of the mold design.
ii. Parametric design analysis and optimization of the part and mold cavity design. This includes the virtual geometry analysis of the mold cavity in relation to the shape of the parts to be produced. This eliminates cost of reconstruction and early identification of a likely problem if trial-and-error methods were used. In addition, the technique will determine and establish optimum mold design and operating conditions.

iii. Modeling of the material properties such as thermal, residual stresses, specific heat coefficient, and processing conditions of melt flow during filling and cooling, which would be useful in estimating the cycle time and determining the critical processing variables and factors.
iv. To identify postprocessing properties and factors, which influence finished part quality characteristics such as shrinkage, warpage, weight, density, and surface finish.
v. To measure and validate empirical data such as warpage and volumetric shrinkage of the part, which are not easily determined experimentally. These quality characteristics are monitored through computer simulation, some of which influenced quality of the finished part.

Despite success of the simulation techniques in micro-injection molding, several factors affect the accuracy of model results.[71] Peter and Rong[110] generalized the complications as:

i. the nature of injection molding, particularly the basic physics of the process
ii. the properties of the material
iii. the geometric complexity of the mold.

1.16.4.3.1 Developments in the simulation of injection molding process

There are several milestones in the history of computer aided engineering (CAE) applications for injection molding. The history of simulation and computer software development are described in detail by Peter and Rong,[110] Zheng *et al.*,[111] and Zhou.[112]

According to Liu *et al.*,[41] computer simulation is used to reduce the design-to-manufacture cycle time through optimization of both design and process parameters. A survey of literature indicates that melt temperature, mold temperature, holding pressure, injection pressure, and injection speed were mostly investigated; these parameters directly influenced part quality.[113] Other factors such as material properties, powder loading, and surface finish of the mold may influence part quality. Therefore, software and codes are developed to predict quality characteristics of products in IM. For some quality characteristics, properties and/or factors are not easily measurable experimentally.[105,114] Several commercial software programs such as ANSYS CFX, PIMSolver, SIGMASOFT, CMOLD, Moldex3D, Moldflow, Solidworks plastics, and others are widely used for injection molding simulations.[115] Some of these software programs were originally developed to handle convectional injection molding and other applications. With little modification to the simulation setup, the software is found to very useful for the prediction of quality characteristics of μIM molded parts.

1.16.4.3.2 Computer simulation and molded part quality enhancement

Computer simulation has significantly supported the development of μPIM, starting from the use of applications and codes developed for plastic injection molding. Many studies have been conducted and various findings reveal a better understanding of the technology. The simulation is used for the determination of optimum operating conditions of the process, the inter-relationships, and correlation among parameters. A survey of the literature indicates that application of computer modeling for enhancement of molded part quality in μIM could be categorized into three phases: simulation, optimization, and process control and monitoring, as depicted in Figure 17.

Today, computer applications in PIM are used extensively beginning from part drafting, which involves computer-aided drafting, and sometimes the process is implemented in CAE. CAE is a very wide field of computer applications including finite element analysis, computational fluid dynamics (CFD), multibody dynamics (MBD), and optimization. In addition, optimization in μIM includes both the design and process, as shown in Figure 17. The design aspect of the optimization is the parametric analysis of the virtual part to be produced to determine appropriate part dimensions, shrinkage factors, and other design variables considered. The application of various optimization techniques to determine optimum operating conditions from the process variables is also considered. This aspect has been described in Section 1.16.4.2. Then, the control and monitoring of defect-free parts is to ensure quality variables through the process of machine execution. This is connected to monitoring and control of finished part quality characteristics.

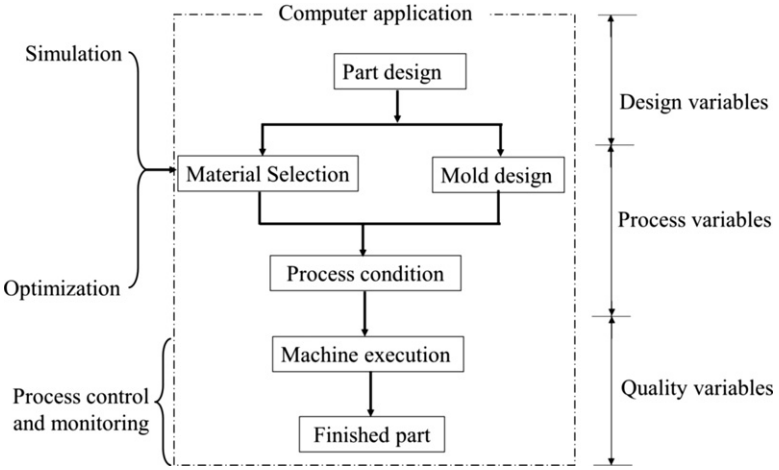

Figure 17 Application of computer modeling for quality enhancement of molded parts in μIM.

However, it is important to investigate the process condition and to establish the influence of process parameters on the quality characteristics of the molded or finished part in μIM. Prior to experimental setup, researchers used computer simulation to investigate the material properties, melt flow into mold cavities (runners and gate). The simulation analysis includes three phases (the filling, packing/holding, and cooling phase) of μIM process.

1.16.4.3.3 Modeling of injection molding process

The success of a defect-free part in μIM depends strongly on the ability of the feedstock melt to flow into the mold cavity for microstructures and nanostructures.[116] Lin *et al.*[117] examined the effects of the processing parameters on the filling of nano feature components through the development of analytical models that were verified and validated experimentally. Their finding indicates that nanoscale filling requires higher mold temperatures. However, whenever the filling aspect ratio is more than 1, the mold temperature should be raised near or above the glass transition temperature of the polymer. The suitability of analytical methods diminishes as the complexity of the microfeature/molded part increases, thus giving rise to the use of numerical methods. Modeling and mathematical derivations have been implemented by the application of suitable numerical methods to solve the governing equations developed or formulated for injection molding simulation.[118–121] These governing equations are formulated to consider the operational condition as well as the material properties of the feedstock.

1.16.4.3.3.1 Feedstock properties and mixing simulation

The material properties of the feedstock considered for injection molding simulation depend on many factors and processing conditions. Thus, rheological investigations of the feedstock are essentially studied for the analysis of melt flow behavior during mixing and injection (filling, packing, and cooling phase) of molded part modeling. Some of these properties considered are viscosity, shear modulus, specific heat capacity, elastic modulus, thermal conductivity, and pressure–volume–temperature (PVT), among others. A general rule-of-mixtures model for some of these properties is presented in Section 1.16.3.1.3. Due to the importance of viscosity and availability of models, it is further discussed here. For the model injection molding process, a viscosity model (function) is required to predict the fluid flow behavior. The viscosity curves of most thermoplastics and polymeric binders used in the PIM process have the same dependence on shear rates. The viscosity hardly changes when the rate of shear is very low or very high; at this time, pseudoplastic fluid acts similar to a Newtonian fluid. At least four parameters are required to reflect this relationship between viscosity and shear rate.

Modeling of viscosity has attained remarkable landmarks by models proposed by Cross[122] in 1965 and Carreau[123] in 1972, respectively. These models are believed to be better than the others in terms of representation of characteristics of the thermoplastic polymer investigated. In addition, the Sisko model[124] proposed by Sisko in 1958 combined the characteristics of Bingham plastics and the power law model. Models such as the Prandtl–Eyring model, Ellis model, Casson model, and fractional exponential model are developed for other specific applications. Currently, the power law and the cross model are widely used in injection molding to describe the viscosity function.[125] Therefore, an overview of these models and the mathematical relationship is presented.

1.16.4.3.3.1.1 Power law model

This is a well-known viscosity model that is often used in most injection molding simulations. de Waele in 1923 and Ostwald in 1925 proposed the power law model,[122] also known as the Ostwald–de Waele relationship, which has been used successfully to predict the shear thinning region. This model has the following form:

$$\eta = \eta_0 |\dot{\gamma}|^{n-1} \quad [47]$$

$$\eta_0 = B\left(\frac{T_b}{T}\right) \quad [48]$$

where η_0 is the Newtonian viscosity or zero shear rate viscosity, which is defined as the viscosity at zero shear rate, B is a constant called the consistency index, T_b is a constant showing the temperature sensitivity of this material, T is the melting temperature, and n is the power law index with a value between $0 < n \geq 1$ for polymer melts. The natural logarithms of the eqn [48] give:

$$\ln(\eta) = (n-1)\ln(\dot{\gamma}) + \ln(\eta_0) \quad [49]$$

Flow behaviors of a power law fluid depend on the value of n[126] for:

$n < 1$, the fluid exhibits shear-thinning properties;
$n = 1$, the fluid shows Newtonian behavior;
$n > 1$, the fluid shows shear-thickening behavior.

According to Thavanayagam *et al.*,[37] feedstocks that exhibit shear thinning ($n < 1$) are suitable for PIM. Feedstock with dilatant flow behavior ($n > 1$) is not suitable for PIM because powder and binder separation can occur under a high shear rate. Therefore, rheological properties should be assessed over a wide range of shear rates.

Equation [49] is termed the first-order viscosity model and used in Moldflow software for flow analysis of the injection molding process. To improve the modeling of viscosity in the low shear rate region, the second-order model was developed by Moldflow and expressed as:

$$\ln \eta = A_0 + A_1 \ln \dot{\gamma} A_2 T + A_3 (\ln \dot{\gamma})^2 + A_4 T \ln \dot{\gamma} + A_5 T^2 \quad [50]$$

where A_i are constants and T is temperature. According to Koszkul and Nabialek,[127], this model has been criticized on the grounds that it is based on empirical observations. This is of little relevance for our purposes. What is required is a model that fits the experimental data as closely as possible, and the second-order model is able to characterize the observed behavior of polymer melts. In particular, the second-order model can model the following features of polymer melts:

a. convergence of iso-shear rate curves with increasing temperature,
b. convergence of isotherms with increasing shear rate,

c. the increasing rate at which viscosity decreases as shear rate is increased,
d. the increasing rate at which viscosity decreases with increasing temperature.

In general, the literature demonstrates that the power law represents the behavior of polymer melts in the high shear rate region, and it is also quite easy to fit experimental data for the model and determine the constants η_0 and n. In the Moldflow simulation software, the first is developed based on empirical data. The second model is used to characterize the behavior of the melts. However, the main disadvantage of the model is in the low shear rate range. Despite this shortcoming, the model has been widely used for modeling flow in injection molding. It is important to consider the phase of the process under consideration independently. For instance, particularly in the filling phase, shear rates are frequently high enough to justify the use of the first-order model. Shear rates are often low in the packing phase. Also, it is possible to have low shear rates in the filling phase when the filling pattern is unbalanced.

1.16.4.3.3.1.2 Cross Model

The cross viscosity model is expressed as:

$$\eta = \frac{\eta_0}{1 + \left(\frac{\eta_0|\dot{\gamma}|}{\tau^*}\right)^{n-1}} \quad [51]$$

where τ^* is the shear stress at the transition between Newtonian and power law behavior, which can be modeled using the widely accepted seventh constant cross model

$$\eta_0 = D_1 \exp\left[-\frac{A_1(T - T^*)}{A_2 + (T - T^*)}\right], \quad A_2 = A_3 + D_3 P, \quad \text{and} \quad T^* = D_2 + D_3 p \quad [52]$$

where η_0, n, τ^*, and $\dot{\gamma}$ denote the zero heat rate viscosity, the power law index, the critical stress level at the transition to shear thinning, and the shear rate. T^* is the glass transition temperature, p is the pressure, and A_1, A_2, A_3, D_1, D_2, and D_3 are data-fitted coefficients.

Compared to plastic injection molding, PIM is more prone to IM defects such as jetting and nonuniform flows, and both PIMSolver and Moldflow are useful simulation software for predicting injection molding filling defects. However, a follow-up with experiments is highly recommended, especially for PIM. Concentrated powder/binder mixtures have a peculiar nature of yield stress with shear-thinning viscous behavior. To be able to simulate these natures, the modified cross model for viscosity as a function of the effective shear rate and temperature is used for PIMSolver.

$$\eta(\dot{\gamma}, T) = \frac{\eta_0}{1 + C(\eta_0\dot{\gamma})^{1-n}} + \tau_y\dot{\gamma} \quad [53]$$

where η_0, n, τ^*, and Tb denote the zero shear rate viscosity, the power law exponent, the transition shear stress, the constant amplitude, and the reference temperature in absolute scale for the Arrhenius temperature dependence of the viscosity. A new term τ_y is added to the modified cross model in eqn [53] for the yield stress.[128,129] Equation [56] is a viscosity model developed by PIM specialists for PIMSolver software.

1.16.4.3.3.1.3 Carreau model

The Carreau model has the form:

$$\frac{\eta - \eta_\infty}{\eta_0 - \eta_\infty} = [1 + (\lambda\dot{\gamma})]^{(n-1)/a} \quad [54]$$

where η_∞ is the viscosity at infinite shear rate, η_0 is the viscosity at zero shear rate, n is a dimensionless constant with the same interpretation as the power law model eqn [47], and K is a material time constant parameter. The Bird–Carreau model is given by $a=2$. For many shear thinning fluids, $a \approx 2$.

1.16.4.3.3.1.4 Ellis Model

The Ellis model presents the viscosity as a function of shear stress τ, mathematically represented as:

$$\frac{\eta_0}{\eta} = 1 + \left(\frac{\tau}{\tau_{1/2}}\right)^{\alpha-1} \quad [55]$$

where $\tau_{1/2}$ is the value of shear stress for which $\eta=\eta_{0/2}$ and $\alpha - 1$ is the slope of the graph $\ln[(\eta_0/\eta) - 1]$ versus $\ln(\tau/\tau_{1/2})$.

However, the research effort is still ongoing for a more suitable model for different material. Recently, Hidalgo *et al.*[35] proposed a generalized rheological model that involves the following parameters: shear rate (γ), temperature (T), solid loading (Φ), and particle size (PS). The model is expressed as:

$$\eta(\dot{\gamma}, T, \phi, \mathrm{PS}) = \frac{C_u}{d_{50}} \cdot \exp\left(\frac{E_a}{\mathrm{RT}}\right) \cdot \left(\frac{\tau}{\dot{\gamma}} + \left(\frac{\eta_0}{1 + K\dot{\gamma}^n}\right)\right) \cdot \left(\frac{\phi_{\mathrm{crit}}}{\phi_{\mathrm{crit}} - \phi}\right)^m \quad [56]$$

Having fully understood the properties of the metal powder, valuable information will be obtained from simulation of the mixing process.

1.16.4.3.3.1.5 Modeling of feedstock mixing

In practice, distributive mixing of feedstock constituents is investigated without concern for molecular diffusion. Although the behavior of melt during preparation is analyzed by fluid flow governing equations for specific mixer geometry for given material properties and operating conditions. Finite element method (FEM) is used mostly for the analysis of the governing fluid flow equation. According to Huang and Kuo,[130] computer simulation is a numerical tool that is more cost-effective than performing experiments in complex systems. This establishes a basis for design optimization, scale-up, and control of the system. Nevertheless, there are two common numerical approaches for studying particle mixing: the discrete approach and the continuum approach. The Monte Carlo method, cellular automata, and discrete element method (DEM) were developed based the on discrete approach. In addition, researchers now prefer to analyze granular flow with CFD because the continuum approach does not account for a system size relative to DEM. The flow pattern of mixing particles can be described as either dispersive or distributive mixing,[131] as illustrated in **Figure 18**.

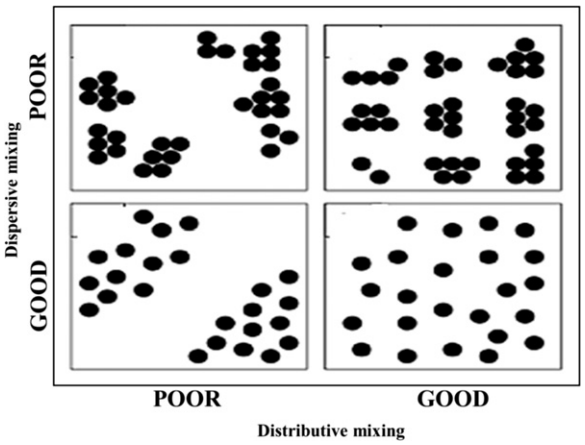

Figure 18 An illustration of dispersive and distributive mixing.

Therefore, the governing equations for the analysis of the feedstock melt during mixing are as follows:

$$\nabla \cdot \vec{V} = 0 \quad [57]$$

where $\vec{V}$ is the local velocity of the moving part

$$H(v - \vec{V}) + (1 - H)\left[\nabla \cdot \vec{\tau} - \nabla p + \rho\left(\frac{\partial v}{\partial t} + v \cdot \nabla \vec{V}\right)\right] = 0 \quad [58]$$

where H is a step function equal to 0 for fluid field and 1 for inner moving parts, v is the fluid velocity, $\vec{\tau}$ is the strain rate tensor, P is the fluid pressure, ρ is the fluid density, and t is the time.

$$\rho C(T)\left(\frac{\partial T}{\partial t} + v \cdot \nabla T\right) = T \cdot \nabla v + r - \nabla \cdot q \quad [59]$$

where $C(T)$ is the heat capacity as a function of temperature, r is volumetric heat source, and q is the heat flux.

Equation [57] is the continuity equation, eqn [58] is the momentum, and eqn [59] is the energy equation. The stress tensor and the shear rate are defined by eqn [60] and expressed as:

$$\vec{\tau} = 2\eta(\dot{\gamma}, T)\vec{D} \quad [60]$$

$$\dot{\gamma} = \sqrt{2\vec{D} : \vec{D}} \quad [61]$$

Suitable viscosity model is selected or developed from empirical data to describe the material behavior of the feedstock.

The equations formulated are solved by the numerical method, but the FEM is dominantly used. The particle tracking method has been successfully applied. Analysis of feedstock mixing by the particle tracking scheme involved three steps:

- flow analysis to obtain a velocity field of a mixing device;
- particle tracking step to obtain distribution of particles at the end of the mixer;
- quantification of mixing from the obtained particle distribution.

Then, to track the relative position of particles within a specified domain, the solution of the physical model involved is an ordinary differential equation (ODE):

$$\frac{dx}{dt} = u \quad [62]$$

where x is the particle position vector, u is the particle velocity, and t is the time. The numerical method is used for the solution of the 3D problem. These equations are sometimes simplified to 2D to save time and resources. The fourth-order Runge–Kutta method is widely used for solving eqns [62].

The homogeneity of the powder-binder mixture is evaluated by the mixing uniformity to achieve the required distribution of the particles. A proper measure of mixing is the uniformity of the particle distribution as well as information on material properties such as the entropy of the particles at any given cross-section within the mixing domain based on tracking method. The characterization of the mixing progress requires first the division of the mixer cross-section into a number of cells. Then, for a certain particle configuration, the mixing entropy S is defined as a sum of the information entropy of individual cells constituting the cross-sectional area, defined by:

$$S = -\sum_{i=1}^{N} n_i \log n_i \quad [63]$$

where N is the number of cells and n_i is the particle number density at the ith cell. Instead of directly using the information entropy in the mixing analysis, we use a normalized entropy. Increased S^* as a measure of mixing is given by:

$$S^* = \frac{S - S_0}{S_{max} - S_0} \quad [64]$$

where S_0 is the entropy at the inlet and S_{max} is the maximum possible entropy, defined by log$N$, which is the ideal case with a uniform distribution of the particles, such as $n_i = 1/N$.

1.16.4.3.3.2 Fundamentals of governing equations and boundary conditions

The governing equations are a set relationship describing the physical model or system. In typical fluid flow, the conservation equation of mass, momentum, and energy are expressed in a similar form. The mathematical representations of these equations are based on fundamental physical principles, on which all fluid flow is derived. However, formulation or choice of a suitable equation for the analysis of the fluid flow is very important and fundamental for CFD. When obtaining the basic equations of fluid dynamics, the following philosophy is always followed:

(1) The governing equations are derived from the fundamental physical concepts of physics, namely:
   - mass is conserved
   - conservation of momentum F = ma (Newton's second law)
   - energy is conserved.

(2) The fundamental physical concepts are applied to a suitable model to describe the fluid.

(3) Mathematical modeling for the fluid.

A suitable boundary condition is imposed on the ODE or partial differential equation (PDE). These conditions (such as slip, inertia, isothermal, isobaric, etc.) and specified values for the independent variable(s) such as temperature, pressure, and velocity over a range at which the solution being analytical or numerical is expected to converge.

1.16.4.3.3.3 Melt flow behavior in micro-size channel

The actual design of the runner is usually trapezoidal in the cross-section, which allows easy ejection of the part from the mold. However, most 2.5D mold-filling simulation software programs approximate the geometry of the channel to the circular cross-section runner. The graphical user interface of the software may provide various alternatives, but usually the black-box evaluation of the software approximates to an equivalent circular cross-section. This approach is not a satisfactory approximation and may introduce an appreciable error in computational results of the software. Therefore, there is a need for analytical modeling or in-house code to study the melt front flow behavior in microcavity filling of μIM.

The flow and filling analysis of the mold cavity during μIM by the feedstock melt has been investigated. In this analysis, a single point injection of melt is considered through the runner channel to the mold cavity. **Figure 19** is a schematic representation of the runner channel. It is important to note that some assumptions were made. The injection flow rate is considered to be constant during the filling process of the cavity and locally filled. Likewise, the volume in the part required is far smaller as compared to the main cavity. The amount of melt flow rate in the main cavity is assumed to be the same as the injection rate. For one-dimensional viscous flow, the momentum equation can be expressed as:

$$\frac{dp}{dx} = \frac{d}{d\gamma}\left(\eta \frac{du}{d\gamma}\right) \quad [65]$$

where η is the viscosity and, for a power law fluid, can be written as

$$\eta = m_x \dot{\gamma}^{n-1} \quad [66]$$

where $\dot{\gamma}$ represents the shear rate, m_x is the flow consistency index, and n is the power law index. The microinjection molded cavity feature is filled within a short period of time. Then, the temperature of the melt within the thickness (h) of the main flow path is assumed to be constant. The consistency index (m_x) can be expressed as:

$$m_x = m_o e^{-a_0(T_m - T_0)} \quad [67]$$

where T_m is the melting temperature at the main cavity, and m_o, a_o, and T_o are material constants. To solve for the velocity of the flow (u), eqns [66] and [67] are substituted into eqn [65] and expressed as:

$$u = \left(\frac{1}{m_x}\right)^{\frac{1}{n}} \left(\frac{n}{n+1}\right) \left|\frac{dp}{dx}\right|^{\frac{1}{n}} \left[\left(\frac{h}{2}\right)^{\frac{n+1}{n}} - \gamma^{\frac{n+1}{n}}\right] \quad [68]$$

and the injection flow rate (Q) across the cross-section of the flow channel is given by:

$$Q = \left(\frac{1}{m_x}\right)^{\frac{1}{n}} \left(\frac{2nw}{2n+1}\right) \left|\frac{dp}{dx}\right|^{\frac{1}{n}} \left(\frac{h}{2}\right)^{\frac{2n+1}{n}} \quad [69]$$

Also, the pressure (P_o) at point o, as indicated in **Figure 19**, depends on the melt filled distance (x_o) from the point to the flow front, which is assumed to be constant across the thickness of the main cavity and expressed as:

$$P_o = \frac{2^{n+1}(2n+1)^n}{n^n} \frac{m_x x_o}{w^n h^{2n+1}} Q^n \quad [70]$$

The melt velocity (V_x) along the flow path of the main cavity is expressed as:

$$V_x = \frac{dx}{dt}$$
$$\frac{dx}{dt} = \frac{Q_x}{wh} \approx \frac{Q}{wh} \quad [71]$$

where w is the width of the channel and h represents the depth of the micro-size channel. It is assumed that the amount of melt into the channel is quite small, and Q_x represents the flow rate at the main cavity. Also, Q_x is approximately the same as the injection flow rate, Q. Then, evaluating eqn [71] to estimate the flow front from point o is expressed as:

$$x_o = \frac{Qt}{wh} \quad [72]$$

From eqn [68], pressure drop can be estimated and evaluated using:

$$\frac{dp}{dx} = m_x \left(\frac{2nw}{2n+1}\right)^{-n} \left(\frac{h}{2}\right)^{-(2n+1)} Q^n \quad [73]$$

Then, substituting for m_x in eqn [73], the pressure drop can be expressed as a function of both the melt flow filled distance x_0 and the temperature.

$$\frac{dp}{dx} = \left(\frac{2n+1}{nw}\right)^n \left(\frac{h}{2}\right)^{-(2n+1)} Q^n m_o e^{-a_0(T_m - T_0)} \quad [74]$$

Integrating eqn [74] or substituting for m_x in eqn [70] yields an expression for pressure in terms of the material properties and as a function of the temperature.

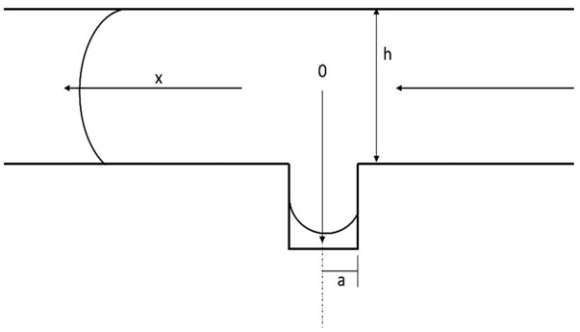

Figure 19 Schematics of the physical model for μIM flow channel.

$$p(x_0, T_0) = \left(\frac{2n+1}{nw}\right)^n \left(\frac{h}{2}\right)^{-(2n+1)} Q^n x_0 m_o e^{-a_0(T_m - T_0)} \quad [75]$$

Total pressure drop is a summation of the losses across the sprue, runner, and gate, as well as the within the mold cavity.

$$\Delta p = \Delta p_{\text{Pipe}} + \Delta p_{\text{cavity}} \quad [76]$$

Lin and Young[116] derived an analytical model for the estimation of pressure drop in the mold cavity as well as in the pipe. The combined effect of the pressure drop in the sprue, runner, and gate is referred to as Δp_{pipe} and expressed as:

$$\Delta p_{\text{Pipe}} = \left[\frac{2m_x(3n+1)^n \Delta x}{n^n \pi} R^{-(3n+1)}\right] Q^n = \overline{R}_{\text{pipe}} Q^n \quad [77]$$

where $\overline{R}_{\text{pipe}}$ is the hydraulic radius of the sprue, runner, and/or gate.

1.16.4.3.3.4 Filling phase of injection molding

The filling phase of injection molding is a very complex process. Its analysis is based on the generalized Hele-Shaw model with incompressible, generalized, non-Newtonian fluid under nonisothermal conditions. The governing equations of the feedstock melt are expressed as follows.

The continuity equation is expressed as:

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z} = 0 \quad [78]$$

The momentum equations are expressed as:

$$\frac{\partial p}{\partial x} = \frac{\partial}{\partial x}\left(\eta \frac{\partial u}{\partial z}\right) \quad [79]$$

$$\frac{\partial p}{\partial y} = \frac{\partial}{\partial y}\left(\eta \frac{\partial v}{\partial z}\right) \quad [80]$$

$$\frac{\partial p}{\partial z} = 0 \quad [81]$$

From eqn [78], V_x, V_y, and V_z represent velocity function along the x, y, and z axes, respectively, whereas p is the pressure and η is the viscosity. Most textbooks use u, v, and w for V_x, V_y, and V_z; these are only used for clarity. Then, combining eqns [78], [69], and [80] and integrating them along the z-direction (thickness direction) gives the fluid flow governing equation for the filling stage, expressed as:

$$\frac{\partial}{\partial x}\left(s\frac{\partial p}{\partial x}\right) + \frac{\partial}{\partial y}\left(s\frac{\partial p}{\partial y}\right) = 0 \quad [82]$$

$$s = \int_{-b}^{b} \frac{z^2}{\eta}\, dz \quad [83]$$

Based on the lubrication and Hele–Shaw approximations, the energy equation governing the mold cavity filling stage during injection molding by the melt is express as:

$$\rho C_p \left(\frac{\partial T}{\partial t} + V_x \frac{\partial T}{\partial x} + V_y \frac{\partial T}{\partial x}\right) = K \frac{\partial^2 T}{\partial x^2} + \eta \dot{\gamma}^2 \quad [84]$$

the shear rate $(\dot{\gamma})$ is express as:

$$\dot{\gamma} = \left[\left(\frac{\partial v_x}{\partial z}\right)^2 + \left(\frac{\partial v_y}{\partial z}\right)^2\right]^{\frac{1}{2}} \quad [85]$$

From eqn [69], the absolute temperature (T), time (t), melt density (ρ), specific heat of the feedstock (C_p), and K represent thermal conductivity of feedstock. The energy equation for the solid phase is expressed as:

$$\rho_s C_{p_s} \frac{\partial T_s}{\partial t} = K \frac{\partial^2 T_s}{\partial {z_s}^2} \quad [86]$$

where the subscript s represents the solid phase referring to the ceramic or metal powder constituent of the feedstock. Once the governing equations are derived from the continuum-based conservation laws and the constitutive relations, the next task is boundary conditions. A boundary condition for the governing equations involves specification of parameter value(s) and conditions for the filling stage, typically:

Flow equation: melt flow rate at injection point; slip/no slip at cavity wall; free surface at melt front.
Energy equation: melt/injection; temperature at injection point; mold wall temperature; free surface at melt-front.

Note that the boundary conditions are required to solve the governing equation. Therefore, the initial values of the flow rate and injection temperature at the injection node are required. Jiang *et al.*[132] analyzed the feedstock melt and solid phase considering basic assumptions of non-Newtonian and nonisothermal fluid flow.

1.16.4.3.3.5 Packing phase of injection molding

As illustrated in **Figure 8** in Section 1.16.3.2, as the mold cavity filling is nearly completed, the packing phase began. A switchover is experienced as the ram/screw control strategy of the IMM changes from velocity control to pressure control.

Pressure control is required to ensure full filling of the mold cavity and to provide the needed pressure by the filled cavity prior to freezing of the gate. It is important to note that the packing pressure is used to compensate for the anticipated shrinkage in the cooling stage.

In the analysis of the packing stage, it is important to include the effect of melt compressibility. The melt compressibility is dependent on the specific volume of pressure and temperature; this leads to a feedstock-specific PVT relationship/equation state.

Then, suitable PVT and viscosity models are required for the analysis of the packing stage based on the continuum approach; the governing equations are presented as follows.

Mass conservation of the feedstock is expressed as:

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho V_x)}{\partial x} + \frac{\partial(\rho V_y)}{\partial y} + \frac{\partial(\rho V_z)}{\partial z} = 0 \quad [87]$$

Assuming that pressure convection terms are ignored in the packing stage, then eqn [87] becomes:

$$K\frac{\partial \rho}{\partial t} - \beta\left(\frac{\partial T}{\partial t} + V_x\frac{\partial T}{\partial x} + V_y\frac{\partial T}{\partial y}\right) + \left(\frac{\partial V_x}{\partial x} + \frac{\partial V_y}{\partial y}\right) = 0 \qquad [88]$$

Where K is the isothermal compressibility coefficient of the material. The energy equation for this processing stage is expressed as:

$$\rho C_p\left(\frac{\partial T}{\partial t} + V_x\frac{\partial T}{\partial x} + V_y\frac{\partial T}{\partial y}\right) = K\frac{\partial^2 T}{\partial x^2} + \eta\dot{\gamma}^2 + \beta T\frac{\partial P}{\partial t} \qquad [89]$$

To replicate the physical model, the same value of shear rate is used for both packing and mold cavity filling, respectively. Typical boundary and initial conditions for the packing analysis stage of IM is presented as follows:

- mass and momentum conservations: specified pressure at injection point, slip condition at cavity wall, and free surface at melt-front.
- energy equation: specified temperature at injection point, mold wall temperature condition at the cavity wall, and free surface at melt-front.
- initial conditions: pressure, velocity, temperature, and density from the results of the filling stage analysis are used.

1.16.4.3.3.6 Cooling phase of injection molding

Mold filling and other preceding processes significantly contribute to the quality of the molded part, but the successful completion of the cooling stage enhances the productivity and the quality of the final component. Cooling starts immediately upon injection of the melt into the mold cavity; theoretically, cooling time is referred to as the period that elapses between when the gate freezes and part ejection.

In the cooling analysis of the mold, the main focus is on the temperature profile at the cavity walls as well as on surface of the mold. The boundary condition will be guided by the melt or filling/injection temperature and the packing phase. When the injection molding process is in the steady state, the mold temperature will fluctuate periodically over time due to the interaction between the hot melt and cavity surface supported by the activities of the cooling medium. Therefore, analysis of the cooling phenomena is investigated to determine the effect of the variant temperature on the molded part. A 3D cycle-averaged approach is adopted for the determination of the cycle-averaged temperature field and its effects on the molded part. This method is chosen to reduce the computation time for the transient component of the thermal analysis of the process. The governing equations of the heat transfer for the injection mold cooling stage based on the cycle-averaged concept is expressed as:

$$\nabla^2\overline{T} = 0 \qquad [90]$$

$$\rho C_p\frac{\partial T}{\partial t} = K\frac{\partial^2 T}{\partial z^2} \qquad [91]$$

Next, specifications of the initial and boundary conditions for the solution of the governing equations are presented. Typically, the initial and boundary conditions for the cooling stage of injection molding are:

- process condition used or specified during packing stage analysis is maintained as initial conditions
- considerations for convective heat transfer associated with the cooling medium, natural convection heat transfer with air, and material properties of the melt and mold.

1.16.4.4 Analytical and Numerical Methods for Injection Molding Simulations

The governing equations are solved using analytical methods, but as the physics of the problem becomes more complex, the use of numerical methods and/or software is implemented. However, FDM, FVM, and FEM[133–135] methods were mostly used for the analysis of melt flow with variant conditions such as isothermal, nonisothermal,[136] and non-Newtonian.[137] Due to the challenges of handling mesh or elements in the aforementioned methods, the use of mesh-free methods[133,138] for the injection molding process is now being investigated. Kim and Turng[139] present a comprehensive review of the developments of 3D CAE simulation for injection molding. The study is aimed at providing insights into the emerging 3D CAE tools to facilitate judicious application and further developments for the design and manufacturing of complex injection molded parts.

1.16.4.5 Process Simulation and Quality Characteristics for Defect-Free Parts in PIM

Process simulations are performed to evaluate quality characteristics of the products at various processing stage of PIM. Simulations are implemented to gain a better understanding of the relationship between processing conditions and part quality, which may be possible by experience alone. This has been the main reason for the development of injection molding simulation. The target goal of setting up simulations in injection molding is outlined in Section 1.16.4.3.

Specifically, simulations are set-up to evaluate the effect of processing conditions on quality characteristics of the product. Some of these response factors or quality characteristics tested are homogeneity of feedstock, mold cavity filling, dimensional, mechanical, surface-finished and microstructural morphological, optical thermal, and electrical properties. Attention is always directed toward finished part quality, which can be broadly classified into two groups: internal properties and external properties. The internal properties that characterized the microstructure of a molded part are the internal stress, molecular weight, degree of crystallization, orientation, spherulite size, and the distribution of fillers and reinforcements. The external properties are the dimension, shape, surface, electrical, optical, and mechanical properties. However, research themes and literature on molded part quality are mostly concerned with the external properties and less on the internal properties of the injection molded parts. Molded part quality is critically influenced by material properties, IMM, part/mold cavity design, and processing conditions. Therefore, research interests are focused on the effects of processing parameters and conditions for improved molded parts. These

investigations include modeling and experimental validation of the simulation and predicted results. Simulation and modeling of microinjection molding have been presented in this chapter. However, it is important to remember that debinding of the polymeric binder is critical and requires extra caution for successful PIM. Therefore, several efforts have been put forth to model and predict the decomposition of the polymeric binder during the debinding process to improve production of defect-free parts. Based on the free decomposition model, the depolymerization of polymeric binder components can be described by first-order reaction kinetics. Shi *et al.*[83] proposed a diffusion-controlled model for predicting the remaining weight fraction of the polymeric binder (h), assuming a linear heating rate (z) is expressed as:

$$h = \exp\left\{\frac{K_0 RT^2 \exp[-E/(RT)]}{ZE}\left[1 - \frac{2RT}{E} + \frac{6(RT)^2}{E^2}\right]\right\} \cdot (t \le t_{\mathrm{db}}) \quad [92]$$

When heating rate is high and temperature is uniform, then the polymeric decomposition within the period is relatively small, especially for metal powders, which are good conductors. An estimate of the remaining polymeric weight fraction (h_{db}) at the debinding temperature (T_{db}) is obtained by substituting T_{db} for T in eqn [92]. However, when ($t > t_{db}$), the remaining weight fraction of the polymer is expressed as:

$$h = h_{\mathrm{db}} \exp\left[-K_0 (t - t_{\mathrm{db}}) \exp\left(-\frac{E}{RT_{\mathrm{db}}}\right)\right] \quad [93]$$

The monomer production rate $\dot{Q}$ based on the volume of the polymer particle is estimated from the relationship:

$$\dot{Q} = \frac{V_p}{V_2}\frac{\mathrm{d}(1-h)}{\mathrm{d}t} = \frac{V_p}{V_2} Kh \quad [94]$$

alternatively expressed as:

$$\dot{Q} = \rho_p V_p K_0 \exp\left(-\frac{E}{RT}\right) \exp\left\{\frac{K_0 RT^2 \exp[-E/(RT)]}{ZE}\left[1 - \frac{2RT}{E} + \frac{6(RT)^2}{E^2}\right]\right\} \quad [95]$$

where ρ_p is the density of the polymer, V_P is the polymer volume fraction, K_o is the specific rate constant, Z is the heating rate, E is the activation energy for thermal degradation, and T is the absolute temperature.

Considering diffusion-controlled decomposition situations, the free decomposition model assumes that the monomer pressure in the polymer has no effect on the decomposition kinetics. Therefore, $\dot{Q}$ is expressed as:

$$\dot{Q} = \frac{V_p}{V_2} Khf = \frac{V_p}{V_2} K(1 - W_1)(1 - a_1) \quad [96]$$

where f is the limiting factor that depends on the activities of the monomer and expressed as:

$$f = 1 - \frac{a_1}{a_e} \quad [97]$$

This expression indicates that the limiting factor depends on the ratio of the activity of the monomer (a_1) to the equilibrium activity, and the depolymerization will go to completion at the debinding temperature even in the presence of monomers. The monomer activity in the aforementioned equation can be calculated using the Flory–Huggins relation expressed as:

$$a_1 = \theta_1 \exp\left[(1 - \theta_1) + x(1 - \theta_1)^2\right] \quad [98]$$

where θ is the volume fraction of monomers in the polymer–monomer solution, and x is an interaction parameter for the polymer–monomer system which also appears later in the free volume theory of diffusion. Alternatively, if the monomer vapor pressure over the polymer–monomer solution, P_1, is known, then the activity of the monomer can be obtained as:

$$a_1 = \frac{P_1}{P_1^0} \quad [99]$$

where P_1^0 is the monomer vapor pressure and can be estimated by the Clausius–Claperon relation expressed as:

$$\ln P_1^0 = -\frac{\Delta H_{\mathrm{vap}}}{RT} + I \quad [100]$$

where H_{vap} is the enthalpy of vaporization, I is a constant, and its value depends on the pressure unit used.

Therefore, the monomer concentration (C) within the undegraded core is estimated by the PDE

$$\frac{\partial C}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(rD\frac{\partial C}{\partial r}\right) + \dot{Q} \quad [101]$$

where r is the radial distance and D is the diffusion coefficient of the monomer through the powder–polymer suspension. Considering two-phase medium containing polymer and particle, the D is estimated by:

$$D = \left(1 - \frac{3V_c}{\partial r}\right) D_p \quad [102]$$

$$D_p = D_{01}(1 - \theta_1)^2(1 - 2x\theta_1) \exp\left[\frac{W_1 V_1(0) + \zeta(1 - W_1)V_2(0)}{V_{Fh}/\omega}\right] \quad [103]$$

$$D_{01} = D_0 \exp\left(-\frac{E_d}{RT}\right) \quad [104]$$

where D_{01} is the pre-exponential factor, D_0 is a constant, and E_d is the activation energy for monomer diffusion. The subscripts 1 and 2 in eqn [103] denote monomer and polymer, respectively. x is the ratio of critical molar volumes of hopping units of the monomer and the polymer. The average hole free volume per unit mass (V_{FH}) is defined in terms of an overlap factor for free volume (ω), K_{11}, K_{12}, K_{21}, and K_{22} represent free volume parameters, and $(T_g)_1$ and $(T_g)_2$ are the glass transition temperatures of the composites materials, expressed as:

$$\frac{V_{FH}}{\omega} = \frac{K_{11}}{\omega} W_1 \left[K_{21} + T - (T_g)_1\right] + \frac{K_{12}}{\omega}(-W_1)\left[K_{22} + T - (T_g)_2\right] \quad [105]$$

1.16.5 PIM Part Fabrication and Applications

Microfabrication of parts and components can be categorized under three main types: microprecision parts, micropatterned parts, and single microparts.[68] These categories are based on precision, scale, and tolerance limits of the components and fabrication capabilities of the techniques.

1.16.5.1 Fabrication Capabilities of μMIM

Fabrication of 3D hollow[140,141] and movable[142] parts by μMIM is now possible. Attia *et al.*[142] developed a novel framework for fabrication of a moving interface by a powder micromolding process. The fundamental principles and techniques of μMIM machines are utilized in pharmaceutical industries for the production of drugs.[143]

1.16.5.2 Inspection and quality control of MIM products

Application of inspection and quality control techniques to products in MIM enhanced finished part quality and productivity. In general, quality control evaluation techniques can be either destructive or nondestructive.[144] These measures are taken to control product defects at various processing stages of MIM and are supported by statistical quality control.[145] This is to correct production inconsistency and product defects such as short shot, shrinkage, distortion, void, sink mark, weld line, and cracks. MIM involved many processing parameters that are interrelated to one another; hence, the defect identified can be handled in multiple ways. **Table 14** illustrates some common defects, causes, and remedies to improve finished part quality. However, finished part quality is enhanced through effective control and monitoring of the process conditions at different stages.[146] Quality characteristics include homogeneity of the

Table 14 Potential causes and remedies of common defects in MIM

Defects	*Potential causes*	*Remedies*
Flash	Viscosity issue	Increasing feedstock solids loading to improve melt viscosity; introduce high-molecular-weight polymers to improve viscosity of the melt
	Low clamp tonage	Decrease injection pressure as well as pack pressure; use higher tonage machine
	Misalignment of parting line, tooling issue	Ensure tooling is appropriately positioned and clamped, parting line
Incomplete fill	Deficient of molten feedstock into mold cavity	Increase pack pressure, injection speed, melt temperature, mold temperature, and shot size; in addition, increase venting
	Material feeding problem	Decrease back pressure and size of feedstock and regrind; if hygroscopic material is involved, ensure that it dried
Sink mark	Poorly filled part	Increase pack pressure, melt temperature, mold temperature, and back pressure for screw recovery; in addition, increase venting and gate size
Voids	Trapped gas and moisture issue	Increase holding pressure and mold temperature and decrease injection speed; in addition, increase gate size
Weld line and/or wrinkle	Premature solidification of molten feedstock (material)	Increase injection speed, melt temperature, pressure for switchover to pack control
	Gas entrapment	Decrease injection speed and increase venting on runner and part
Shrinkage and/or warpage	Part or component distorts during ejection	Decrease mold temperature and increase cool time; in addition, use improved cooling tools and means
	Pressure gradient in component	Decrease hold pressure
Crack	Part cracking during ejection	Decrease pack pressure and melt temperature and increase mold temperature; in addition polish tool
	Cracking after solvent debinding due to stress	Increase venting and mold temperature, then anneal the finished part

Table 15 Comparison of PIM and other manufacturing process

Characteristics	*PIM*	*Sintering*	*Investment casting*	*Machining*
Density[a] (%)	98	86	100	100
Magnetic force[a] (%)	100	70	95	100
Stress[a] (%)	100	70	100	100
Surface finish (μm)	0.8	1.6	3.2	1.6
Weight (g)	0.1–100	5–2000	30–4500	No limit

Design flexibility	High	Medium	Medium	Low
Shape complexity	High	Low	Medium	High
Production rate	High	High	Low	Medium
Material range	High	High	High	Medium
Dimensional tolerance	Close	Poor	Poor	Poor

[a]These quantities are expressed as a percentage of the actual measurement of the quantity.

feedstock test as well as physical and mechanical properties and microstructure of the molded parts.

Despite part defects encountered during the production process of PIM, the technology still stands out and compares favorably with other processes. Table 15 is a comparison of PIM with sintering, investment casting, and machining based on some selected characteristics.

1.16.5.3 Applications and Market Trend of PIM Products

Increased consumer demand and manufacturing for complex, intricate miniature parts and microdevices were catered to by MIM. Application of injection molding to parts and components fabrication has changed product design significantly across all sectors. PIM has applications in many fields of human life, including electronics industry, mechanical parts, armaments industry, household products, medical appliances, automotive parts, tooling, sporting goods, and many more. Table 16 presents an outline of industries and areas of PIM applications, but the technique still faces some challenges, just like other manufacturing processes. Despite these challenges, there is a brighter indication for PIM application in electronic devices and medical implants.[147]

German [148] conducted a survey of available MIM products by region (North America, Europe, Asia, and the rest of the world [ROW]) for various applications. Findings indicated applications that lead in these regions are medical in North America, automotive in Europe, electronics in Asia, and firearms in ROW. Available records have indicated that MIM is heading toward high-volume production of medical, automotive, electronics, and consumer goods for larger and more sophisticated microproducts.[149]

Table 16 Industrial sectors and areas of PIM applications

Industry	*Applications: parts/components*
Electronics	Printer components Digital cameras Disk drive components Heat sinks Mobile SIM card connectors PIN connectors for mobile phone Mobile phone components
Medical	Orthodontic bracket Orthopedic implants Forceps Surgical equipment Sensor housing implantables Aseptic expandable precision blade
Mechanical	Weaving machine components Welding nozzles Mechanical heat engine components Small transmission parts Lock mechanism Gear wheel for microgear Microfluidic devices
Armaments	Rifle sights Magazine catch Trigger and trigger guard Tocket guidance components Projectile stabilizer fin
Tools	Investment casting core Drill bit inserts Wood cutting bit Machining tools
Automotive	Valves Injection nozzles Transmission parts Airbag components Seat worm gear
Consumer	Jewelry Electric toothbrush microgears Watch components Tea and coffee cups Hair-cutting shears
Sports	Golf club heads Spikes/cleats Bicycle parts Ski bindings

1.16.6 Future Research Outlook

Process development is achieved through systematic innovations, and research investigations of injection molding processes over the years have witnessed remarkable achievements. The process of μ-PIM has been developed in recent years with the objective of making ceramics, metals, and its alloys available through mass production of microparts, components, and microdevices. Competing manufacturing technologies such as sintering, investment casting, or micromachining are often limited concerning processable materials and/or large-scale production capability. The process allows introducing new materials (feedstock) with additional properties such as high-temperature stability, strength, toughness, high precision, and surface finishing, as well as heat conductivity and magnetic properties when subject to life applications. Moreover, comparable to microinjection molding of plastics, biomaterial processing has been developed for μPIM to allow in-process joining of two different metallic materials during the injection molding process and within injection machines.

Process development involved all the processing steps of PIM, from powder selection and feedstock preparation to adjustment of injection molding parameters, debinding, and co-sintering conditions of the metal powders. However, more research is needed to enhance both process and part quality. Therefore, the future research outlook of injection molding can be summarized as follows:

i. Developments and investigations of new feedstock moldability in terms of the binder composition and the metal powder. Also, the successful implementation of the PIM process, especially the debinding and sintering processes.
ii. Further development of related manufacturing techniques such as two-component micrometal injection molding (2C-μ-MIM), bicomponent, biomaterial, and multimaterial, among many other new processing techniques of injection molding in terms of tooling and quality part are being

investigated. This produces net-shape parts with solid interfaces of either different colors or different materials obtained.

iii. Process integration and development to enhance capability and wider application. This could be integration of mixing mechanism and injection process via rapid prototyping and/or additive manufacturing techniques with μMIM.

iv. Development of improved microinjection system with high precision and control capability over the present custom-made μMIM machine in terms of enhanced speeds and control, and process monitoring for producing defect-free parts.

v. To investigate process conditions as they affect molded part quality. A robust design and formulation of multiobjective optimization frameworks allow multiple quality criteria for μIM. The development of these frameworks is to establish a relationship between process parameters and quality characteristics such as part dimensions, surface finish, and mechanical properties as they affect part quality.

vi. Modeling and simulation have improved microinjection molding processes over the years but are still hindered by a number of challenges. Therefore, development of new suitable software or improvement of the existing software, especially for PIM, is highly recommended.

1.16.7 Conclusions

Modern manufacturing processes adopt nearly net-shape techniques for fabrication of parts and components, which requires a minimum number of processing steps and cost. Micrometal PIM technology as a net-shape microfabrication technique has been widely adopted in the manufacturing of various consumer products and medical and electronics components. In general, μPIM has achieved this over the years due to its advantages, such as:

i. suitability for mass production of various products with minimum production cost and short cycle times;

ii. process and product development of the technology has been improving over the years, with the capability of producing two-material/two-color and movable parts;

iii. ability to process various materials such as polymers, ceramics, and metal powders.

Although μPIM technology has been described as a net-shape microfabrication technique, some challenges are encountered at various processing stages. Powder–binder segregation, short shot, void, sink mark, weld line, cracks, shrinkage, and warpage are some of the defects. Furthermore, difficulties in measuring some material properties and factors, which cannot be easily determined experimentally, are now being investigated by modeling, optimization, and process control to improve the quality of molded parts. Therefore, application of computer simulation has improved the quality of molded parts.

Multimedia

Overview of the production process of fabricating net-shape microparts by the metal injection molding (MIM) technique is illustrated in four video tracks. These video files illustrate the processing steps of the MIM showing powder-binder mixing, injection molding, debinding, and sintering processes (Videos 1–4).

1.17 Review of Miniature Gear Manufacturing

NK Jain and SK Chaubey, Indian Institute of Technology Indore, Indore, India

© 2017 Elsevier Inc. All rights reserved.

1.17.1	**Introduction**	505
1.17.1.1	Classification of Gears	506
1.17.1.2	Gear Materials	506
1.17.1.3	Quality of Gears and Its Standards	507
1.17.1.4	Miniature Gear Manufacturing Processes	508
1.17.2	**Subtractive Process of Miniature Gear Manufacturing**	508
1.17.2.1	Gear Hobbing	508
1.17.2.1.1	Types	510
1.17.2.1.2	Advantages	510
1.17.2.1.3	Limitations	510
1.17.2.1.4	Applications	511
1.17.3	**Additive Process for Miniature Gear Manufacturing**	511
1.17.3.1	P/M Process	511
1.17.3.1.1	Advantages	513
1.17.3.1.2	Limitations	513
1.17.3.1.3	Applications	513
1.17.3.2	Die Casting	514
1.17.3.2.1	Types	514
1.17.3.2.1.1	Hot chamber die casting process	514

1.17.1 Introduction

Miniaturization and demands of miniaturized components, devices and products are increasing at a very fast rate in modern manufacturing industries due to the reduction in the physical scale of machines and electronic components to micro- or even to nano-scale with their dimensions ranging from tens of nanometers/micrometers to a few millimeters. Micro-components and devices are extensively used in various micro-products and micro-systems such as micro/nano electromechanical systems (MEMS/NEMS) and micro-systems. Most of these micro-systems use miniature gears for the purpose of motion and/or power transmission. Figure 1 shows different applications of the miniature gears which are used as important actuating elements in MEMS and NEMS and are extensively used in various medical, aerospace, automotive, communication, and military/defense

Figure 1 Various applications of the miniature gears.

applications.[1] With continuously increasing demands for MEMS, NEM and micro-products necessity to manufacture high quality of fine pitched miniature gears is ever growing. The functional characteristics and performance of these devices mainly depend on the micro-geometry, macro-geometry and surface quality and surface integrity of the miniature gears. Therefore, miniature gear manufacturing process should be highly precise and accurate because service life and operating performance of miniature gears primarily depend on the manufacturing quality of the gear tooth profile.[2] The miniature gear tooth profile should be accurate in form and burr-free to ensure satisfactory, smooth, and noiseless operation.

1.17.1.1 Classification of Gears

Gear is a modified form of a wheel having teeth uniformly spaced around its circumference. Gear is the one of most important and widely used mechanical element to transmit power and/or motion from one shaft to another through successive engagement of teeth without slipping and connected shafts rotate at constant speed and velocity ratio. Basic requirements of gears are noiseless, accurate and efficient transmission of motion and/or power transmission, higher torque transfer capability, better operating performance without wear and tear, and longer service life. To fulfill these requirements, gears should have accurate dimension and form, better surface finish, and wear resistance at their tooth flanks.

Various types of gears are used in different industrial, commercial, domestic, scientific, entertainment, and other applications. **Table 1** presents classification of gears according to different criteria whereas **Figure 2** depicts different types of gears. According to the outside diameter, gears are classified into two categories namely miniature gears and macro-gears as shown in **Figure 3**. Gears having outside diameter in a range from 0.1 to 10 mm are known as 'miniature gears.' Gears having outside diameter greater than 10 mm are known as 'macro-gears.' Miniature gears are further classified as 'micro-gears' (having outside diameter in the range from 0.1 to 1.0 mm) and 'meso-gears' (having outside diameter in the range from 1.0 to 10 mm). Main advantages of using miniature gears include compactness, higher precision and accuracy, higher efficiency, better operating performance, longer operating life, zero backlash, and sustaining their performance characteristics at extreme environmental conditions.[2,3]

1.17.1.2 Gear Materials

Gears can be made of different materials which are generally classified as metallic and nonmetallic materials as shown in **Figure 4**. Metallic materials are further classified as ferrous and nonferrous materials. Nonmetallic gear materials mainly include different types of plastics. Ferrous materials are used for low speed and high load application while nonferrous materials are preferred for high speed and no-load to low-load

Table 1 Classification of gears according to different criteria[4,5]

Criteria of classification	*Type of gears*	
According to the position of axes of the shafts	1. Parallel shaft	• Spur gear • Helical gear
	2. Intersecting shaft	• Miter gear • Straight bevel gear • Spiral bevel gear
	3. Nonparallel and nonintersecting shafts	• Worm and worm wheel • Screw gear
According to the peripheral velocity of gears	1. Low velocity (<3 m s^{-1}) 2. Medium velocity (3–15 m s^{-1}) 3. High velocity (>15 m s^{-1})	
According to the type of gearing	1. External gearing 2. Internal gearing 3. Rack and pinion	
According to the position of the shaft on gear surface	1. Straight 2. Inclined 3. Curved	
According to the operation	1. Motion transfer gear 2. Power transfer gear 3. Precision gear (used in the scientific instruments)	
According to the form of tooth profile	1. Standard gear 2. Profile shifted gear • Positive profile shifted gear • Negative profile shifted gear	

Figure 2 Various types of gears.

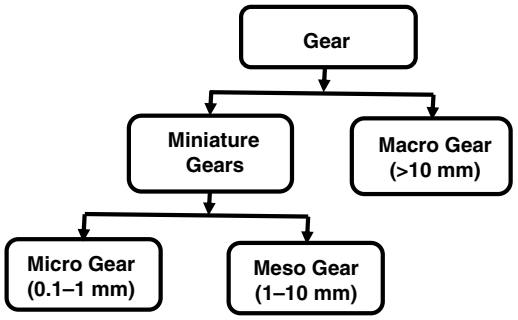

Figure 3 Classification of gears according to the outside diameter.

applications. Nonferrous materials are generally used for noiseless operation at high speed at no-load application. Selection of gear materials depends on various factors such as cost of materials, characteristics, strength, and type of application. Table 2 presents summary of different gear materials, their characteristics, features, and applications.[6]

1.17.1.3 Quality of Gears and Its Standards

Quality of a gear indicates accuracy in its micro-geometry (deviations in form, i.e., lead and profile, and deviation in location, i.e., pitch and runout), macro-geometry, (deviations in span, outside diameter, chordal tooth thickness) and topography of gear tooth flank surface. Gear quality is determined by gear manufacturing, gear finishing, and surface treatment processes. Poor gear quality leads to vibrations, noise, poor transmission characteristics, and less operating life thus giving overall poor operating performance. Therefore, level of gear quality is used to classify suitability of a gear for different applications. Following standards are available to indicate gear quality:

- American Gear Manufacturers Association (AGMA) standard
- Deutsches Instut fur Normung or German institute for standardization (DIN) standard
- British Standards Institute (BSI) standard
- French Gear standard
- Italian Gear standard
- Australian Gear standard
- Japanese Industrial Standards (JIS) gear standard
- Japanese Gear Manufacturing Association (JGMA) standard
- Indian Standard Specifications (ISS)
- International Organization for Standardization (ISO) gear standard.

Out of these gear standards, AGMA, DIN and JIS are the most commonly used gear standards. Gear quality is classified into 12 categories in DIN and BSI gear standards; into 15 categories in AGMA gear standard; and into 10 categories in ISS. Higher value in AGMA standard and lower value in DIN standard indicate better gear quality. Table 3 presents details of AGMA, DIN, JIS, ISO, BSI, and ISS gear standards.

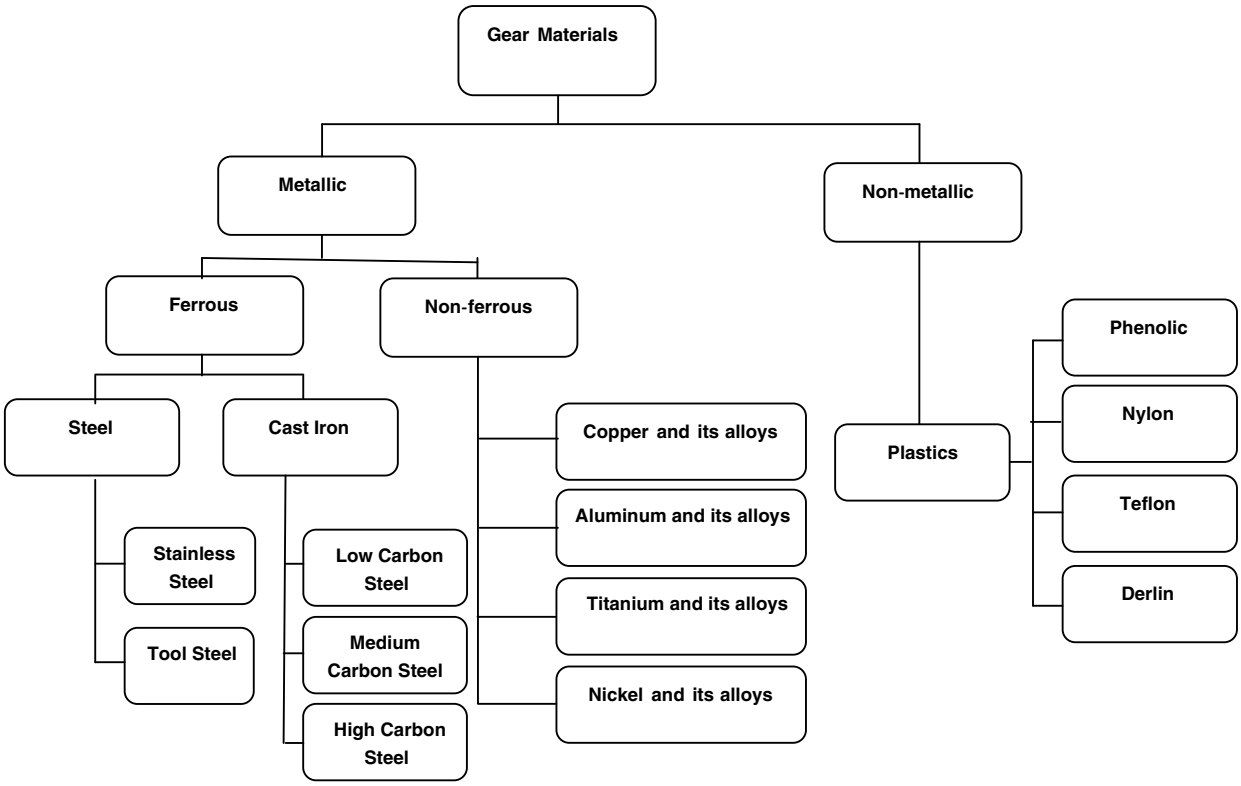

Figure 4 Classification of different gear materials.

1.17.1.4 Miniature Gear Manufacturing Processes

Miniature gears can be manufactured by conventional and unconventional or advanced processes. Table 4 presents different processes used for manufacturing miniature gears. Conventional manufacturing processes give poor quality (DIN standard 9–12) of miniature gears. Moreover, secondary finishing and treatment operations are required to achieve the desired quality of the miniature gears. To overcome the limitations of conventional processes, spark-erosion-based processes such as electric discharge machining (EDM), wire electric discharge machining (WEDM), and their micro versions have been explored for near net-shape manufacturing of high quality fine pitched miniature gears with better dimensional accuracy and surface quality. WEDM has been reported to achieve gear quality up to 6 DIN standard.[3]

1.17.2 Subtractive Process of Miniature Gear Manufacturing

Subtractive type manufacturing process, referred as machining, is the only process by which all types of gears can be manufactured in all sizes. Machining still is unsurpassed for those gears that must have very high accuracy. Gear machining processes can be divided broadly into form cutting and generating processes. In the 'form cutting,' the gear tooth profile is obtained by using a form cutting tool which may be a multiple-point cutter as used in a gear milling and broaching process or a single-point tool as used in a shaping machine. In the gear 'generating process,' the gear tooth profile is obtained by a tool that simulates one or more teeth of an imaginary generating gear. A relative rolling motion of the tool with the gear blank generates the gear tooth surface. This method is used in gear hobbing, gear shaping, and gear milling processes for manufacturing spur and helical gears and in the face milling and face hobbing of bevel gears. Out of different gear machining processes, only gear hobbing is used for manufacturing miniature gears.

1.17.2.1 Gear Hobbing

Hobbing is a generating type gear machining process in which both the cutting tool (known as hob) and the workpiece (i.e., gear blank) revolve in a constant relative motion as the hob is being fed across the face width of the gear blank as schematically illustrated in Figure 5. Hob is similar to a fluted worm in appearance and has form-relieved cutting edges. It rotates about an axis normal to that of the gear blank per forming teeth cutting on a rotating gear blank in succession each time cutting in a slightly different position. Tilting of the hob is maintained according to the hob thread angle and helix angle of the gear teeth. The hob travels radially to the desired depth of the teeth a little clear from the blank and then feeds axially along the width of the gear teeth. The gear teeth are generated progressively by a series of cuts.[8,9] It is widely used for cutting involute teeth on gears with hob having essentially straight sides at the given pressure angle. In this process gear blank and hob rotate in a definite relationship that depends on the number of teeth on the hob and the number of teeth to be on the gear blank. The index-change gears formula for hobbing

Table 2 Summary of different gear materials, their characteristics, features, and applications[7]

Material type	*Characteristics*	*Features and applications*
(A) Ferrous materials		
Cast irons	Low cost, good machinability, and high internal damping	For large-sized gears, moderate power rating, and for commercial applications
Cast steels	Low cost and high strength	For power gears, medium power rating, and for commercial applications
Plain-carbon steels	Good machinability and heat treatable	For power gears, medium power rating, and for commercial to medium precision applications
Alloy steels	Very high strength, heat treatable, and durability	For very high power requirement and for precision and high-precision applications
Stainless steel (300 series)	High corrosion resistance, nonmagnetic, and non-hardenable	Low power rating and for precision applications
Stainless steel (400 series)	Moderate corrosion resistance, magnetic, and hardenable	Low to medium power rating and for high-precision applications
(B) Nonferrous materials		
Aluminum alloys	Lightweight, noncorrosive, and excellent machinability	For extremely light-duty instrument gears and for high-precision applications
Brass alloys	Low cost, noncorrosive, and excellent machinability	For low-cost commercial equipment and for medium precision applications
Bronze alloys	Excellent machinability, low friction, and good compatibility with steel gears	Mating gears for steel power gears and for high-precision applications
Magnesium alloys	Extreme lightweight and poor corrosion resistance	For low-load applications and for medium precision applications
Nickel alloys	Low thermal expansion coefficient and poor machinability	For special thermal applications and for commercial applications
Titanium alloys	Higher strength to weight ratio and corrosion resistant	For lightweight strength applications and for medium precision applications
Die cast alloys	Low cost, low precision, and low strength	Higher production rate, low quality, and for low-grade commercial applications
Sintered powdered alloys	Low cost, low quality, and moderate strength	Higher production rate, low quality, and for commercial applications
Nonmetallic materials		
Delrin	Wear resistant, longer life, and low water absorption	Less noise, low loads, and for commercial applications
Phenolic laminates	Quiet operation and highest strength plastic	Medium loads and for commercial applications
Nylons	Low friction, less noise, and no lubricant	Longer life and for low-load commercial applications
Teflon	Low friction and no lubricant	For low friction commercial applications

Table 3 Details of most commonly used gear standards

Details	*Name of gear standard*		
	AGMA	*DIN*	*JIS*
Number of gear quality categories and range	15 (1–15)	12 (1–12)	8 (0–8)
Category for the worst quality (coarse gears)	1	12	8
Category for the best quality (high-precision gears)	15	1	0
Equivalence between different gear standards	13	4	0
	12	5	1
	11	6	2
	10	7	3
	9	8	4
	8	9	5

process as given below[4]:

$$\text{For spur gears,}\quad \text{Index gear ratio} = \frac{KT}{N} \qquad [1]$$

$$\text{For helical gears,}\quad \text{Index gear ratio} = \frac{KCT}{(CN) \pm 1} \qquad [2]$$

where, K is machine index constant, C is constant, T is number of threads on hub, and N is number of teeth on gear.

For the helical gear hobbing, differential change gears are calculated by formula which is given below to satisfy the relationship between the axial feed screw and the gear blank table rotation.[4]

$$\text{Differential change gears} = \text{Revolution of axial feed screw} \times \text{Lead of axial feed screw} \qquad [3]$$

The time required to manufacture a gear by hobbing can be calculated by following formula[5]:

$$\text{Hobbing time (min)} = \frac{\text{number of teeth to be cut (face + gap)}}{\text{number of hob teeth} \times \text{hob feed rate} \times \text{rpm}} \qquad [4]$$

Figure 6 shows manufacturing of miniature gear by the hobbing process and **Figure 7** depicts mini-hob cutter used in this process. Surface finish of the hobbed gear teeth is

Table 4 Different manufacturing processes for miniature gear

Type	*Basic nature*	*Process name*
Conventional processes	Subtractive	• Hobbing
	Additive or accretion	• Powder metallurgy • Die casting • Metal injection molding • Injection compression molding • Micro-powder injection molding • Lithography, electroforming and molding process
	Deformative	• Stamping • Extrusion • Forging • Hot embossing
Advanced or unconventionalprocesses	Controlled spark-erosion	• Electric discharge machining and micro-electric discharge machining • Wire electric discharge machining and micro-wire electric discharge machining

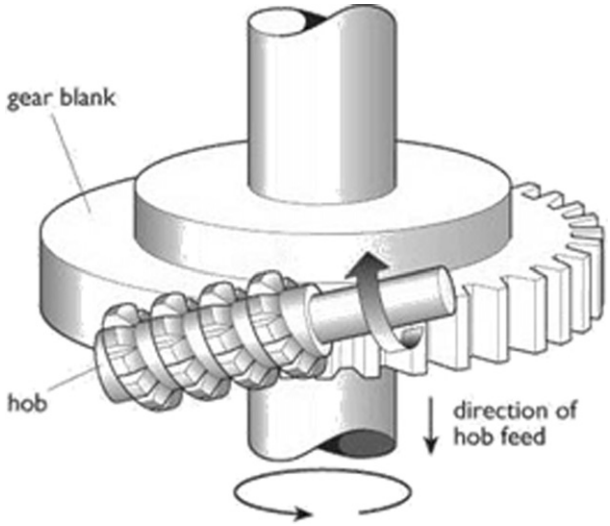

Figure 5 Working principle of gear hobbing process.

significantly dependent on the accuracy, rigidity, and feed rate of the hob cutter. Hobbed gears can have AGMA gear quality standard number 12. A very fine surface finish about 0.4 μm on gear tooth profiles can be achieved with proper tooling and small amount of feed. Using coarse feed, 4 μm surface finish can be achieved in roughing operation. Shaving or grinding operation is required for the semifinished hobbed gears.

1.17.2.1.1 Types

Following are three versions of the gear hobbing process according to relative position of the gear blank and hob and feed direction of the hob.[11]

- Hobbing with axial feed: this method is mainly used for cutting spur or helical gears. Firstly the gear blank is brought toward the hob to get the desired tooth depth and then the gear hob is fed against gear blank along the face of the gear blank and parallel to its axis. Gear cutting by with axial hobbing is obtained by 'climb noting' or 'conventional hobbing.'
- Hobbing with radial feed: this method of hobbing is generally used for cutting worm wheels. In this method the hob and gear blank are set with their axis normal to each other. The gear blank is continuously rotated at a set speed about its vertical axis and the rotating hob is given a feed against the gear blank in the radial direction or perpendicular to the axis of gear blank. The feed of hob is stopped when the required depth of tooth is obtained.
- Hobbing with tangential feed: this method is also used for cutting worm wheel teeth on gear blank. In this method, the hob is held at right angle to the axis of the gear blank but on horizontal axis. The hob is set at full depth of the tooth and then fed forward axially. The front part of the hob is tapered up to a certain length and fed in tangential to the face of gear blank and therefore it is known as 'tangential hobbing.'[11]

1.17.2.1.2 Advantages

The hobbing process offers following advantages:

- fast, accurate, and economical method for manufacturing external gears,
- higher production rate,
- excellent surface finish,
- close tolerances,
- less tool wear,
- economical production cost, and
- low tooling cost as compared to broaching and shear cutting.

1.17.2.1.3 Limitations

Following are the limitations of the hobbing process:

- cannot be used for manufacturing conical and internal gears;
- tool marks left on the gear teeth;

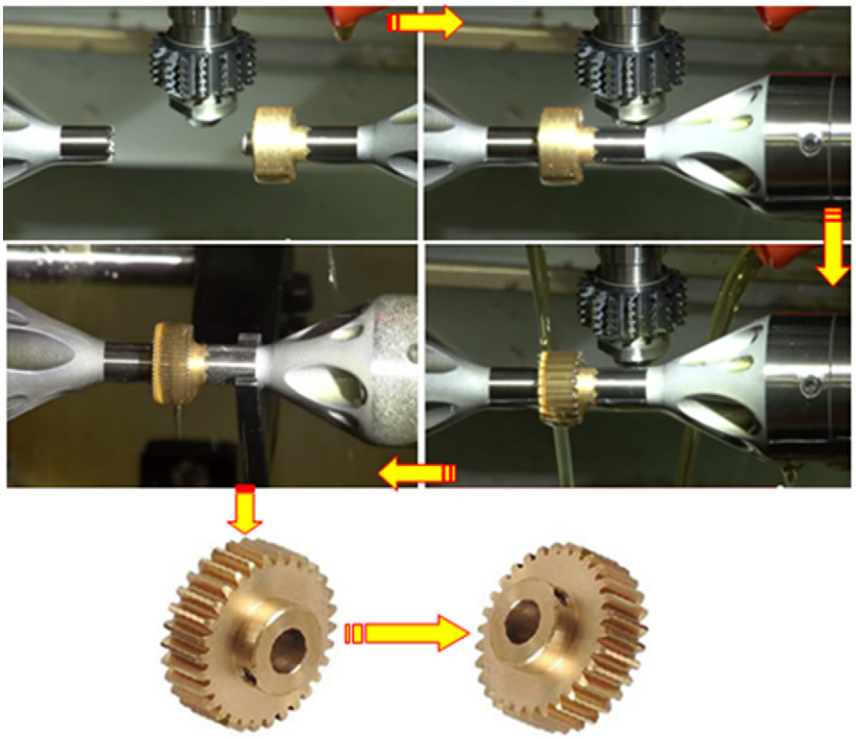

Figure 6 Manufacturing of a miniature gear by the hobbing process.

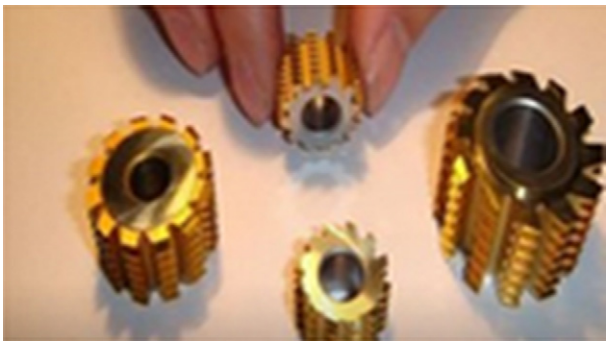

Figure 7 Mini-hob cutters used in manufacturing miniature gears by hobbing.[10]

- poor micro-geometry, i.e., hobbed gears require subsequent finishing operation to achieve desired gear quality; and
- longer setup time.

1.17.2.1.4 Applications

Gear hobbing is the most productive process for all type of gears such as spur gears, helical gears, herringbone gears, worms, worm wheels, splines, gear sprockets, and many special forms in all types of materials. Gears from ferrous, nonferrous, and nonmetallic materials are cut by high speed TiN coated steel hobs. Carbide tip hob is used to cut steel gears for automobile applications. It is most suitable for medium to high volume production but easily adaptable to small-lot production also.[4]

1.17.3 Additive Process for Miniature Gear Manufacturing

Additive or accretion type processes for manufacturing the miniature include: powder metallurgy (P/M) process, die casting, metal injection molding (MIM), injection compression molding (ICM), micro-powder injection molding (μ-PIM), and Lithography, electroforming and molding (LIGA). They are described in the following section.

1.17.3.1 P/M Process

P/M has been used since 1930s to manufacture various types of parts and components from the raw materials in the powdered form.[4] The first P/M gear was used in an oil pump in 1938. The size of P/M gears ranges from few millimeters to 300 mm in diameter depending on the available press size. It consists of the following five major steps as shown in **Figure 8** along with the processes that are used to perform every step of P/M.

- Production of powder: The P/M process begins with preparation of product material in the powder form which may be pure metal or combination of different metals. Metallic powder can be prepared by various processes such as atomization, chemical reduction, electrolytic dissolution, granulation process, mechanical pulverization, and ball milling. Nickel steels are used to produce gears with high strength, high impact properties, and excellent wear properties.
- Blending of powders in a mold/die: After powder preparation, the powder is blended with lubricants and

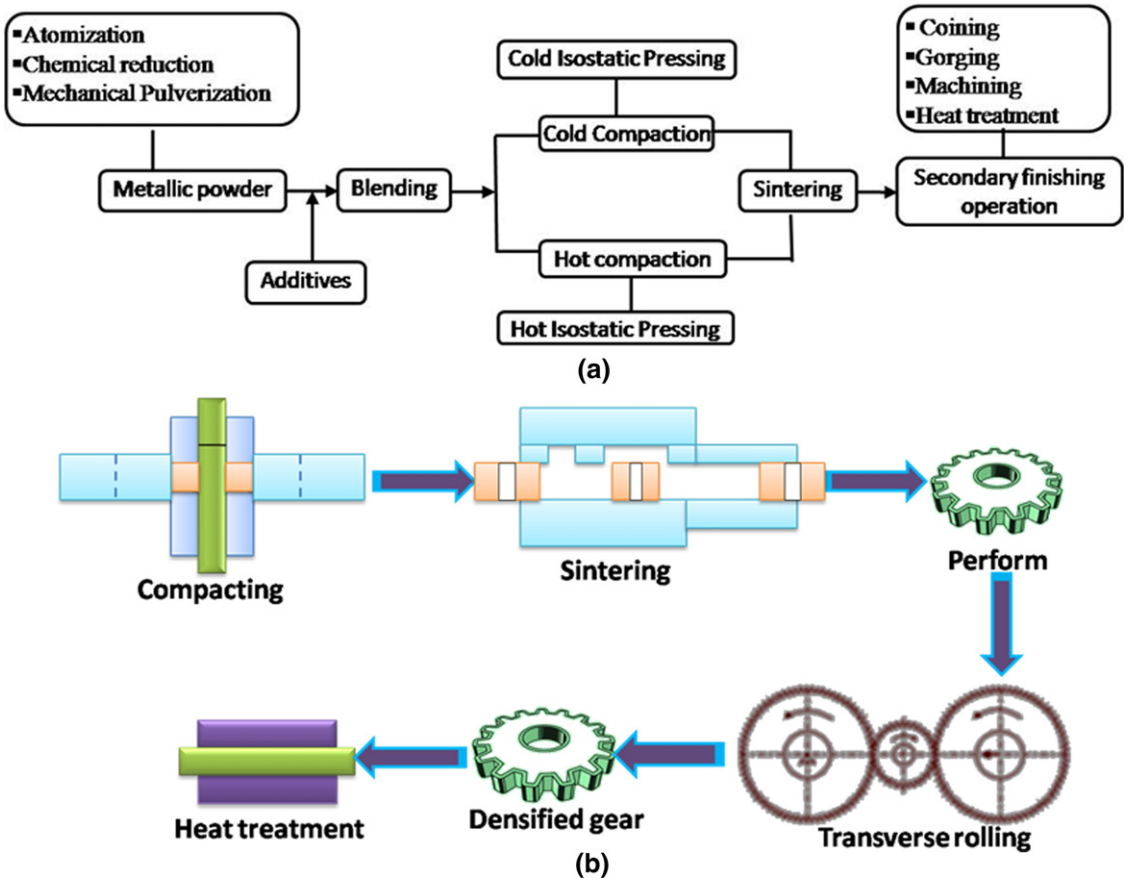

Figure 8 (a) Five major steps involved in the powder metallurgy (P/M) process and (b) processing sequence to manufacture gears by the P/M process.

suitable binders to form a homogenous mixture. Binder improves the 'green strength' of green compact. Both binder and lubricant burns off during the sintering process.

- Compacting of powders in the mold/die: After proper mixing, the powder is poured into a die cavity and compressed with a punch having its cross-section and geometry corresponding to the die on a press. Compacting is generally performed at room temperature and at high pressure and compacted powder is known as 'green part.' In conventional pressing, the pressure is applied uniaxially which limits the part geometry because metallic powders do not readily flow in the directions perpendicular to the applied pressure and leads to density variation in the compact after pressing. Whereas, in isostatic pressing (cold and hot isostatic pressing), pressure is applied from all the directions against the powders by using hydraulic pressure to achieve the compaction. In the 'cold isostatic pressing (CIP)' process, compaction water or oil is used to compress the powder into mold cavity by the hydrostatic pressure and carried out at room temperature. Mold is made of either rubber or some other elastomer and is oversized to compensate for shrinkage. The CIP process provides uniform compaction giving uniform density with less expensive tooling within shorter production runs. 'Hot isostatic pressing (HIP)' is carried out at higher temperatures and pressures combining pressing and sintering in single step using a gas such as argon or helium as the compression medium. Despite this apparent advantage, it is a relatively expensive process and its applications seem to be concentrated in the aerospace industry. P/M parts with high density (porosity near zero), thorough interparticle bonding, and good mechanical strength are achieved by HIP.[12] **Figure 9** shows the compaction of powders to manufacture a gear.
- Sintering: after pressing, sintering is performed in which green compact is heated to a temperature below the melting point of powdered material to bind its particles so as to increase the strength of the final product. Binding among the powder particles takes places in three ways: (1) melting of minor constituents in the powder particles, (2) diffusion between the powder particles, and (3) mechanical bonding. Sintering is usually done at an elevated temperature but at atmospheric pressure. **Figure 10** shows sequence of sintering process on the microscopic scale showing initiation of particle bonding at contact points (**Figure 10(a)**); formation of necks (**Figure 10(b)**); reduction in interparticle distance (**Figure 10(c)**); and formation of green boundaries between particles at the points of the necks (**Figure 10(d)**). Tolerances of P/M gears are determined by the compaction tooling, compaction process, sintering process, and the gear material. Dimensional control is difficult during sintering if density variations during compaction exceed 0.2 g cm^{-3}.

- Finishing operation: after sintering, some finishing operation such as re-pressing, coining, forging, machining, infiltration, and plating may be needed to achieve the desired dimensional accuracy and quality of the product. The P/M process is capable of manufacturing high strength and precision gears with high repeatability at reasonable low cost per piece and giving gear quality value in a range from 6 to 9 in AGMA standard.[6] Re-pressing and coining operation after sintering are required to achieve the AGMA gear quality value 9 while, a value of 6 can be achieved after sintering operation also. Repressed gears exhibit excellent surface finish while conventional sintered gears have sufficient porosity gears and can be vacuum-impregnated with oils for longer lubrication duration.[9]

1.17.3.1.1 Advantages

Following are the major advantages of the P/M process:

- capability to manufacture the gears with multifunctional features such as bosses, notches, collars, keyways, projections, and other irregular shapes without additional operations which reduces the manufacturing cost;
- minimized secondary finishing operations by producing near net-shaped gears;
- improved surface finish on gear tooth by elimination tool marks;
- higher density or porosity to suit a particular application;
- excellent repeatability and uniformity of part features;
- production of light-weight gear;
- tight tolerances;
- lower energy consumption;
- higher production rate; and
- economical in mass production.

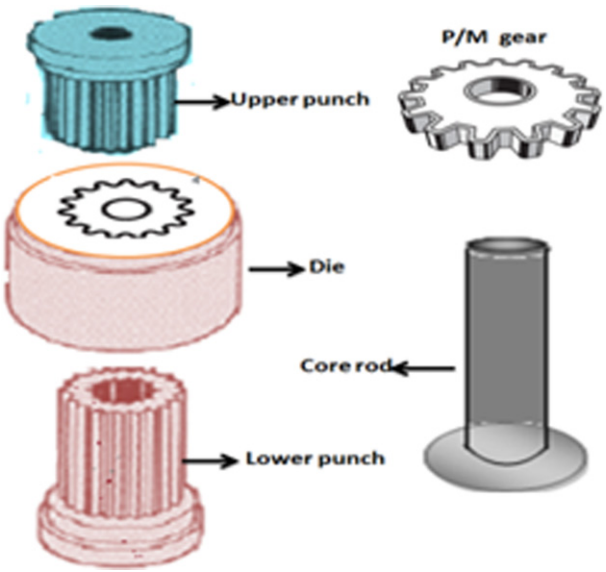

Figure 9 Compaction of powders to manufacture a gear.

1.17.3.1.2 Limitations

P/M process has following limitations:

- higher cost of preparing metallic powders;
- difficulty in storage of the fine metallic powders;
- difficulty in removal of part from the mold/die;
- variations in material density throughout the part, especially for complex part geometries;
- higher porosity which decreases mechanical properties of the P/M components;
- gears are subjected to re-pressing or coining after sintering;
- intricate designs are difficult to produce;
- lower material utilization;
- size of a part is limited by the press capacity;
- higher tooling and equipment cost; and
- longer processing cycle time.

1.17.3.1.3 Applications

The P/M process is used to make components and products used in many applications. Some applications worth mentioning are:

- Automotive applications: brake pads gear parts, connecting rods, planetary carriers, sintered engine bearings, etc.
- Aerospace applications: light-weight aluminum-based structural materials, high temperature composite materials, etc.
- Medical applications: dental implants, surgical instruments, etc.
- Applications in atomic energy: fuel elements, control rod systems, etc.
- Applications in electrical, electronic and computer parts: permanent magnets, electrical contacts, electric light bulbs, fluorescent lamps, radio valves, oscillator valves, etc.

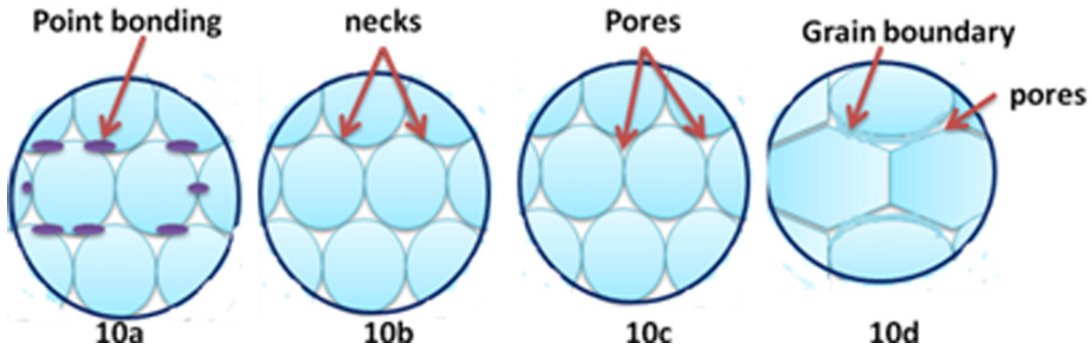

Figure 10 Sintering process on microscopic scale; (a) particle bonding initiated at contact points; (b) formation of necks; (c) reduction in interparticle distance; and (d) formation of grain boundaries between particles at the points of necks.

- Applications in cutting and machine tools: hard metals, diamond containing materials, master gear electrodes for EDM process, various parts of lathes, drilling, threaded guides, grinding and polishing wheels, and disks.

The P/M process can be used to manufacture spur gear, helical gear (with maximum helix angle 35°), bevel gear, face gear and hypoid gears, eccentric gear, reduction gears, powder forged internal ring gear, etc. Gear with fine pitches up to 64 can be produced by the P/M process. Fine pitch P/M gears are used for power tools, small appliances and fractional horse power electric motors while, coarse pitch P/M gears are widely used for heavy appliances, automotive equipment and agricultural equipment.[4] It is an effective and economical process for manufacturing powdered metal gear in large quantities due to the high tooling cost. **Figure 11** depicts different gears manufactured by the P/M process.

1.17.3.2 Die Casting

Die casting is a precision, high volume manufacturing process that was developed in the early 1900s. Traditional die casting process is also known as 'high pressure die casting process (HPDCP).' It is similar to plastic injection molding in which molten material is used instead of plastic. In this process molten material is injected into a mold cavity with high velocity and under high pressure in a range from 20 to 200 bar maintained till solidification stage. The mold cavity is formed by using two blocks of hardened, heat resistant tool steel which is machined to net-shape or near net-shape of the die cast parts along with the parting line. Fine vents are provided to allow the air to escape from them old cavity during pouring of molten material in it. Otherwise, air is trapped into the molten material and form blow holes and porosity in the die cast product.

1.17.3.2.1 Types

There are two types of the die casting process namely (1) hot chamber die casting process and (2) cold chamber die casting process. Size and materials of the gears are two important factors on which proper selection of die casting process depend. For example, cold chamber process is a more efficient choice for the aluminum than the hot chamber method.

1.17.3.2.1.1 Hot chamber die casting process

Hot chamber die casting process is also known as 'gooseneck casting.' In this process melting unit is an integral part of the machine which primarily consists of a hot chamber and a gooseneck type cast iron container as shown in **Figure 12**. The cylinder chamber of the injection system is completely submerged in the molten material bath. The die is split into two halves. The front half is known as cover die and is mounted on the stationary platen and is aligned with the gooseneck channel. Other half of the die is known as the ejector die and it is mounted on the movable die platen. The molten material from the container is injected into die cavity under high pressure by a hydraulically operated plunger submerged in the molten material. When the plunger moves upward, the molten material comes and fills the cylinder which is then forced into the die cavity through a nozzle in the gooseneck of the container during downward motion of the plunger. Injection pressure can range from 69 to 345 bar. Alloys with high melting temperature and having tendency to dissolve iron and steel cannot be used in this process since they would react with plunger and cylinder. Therefore, this process is suitable only for the low melting temperature metals and alloys such as zinc, tin, and lead-based alloys. The advantage of this process is short cycle time (around 15 cycles min^{-1}) as molten material is not transported from separate furnace.

1.17.3.2.1.2 Cold chamber die casting process

The cold chamber die casting is a permanent mold casting process. The melting unit is not an integral part of the machine for this process. Therefore, material is melted in a separate furnace, and then ladled, either by hand or with mechanical ladle, into a cold chamber where it is fed into an unheated shot chamber or injection cylinder as shown in **Figure 13**. Then the molten material is forced into the desired mold cavity by a hydraulically or mechanically operated plunger maintaining the pressure till solidification stage. The process is completed into following four steps:

- pouring of the molten material in the cold chamber and placing the moveable platen and cores in position;
- injecting the molten material into the mold cavity under high pressure by the plunger;
- removing cores and dies; and
- ejecting casting from movable dies platen.

This process mainly focuses on minimizing machine corrosion than production efficiency. Major disadvantage of this process is slower cycle time due to transfer of molten material from furnace to the cold chamber. This process is better suited for high melting temperature alloys such as aluminum, brass, and magnesium.

1.17.3.2.2 Advantages

Following are the major advantages of the die casting process:

- Ability to manufacture gears having dense and homogeneous microstructure without any impurities.

Figure 11 Different types of gears manufactured by powder metallurgy process.

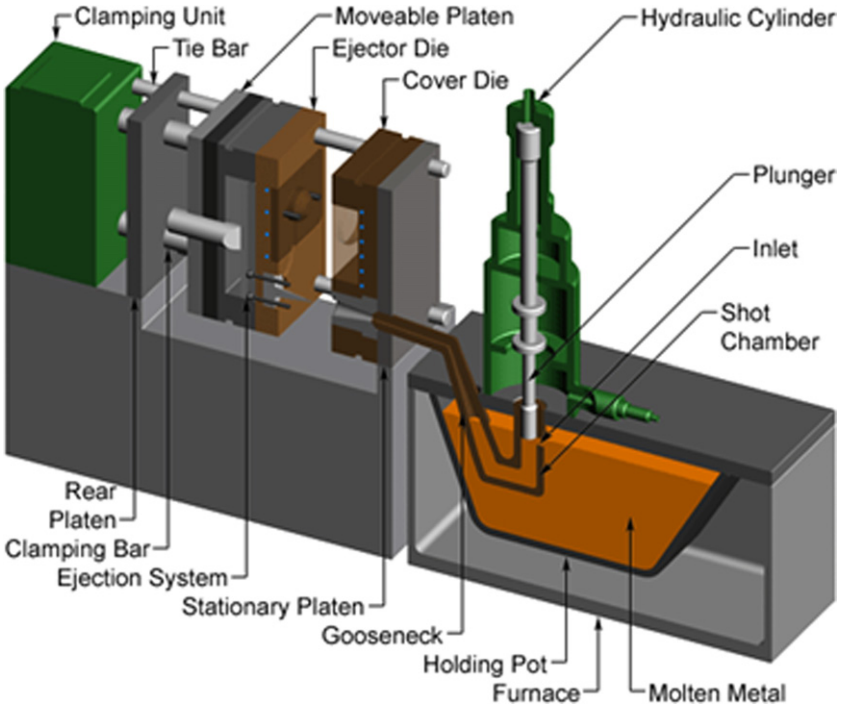

Figure 12 Hot chamber die casting process.[13]

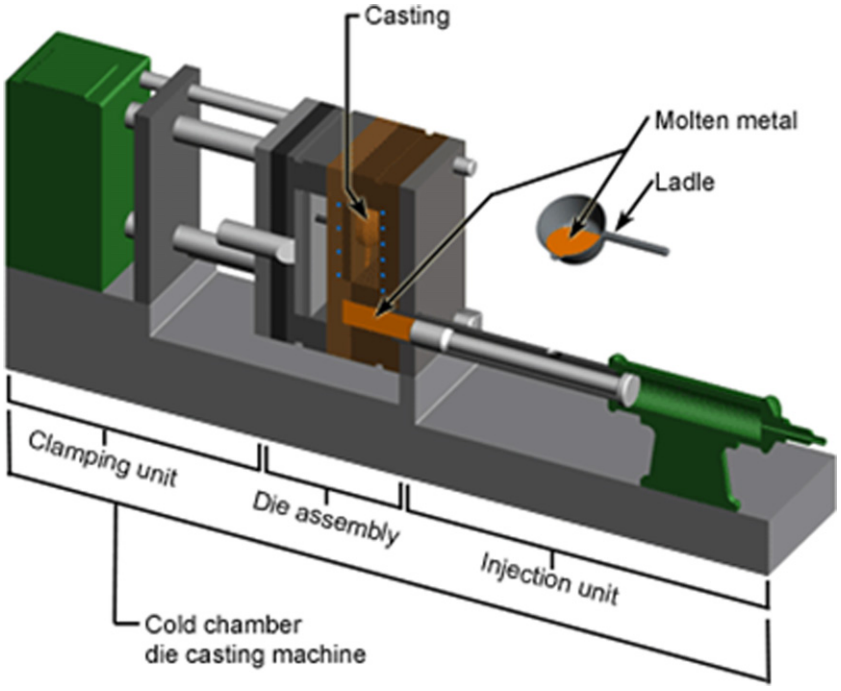

Figure 13 Cold chamber die casting process.[13]

- It can manufacture different types of gears such as spur, helical worm, clusters, and bevel gears and also with multifunctional features.
- Higher dimensional accuracy (tooth spacing and concentricity), better surface finish and stability.
- Die cast gears are stronger and light in weight than the injection molded gears of same dimensions.
- No or very little post-manufacturing finishing is required.
- Gears of AGMA quality value 8 can be produced by die casting process.

- Higher operating performance, repeatability, wear resistance, and production rate.
- Capability to produce fine surface texture with tight tolerance.
- Ability to manufacture thin-wall parts with uniform thickness.
- Low manufacturing and labor cost.
- Faster production rate.
- Economical and cost-effective process for mass production of the miniature gears.

1.17.3.2.3 Limitations

Die casting process has following limitations:

- not suitable for gear manufacturing for high speed and high load applications;
- limited to nonferrous materials having high fluidity and low melting-point temperature;
- cannot be used where high accuracy is needed;
- suitable for high volume production only;
- a certain amount of porosity is common;
- requires secondary finishing operations after gear manufacturing; and
- higher capital and tooling costs.

1.17.3.2.4 Applications

Die casting process is mainly used for nonferrous materials with high fluidity and low fusion temperature such as zinc and its alloys, copper, aluminum, brass, magnesium, and tin-based alloys. Approximately 50% of gears made of zinc-based alloys are manufactured by the die casting process.[14] Die cast gears are used in various industries and appliances such as automobile, aerospace, machine and power tool, instruments, cameras, business machines, washing machines, gear pumps, small speed reducers, lawn movers, and household appliances.[4] This process allows manufacturing of gears with high degree of accuracy and repeatability. Figure 14 depicts the different types of miniature gears made of zinc and manufacture by die casting process.

1.17.3.3 MIM

MIM process was developed by Raymond Wiech of the USA in the 1970s for the processing the metallic powders. This process is a combination of injection molding and P/M for net-shape or near net-shape manufacturing of complex and small components. It is also referred as PIM process because it uses fine metallic powders with organic binder injected into a die under high pressure instead of allowing to flow under gravity. It is a cost-effective alternative process to the many conventional processes such as investment casting, P/M, and stamping. It consists of the following five major steps[15] as shown in Figure 15:

- Feedstock preparation: the MIM process begins with blending of fine metallic powders (having particle size less than 20 μm) with organic binder (polymer and wax) in a ratio of 60:40 for preparation of a moldable powder. This blend is placed in special mixing equipment and heated to a temperature causing the binders to melt. Subsequently, it is mixed mechanically until the powder particles are uniformly coated with the binders. Then it is cooled and granulated into free flowing pellets termed as feedstock which can be accepted by the injection molding machine.
- Injection molding process: plastic injection molding is used to shape the feedstock into the desired shape. The pelletized feedstock is fed through hopper by gravity to the barrel of a conventional plastic injection molding machine where heater melts the binder at 200 °C. Then the feedstock injected under high pressure by reciprocating screw of the plastic injection molding machine into a two-part die or desired mold cavity trough the opening called gates. The molded part is known as 'green part' which is approximately 20% larger than the final product size to compensate for shrinkage of the green part during sintering. Shrinkage allowance depends on type of the material.
- Debinding: it removes the binders from the green part. About 80% binders are removed either by closed loop solvent or catalyst process or by heating process or combination of them. Time required for debinding is directly related to wall thickness. A debound part is called a 'brown part' which is semi-porous and fragile with no change in size. Remaining binders are removed during the sintering process.
- Sintering: sintering is performed by heating the brown part in a vacuum furnace at an elevated temperature but below the melting point of its material so that the particles fuse together to eliminate the void space between the particles. This achieves high dimensional accuracy and shrinkage, about 15–25%. The sintered part density is normally 95–99% of the theoretical density for most of the materials.

Figure 14 Different types of miniature gears manufactured by die casting.

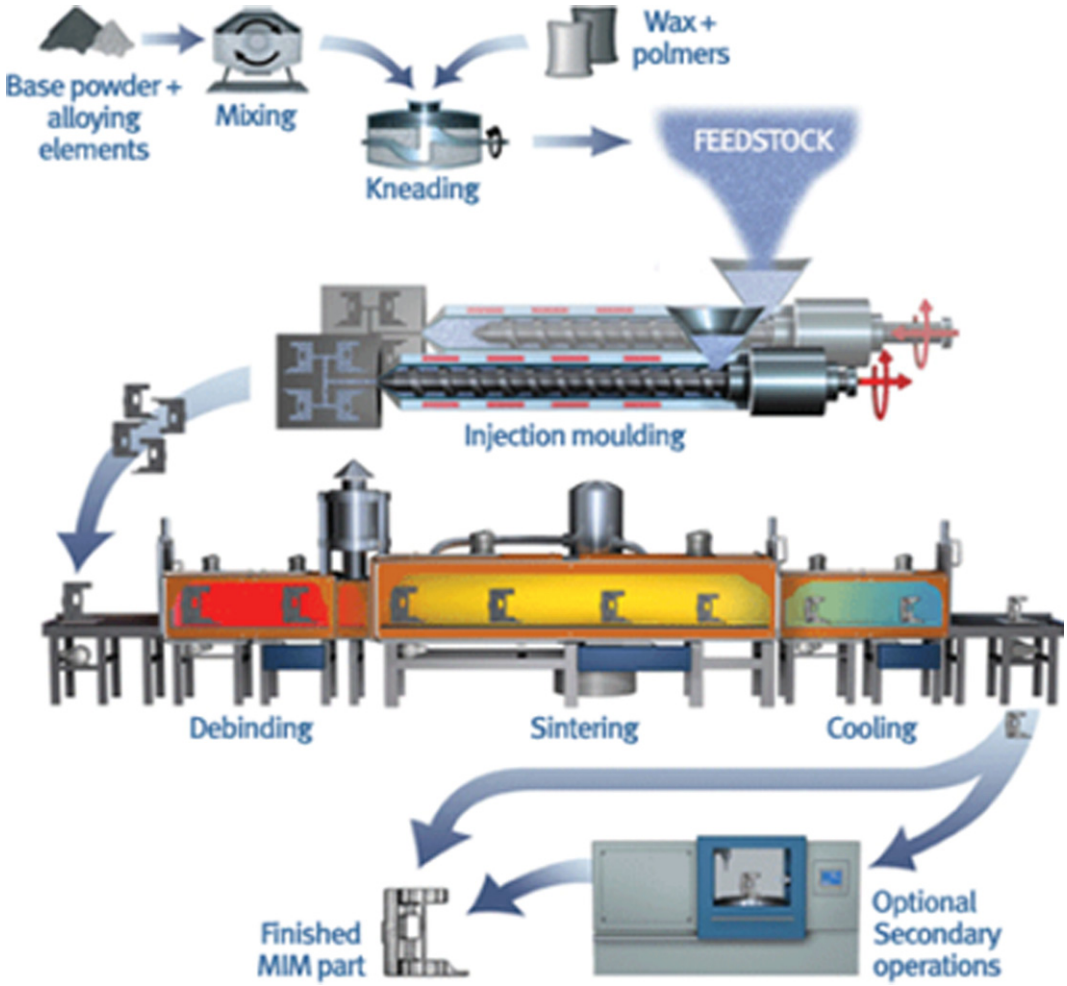

Figure 15 Major steps involved in metal injection molding process.[15]

Properties of the sintered parts are similar to the wrought product. The entire cycle including debinding generally takes 24–36 h.

- Post sintering process: the physical characteristics and properties of final MIM components can be further improved according to requirement of the final product using a wide range of secondary operations such as heat treatment, coating, plating, cold working, etc.

1.17.3.3.1 Process capabilities

MIM process possess following capabilities that make it a versatile process[16]:

- Complexity: MIM provides three-dimensional (3-D) design freedoms with excellent material properties similar to plastic injection molding which gives almost unlimited shape production capability. MIM is cost-effective process as compared to conventional process for production of multifunctional components.
- Precision: MIM is a precision manufacturing process to produce net-shape or near net-shape components with tolerance from ± 0.3 to $\pm 0.5\%$ of the dimension. Certain features can be made net-shape to $\pm 0.3\%$. Tolerances that cannot be achieved by MIM alone can be achieved through various finishing processes. This makes this process more competitive than investment casting and machining process.[17]
- Materials: MIM process is capable to produce small and complex components from variety of materials including ferrous alloys, super alloys, titanium alloys, copper alloys, refractory metals, cemented carbides, ceramics and metal matrix composites.[18] Nonferrous alloys such as aluminum and brass can be also used as powder material for MIM process.
- Weight and size: very small and micro-sized parts having weight less than 0.1 g can be easily manufactured by MIM process. This is effective and economical process for parts having weights less than 100 g. However, part weight up to 250 g can also be processed.
- Section thickness: the MIM process is suitable for components with wall sections of less than 6 mm; however, thicker sections can also be process easily.
- Production volume: MIM is a highly scalable process. Low volume of several thousand parts annually up to millions of parts can be economically achieved. A tooling and engineering investment is necessary for the MIM process

similar to casting or plastics, which will normally drive the decision process for low volume products.
- Manufacturing cost: manufacturing cost of products manufactured by MIM is 50% less than investment casting and CNC machining.
- Applications assistance: MIM provides comprehensive assistance for materials selection and in product design and development such as industrial product design, rapid prototyping finite element analysis, and laser scanning.

1.17.3.3.2 Advantages

Following are the major advantages of the MIM process:

- Net-shape or near net-shape manufacturing of metallic, small, and complex geometrical features such as internal and external threads, profiled holes and knurling.
- Capability to produce multiple components simultaneously thus reducing part and assembly costs.
- Capability to produce features such as small holes, thin walls, and fine surface that cannot be achieved by conventional methods such as investment casting and P/M.
- Higher repeatability, excellent surface quality, higher density components, tight tolerances.
- Less material wastage and overall product cost.
- Eliminate secondary machining operation.
- Reduced production cycle time as compare to investment casting.
- Economical and cost-effective process for complex and small components in high volume.

1.17.3.3.3 Limitations

Following are the limitations of the MIM process:

- suitable for manufacturing small components only;
- lead time is higher than the injection molding;
- materials shrinkage about 25–30% during sintering;
- due to multiple steps, the processing costs are more expensive than injection;
- higher material and mold cost.

1.17.3.3.4 Applications

MIM is an additive manufacturing process used to produce 3-D small, complex, intricate and precision parts and components with tight tolerances from a variety of materials without needing any secondary machining operation.[19] Micro-gears are manufactured by μ-MIM process.[20] MIM manufactured components are widely used in various industrial and commercial applications such automobile, military, aerospace, medical and surgical, food processing, lock and armature, consumer appliances, measurement and control systems, precision engineering equipment, tool engineering, domestic appliances, power hand tools, cellular phones, sporting equipment, electronics (connectors, hard drives, housings), implants for orthopedic and dental applications, laparoscopic instruments for grasping tissue and cutting, micro-wheel and impeller, micro-gears, etc.[19–22]

1.17.3.4 ICM

ICM process is modified form of the injection molding process with an additional compression system thus combining the techniques of the rapid charging of the injection molding and uniform compression of the compression molding process. This combination increases the production rate by eliminating manual cutting and placement of sheet molding compound (SMC) because raw material is injected through a gate during injection phase. It is also called coining, stamping, compressive-fill, or hybrid molding. **Figure 16** schematically depicts working principle of the ICM process showing major steps which involves (1) bringing the mold close to compression gap; (2) filling the mold cavity with molten plastic by injection process; (3) complete filling and packing of the mold by compressing the molten plastic into the mold cavity by compression process; and (4) cooling, opening, and ejection of the molded part.[23] Entire process sequence occurs in phases, i.e., injection phase and compression phase, therefore ICM process is considerably more complex and difficult to simulate than the compression molding process.[24]

- Injection phase: in this phase, thickness of the target part is designed to be smaller than the mold cavity thickness to ensure easy flow of the molten plastic under low pressure and stress to the extreme corners of the mold cavity. The mold is initially kept partially open so that the plastic material within the mold is either partially stressed or completely unstressed. This helps to reduce the flow resistance by providing high porosity in fibrous medium. The filling process begins by injecting a required amount of catalyzed plastic material into the mold through inlet gates. After completion of the injection phase, all inlet gates are closed and the filling stage is finished by compressing the mold to the final configuration of the part.
- Compression phase: during this phase, a compressive force reduces the part thickness by forcing the plastic material to the unfilled portions of the mold cavity. It produces more uniform packing pressure across the mold cavity and the plastic material is set to the final part geometry. Consequently, ICM process gives more homogeneous physical properties with less molding stresses as compared to conventional injection molding process.[25]

1.17.3.4.1 Advantages

Various advantages of ICM process include[26]:

- capability to manufacture large, complex and low tension plastic components;
- higher dimensional accuracy due to uniform distribution of the raw material;
- less molding pressure, injection pressure, variation in density and residual stress;
- easy and fast mold filling with improved venting;
- uniform packing and filling permits overfilling of the mold cavity;
- compensates uneven shrinkage by compressing the melt through the clamping movement;
- high dimensional stability by eliminating warpage;
- requires less clamping force during compression;
- minimizes holding pressure time, shortens cycle times;
- minimum molecular orientation and alignment during injection;
- eliminates sink mark with thicker wall section;

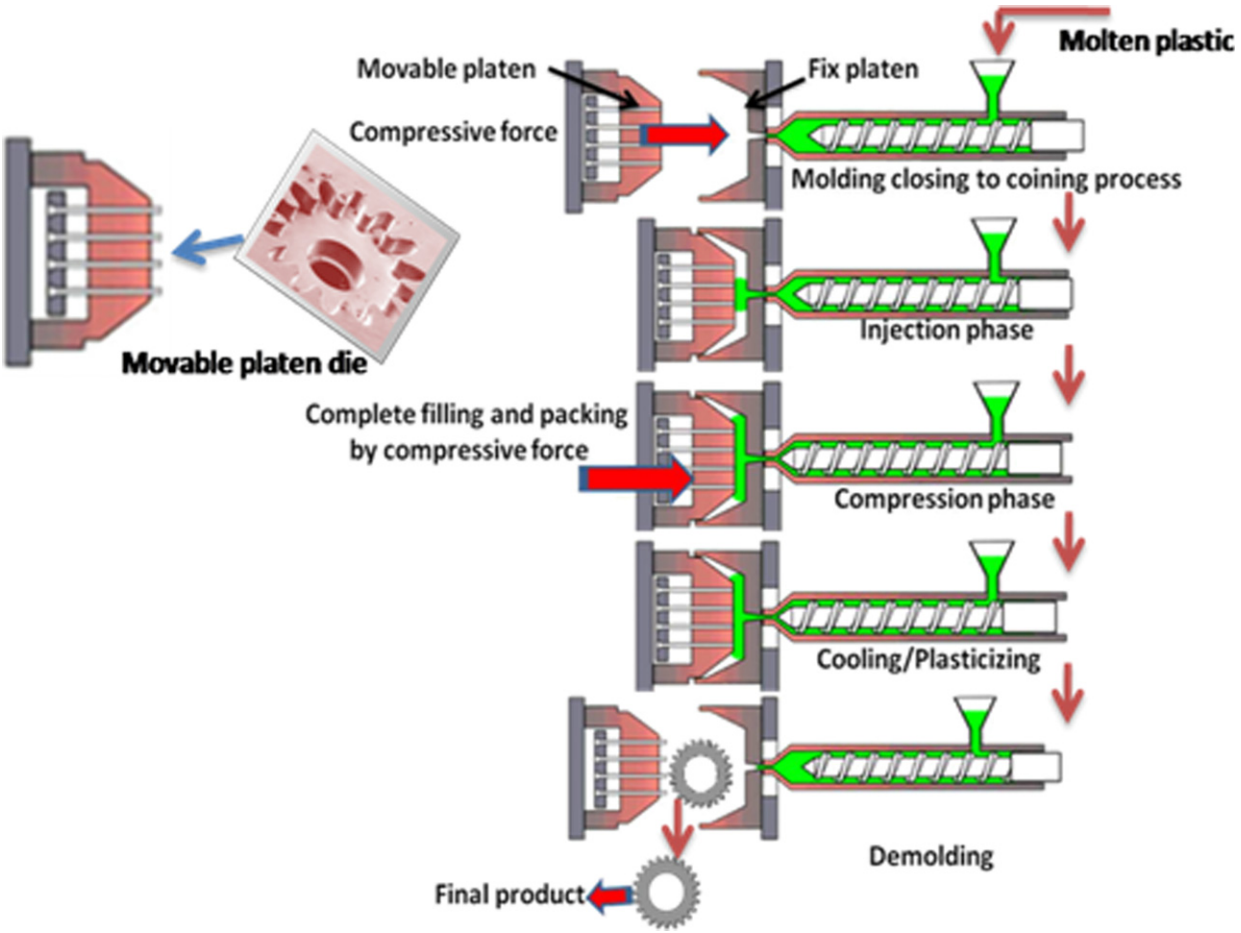

Figure 16 Working principle of injection compression molding process for manufacturing miniature gears.

- reduces film stresses in direct back injection for decorative parts;
- produces low stress, thick-walled components with high contour accuracy;
- minimizes birefringence;
- improved mechanical properties by reducing fiber degradation in long-fiber-reinforced thermoplastics (LFTs) parts; and
- improved optical properties for parts made of transparent material.

1.17.3.4.2 Limitations

Limitations of the ICM process are as follows:

- not suitable for parts having higher depth toward injection;
- material wastage due to mold overfilling;
- higher cost of machine and mold;
- slower process;
- difficulty in flash control;
- complex process control; and
- contamination.

1.17.3.4.3 Applications

ICM process is capable of producing parts which are relatively stress-free and dimensionally stable using low clamping force. It is generally used to produce high volume of plastic components with features and qualities that cannot be produced by the conventional injection molding process.[27] It is widely used to manufacture strong, lightweight, stiff, and high quality mechanical and auto components made of fiber reinforced plastics for automobile applications such as gears. Other major applications of ICM process are[26]:

- manufacturing of various optical parts, foamed parts, decorative parts, thin-wall packaging parts;
- finely textured surfaces;
- cell phone cover, notebook cover;
- fuel cell bipolar plate, sd card, etc.

1.17.3.5 μ-PIM

μ-PIM is combination of micro-injection molding and P/M and was developed at Forschungszentrum Karlsruhe. It is an additive process of manufacturing the micro-components with feature size less than 50 μm for micro-system devices and has become a reliable process to manufacture ceramic micro-gears. Ceramic powders are readily available in submicron size and are easier to handle as compared to the metallic powders which often become pyropheric when powder particle size is reduced to nano-level thus posing safety risks and making

their handling difficult.[28] The μ-PIM process is performed at higher injection pressure as compared to low pressure injection molding process. It involves following steps[29] as shown in Figure 17:

- Feedstock preparation: by mixing the micro- or nano-sized metallic or ceramic powder with an organic binder and then pelletizing the mixture to an appropriate shape in equipment such as extruder or mixer. The binder acts as a carrier medium for the powders and removed in a subsequent step when a part is molded. Use of feedstock powder at submicron or nano-level is required to utilize the complete potential of μ-PIM process for better shape retention and flow behavior. Variotherm process is often used to avoid freezing risk of the feedstock as thermal conductivity of the feedstock is very high but dimensions of the cavity are very small and the mold is heated during the injection process and then cooled down to room temperature before ejecting the part.
- MIM: it involves feeding the feedstock to the mold cavity to produce the desired shaped 'green part.' This step similar to conventional plastic injection molding with some changes to take care of compressibility and viscosity of the feedstock. Shrinkage during sintering is controlled by using oversized mold.
- Debinding: removing the binder from the molded green part and the resulting part is referred as the 'brown part.' It can be performed in three ways, i.e., (1) debinding by thermal degradation and elimination of the organic components of the binder using organic solvents or water; (2) debinding by using supercritical carbon dioxide in an autoclave which normally operates at temperature more than 57 °C and 300 bar pressure; and (3) debinding using a solvent or catalyst.[30]
- Sintering: sintering is performed to obtain good mechanical properties of the 'brown part' and carried out in a tube furnace having 88 mm diameter and 600 mm height. Air supply is used for sintering of the ceramic micro-parts while a reducing H_2 atmosphere is used for the metallic micro-parts to prevent their oxidation. Approximately 20–30% shrinkage take place during the sintering process which depends on the proportion of the powders in the feedstock.[31] Properties of final component are similar to that of the base material.

1.17.3.5.1 Advantages

The μ-PIM process offers following advantages[32]:

- It is a net-shape or near net-shape and cost-effective process to manufacture complex metallic and ceramics micro-components with high precision, dimensional accuracy, and replication.
- It combines design flexibility of the injection molding process and the advantage of P/M for nearly unrestricted variety of materials.
- It overcomes various difficulties the MIM process while manufacturing the micro-components such as incomplete filling of narrow cavities, failure in removal of the fragile green compacts, deformation in debinding and sintering processes.
- It can manufacture 3-D micro-components of complex shapes with good accuracy and replication.
- Higher material utilization.
- Economical and cost-effective for mass production.

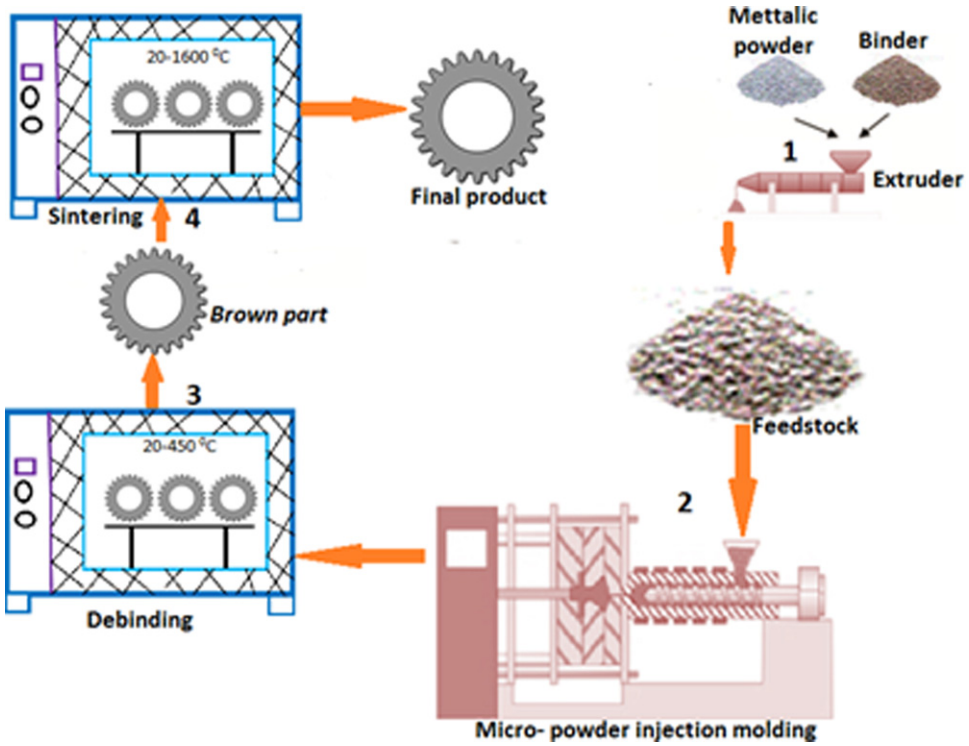

Figure 17 Steps of manufacturing of micro-gears by the micro-powder injection molding process.

- Low-pressure PIM (L-PIM) can be used for small size and prototyping where pressure values are limited to 1–10 bar and low-viscosity paraffin or wax is used instead of a high viscosity polymeric binder.

1.17.3.5.2 Limitations

Following are the limitations of the μ-PIM process:

- Surface roughness and minimum size of micro-components depend on the powder particle size.
- Can be used for fine powder size (less than 5 μm) only.
- Grain growth during sintering and presence of porosity may adversely affect the mechanical properties of the manufactured micro-products.
- Higher investment cost particularly for mold fabrication.
- Long processing time due to time consumed in debinding and sintering.
- Considerable amount of the feedstock could be scrapped as the size of the runner system become large relative to the size of the micro-product.

1.17.3.5.3 Applications

The μ-PIM process can be used for manufacturing the micro-components used in following applications:

- Micro-mechanical components: micro-gearbox, steeped gear wheel structures, micro-mold inserts, μ-EDM electrodes, micro-components for camera, operating cams, and weights for clock parts.
- Micro-system components: ceramic nozzle structures, components for communication devices, optical-electronic systems, data storage devices, and automotive systems such as airbag components.
- Micro-fluidics: micro-fluidic devices for chemical and medical applications such as micro-mixers and micro-heaters.
- Micro-reaction technologies: reactors for highly corrosive media, and high temperature gas phase reactors.
- Medical applications: surgical tools, dental equipment, micro-needles, small substitute bones, pharmaceutical powder inhalers, hearing aids, cranium reconstruction, tiny endoscopes, biopsy forceps, and sensors.

Figure 18 shows the micro-gears manufactured by μ-PIM process: a micro-gear having 1 mm outside diameter and 1 mm face width (Figure 18(a)), scanning electron microscope (SEM) micrograph showing distribution of powder and binder at the gear tooth (Figure 18(b)), and SEM micrograph of a double gear (Figure 18(c)).

1.17.3.6 LIGA

LIGA is an acronym for the German terms lithography (X-ray lithography), galvanoformung (i.e., electrodeposition) and abformung (i.e., molding).[35] It was developed at the Karlsruhe nuclear research centre in Karlsruhe (Germany) to manufacture nozzle for uranium enrichment process in 1990s.[36] Combination of electrodeposition and X-ray lithography process was first used by Romankiw and co-workers at IBM in 1975.[37] Figure 19 illustrates the processes and their sequence to manufacture micro-gear by LIGA process. It involves the following steps:

- Preparation of X-ray mask: a thin film of gold on beryllium is used as the X-ray mask which prevents transmission of X-rays to the photoresist material other than the patterned area.
- Substrate preparation: LIGA process uses collimated deep X-ray lithography (DXL) which illuminates and develops the desired patterns on thick film of an X-ray sensitive photoresist material such as polymethyl methacrylate (PMMA) or acrylic glass or plexiglass, polycarbonate, epoxy phenol resin, ploy vinylidene fluoride (PVDF), polysulfones, and polyether ketones. The substrate material used in the LIGA process should have (1) high resistance to dry and wet etching; (2) thermal stability up to 1400 °C; (3) exhibit excellent adhesion tendency to the substrate during electroplating; and (4) the unexposed resist must be absolutely insoluble during development. Suitable size of photoresist material is chosen to make substrate then it is cleaned properly to remove foreign material from its top surface. This is placed on a base material. Base material in LIGA process can be electrically conductive or insulator coated with an electrically conductive material in order to facilitate the subsequent electroplating over photoresist mold. Austenitic steel, titanium, nickel, silicon wafers with thin titanium and copper plated with gold are used as substrate materials. Sometimes, glass plates with thin metallic coating can also be used as base material.[38]
- Pattern transfer or exposure of the substrate: the prepared substrate is placed beneath the X-ray mask then it is exposed to synchrotron X-ray radiations of short wavelength. It provides deeper penetration into the photoresist material which is necessary for high resolution and high aspect ratio. It also results in formation of the desired pattern having sharp,

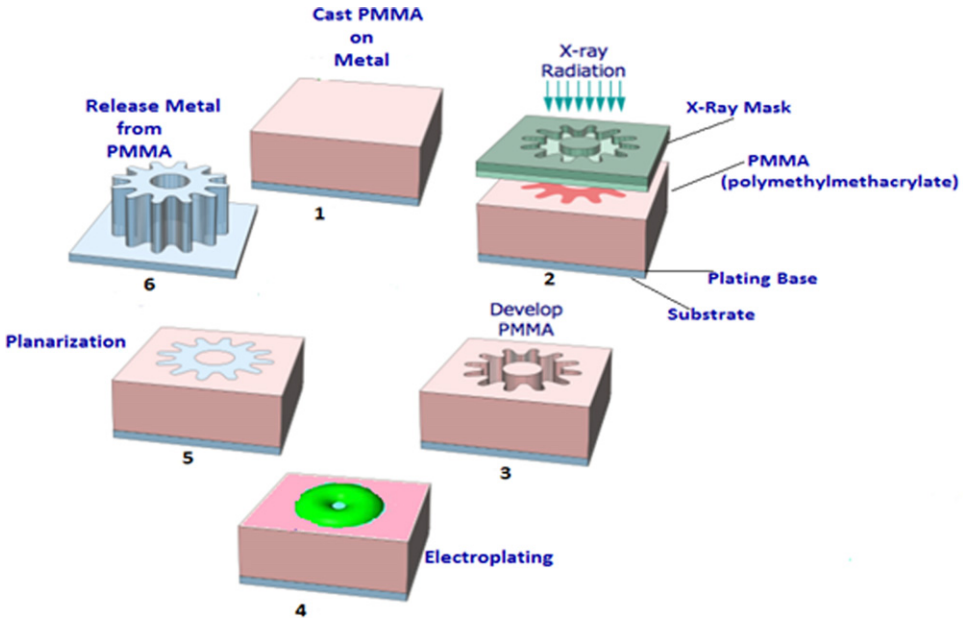

Figure 19 Processes and their sequence to manufacture micro-gear by the lithography, electroforming and molding process.[40]

thin, and deep cavities on the photoresist material. Line width of 0.2 μm and aspect ratio of 100 can be achieved by using short wavelength X-ray.

- Development of mold in the exposed substrate: the photoresist material, present in the exposed geometry corresponding to pattern image, gets melted due to its exposure to the X-ray radiations. This material is removed to develop the mold cavity in the photoresist material.
- Electrodeposition of the work material in the mold: the patterned photoresist material is placed in an electroplating bath in which mold cavities are filled with the material of the product by electrodeposition process. The final product can also be used as mold to manufacture thousands of similar products by hot plastic embossing and injection molding.[39]
- Planarization: it involves removal of excess eletrodeposited material from the top surface of the patterned mold so that top surface of the final product is perfectly flat.
- Release or separation of the final product: it involves removal or stripping of the surrounding photoresist material from the final product.

1.17.3.6.1 Advantages

The LIGA process offers following advantages:

- capability to manufacture high-precision metallic and plastic micro-parts;
- flexibility in configuration and geometry of the micro-parts;
- ability to manufacture high aspect ratio micro-parts;
- higher dimensional accuracy (<1 μm) and better surface finish (<50 nm);
- high-precision metallic parts without edge formation;
- suitable for mass production; and
- no thermal distortion.

1.17.3.6.2 Limitations

Following are the limitations of the μ-PIM process:

- Complex process because it requires multiple steps.
- Requires X-ray generation source, preparation of mask, substrate, and development of the mold.
- Requires special protection for the operator against exposure to X-ray radiations.
- Difficulty in maintaining tight tolerances in the pattern design.
- Very expensive process due to high equipment cost.

1.17.3.6.3 Applications

LIGA is an additive manufacturing process which is used to manufacture complex and intricate 3-D micro-parts having submicron size and high aspect ratio. It is used for following applications:

- Micro-mechanical parts: micro-gears, micro-motors, micro-actuators, and micro-nozzles for variety of application.
- Micro-opto-electro-mechanical systems (MOEMS) and communication: micro-sensors.
- Micro-fluidics: micro-valves, micro-channels, and micro-pumps.

Figure 20 shows SEM image of a high aspect ratio micro-gear manufactured by the LIGA process.

1.17.4 Deformative Processes for Miniature Gear Manufacturing

Deformative processes used for manufacturing the miniature gears are stamping, extrusion, forging, and hot embossing process. They are described in the following sections.

1.17.4.1 Stamping

Stamping is a fast and cost-effective process of manufacturing small gears from a thin metallic sheet. Thickness of metallic

sheet depends on the coarseness of stamped gears teeth and ranges from 0.25 to 3 mm.[6] **Table 5** presents recommended thickness of sheet for different ranges of the gear pitches. Before stamping, the metallic sheet is passed through a roll straightener which flattens the sheet. Gears from a thin sheet are cut by placing it between an upper die (or punch) and lower die and shearing it by the punch under very high pressure supplied by a hand operated press or a hydraulic press. **Figure 21** shows die set used in the gear stamping process. When upper punch comes into contact with sheet then sheet enters into lower die with upper punch and shearing action take place which produces gears of similar shape that of the upper punch die to a mating hole attached to the lower die. High speed press operating at speed of 200 strokes min^{-1} has capability to produce 400 gears min^{-1}. The press is equipped with a set of stamping dies in which toothed gear elements are formed to produce net-shape or near net-shape gears. The stamping die is designed by considering the various aspects of gear tooth such as backlash, whole depth, and corrected tooth thickness. Generally, an additional allowance is provided to the whole depth of gear stamping die to compensate for the die wear. 'Drawdown' is a phenomenon in stamping process by which teeth and outside periphery of gear is rounded due to shearing action. Usually, shaving operation is performed to reduce the drawdown and achieve close tolerance and accuracy of gears.

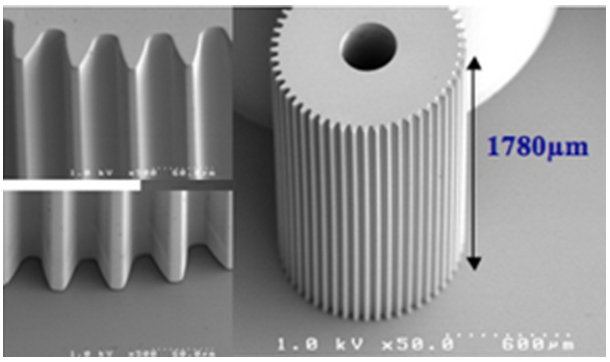

Figure 20 SEM images of the high aspect ratio micro-gear manufactured by the lithography, electroforming and molding process.

Table 5 Recommended sheet thickness for stamping of gears[4,6]

Pitch range	*Sheet thickness (mm)*
20–36	0.51–1.98
38–60	0.38–1.57
62–72	0.25–1.02
74–90	0.25–0.89
92–120	0.25–0.64

1.17.4.1.1 Advantages

Main advantages of stamping process include:

- Capability to manufacture light-weight stamped gears made of brass, full hard aluminum, high carbon steel, and AISI 1010 steel at high production rate without special die requirement.
- Gears of AGMA quality value 9 can be manufactured.
- Uniform dimensional accuracy and quality of the manufactured gear; and
- Ability of manufacturing gears of different materials.
- Economical and efficient process for manufacturing of small, light-weight gears in large quantity.
- Higher production rate, i.e., can manufacture 35–200 gears min^{-1}.
- Easy to automate.

1.17.4.1.2 Limitations

Following are disadvantages of the stamping process:

- can manufacture gear having face width up to 3 mm only;
- size of stamped gears ranging from 20 to 120 diametral pitch;

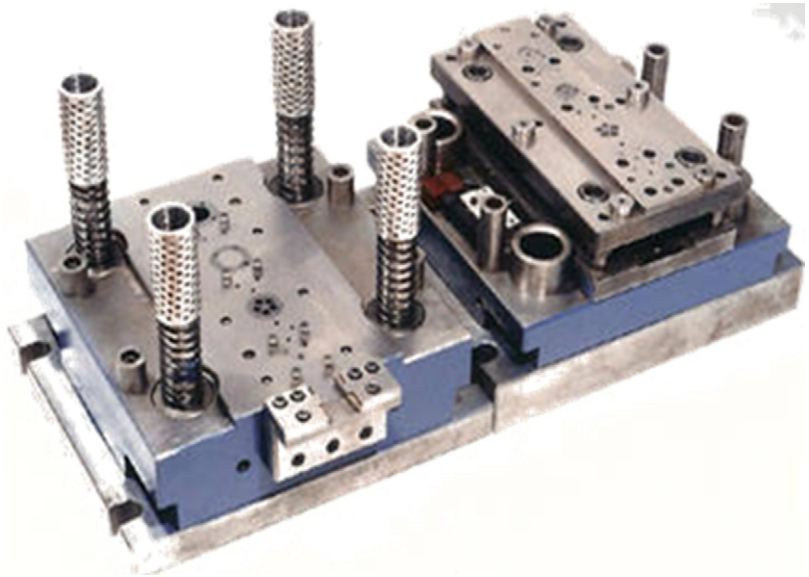

Figure 21 Die set used in stamping process for manufacturing thin gears.[41]

- particular die can perform a particular specific operation;
- applicable for no-load to medium-duty gears only;
- poor surface finish and accuracy;
- requires shaving operation after stamping;
- longer tooling time;
- fabrication of die and punch are difficult and complex; and
- higher equipment and die cost.

1.17.4.1.3 Applications

tamping is used to manufacture spur gears having face width (or sheet thickness) less than 3 mm. Stamped gears are widely used in toys, clocks, watches, timer mechanism, water and electric meters, in small appliances such as mixers, blenders, toasters, can openers, in larger appliances such as washers, dryers, and hand operated machine gears for slow speed mechanism.[4,6]

1.17.4.2 Extrusion

In extrusion process, a long round bar of 3–3.7 m long and approximately 6 mm in diameter is used to form the desired gear teeth on its entire length. The process begins with pre-heating of the metallic bar known as 'ingot or billet' to the plastic stage then placing it into a chamber known as 'container' in which hydraulically operated ram forces the material through a series of several dies to form the desired tooth form on entire length of the bar. Generally 5–7 dies in progression are used in this process. The first die has a similar shape of the desired pinion but larger in size so that material can easily pass through this die. After each pass, the metallic bar is annealed for next pass and with each succeeding pass bar assumes a shape close to the final shape. The bar comes into final shape after last pass. The time required to produce teeth on round bar is the time required to pull the metallic bar through series of dies.[5] Gear of desired thickness is cut-off from the extruded bar as shown in **Figure 22(a)**. The cut-off time depends on the extruded bar and the gear diameter. Various allowances are provided to the die to compensate the backlash, whole depth, and corrected tooth thickness in the final gear tooth shape. An additional whole depth is provided to compensate for the tool error at the root of gear tooth.[4,6] **Figure 22(b)** depicts the extrusion die set for spur gear.

Extruded gear should have number teeth in range of 15–24. Gear module may range from 0.25 to 1 mm with 20° pressure angle. The tooth contour should have a full radius root fillet and a full radius at the outside diameter with sufficient addendum to avoid undercut. Since, the material is displaced by pressure the outside surfaces of the extruded gears are quite hardened and smooth.[4] Material flow during extrusion depends on various factors such as material properties during preheating, billet–container interface and metal–die interface friction, and extrusion ratio.[43]

1.17.4.2.1 Advantages

Advantages of gear extrusion process include:

- Any desired gear tooth form can be produced by this process.
- Gear quality of AGMA 6 standard can be achieved by extrusion process.
- Better utilization of material and energy.
- Minimum or no loss of the gear material.
- Enhanced mechanical properties.
- Clean and porosity-free edges.
- Dense structure and higher strength of gear.
- Good surface finish and work-hardened surface of the extruded gears
- Requires least tool expenditure for mass production of spur gears.
- Higher production rate.

1.17.4.2.2 Limitations

Following are limitations of the gear extrusion process:

- surface cracking occurs;
- suitable for nonferrous materials having good drawing property such as aluminum and cooper;

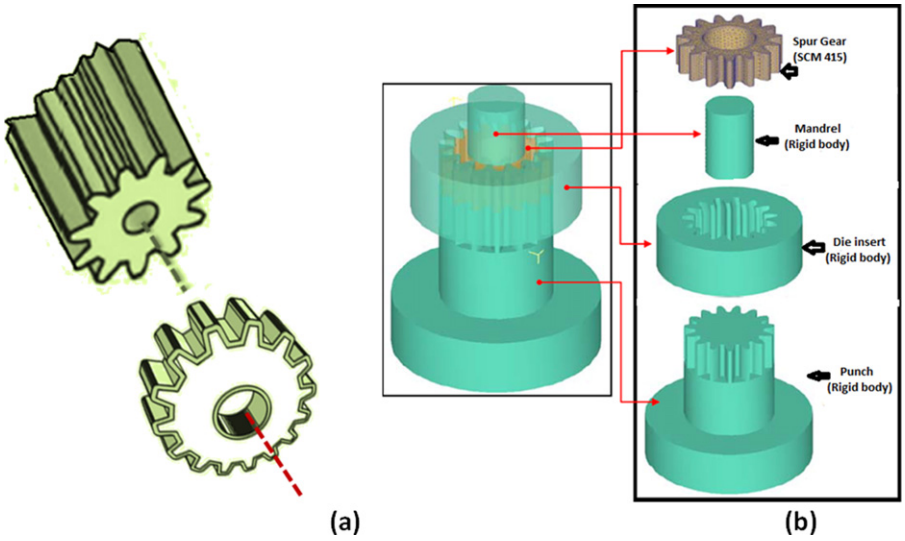

Figure 22 (a) Gear cut from an extruded bar; (b) die set for extrusion of a spur gear. Reprinted from Ref. [42] with kind permission from Springer Science and Business Media.

- secondary drawing operation is required after extrusion to improve the gear accuracy; and
- excessive wear of the extrusion die.

1.17.4.2.3 Applications

Gears and pinions manufactured by extrusion process are used in variety of commercial applications such as watches, electric clocks, spring-wound clocks, instruments, typewriters, multigraph machines, motion picture machines, carburetors, small motors, switch apparatus, taximeters, cameras, slot machines, mechanical toys, and other appliances.[6] Figure 23 shows the gears manufactured by the extrusion process: micro-gear made of 7075 aluminum (Figure 23(a)), extruded spur gear (Figure 23(b)), and helical gear manufactured by extrusion process (Figure 23(c)).

1.17.4.3 Forging

Forging is a net-shape or near net-shape metal forming process which can be used to manufacture gears by compressing their heated blanks in the forging dies by applying compressive forces manually or through power press. Gear forging involves an additional step as compared to the conventional forging process. Gear blanks are prepared from a billet by reducing it to the required size and shape by turning process, removing sharp corners by centerless grinding, improving surface finish by polishing, heat treating in an electric induction furnace, and cutting into exact weight and width for rough and finish forging. The gear blank is placed between upper and lower die and forced into the lower die cavities to form the shape of finished gear. The forged gears are manufactured in a single blow. The forged gear is air cooled to the ambient temperature. Controlled cooling is necessary to reduce the thermal distortion in forging. For effective cooling, a rotating cooling table is used to ensure the uniform distribution of the air around the forged gear. A scale is formed on forged gears after cooling which is removed by shot blasting before heat treating or finishing the forged gear. An envelope of excess material (or stock allowance) is formed around the forged gear tooth profile which is subsequently removed by grinding or finishing operation. Generally, forging dies are manufactured by EDM process.

1.17.4.3.1 Types

Forging process can be performed in different ways. Following are its variants[8,45]:

- Open die or flat die forging: in this process, the desired shape is obtained by repeated blows of powered flat-faced hammer reducing height of the billet and increasing its area of cross-section. This process can be computer controlled to obtain high accuracy of the final product. It is widely used for production of rough or near net-shaped gears.
- Closed die or impression forging: it is also known as hot stamping. In this process, two die halves are used to form an enclosed cavity corresponding to the desired shape of the product. The upper die attached to the drop hammer is allowed to fall freely on lower die by means of pneumatic or mechanical pressure and gear blank is deformed to fill the die cavities. Trimming operation is used to remove the surplus material known as 'flash' from the edges of forged part.
- Hot upset forging: in this process hot material fills the die cavity to form the desired product. Excess material squeezes out around the cavity in the form of flash which is trimmed off by a trimming die. The portion of billet which is not upset, is clamped by a clamping die and process is performed either as open or closed die forging process.
- Precision forging: precision forging is used to manufacture highly stressed net-shape, near net-shape or flashless forged products reducing the post-forging finishing processes. The net forged products do not require any further secondary finishing process while minimum finishing is required for near net-shape forged products. Only about 0.015 in of material on each side of the gear tooth is required for finishing the near net-shaped forged gears.
- Flashless forging: in this process no excess material (or flash) is squeezed between the die halves thus eliminating any post-forging process such as cutting or grinding. Figure 24 depicts the sequences of flashless die forging of a pinion gear.

1.17.4.3.2 Advantages

Main advantages of the forging process are:

- net-shape or near net-shape gear manufacturing;
- most suitable for straight bevel gears and face gears;
- forged gear have greater load carrying capacity;
- forged gears are stronger than cast or machined gear;
- refines the structure of the gear material;
- high strength to weight ratio;
- minimum or no material loss during forging of gears; and
- low manufacturing cost as compared to gear machining.

1.17.4.3.3 Limitations

Following are limitations of the forging process:

- requires high forging force;
- sometimes cracking and distortion of the material occurs;

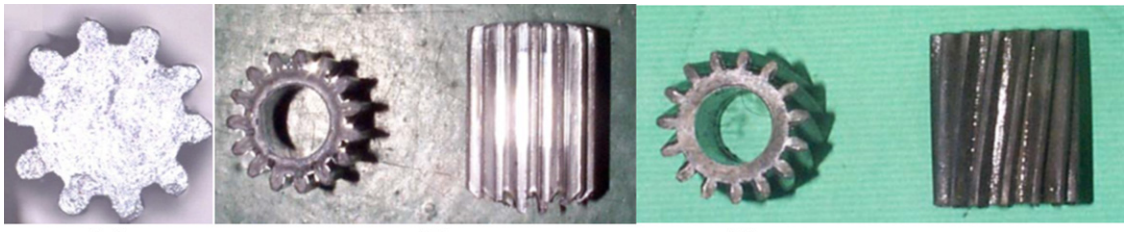

Figure 23 (a) Micro-gear made of 7075 aluminum. Reprinted with permission from Ref. [44]. © Elsevier 2015; (b) extruded spur gear; and (c) extruded helical gear. (b) and (c) reprinted with kind permission from Ref. [42].

- not suitable for spur gear due to short die life;
- short life of the forging die due to excessive wear; and
- higher initial cost.

1.17.4.3.4 Applications

Precision forged gears are commonly used in automotives, axle and differential of heavy trucks, aerospace, helicopter, railroad, marine applications, agriculture, material handling equipment, energy, and mining applications.[4,6] Figure 26 shows the different types of gears manufactured by the forging process: different types of forged gears (Figure 25(a)), and spiral bevel gear manufacture by forging process (Figure 25(b)).

1.17.4.4 Hot Embossing

Hot embossing process was developed by a group of researchers from RCA laboratories in Princeton, New Jersy (USA) in 1970s.[47] It is one of the most productive and extensively used techniques for the parallel replication of precise micro- or nano-features on thermoplastic substrates at elevated temperature by applying high pressure (approximately 10 bar) over a very small area.[48] A master die or stamp is pressed into a thermoplastic material to form the desired microstructure pattern on the substrates. Identical structures such as arrays of holes, dots, wires, and ring transistors can be reproduced on substrates using a single master die. Micro-gears are manufactured by micro-hot embossing process.[49] Hot embossing involves following four major steps[47,50] as depicted schematically in Figure 26:

- Preparation: a micro- or nano-structured mold is placed above the polymer substrate to form a stack. This stack is placed on the lower heating plate which contains cooling channel in which high heat capacity oil is circulated that allows isothermal heating and cooling of both the mold and the substrate.
- Hot embossing: the lower heating plate is moved upwards so that the stack is heated and pressed by upper and lower heating plates under a certain pressure applied by a pneumatic or hydraulic cylinder for a few minutes to ensure full replication of microstructure on the substrate. In order to transfer mold pattern completely on the substrate, mold and substrate are heated above the glass transition temperature of the substrate material to soften it and to minimize the force required for the material to flow into the desired mold cavities.
- Cooling: cooling of embossed or molded parts by the cooling plates to the demolding temperature while maintaining the pressure.
- Demolding: separating the mold and part from each other.

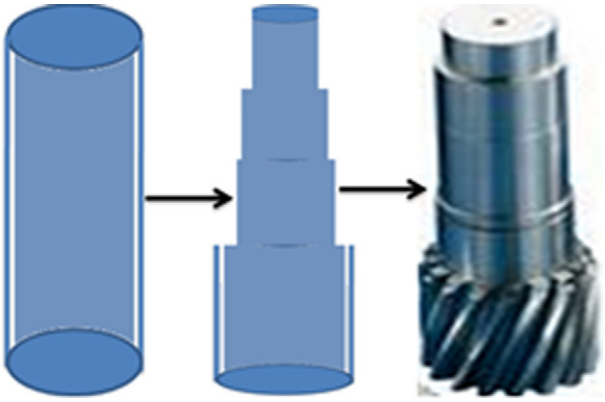

Figure 24 Steps involved in flashless forging to manufacture a pinion shaft.

1.17.4.4.1 Advantages

Hot embossing is the best replication process for micro- and nano-structures due to requirement of simple setup and short lead time for implementation. Other advantages of the hot embossing process include:

- higher dimensional accuracy;
- suitability for high aspect ratio features;
- easy manufacturability;
- mold can be used more than a thousand times;
- low shear stress;
- cost-effective process for high volume production; and
- lower gear manufacturing cost.

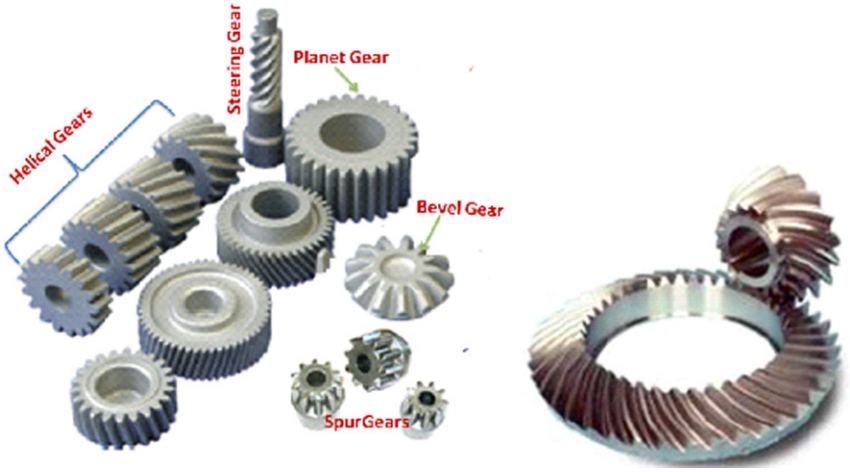

Figure 25 Different gears manufactured by the precision forging process.[46]

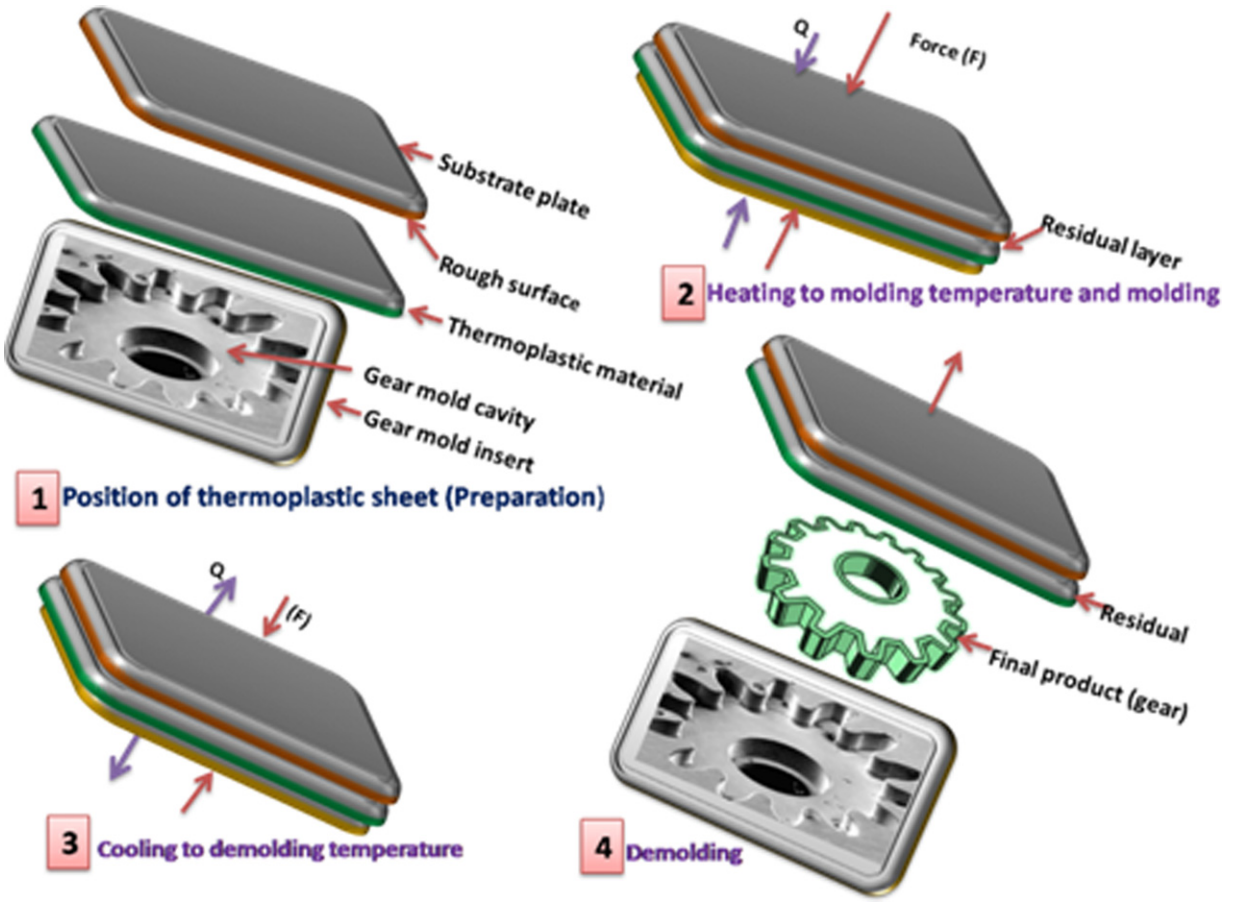

Figure 26 Major steps involved in the hot embossing process.

1.17.4.4.2 Limitations

Following are the limitations of the hot embossing process:

- suitable for thermoplastic materials only;
- slower process (requires four steps);
- difficulty in attaining high embossing pressure; and
- complex and expensive mold and equipment.

1.17.4.4.3 Applications

Hot embossing can fabricate a variety of materials but it is most suitable for thermoplastics. An amorphous and semi-crystalline thermoplastic can be hot embossed but amorphous materials can also easily be embossed due to process flexibility which allows its application for a wide range of embossing temperature. It is used for following applications[51]:

- Micro-optical applications: compact disk, optical lenses, wave guides, and switches.
- Micro-fluidics: lab-on-chip analysis devices, valves, pressure sensors, and flow sensors.
- Micro-electrical applications: acceleration sensors, electrical switches, and combo drives.
- Micro-mechanical applications: micro-gears for MEMS devices.
- Biomedical applications: biosensors and bio-MEMS devices, micro-total analysis system (μ-TAS), rapid prototyping, and patterned media.

Figure 27 Shows the SEM image of the micro-gears and molds manufactured by the hot embossing process: PMMA gear (Figure 27(a)), and gear on etched silicon wafer (Figure 27(b))

1.17.5 Miniature Gear Manufacturing by Spark-Erosion-Based Processes

EDM, WEDM and their micro-versions namely μ-EDM, and μ-WEDM processes are the spark-erosion-based processes which are used for manufacturing the miniature gears. Gupta *et al.*[54] have critically reviewed the spark-erosion-based processes from application aspect of miniature gear manufacturing. These processes are described in the following sections.

1.17.5.1 EDM

An English scientist, Sir Joseph Priestly was discovered the phenomenon of material removal by electrical sparks in 1768. But, this could not be used for machining purpose till 1943 when two Russians scientists B.R. Lazarenko and N.I. Lazarenko developed a circuit to supply pulse power required for material removal by the controlled spark-erosion phenomenon. A computer numerical controlled (CNC) machine for EDM process was developed in the USA in 1980s.[55] EDM is an unconventional machining process which approximately reproduces complimentary image of an electrically conducting tool on an

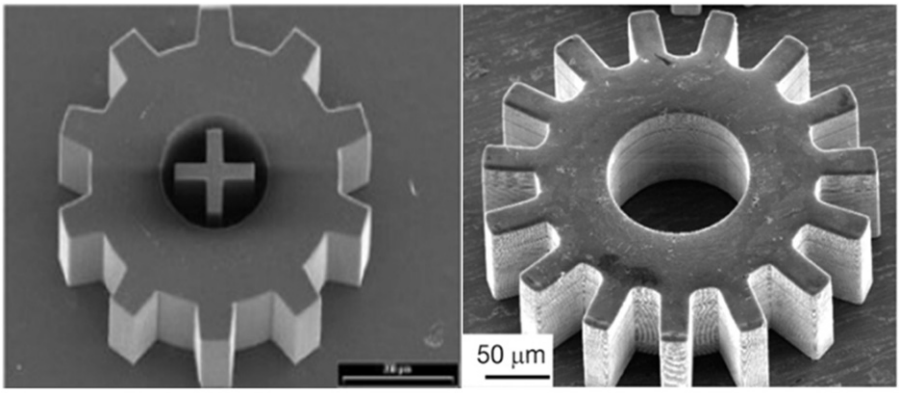

Figure 27 Scanning electron microscope images of the micro-gears manufactured by the hot embossing process and micro-gear mold insert for micro-hot embossing: (a) polymethyl methacrylate gear[52] and (b) gear on etched silicon wafer.[53]

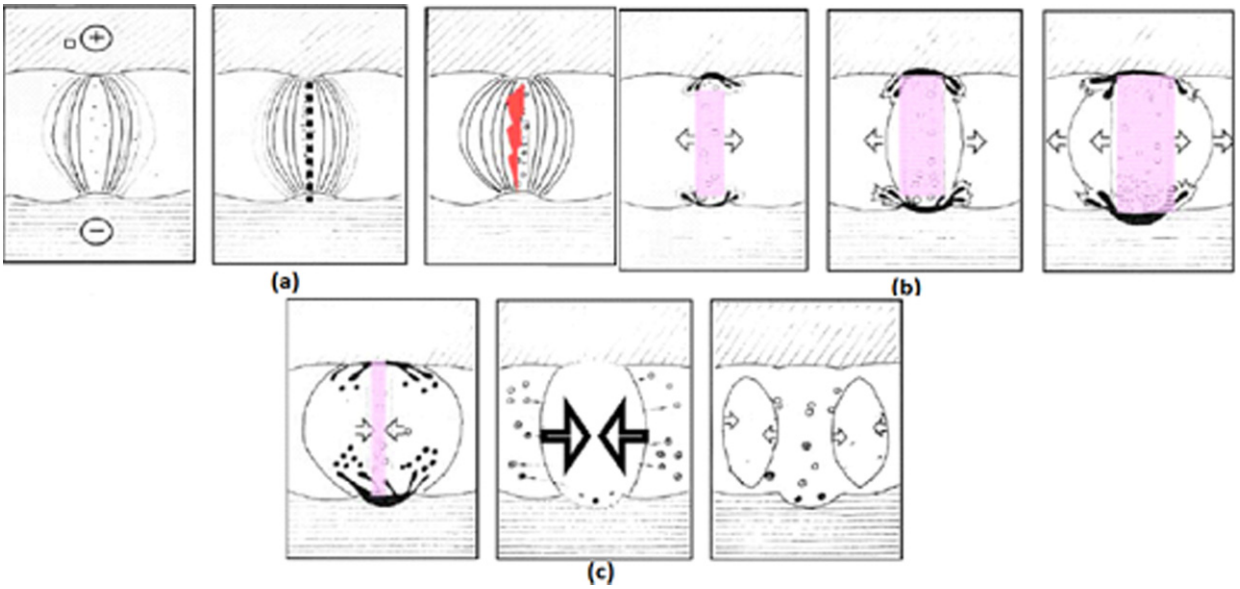

Figure 28 Different phases of spark generation in the EDM process. (a) Preparation phase, (b) discharge phase, and (c) interval phase. Reprinted with permission from Ref. [59]. © Elsevier 2004.

electrically conducting workpiece by a series of sparks occurring in the tool-workpiece gap (or interelectrode gap, IEG) in the presence of a suitable dielectric. Figure 29 depicts the generation of spark phenomenon in EDM process: preparation phase (Figure 28(a)), discharge phase (Figure 28(b)), and interval phase (Figure 28(c)). Generally, workpiece and tool are connected to positive (i.e., anode) and negative (i.e., cathode) terminals of a direct current (DC) pulsed power supply provided a pulse generator system. Constant value of IEG (approximately 0.01–0.5 mm) is maintained by a servo-system. DC voltage in the range of 80–200 V having pulse frequency in some kilohertz is supplied between the two electrodes with and IEG is flooded with a suitable dielectric. During the pulse-on time, electrons emitted from the cathode move toward the anode and ions toward the cathode. When the supplied voltage becomes more than the breakdown voltage of the dielectric then dielectric molecules also ionize releasing secondary electrons. This results in forming a high conductivity channel at a point where IEG has minimum value. In this channel, electrons continuously strike the anode and the ions strike the cathode converting their kinetic energy into heat energy. This causes momentary impulse resulting in a generation of a short duration spark at the point of minimum IEG increasing temperature to a very high value which is sufficient to melt and even vaporize the electrode materials. This causes spark-erosion of both the electrodes but erosion of cathode is very less as compared to anode because the velocity of the electron is higher than the ions. Most of molten workpiece material is ejected with a pressure forming a crater on the workpiece surface thus changing the value IEG at this location. During the pulse-off time, the eroded material is flushed away from the IEG by the flow of the dielectric. Same cycle of events occur at the next location where IEG is minimum. Thus, spark keeps occurring throughout the IEG. Some of the molten material is redeposited on the workpiece surface

forming a very hard layer known as 'recast layer.' The EDM-manufactured components have better wear resistance and improved fatigue strength.[56] The technology and applications of EDM process has matured and spread significantly from 1950 onwards to an extent that most of EDM machines are CNC machines and it is no longer considered as an unconventional or nontraditional process.

1.17.5.1.1 μ-EDM

EDM process is the variant of EDM for micro-machining applications including manufacturing the miniature gears and other micro-parts. The physical characteristics and working principle of μ-EDM is similar to the EDM process except the size of the electrode, the power supply, (current, voltage, and pulse frequency) and the resolution of the *X*, *Y*, and *Z*-axes.[57] **Table 6** presents the comparison between EDM and μ-EDM.[58]

Main objective in μ-EDM is to minimize the erosion of workpiece in a single discharge while EDM maximizes the erosion of workpiece so as to minimize machining time. Generally, μ-EDM process uses deionized water as dielectric to avoid the formation of the white or recast layer which usually occurs with a mineral oil such as kerosene. The pulse generator used in μ-EDM process produces very small pulses of few microseconds or nanoseconds duration enabling μ-EDM to use low discharge energies to remove small volumes of the material making possible manufacturing of micro-gears, micro-dies, micro-holes, micro-slot, etc. Low setup cost, high aspect ratio, improved precision, and improved design freedom are other advantages of μ-EDM process.[57] Limitations of μ-EDM include low MRR, high tool wear rate per spark and formation of the heat affected layer. Tool wear leads to poor dimensional accuracy. The μ-EDM process is extensively used for various applications in MEMS, biomedical devices, automotive industry, and defense industry. **Figure 29** illustrates the machine for μ-EDM process.

1.17.5.1.2 Advantages

EDM and μ-EDM processes have following advantages:

- It can machine any electrically conducting material irrespective of their melting points, hardness, toughness, brittleness, and microstructure.
- Capability to produce micro-parts having complex and intricate shapes.
- Capability to produce micro-holes with high aspect ratio.
- Capability to machine very thin fragile materials and brittle materials.
- No direct contact between tool and workpiece.
- Minimum tool wear and no tool breakage.
- Tool material need not be harder than work material.
- Easy to automate and requires little attention from machine operator.
- Burr-free process, thus eliminates the secondary finishing operation.
- Low operating fixtures and tooling cost.

1.17.5.1.3 Limitations

Following are the limitations of the EDM and μ-EDM processes:

- Both tool and workpiece material should be electrically conductive.
- Fabrication of master tool electrodes for gear is complex and difficult.
- Gear cutting rate is slow as compared to the conventional process.
- Not suitable for mass production of gears.
- Not applicable for very large gears.
- Chances of formation of recast layer.
- Higher capital cost.

1.17.5.1.4 Applications

EDM process is used for machining electrically conducting but difficult-to-machine materials such as superalloys, Ti-based alloys, tool steels, alloy steels, refractory materials, metal matrix composites, tungsten carbides, etc. It is used for two-dimensional (2-D) profiling, 3-D contouring, making dies having complicated profile, stamping of tool dies, making blind complex cavities, drilling of various hole shapes including noncircular holes, drilling of micro-holes for nozzles and aerofoil blades, drilling of inclined holes (hole axis having inclination with the top surface as low as 20°), through cutting of noncircular holes,

Table 6 Comparison between electric discharge machining (EDM) and micro-electric discharge machining (μ-EDM)

Parameter	*EDM*	*μ-EDM*
Current	0.5–400 A	0.1–10 mA
Voltage	40–400 V	60–120 V
Pulse duration	User defined: 0.5 μs–8 ms	Not constant: nano- to micro-seconds
Interelectrode gap	10 μm	1–5 μm
Current and gap voltage	Mechanism for constant gap voltage and current during spark	Single capacitive discharge, gap voltage, and current are variable
Effect of gap voltage on machining	Significant	Negligible effect
Dielectric	Mineral oil	Mineral oil, deionized water
Dielectric flushing	External and internal flushing	Internal flushing
Tool material	Copper/graphite	Tungsten
Pulse generator	Switch circuit	RC circuit
Electrode wear ratio	1–5%	1.5–100%
Surface roughness	0.8–3.1 μm	0.07–1 μm
Efficiency of process	Low	High
Typical applications	Automotive, defense, aerospace, prototype production, coin and die making, etc.	Fabrication of micro-nozzles, micro-gears, micro-punches, micro-holes, micro-slots, ink jet nozzle, etc.

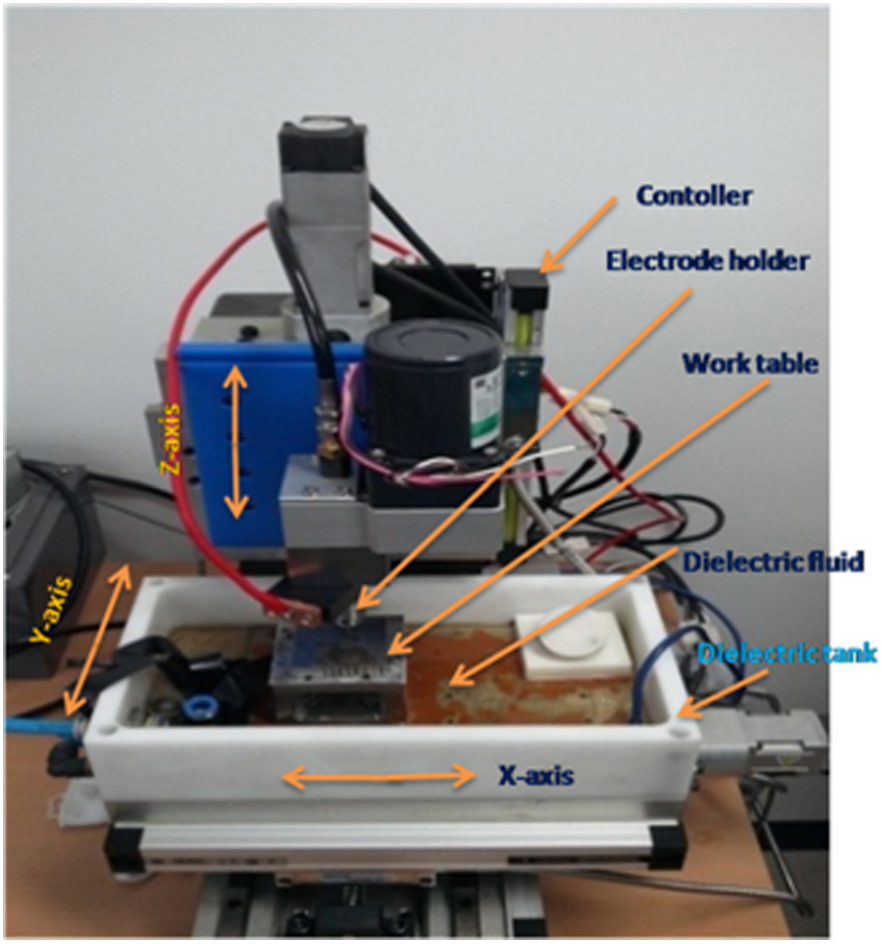

Figure 29 Machine for the micro-electric discharge machining process.[60]

cutting of narrow slots, etc. Main applications of μ-EDM process include manufacturing of micro-holes for different nozzles, narrow slots, high aspect ratio (i.e., deep) micro-holes, non-circular micro-holes, blind complex micro-cavities, turbine blades, high quality miniature gears, etc.

1.17.5.2 WEDM

Manufacturing the tool is the most challenging aspect in EDM. This problem is overcome by using a very fine wire having diameter in the range from 0.05 to 0.3 mm, as the tool in the derived version of EDM process which known as WEDM process. This process is similar to band saw in which a small diameter wire continuously fed under tension, acts as 'saw' for cutting as illustrated schematically in Figure 30. Commonly used wire materials are brass, copper, molybdenum, tungsten, and zinc coated wire. Wire and workpiece are separated by a very small IEG and deionized water is used as dielectric supplying it coaxially with wire feeding resulting in localized dielectric flushing. Use of very thin wire as tool necessitates use of small value of voltage, IEG (in the range of 0.025–0.05 mm), pulse-on time and pulse-off time, i.e., very high pulse frequency in the order of megahertz, in the WEDM process. Constant value of IEG between the wire and workpiece is maintained by a servo-system. The mechanism of material removal in WEDM is the same as that of EDM. Workpiece material ahead of the continuously moving wire is eroded by rapidly occurring discrete electric sparks in the kerf (profile generated by the travel of the wire as shown Figure 30). The material removal rate determines the economics of machining and rate of production where the kerf governs the degree of precision. WEDM is a very slow process and material removal rate is slower than the EDM and other machining processes.[61]

1.17.5.2.1 μ-WEDM

μ-WEDM is a variant of WEDM process and became one of the most popular and versatile micro-machining processes to manufacture complex micro-parts from electrically conductive material of any hardness. The process principle of μ-WEDM is similar to WEDM except the size of wire, voltage, and current. μ-WEDM uses a micro-wire made of copper, brass, tungsten, and molybdenum and having diameter in a range from 0.02 to 0.1 mm as the tool. Consequently, even smaller amount of material than WEDM is removed by the sparks generated in the IEG. Figure 31 illustrates the machine for μ-WEDM process. It is an effective machining technique used for machining of micro-components from difficult-to-machine materials using micro-wire as tool with advantages of high machining efficiency and precision. It is extensively used in various applications in different industries such as automotive,

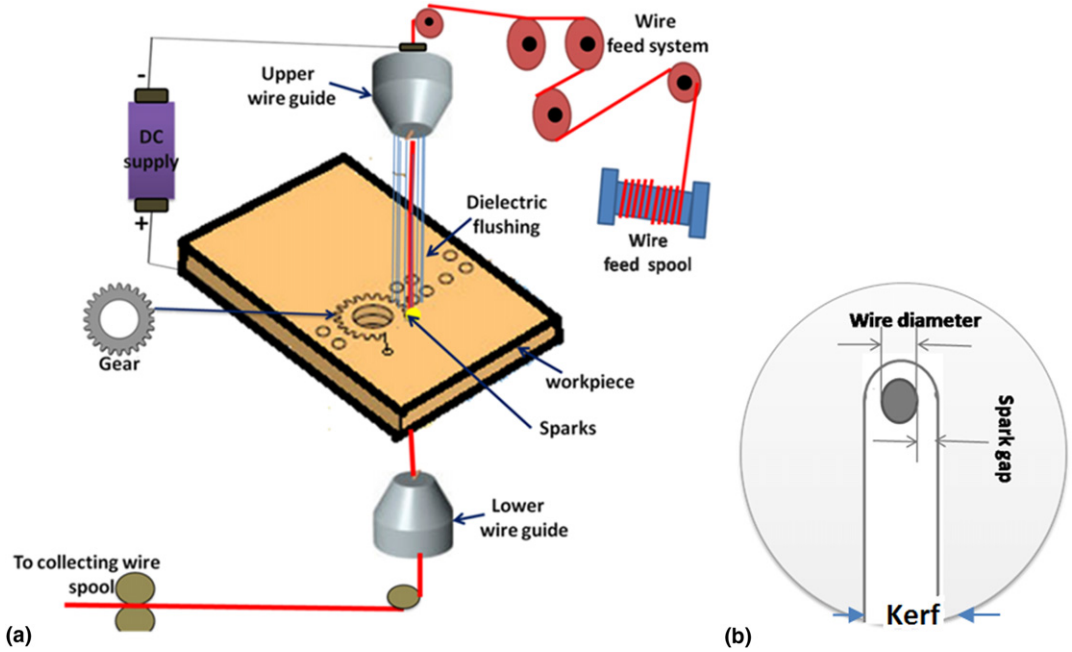

Figure 30 Schematic diagram of miniature gear manufacturing by the wire electric discharge machining process.

aerospace, defense, electronics, telecommunications, healthcare, environmental, industrial, and consumer products, etc. having micro-features requiring nano-finishing and nano-level dimensional accuracy.

1.17.5.2.2 Advantages

The main advantages of WEDM and μ-WEDM processes are:

- does not require design and fabrication of a special tool;
- can machine any electrically conductive material irrespective of its hardness and other mechanical properties;
- can manufacture 2-D and 3-D complex and intricate shapes;
- μ-WEDM process can easily machine very thin and fragile sections;

- high degree of accuracy and surface finish and excellent repeatability;
- burr-free process thus eliminate secondary finishing operation;
- unattended gear manufacturing for a long period; and
- no mechanical stresses and tool marks.

1.17.5.2.3 Limitations

Following are the limitations of WEDM and μ-WEDM processes:

- Suitable for electrically conductive materials only.
- Suitable for through cut only.
- Not suitable for mass production.

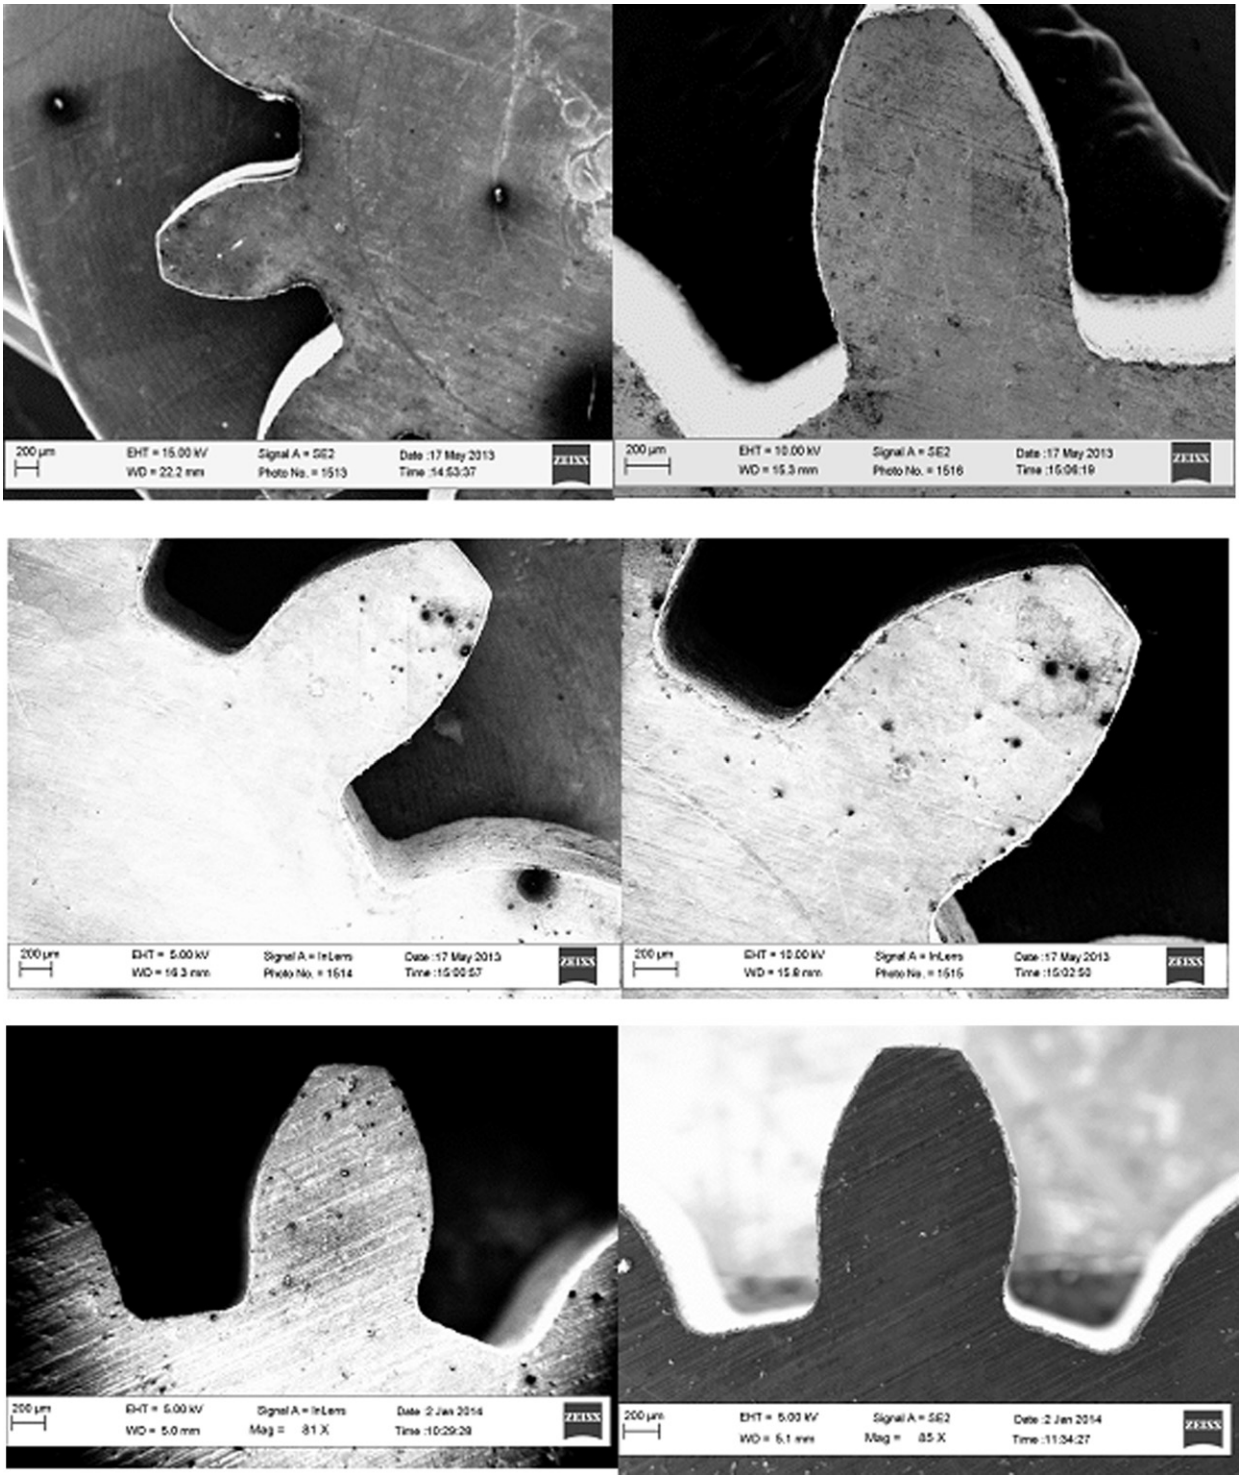

Figure 32 Scanning electron microscope images of the best quality brass miniature spur gear manufactured by wire electric discharge machining. Reprinted from Ref. [54] with kind permission from Springer Science and Business Media.

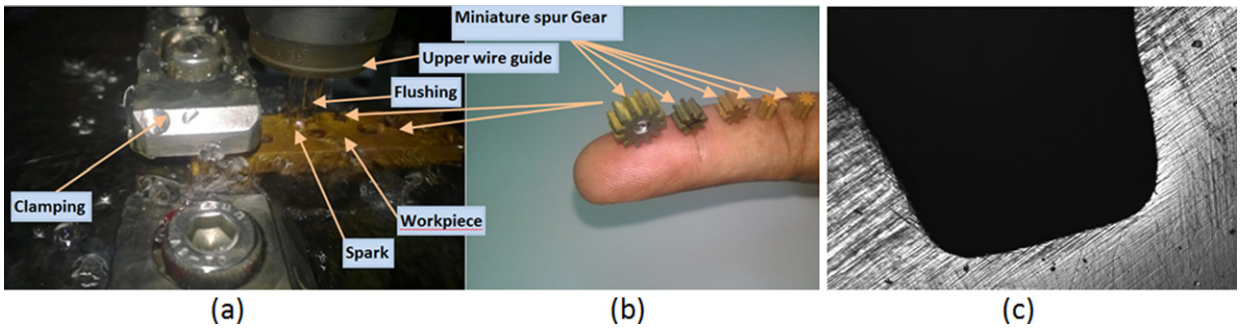

Figure 33 Manufacturing of miniature spur gears by wire electric discharge machining at IIT Indore: (a) photograph of the actual process; (b) photograph of manufactured miniature gears of different size and different materials; and (c) microscopic images of gear tooth profile of SS 304 miniature spur gear.

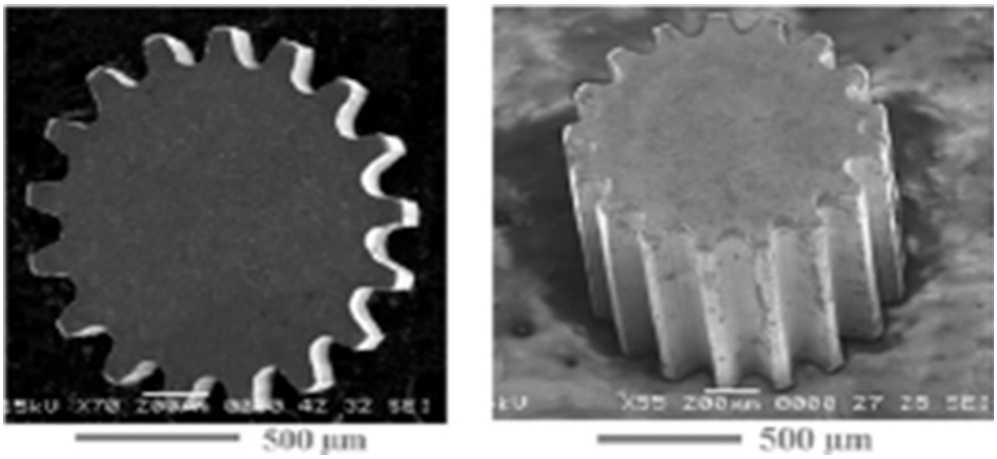

Figure 34 Scanning electron microscope images of micro spur gear manufactured by micro-wire electric discharge machining process. Reprinted from Ref. [66] with kind permission from Springer Science and Business Media.

- Material removal rate is low as compared to conventional processes.
- Requires precise and uniform wire fed under constant tension.
- Wire breakage causes interruption in the process.
- Formation of recast layer.
- Not efficient and economical for a very large-size gears.
- High capital and operating cost.

1.17.5.2.4 WEDM Applications

WEDM process is used to manufacture complex and intricate 2-D and 3-D components from an electrically conductive material regardless of its hardness and other mechanical properties just using a simple thin wire. It is routinely used for manufacturing various dies and molds, EDM tools, complex profiles, accessories and equipment used automotive, aerospace, electronics, medical and surgical applications, parting-off applications, miniature gears, etc. Gupta and Jain have worked extensively in establishing WEDM process for net-shape manufacturing of miniature spur gears made of brass; investigating and optimizing the micro-geometry,[63] surface finish[64] and surface integrity[65] of the manufactured miniature gears. They have reported that though WEDMed miniature spur gears have better micro-geometry and surface integrity than hobbed miniature gears but hobbed gears have better surface finish.[2] Figure 32 depicts SEM images of the best quality miniature spur gear (having outside diameter 9.8 mm; module 0.7 mm; and number of teeth 12 manufactured by WEDM process.[54] Figure 33 depicts some results of ongoing research work on manufacturing of different types of miniature gears (i.e., spur, helical, and bevel gears) of different materials and different sizes by WEDM process at IIT Indore showing photograph of actual process (Figure 33(a)) manufacturing miniature spur gears, manufactured miniature gears of different size and different materials (Figure 33(b)), and microscopic images of stainless steel (SS 304) miniature spur gear showing gear tooth profile (Figure 33(c)).

μ-WEDM process is commonly used for manufacturing micro-components, making micro-features, micro-holes, cutting micro-profiles in any electrically conducting material in general and in high strength, high corrosion, and wear resistant materials in particular. Figure 34 shows SEM images of a micro spur gear manufactured by μ-WEDM process.

1.17.6 Comparative Evaluation

Manufacturing process	*Capabilities*	*Limitations*	*AGMA gear quality*	*Material*	*Applications*
Hobbing	• Fast and continuous process • Higher production rate • Excellent surface finish • Close tolerances • Economical production cost • Minimum tool wear	• Cannot be used for manufacturing conical and internal gears also • Tool marks left on gear teeth • Poor micro-geometry, i.e., hobbed gears require subsequent finishing operation to achieve desired gear quality • Longer setup time	8–13	Ferrous and nonferrous	Instruments, cameras, automatic transmission systems, and high speed machineries
P/M	• Multilevel gears production • Higher repeatability • Higher production rate • Lower energy consumption • Tight tolerances • Minimize secondary finishing operations by producing near net-shaped gears	• Arrangement and storage of fine metallic powder of all type is difficult • Higher cost of metallic powders • More porosity which decreases mechanical properties of P/M components • Gears are subjected to re-pressing or coining after sintering • Removal of part from mould is difficult	6–9	Metallic and Nonmetallic material	Hand tools, pumps, clocks, slow speed machineries, and various appliances
Die casting	• Higher production rate • Can be used for manufacturing any type of gear, i.e., spur, bevel, helical, worm, and spiral • Economical process for high volume production of miniature gear	• Higher initial cost • Limited to high-fluidity materials only • A certain amount of porosity is common • Suitable for gear manufacturing for light load application • Cannot be used where extreme accuracy is needed • Requires of finishing operation after gear manufacturing	5–8	Nonferrous material	Toys, washing machines, hand tools, cameras, business machines, small appliances, etc.
MIM process	• Net-shape or near net-shape gear manufacturing with minimal material waste	• Higher tooling costs and lead time • Higher process cost due to multiple steps	6–7	Nonferrous	Small appliances, clocks, small motors, toys, instruments, small tools, etc.

	• Requires minimum finishing operations	• Shrinkage of injected material in sintering • Requires sintering after metal injection process			
ICM	• Higher dimensional accuracy of gear due to uniform distribution of materials • Eliminates shrinkage marks, stresses and warpage	• Higher cost of machine and mould • Slower process • Control of flash is difficult • Material wastage due to mould overfilling • Contamination • Complicated process control	4–8	Plastic	Micro-motors, toys, instruments, communication devices, etc.
μ-PIM	• Can be used for manufacturing of micro gear of different metallic materials and ceramics • Higher dimensional accuracy of micro-gears	• Requires the micro-mold • Need of vacuum prior to injection • Risk of freezing of feed stock during injection molding • Complex process parameters for micro-injection molding	Not available	Plastic	Surgical and dental instruments, Miro-motors, and other appliances
LIGA	• Higher dimensional accuracy (<1 μm) • Better surface finish (<50 nm) • High Aspect ratio	• Very expensive process • Complex process (requires multiple steps) • Requires mask, resist and X-ray source • Tight tolerance for pattern overlay	Not available	Metallic, alloys and polymer	Micro-pump, Micro-motor, and watches
Stamping	• Uniform dimensional accuracy and quality of gear • Higher production rate • Lower labor cost • Easy to automate • Ability of manufacturing gear of different materials	• Can manufacture gear up to 3 mm thickness only • Applicable for no-load to medium-duty gears only • Requires shaving operation after stamping • Higher tooling cost (both equipment and die) • Poor accuracy due to higher tolerances • Longer tooling time	6–9	Sheet metal	Toys, timer mechanism, watches, mixers, and other appliances
Extrusion	• Good surface finish with clean edge and porosity-free edges with dense structure	• Surface cracking occurs • Suitable for nonferrous	4–6	Aluminum, copper, naval brass, architectural	Watches, Electric clocks, spring-wound clocks, typewriters, small

	and higher strength of gear • Higher production rate	materials such as aluminum and copper alloys • Secondary drawing operation is required after extrusion to improve the gear accuracy • Excessive wear of extrusion die		bronze, and phosphor bronze	motors, cameras, etc.
Forging	• Net-shape or near net-shape gear manufacturing • Greater load carrying capacity of forged gear	• Requires high forging force • Short life of the forging die due to excessive wear	Not available	Ferrous	Marine, stern drives, differential, etc.
Hot embossing	• Higher dimensional accuracy • Lower gear manufacturing cost	• Suitable for polymers only • Slower process (requires four steps) • Difficulty in attaining high embossing pressure	Not available	Polymer	Toys, instruments, micro motor, and small appliances
EDM and μ-EDM	• High dimensional accuracy and surface finish • Less material loss • Gear can be cut from thin and fragile material • No mechanical stresses and burr-free process	• Suitable for only electrically conductive material • Slower process • Not suitable for mass production • Fabrication of tool electrodes are difficult and complex • Chances of formation of recast layer	Not available	Electric conductive material	Aerospace, micro pump, micro motor, medical and dental instruments, etc.
WEDM and μ-WEDM	• High dimensional accuracy and surface finish • Gear DIN quality standard upto 6 can be produced • Gear can be cut from thin and fragile material • No mechanical stresses and burr-free process • No secondary finishing operation is required	• Limited to electrically conductive material only • Requirement of precise, accurate and uniform diameter wire • Slower process • Not suitable for mass production • Fabrication of tool electrodes are difficult and complex • Chances of formation of recast layer		Electric conductive	Master die gears for EDM, aerospace, micro pump, micro motor, medical and dental instruments, etc.

1.17.7 Summary

Manufacturing of miniature gears is a complex and challenging task which should be highly precise and accurate because performance and functional characteristics of devices are highly dependent on the quality of the miniature gears. The various conventional and nonconventional manufacturing processes are used to manufacture miniature gears. Most of the conventional miniature gears manufacturing processes produce miniature gears quality ranging between 9 and 12 DIN standard and require secondary finishing process to achieve the desired gear quality, i.e., they are not net-shape miniature gear manufacturing processes. Spark-erosion-based processes can achieve gear quality up to DIN standard 6 thus eliminating requirement of any secondary finishing operations. WEDM and μ-WEDM processes have the potential to be established as net-shape manufacturing process for high quality meso- and micro-gears respectively. Sustained research is in progress at the author's institute to establish WEDM for net-shape manufacturing of high quality meso-gears of different types and of different materials. Following conclusions can be drawn from review of miniature gear manufacturing processes:

- Miniature gears are extensively used in MEMS, aerospace, medical, defense, precision instruments, automobile, toys, and other appliances.
- Hobbing process produces miniature gears with high surface finish, but micro-geometry is poor as compared to those manufactured by the spark-erosion-based processes.
- Conical and internal gears cannot be manufactured by Hobbing process.
- ICM and LIGA processes can be used for polymer materials only.
- High aspect ratio miniature gears are manufactured by μ-PIM, LIGA, and hot embossing process.
- Stamping is suitable for thin sheet up to 3 mm thickness only.
- Die casting, extrusion and MIM processes are limited to high fluidity, nonferrous materials only.
- MIM, extrusion, and forging near net-shape gear manufacturing processes.
- Spark-erosion-based processes are net-shape miniature gear manufacturing processes and their performance does not depend on gear material hardness and other mechanical properties. These processes manufacture miniature gears of very good quality, but they can be used only for electrically conductive materials

EDITOR-IN-CHIEF

Saleem Hashmi is emeritus professor in the School of Mechanical & Manufacturing Engineering at Dublin City University, Ireland. He founded the School in January 1987, in addition to setting up the Materials Processing Research Centre (MPRC), a research centre of excellence in the field of materials processing.

In 1990, Professor Hashmi established Advances in Materials and Processing Technologies (AMPT), a much-needed international conference in materials processing. He continues to be the chairperson of the steering committee for this series of conferences. In 1998 he was appointed as editor-in-chief of Elsevier's *Journal of Materials Processing Technology* and continued in this role until 2008.

In 1995, Professor Hashmi was awarded the higher doctorate degree of DSc, by the University of Manchester, the highest academic degree any university in the UK can award.

Professor Hashmi has supervised or co-supervised 112 PhD and 55 MEng research students to successful completion. Over the years he has also acted as an external examiner and expert assessor for PhD candidates and engineering departments with universities in Ireland, the UK, India, Pakistan, Bangladesh, Hong Kong, Canada, Australia, and Malaysia. He has published in excess of 460 papers and 25 books so far.

Professor Hashmi was the editor-in-chief for Elsevier's 13-volume major reference work *Comprehensive Materials Processing* which was published in 2014.

He has been appointed as the editor-in-chief for Elsevier's *Materials Science and Materials Engineering Reference Module*, a 14-section online resource comprising around 3500 reviewed articles. This launched in December, 2015 and is constantly being updated.

VOLUME EDITORS

Imtiaz Ahmed Choudhury is currently a professor at the Department of Mechanical Engineering, University of Malaya (UM), and has been with UM since 1996. He received his Bachelor degree in Mechanical Engineering from Bangladesh University of Engineering and Technology (BUET), MEng from Asian Institute of Technology (AIT), Thailand, and MSc in Mechanical Engineering from Arizona State University, USA. He obtained his PhD from Dublin City University. He started his career as an assistant engineer in a gas transmission and distribution company, Dhaka, Bangladesh. He worked as a maintenance engineer in a power station for 3 years in Libya. He started his academic career in 1982 as an assistant professor in an engineering college, Bangladesh. Since then, he has been working in academia. Imtiaz's research interests include traditional/nontraditional machining with vegetable oil-based lubricant, tool condition monitoring, machining difficult-to-cut and high strength materials, injection molding and application and use of solar energy. He has been a member of a panel of judges for the SME innovation award 2011–2013, Malaysia, under the category of "Manufacturing Sector." He was a Senate member of the University of Malaya. He has authored and coauthored about 100 papers in referred journals, more than 60 conference papers and some book chapters published in Elsevier works. He has also been a reviewer of various international journals. Imtiaz is a Fellow of Institution of Mechanical Engineers, UK (IMechE), and a life Fellow of Institution of Engineers, Bangladesh (IEB). He is a chartered engineer, UK (CEng).

Professor Shahjahan Mridha was born in Bangladesh and obtained his BSc and MSc in Metallurgical Engineering at the Bangladesh University of Engineering & Technology (BUET), Dhaka, and PhD at the University of Leeds in UK (1980) on Gas Nitriding of Low Alloy Steels. Since 1972 he has worked at the Department of Metallurgical Engineering, BUET for 20 years as a faculty member except for 1986–1987 where he was a Commonwealth Academic Staff member at the University of Birmingham, UK, working on Plasma Nitriding.

Professor Mridha was a senior research fellow at the University of Strathclyde, UK from 1989–1994 and worked on laser processing of aerospace materials in collaboration with UK Ministry of Defence. In late 1994 he moved to Nanyang Technological University (NTU) in Singapore where he was employed as an associate professor until 2001, working on semiconductor materials, composite and intermetallic coatings.

In January 2002 he joined the International Islamic University Malaysia (IIUM) as professor, later assuming the position of Head of the Department of Manufacturing and Materials Engineering. He left IIUM in July 2012 to join the Department of Mechanical and Aerospace Engineering at the University of Strathclyde (UK) as a Leverhulme Trust Professor, and remains there presently as visiting professor.

Professor Mridha has published more than 150 journal and conference papers. His research contributions are primarily on microstructure–properties relationships, semiconductor materials and surface modification of light alloys and steel using high power laser and TIG torch melting technology. He is the pioneer of TIG torch techniques for surface coating applications. Professor Mridha is subject editor of the *Metallic Materials* section in Elsevier's *Reference Module in Materials Science and Materials Engineering* launched in December 2015.

In addition to his academic career, Professor Mridha worked as an international consultant for the United Nations Industrial Development Organization (UNIDO) from 2001 until 2007, delivering expert advice and training to engineers working in manufacturing industries in the Indian and African continents.

Bekir Sami Yilbas is a distinguished professor in the Mechanical Engineering Department, King Fahd University of Petroleum and Minerals, Saudi Arabia. He received his PhD in Mechanical Engineering from Birmingham University, and was awarded a doctorate of Engineering at Birmingham in 2005 due to his significant contribution to his field of study. He has received numerous awards as recognition of his research work. Some of these include President of India's Prize for 1988 by Indian Royal Engineering Society, Technology Prize for 1990 by Science and Technology Foundation in Turkey, Best Research Award for 1997, 2002, 2007 by King Fahd University of Petroleum and Minerals, Silver Jubilee Medal by Silesian University of Technology, Donald Julius Groen Prize for 2007 by Institution of Mechanical Engineers (IMechE), Distinguished University Professor award at King Fahd University of Petroleum and Minerals, 2008 – present by King Fahd University of Petroleum and Minerals, Professor W. Johnson International Gold Medal for 2008 by Advances in Materials and Processing Technologies (AMPT) Steering Committee, Professor Fryderyk Staub Golden Owl Award by World Academy of Metals and Manufacturing, Almarai's Distinguished Scholar Prize by King Abdulaziz City of Science and Technology.

Bekir Sami Yilbas has published 720 journal papers in reputable international journals and presented over 100 papers at international conferences. He has 12 patents issued and is the subject editor of *Arabian Journal of Science and Engineering* and editor of *Journal of Fluids*. He has served as an editorial board member of international journals, including the *International Journal of Machine Tool and Manufacture Design, Research and Application, International Journal of Subsurface Sensing Technologies and Applications, Journal of Materials Processing Technology, Journal of Achievements in Materials and Manufacturing Engineering, International Journal of Nanomanufacturing*, and *Archives of Materials Science and Engineering*, and has received numerous awards as recognition of his research work.

PREFACE

Finish manufacturing processes are final stage processing techniques which are deployed to bring products to a stage where they are ready for marketing and putting in service. Over recent decades, a number of finish manufacturing processes have been developed by researchers and technologists. Some of these new processes have been documented and illustrated both individually and collectively in relation to application in specific areas. The advancement of tools of physics has resulted in considerable changes to these processes, and the precision with which they can be applied. The reporting of these developments are sometimes fragmentary, and this reference work provides a more connected and thorough review of these processes.

Comprehensive Materials Finishing is the primary reference source for researchers at different levels and stages in their career both in academia and industry. This reference work encompasses the knowledge and understanding of many experts into a single, comprehensive work. Containing a combination of review articles, case studies, and research findings resulting from research and development activities in both industrial and academic domains, this reference work focuses on how some of these finish manufacturing processes are advantageous for a broad range of technologies. These include applicability, energy and technological costs, and practicability of implementation. A wide range of materials such as ferrous, nonferrous, and polymeric materials are covered.

This work details the three foremost and distinct types of finishing processes: surface treatment, finish machining processes, and surface coating processes. Surface treatment refers to properties of a material being modified without otherwise changing the physical dimensions of the surface. Finish machining processes involve a small layer of material being removed from the surface by various machining type processes to render improved surface characteristics. Surface coating processes are where the surface properties are improved by adding fine layer(s) of materials with superior surface characteristics to improve the service life of the surface being coated. Each primary surface finishing process is presented in a separate volume, comprising chapters on many of the following relevant specific processes as follows:

Volume 1: Finish Machining and Net-Shape Forming: developments in conventional finish machining processes (honing, lapping, polishing, burnishing, and deburring), fine grinding, free EDM, laser finishing, electrical discharge grinding (EDG), electro-chemical honing (ECH), electrochemical discharge grinding (ECDG), electrochemical grinding (ECG), electrochemical turning (ECT), micro-machining process, and high-speed machining.
Volume 2: Surface and Heat Treatment Processes: This contains aspects of heat treatments, stress relieving, annealing, normalizing, hardening, tempering, austempering, martempering, carburizing (pack, liquid, gas, and post carburizing treatments), nitriding (gas and plasma), salt bath (boriding, chromizing, cyaniding, and carbonitriding), phase transformation of the outer surface (induction, flame, laser, electron beam, and anodizing).
Volume 3: Surface Coating Processes: Plating (electroplating, alloys (bronze/brass and others), chromium, dense chromium, copper and tin, gold, silver and other precious metals, zinc and nickel, electroforming, electroless nickel, hot dip galvanizing, selective/brush plating, surface finish coatings, air spray painting, and chemical vapor deposition (CVD)).

Finishing processes are at the core of successful production of marketable products and address recent progress in materials finishing technologies and science as well as covering recent developments in specific manufacturing processes involved with finishing of products for applications in all areas of engineering, biomedical, environmental, health and safety, and monitoring and control. The in-depth study of these finishing processes as presented in these volumes will assist scientists and engineers in the selection, design, and usage of materials, whether required in small- or large-scale uses across industries.

The initiations for this project began in 2014 and by January, 2015, I had selected the volume editors – Bekir Yilbas, Imtiaz Choudhury, and Shahjahan Mridha and we met with Gemma Tomalin, Joanne Williams, and Graham Nisbet at the Elsevier office in Oxford to finalize the table of contents and plan the project. Throughout 2015, the volume editors and I worked resolutely to select topics to be covered, invite authors, and review their manuscripts, eventually getting all content ready for production by the end of 2015. In 2016, authors returned their proof corrections and final files were produced. To create a work of this scale, the most in-depth reference ever published on materials finishing processes and surface engineering, relies on a collaboration of authors, editors, and the team at Elsevier. I would like to thank the many dedicated authors, whose contributions will be an essential reference for materials scientists and engineers. Each chapter has been reviewed by one of the volume editors, leading experts in their fields, whose knowledge and expertise have proved invaluable. I am indebted to each volume editor and their dedication to making their volume an exhaustive and relevant resource for the scientific community for many years to come. Finally, on behalf of myself and the volume editors, I would like to thank Gemma Tomalin and Joanne Williams at Elsevier for their support, cooperation, and good humor throughout this project – from the first meeting in early 2015, to the publication mid-2016.

MSJ Hashmi
Editor-in-Chief
Dublin City University, Dublin, Ireland

INTRODUCTION TO SURFACE AND HEAT TREATMENT PROCESSES

This volume on Surface and Heat Treatment Processes is one of three volumes in Comprehensive Materials Finishing and comprises of 15 chapters of which 5 chapters are focused on Surface Treatments, while the remaining chapters are on Bulk Heat Treatment Processes. The chapters on surface treatments are limited to surface hardening by structural modification of a surface layer. Although surface treatment is a part of heat treatment processes, for convenience of the readers the title of the volume is spelled out as surface and heat treatment processes.

In metallurgical practice, heat treatment represents a whole class of techniques – involving thermal, mechanical and chemical treatments – by which the desired properties of structural materials are obtained to suit the variety of applications. The properties influence the performance of a material in service. The modification and transformation of crystalline structures can be achieved by employing mechanical and thermal treatments or by infusion of new elements. Within close composition limits, the processing of a material to the finished product controls the microstructure and so the properties. Depending on the various processing parameters, transformed products may be of different phases. Presence of these phases and morphology of the products decide the resultant properties of metals. Heat treatments change the microstructure and make the materials hard or soft. Surface treatments harden the surface layer by infusion of new elements, phase transformation, plastic deformation or surface melting; in all these processes the core microstructures mostly remain unchanged.

The first chapter (2.1) introduces the fundamental principles involved in heat treatment processes applied to metallic components. This chapter provides sufficient information to be of use to metallurgists, researchers and engineers seeking to understand the importance of different thermal treatments to attain material properties required for specific applications. The readers will realize the fundamental importance of the internal structure of the metals; they will also be familiar with the typical features of such structures and understand how they are produced during heat treatments. The second chapter (2.2) on hardenability of steels describes basic aspects on the range and degree of hardening of steels, which are very important in the material selection and design of heat treatment processes in order to achieve properties of specific service requirements.

Chapters 2.3 and 2.4 describe how infusion of carbon (carburizing) and nitrogen (nitriding) using thermochemical treatments modifies the surface microstructures and properties of steels. While chapter 2.5 details the laser treatment that changes surface structures and properties upon resolidification of a melted thin surface layer. Chapter 2.6 is on induction treatment, which relates to the surface transformation hardening technique for steels of close composition limits without significantly modifying bulk properties. Chapter 2.7 contains mechanical treatments at the localized surface areas that create stain hardening by micro-deformation rather than phase transformation.

Heat treatments of important commercials steels, tool steels and cast irons are dealt with in chapters 2.8, 2.9 and 2.10, respectively. Details of microstructural changes related to properties under different heat treatment processes are outlined in these chapters. Each of these chapters gives a comprehensive treatise encompassing treatment, properties and application of all the main groups of steels used in engineering practice. The readers will be able to differentiate processes suitable for developing specific properties in these ferrous materials.

Heat treatments applied to important nonferrous materials are presented in chapters 2.11–2.14. Chapter 2.11 describes heat treatments of titanium alloys. Chapter 2.12 contains general heat treatments of aluminum alloys, while chapter 2.13 on specific processes dealt with solutionizing and aging treatments for strengthening of aluminum alloys. Heat treatments of copper and nickel alloys are given in chapter 2.14. Chapter 2.15 concentrates on cryogenic treatments or cryo-treatments, which refer to a range of subzero heat treatments that are applied to materials with the aim of causing permanent microstructural changes and corresponding changes in mechanical properties and behaviors.

Acknowledgements

I would like to thank all authors for their hard work, and editors, especially the editor-in-chief for inspiration and successful guidance in preparation of the volume. Finally, I am grateful to the Elsevier team particularly Gemma Tomalin and Joanne Williams who continuously supported me with appropriate information and necessary facilities at every stage of this work.

2.1.1 Introduction

Heat treatment is essentially a process of heating and cooling a material to achieve a desired set of physical and mechanical properties. The properties of materials are dependent upon their structural aspects. The structures may be of different scales of magnitude viz. macrostructure, microstructure, nanostructure, crystal structure, or atomic structure. In general, heat treatment of metals and alloys concerns the change in microstructure. Planned thermal treatment may affect desired changes in the defects structure of metallic crystals; this in turn alters the mechanical properties of the metals and alloys. During the course of heat treatment, the metals and alloys may undergo change in crystal structure (polymorphic transformation), change in chemical composition and change in the degree of order; depending upon the system, these changes may take place either singularly or in combination. However these changes have direct bearing on the final properties of the material. Also it will be seen that without any of the above three changes, heat treatment may enable to obtain desired properties of materials by way of changing its substructure. In a nutshell, heat treatment of metals and alloys envisages:

- Polymorphic change with or without change in local composition with in a system. The average composition however remains the same. This type of change is very common and Fe–C system is a classic example.
- Overall change in chemical composition at the surface of a component followed by above mentioned polymorphic change as stated above. This type of change is realized in surface hardening of metals and alloys.
- Change in local composition at a very fine scale of magnitude. Age hardening in alloy exemplifies such incidence.
- Dissolution of unwanted second phase particles, and formation of clean single phase alloy.
- Grain refinement of a pure metal or a single phase alloy which is previously subjected to mechanical working at a low temperature.

It is to be understood that changes stated above are brought about by previously chosen thermal treatment with an eye to achieving a predefined set of properties. Thus the purposes of heat treatment of metals and alloys are:

- To improve strength, hardness, and wear resistance properties.
- To increase toughness and ductility.
- To obtain fine grain size.
- To remove internal stresses induced by differential deformation by cold working, nonuniform cooling from high temperature during casting and welding.
- To improve machineability.
- To improve cutting properties of tool steels.
- To improve surface properties of materials especially in respect of wear and corrosion resistance.
- To improve physical properties viz. electrical and magnetic properties.
- To induce such other unique material functionalities as are possible due to specific phase transformation; some examples are transformation induced plasticity, metamagnetic shape memory effect, etc.

2.1.1.1 Stages of Heat Treatment

The heat treatment as a process is accomplished in the following three stages:

- Heating to a high temperature to obtain homogeneous single phase. In a multiphase alloy system, the homogeneous single phase can be obtained at high temperatures only with special care, as described later.
- Holding at the high temperature for preselected time period.
- Cooling the object under treatment to room temperature or below.

Again, it may be required to repeat the same three stages with different process parameters. It is necessary to know, how to select the heating temperature. Equally important is to acquire the knowledge about the criteria of selecting the rate of heating to reach the selected temperature and the duration of time one needs to spend at the heating temperature. During cooling operation knowledge about the cooling rate to use is also required. If the cooling rate is very slow, equilibrium microstructure in accordance with the prediction of phase diagram of the concerned system is possible to achieve. It is pertinent to remember that, attainment of equilibrium during cooling of a multicomponent system undergoing phase changes may be possible only if infinitesimal rate of cooling is practiced; it is very difficult to impose such a slow cooling rate in practice, although it is not impossible in today's technological scenario. The practice of heat treatment at such slowest possible cooling rate to aim at achieving the equilibrium microstructure is called annealing.

If an iron–carbon alloy contains equilibrium phases in its microstructure, the alloy is said to reach its softest state. This is why annealing of iron–carbon alloy is quite often considered as a softening process, whereas all other processes leading to deviation from equilibrium structures may be looked as hardening process. However this behavior is not generic and is not authenticated in many alloy systems, where the nonequilibrium phase is softer than its equilibrium counterpart. One such example is Cu–Zn–Al alloy, which when rapidly cooled from a high temperature is seen to produce softer phase than that present in annealed condition.

2.1.1.2 Heating Step

One of the main objectives in the heating stage is to obtain a homogeneous single phase unless otherwise dictates of compulsions are there; for example, hypereutectoid steels are

deliberately heated to a two-phase region for accruing certain specific benefits, as narrated in later sections. Another target of heating stage is to attain uniform temperature throughout the cross-section of the object being heat treated. Rapid heating may allow one part of the object to expand faster than another and as a result distortion or warpage may take place. However the heating rate depends on several factors. One important factor is the heat conductivity of the component. A metal with a high-heat conductivity heats at a faster rate than one with a low conductivity. The size of the stock to heat treat and its initial structural condition determine the rate at which it should be heated. A slower heating helps to get rid of thermal shock due to differential heating at surface and at the center. A component with higher cross-sectional area should be subjected to a slower heating rate in order to minimize the difference in temperature between surface and center of the stock. This helps to minimize the chance of warpage and distortion. Parts with nonuniform cross-sections experience uneven temperature rise across the section and hence a slower heating rate must be used to avoid cracking or warpage.

2.1.1.2.1 Heating rate

Whenever there is a phase transformation involving a change in crystal structure, volume change ought to occur. In a heat treatment process, the heating step comes across two different types of stresses: one is the thermal stress due to the existence of temperature differential between surface and center of the object being heat treated. This stress is consequential to thermal expansion of the material.

The other type of stress originates from the volume change accompanying the phase transformation. These two stresses make the component vulnerable to distortion or warpage. In extreme cases cracking may also occur for an otherwise intricate geometry. Difference in magnitude of thermal expansion at the surface and the center of the component depends upon the difference in temperature between the two at any instant of heating. This temperature difference is further dependent on the thermal conductivity, specific heat, and the section size of the object. The rate of heating is therefore decided by both the thermal and the transformational stresses. As previously mentioned, thermal stresses may be managed by a slower heating rate, whereas magnitude of transformational stresses is fixed for a definite phase transformation. However phase transformation takes place within specific range of temperature and so special care is taken in heating the material through this range of temperature. Quite often at temperature near to, where phase transformation is likely to occur, a short holding time is recommended. The purpose of this holding time is to equalize the temperatures at the surface and center of the stock. Thus there is no thermal stress, only the transformation stress is to be taken care.

There are a number of constraints to come across during heating. These are:

- Thermal properties of the material are functions of temperature and these are not accurately known for all metal and alloys under all conditions of heating. This leads to the problem of unpredictable and nonuniform thermal stresses to take care by manipulation of heating cycle.
- The flow stress of the material decreases at elevated temperature and if a phase transformation takes place at a high temperature with appreciable volume change, the stress due to transformation may lead to plastic deformation of the component being heated. Thus distortion or warpage becomes inevitable. In such cases manipulation in heating rate is of little use.
- Beyond the temperature of transformation only thermal stress is important and a slower rate of heating might appear to be a solution. However, it is certainly not because a slower heating implies a higher time to reach the soaking temperature. In many alloy systems there is ample chance of chemical degradation due to heating at high temperature. A slower rate of heating leaves a greater scope for chemical degradation, as the total residence time at the elevated temperature is quite high. So, it is desirable to employ a higher heating rate to reach the soaking temperature as soon as possible. The chemical degradation may be due to reaction with aerial gases in the furnace environment (as in titanium alloys), internal oxidation by entrapped oxygen in aluminium alloys, etc. Further a fast heating across the transformation temperature will raise the transformation temperature due to hysteresis effect and this results in higher degree of superheat and enhancement of driving energies for transformation. A controlled soaking time and temperature envisage the formation of fine-grained single phase alloy. However for cases of heating to subcritical temperature for specific heat treatment types (stress relieving, second stage graphitization in cast iron), a slower heating rate is preferred.

2.1.1.2.2 Heating temperature

The microstructure of the heat-treated component may follow from the dictates of equilibrium phase diagrams; sufficient time at the transformation temperature is available for diffusion processes to take place. Near-equilibrium state is normally attained in case of extremely slow cooling. With increasing cooling rate, availability of time to attain equilibrium at each stage of transformation is a constraint. This leads to a non-equilibrium situation. Thus quantitative estimation of phases by the usual technique of applying lever rule is not tenable. Even under deviation from equilibrium a system may undergo diffusional transformation, and can form phases qualitatively similar to what are predicted by the phase diagrams.

However, the phases so formed will increasingly differ in composition, morphology, and amounts with increasing cooling rate. This aspect is quite prevalent in case of iron–carbon system where normal cooling in air called normalizing, leads to significant difference in structure and property of the alloy. Faster cooling leads to a lower transformation temperature as compared to that of the annealed samples. In such cases it is prudent to study the isothermal transformation behavior of the samples at lower transformation temperatures. However diffusional transformation in solid state is limited by certain critical cooling rate (CCR), beyond which the system can no longer undergo diffusional transformation; rather it tends to produce supersaturated solid solution. Depending upon the system, where polymorphic transformation is unavoidable, crystal structure of the product phase changes through diffusionless shear transformation, where large-scale atomic movement is not required. Such kind of transformation is called martensitic transformation and it is observed in

rapidly cooled iron–carbon alloy. On the contrary, there are many systems, like a number of aluminum alloys, where there is no possibility of polymorphic transition and hence rapid cooling simply produces supersaturated solid solutions. In either case super saturation may be relieved by gently heating the supersaturated solid solution above room temperature so that the solute atoms gather appreciable mobility. Such process of getting rid of supersaturation through rejection of solute-rich phase is called precipitation.

2.1.1.3 Soaking Stage

When the preselected temperature is reached the component undergoing heat treatment is required to be kept at that temperature until the desired degree of structural homogenization take place. This process is generally termed 'Soaking.' The length of time the object is kept at the soaking temperature is known as 'Soaking period.' The soaking period depends upon the chemical composition of the material being heat treated, its thermal history, initial microstructure, maximum section size, and the weight of the component. In parts having different cross-sections the soaking period is decided by the largest cross-sectional area. As mentioned earlier, the temperature at the center of finite-sized workpiece lags behind the temperature at its surface.

Therefore the center of the stock will reach the soaking temperature at a later time than the surface. Hence the soaking time has two components: one is the time required for equalization of temperature at the surface and the center while the other one is the time for the structural homogenization to take place. The homogenization process may be simple dissolution of solute-rich phase into the matrix phase or a combination of both phase transformation with crystal structure change and second phase dissolution.

Figure 1 qualitatively shows the temperature differential to exist between surface and center of the heat treating stock. In most of the practical and industrial operation a time of 15 min is considered sufficient to make the temperature uniform across the section. Taking homogenization time in consideration, a thumb rule of 1 h per 25 mm of section size is normally employed for soaking at the high temperature. However in an industrial situation when a number of components are to be heated together, the thumb rule of 1 h per 25 mm thickness may not work out. In every such case, it is needed to understand the temperature profile within a furnace, and based on this knowledge, the time to be taken for all the items to attain the heat treatment temperature need to be deduced. However the general approach must be to keep the holding time to its minimum possible value. Too high a holding time may lead to grain coarsening and chemical degradation, whereas an inadequate soaking time may not yield homogeneous single phase everywhere within the workpiece.

As shown in Figure 2, sometimes the metal is brought from room temperature to the soaking temperature in more than one step; the workpiece is first heated slowly to a temperature where phase transformation is likely to take place and then it is held at that temperature for some predefined period of time so that the temperature of the workpiece is equalized throughout its cross section. This action is called 'preheating.' Following preheating the workpiece should be finally heated to the required heating temperature at a faster rate.

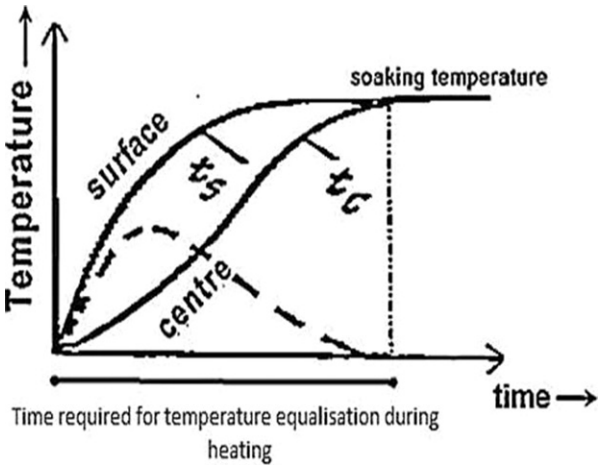

Figure 1 Temperature differential between surface and center.

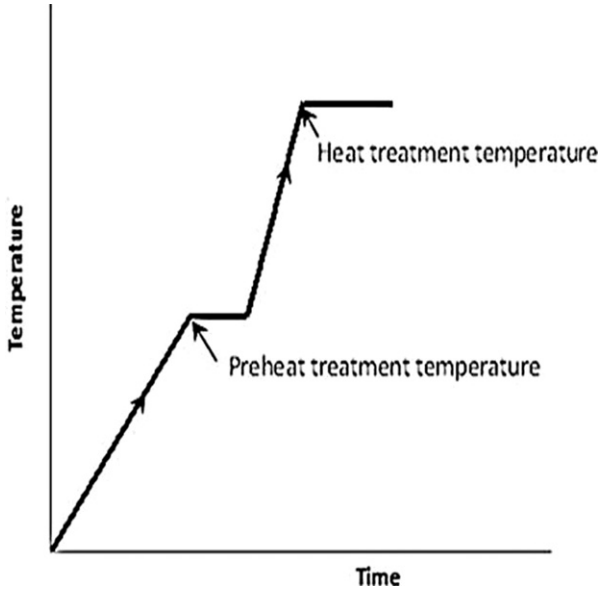

Figure 2 A complex heat cycle.

Different types of heat treatment processes applicable to various material systems are shown in Figure 3.

Majority of the aforementioned heat treatment practices are implemented in different types of steel. Therefore to elucidate the fundamentals of these heat treatment processes, the following discussion is made with reference to steel panel of iron–carbon alloys.

2.1.2 Heat Treatment of Steel

The steel is an alloy of iron and carbon with a maximum carbon content of 2 wt.%. The steel panel of Fe–C phase diagram as shown in Figure 4 is extended up to the extremum of eutectic isotherm.

The present discussion is confined to the metastable phase diagram of the system, because of the obvious reason that

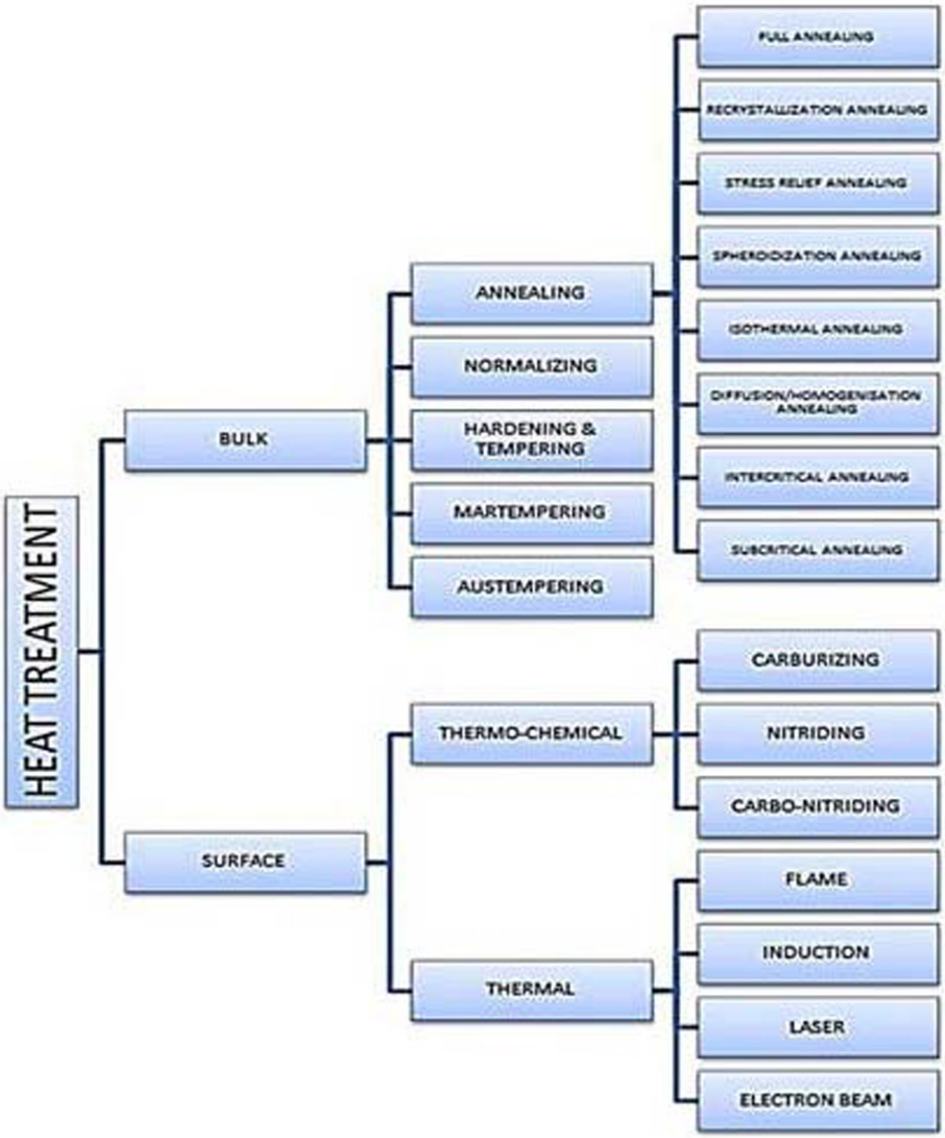

Figure 3 Different types of heat treatment processes.

a very long time is taken by the system to attain the stable state. The information about the different phases present at different temperature–composition combination may be obtained from the above equilibrium diagram. It may be noted that, A_1, the lower critical temperature denotes the minimum temperature up to which austenite(γ) can be present; A_3, is the upper critical temperature describing the equilibrium between γ and ferrite(α); whereas A_{cm}, is the line describing the solubility of carbon in γ. Quite often the suffixes c, e, and r are used with the critical temperatures. For example, Ac_1 denotes the temperature at which γ forms from ferrite during heating. Its equilibrium counterpart is written as Ae_1, whereas Ar_1 stands for γ to ferrite transformation during cooling. Similar meanings are assigned to Ac_3, Ae_3, Ar_3, Ac_{cm}, Ae_{cm}, and Ar_{cm}. Addition of alloying elements tend to alter the position of A_1 and A_3 lines; at the same time it changes the eutectoid composition which is 0.8 wt.%C in pure binary Fe–C alloy. The alloying elements added in iron–carbon system are classified broadly in to two types:

One group of alloying elements is known to stabilize ferrite; these alloying elements are called ferrite stabilizers and in general the crystal structure of ferrite stabilizing elements is body centered cubic (BCC). Cr, Mo, W, Nb, etc. are some examples of ferrite stabilizer.

Similarly, the elements stabilizing austenite are called austenite stabilizer. The austenite stabilizers are mainly those with face centered cubic (FCC) crystal structure; Cu, Mn, Ni, C, etc. are austenite stabilizers.

If ferrite stabilizing elements are added to steel, there will be rise in A_1 and A_3 temperatures, which restrict the austenite phase field; on the other hand the addition of γ stabilizing elements will depress A_3 and A_1 lines in the equilibrium diagram. The effect of commonly used alloying elements on A_1 temperature and eutectoid carbon content is shown in Figure 5.

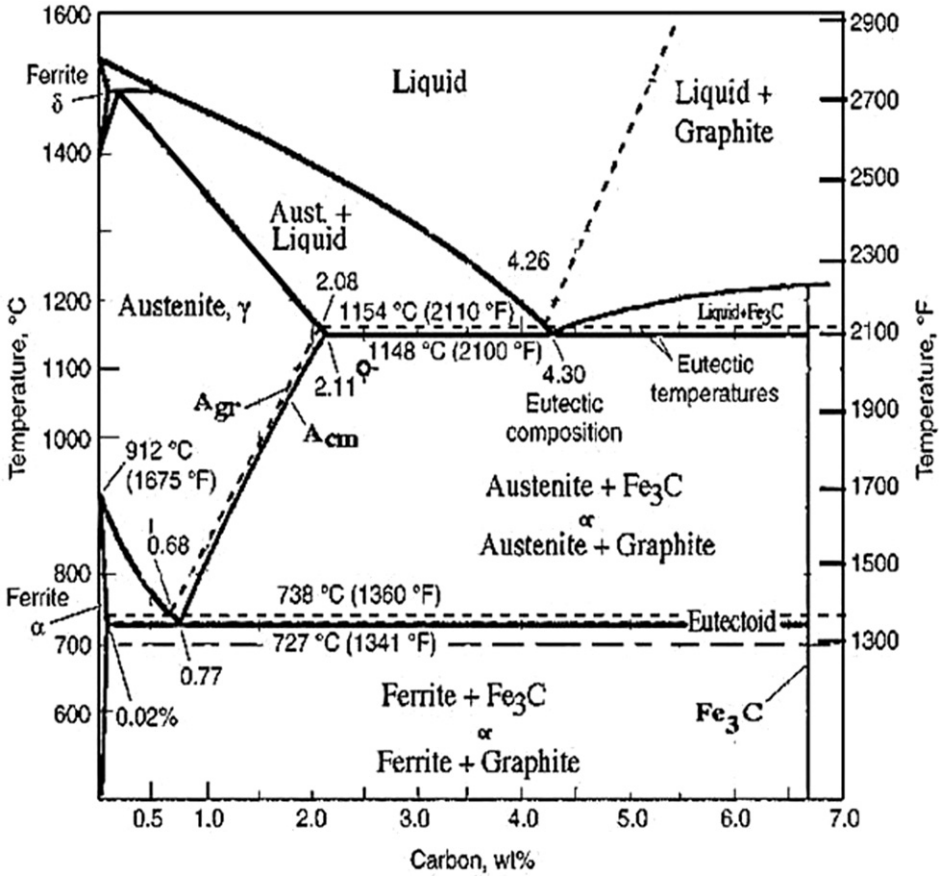

Figure 4 Combined iron–graphite and Fe–Fe_3C phase diagram showing steel panel up to 2.11 wt.% carbon.

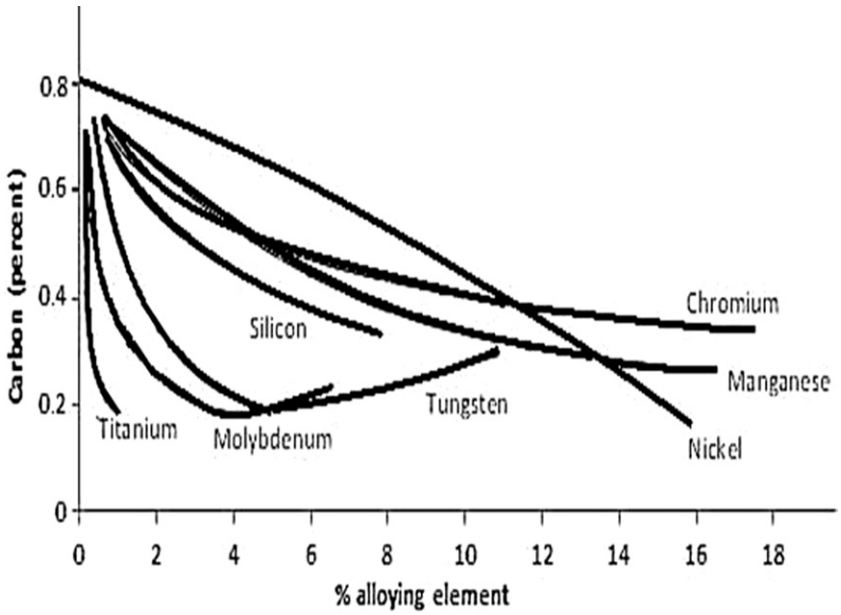

Figure 5 Effect of alloying element on the carbon content of the eutectoid composition.

As stated earlier the prediction of equilibrium phase diagram is of limited use in practical heat treatment processes except for annealing, which attempts to achieve equilibrium microconstituents. The heat treatment practices in general take resort to finite cooling rate causing deviation from equilibrium. As discussed previously that up to a certain degree of

rapid cooling, it is possible to effect diffusional transformation and thus realizing the microconstituents qualitatively similar to what are presented in the corresponding equilibrium diagram. To understand this situation it is important to review the isothermal transformation behavior of steel at temperature below the equilibrium isotherm. This isothermal transformation behavior is described by time–temperature–transformation (TTT) diagram as shown in **Figure 6**.

It is clear from the diagram that for transformation of steel at any temperature less than the equilibrium one needs some time to start the diffusional transformation and this gets completed after some more time as seen in the TTT diagram. The nature of TTT diagram is generic and is applicable for any diffusional transformation. As can be seen from the diagram, it is a C-shaped curve. As the transformation temperature is lower:

- the driving energy for phase transformation, i.e., diffusional decomposition of austenite to ferrite and carbide (pearlite) increases;
- the diffusional transformation of γ is due to nucleation and growth mechanism (readers may consult any text book of physical metallurgy of steel for details of diffusional decomposition of austenite); and
- the increase in driving force for phase transformation tends to lower the critical nucleus size and energy of nucleation.

Thus a higher number of nuclei are formed at lower transformation temperature. This phenomenon accelerates the overall transformation kinetics so long as the growth rate due to lowering of transformation temperature is not reduced to any objectionable value. It is for this reason, the time required to start the transformation called 'incubation period' decreases with decreasing transformation temperature, i.e., with increasing degree of undercooling. The reduction in incubation time continues till a particular temperature is reached. Below this critical temperature, the time required to start the diffusional transformation is seen to increase. This retardation of transformation kinetics below a critical transformation temperature describes the overriding influence of the diminution of rate of growth of the product phase. The growth of a nucleus is accomplished by continuous attachment of the atoms through long-range migration. The mobility or the diffusivity of atoms are strongly dependent on the temperature. Below a certain critical value of temperature, the diffusivity of atoms becomes so low as to stop the growth of nuclei; as a result there is a net increase in the time to start transformation, thereby making the TTT diagram C-shaped.

This is supported by the curve in **Figure 7**, which shows the variation of rate of nucleation and rate of growth with temperature.

The point, at which incubation period is minimum, is known as the nose of TTT diagram. Incidentally, the portion of the curve below the nose of TTT diagram of 0.8 wt.%C steel does not represent same type of transformation as it is above the nose of the curve. It is evident from the equilibrium diagram shown in **Figure 4** that austenite of 0.8 wt.%C completely transforms to pearlite below the eutectoid isotherm. Taking this steel as a reference, the transformation of γ till the nose of TTT diagram represent the transformation of austenite to pearlite and below the nose of plain 0.8 wt.%C steel, austenite decomposes to the aggregate of ferrite and carbide through a different mode of phase transformation known as 'bainitic transformation' (please refer to book *Physical Metallurgy Principles* authored by Robert E. Reed-Hill or any other text book).[1] The TTT diagram of a plain carbon 0.8 wt.%C steel is continuous, and so it is difficult to distinguish the exact point of transition from a pearlitic reaction to a mechanistically different bainitic reaction. It is quite certain that above the nose of TTT diagram, at about 550 °C, only pearlitic reaction takes place; it is also clear that transformation at any temperature below 450 °C austenite undergoes bainitic transformation. It is presumed that from around 550 °C till 450 °C both pearlite and bainite reaction may take place. Isothermal transformation of

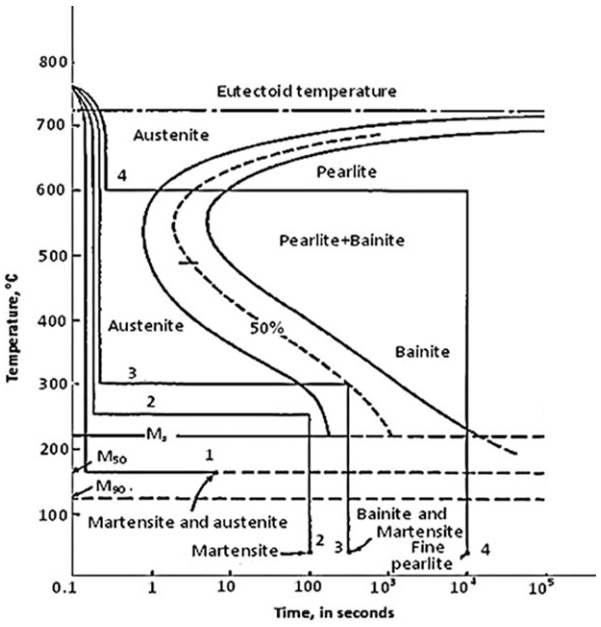

Figure 6 Hypothetical cooling path on isothermal transformation of eutectoid steel.

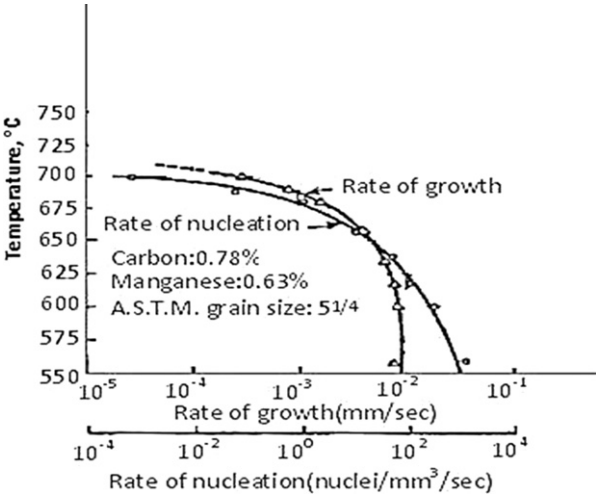

Figure 7 Variation of nucleation and growth rate for eutectoid steel with temperature. Mehl, R. F.; Dube, A. *Phase Transformation in Solids*; John Wiley and Sons, Inc.: New York, NY, 1951; p. 545. © 1951.

austenite indicates several important aspects of phase transformation in steel. It describes the transformation of austenite to pearlite above the nose of TTT diagram; it also helps to understand the bainitic reaction in plain C-steel below the nose of TTT diagram. It is obvious that continuous cooling cannot give rise to the formation of bainite in plain C-steel. If cooling rate is such high, as to bypass the nose of TTT diagram, neither pearlite nor bainite can form; instead, metastable austenite transforms by diffusionless shear mechanism to form a supersaturated solid solution of BCT structure called 'martensite.' In this context it is important to note that equilibrium diagram is of limited use in actual heat treatment operation, as it cannot provide any information about the product of transformation when in industrial heat treatment the cooling rate deviates from equilibrium.

In case of annealing a steel, care is taken to effect the decomposition of austenite at a low supercooling such that the transformation takes place in near-equilibrium condition. Since austenite decomposition envisages diffusion of participating atom species, the alloy steel with higher stability of austenite is required to be annealed at a considerably slower cooling rate, 10 °C h^{-1}. The cooling rate can be effectively controlled at a low value by providing suitable means of power input marginally less than what is required during the soaking period to maintain the constancy of temperature. Incidentally annealing of chromium bearing steels encounters the probability of embrittlement at a temperature around 550 °C. Therefore after transformation of austenite to ferrite and carbide as near to equilibrium temperature as possible, the steel is cooled rapidly to avoid the precipitation of chromium carbide. Whenever stress relieving during annealing is an important issue as is the case of intricate shaped casting, the slow cooling should continue till room temperature.

2.1.2.1 Production of Homogeneous Austenite

As a first step of heat treatment the workpiece is required to be heated to a temperature high enough to produce a homogenous single phase alloy. However there are exceptions like hypereutectoid steel where heating is carried out quite often to a temperature having a two-phase microstructure. In all cases, the final temperature is selected on the basis of information provided by the equilibrium diagram of the concerned system. In many cases (as in steels), achieving a single phase at high temperatures involves both polymorphic transformation and dissolution of the second phase constituent. In such cases, the first formed single phase alloy is compositionally inhomogeneous requiring a special attention to make the system homogeneous. In some other cases the initial microstructure may be of multiphase structure, needing dissolution of solute reach second phase without any phase transformation undergoing in between. In those cases heating temperature is to be decided by the equilibrium diagram which shows the temperature at which a single phase solid solution may be obtained. Only in case of subcritical heating, the kinetic aspect of the target activity is to be paid attention to. For an example, when second stage graphitization is envisaged, that is, when the pearlitic cementite is required to decompose into graphite, temperature of heating is decided by the kinetics of the process.

The fixing of ideal soaking temperature is a critical job. The soaking temperature is always fixed above the critical temperature describing the formation of single phase. For an example, temperature above Ac_3 line in iron cementite diagram. Increasing the soaking temperature has the advantage of making the system homogenous at an earlier time and thereby saving time and energy in the process. But unlimited enhancement of the soaking temperature to take advantage of achievable higher productivity is constrained by the chance of grain coarsening. Many systems require a dissolution of solute rich second phase and subsequent homogenization of these high temperature phases. This is essentially a thermally activated process and is time dependent. Higher is the temperature, shorter is the time requirement to achieve identical result. However large reduction in soaking time is restricted due to the fact that soaking temperature is limited by its greater vulnerability to chemical degradation and higher chance of grain coarsening. Hence optimization of heating temperature is very important. Normally the temperature of soaking is kept 50–75 °C higher than the equilibrium temperature.

2.1.2.2 Effect of Excess Heating Beyond Homogenization

Grain coarsening takes place if heating temperature is made excessively high. Coarsening of grains also results if holding time is unnecessarily prolonged even when homogeneous austenite has been formed. The initial grain size of austenite depends upon the number of nuclei formed due to superheating.

The grain coarsening is a thermally activated process and requires movement of grain boundaries. So long as there are constraints for grain boundary movement in presence of precipitates or compositional heterogeneity, the grain boundary movement is restricted; under such circumstances, once homogenized such barriers are no longer existent.

Any further holding at high temperature will cause, grain coarsening to set in, because coarse grains are thermodynamically stable. Grain coarsening leads to reduction in grain boundary area and thus the surface free energy and hence the total energy of system decreases. It may be noted that there are grains which are inherently fine and can remain so, even if heated to as high as 1000 °C or more. Rapid grain growth in these steels can take place only upon heating to 1050 °C or beyond. In contrast inherently coarse-grained steels exhibit rapid grain growth much earlier. The different tendency for grain growth is ascribed to the internal deoxidation practice. The air melted aluminum-killed steels are known to produce aluminum nitrides which are uniformly distributed within the matrix. These fine precipitates of aluminum nitride inhibit grain coarsening. Likewise many alloying elements, viz. titanium, vanadium, niobium, or other strong carbide formers, retard grain growth till they are not completely dissolved during austenitization. However inherently fine-grained steels do not mean that their grain sizes will always be less than those of the inherently coarse-grained steels; as shown in **Figure 8**, the initial rate of grain growth in inherently fine-grained steel is much slow as compared to that of the inherently coarse-grained steels which start growing appreciably quite early in the heating stage with a nearly constant rate of grain growth.

The inherently fine-grained steels experience an initial slow grain growth, which becomes much rapid at higher temperature and the ultimate grain size can be higher than its inherently coarse-grained counterpart. Quite often alloy steels containing strong carbide forming tendency are required to be austenitized at much higher temperature due the fact the alloy carbides do not go in solution so easily and take longer time or higher temperature to completely dissolve. As a result, they behave as inherently fine-grained steels because grain coarsening can take place only after complete dissolution of all the carbide particles which finally remove the barriers to grain boundaries movement. It is pertinent to remember the importance of achieving small grain size after heat treatment. Hall–Petch relation is given by

$$\sigma_y = \sigma_o + \frac{k_y}{\sqrt{d}}$$

where,

σ_y = yield stress,
σ_o = material constant for starting stress for dislocation movement,
k_y = strengthening coefficient, and
d = average grain diameter.

In accordance with above, yield strength of a single phase alloy is enhanced by its decreasing grain size. In general, structural fineness of a material gives rise to higher strength and toughness of the same; therefore wherever structural fineness is described by grain size, the prediction of Hall–Petch relationship holds good. In order to gain more insight into it, the readers may consult the text book *Mechanical Metallurgy* authored by Dieter.[2]

2.1.2.3 Common Heat Treating Processes

The heat treating practices most commonly employed for commercially important metals and alloys are cited below:

Age hardening is the process where a supersaturated solid solution is formed by heating the material in single phase region and holding there for sufficient time to make up a homogeneous solid solution. Following this, the alloy is rapidly cooled to produce the supersaturated solution. This supersaturated solid solution is heated in a controlled manner; super saturation of solid solution is relieved by precipitation of solute reach phase. If α is the solid solution of B in A and β is a B-rich phase age-hardening process is described by:

$$\alpha_{\text{saturated at high temperature}} \xrightarrow[\text{quench}]{} \alpha_{\text{supersaturated}} \xrightarrow[\text{aging (controlled heating)}]{} \alpha_{\text{saturated at room temperature}} + \beta$$

Annealing is generally a softening process in which the metals are heated to form the equilibrium high temperature phase and then allowed to cool very slowly. The purpose of annealing is to obtain the equilibrium microstructure; it aims to improve machinability, formability, and sometimes magnetic properties.

Normalizing is a process of natural cooling in still air from a preselected high temperature where the required single phase is formed. This results in increase in strength with a little reduction in ductility. Its purpose is to refine grain structure, to improve mechanical properties, and to relieve internal and surface stresses.

Stress relieving is a process of heating to a relatively low temperature to reduce the level of residual stresses in a material.

Quenching is a process of rapid cooling of a material from its homogeneous state at high temperature. The different media may be used to quench the material; it may vary from forced air, oil, water with or without addition of salt, and polymers. Steel is hardened by heating to austenitic phase and then quenching it to room temperature; this results in the formation of martensite which is a very hard and brittle constituent in iron–carbon system.

Tempering involves gentle heating of hardened steel and allowing it to cool slowly so that brittleness of the hardened material is reduced. Tempering of steel refers to softening by decomposition of iron–carbon martensite which is very hard and brittle. Tempering of martensites in steel leads to relieve of its supersaturation through various structural changes as described in later section. Also for nonferrous alloys, tempering brings about precipitation of different phases intragranularly at the internal faults within martensites and also in intercrystalline manner at the lath/plate boundaries of martensite crystals.

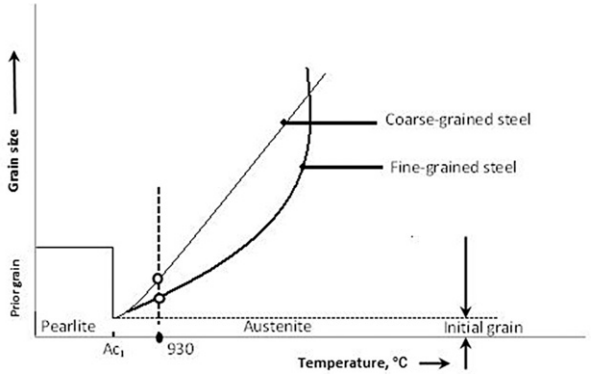

Figure 8 Austenitic grain growth in inherently fine- and coarse-grained steels.

2.1.3 Heat Treatment Process Variables

On the basis of previous discussion it is evident that the major process parameters influencing the quality of heat treatments are holding temperature, holding time, and rate of heating and cooling. The required magnitudes of these variables are decided by the chemical composition, size, and shape of the object along with the desired properties in the metals/alloys. If the chemical composition of the alloy to be heat treated is such that the material is highly prone to oxidation or is inherently coarse-grained material having a high tendency toward grain growth, the heat treatment of the same may result in poor mechanical properties unless special precautions are taken.

In order to minimize the problem of oxidation or grain growth, two salt bath heat treatment furnaces are sometimes employed. In one furnace, the object is heated to a temperature up to which there is no appreciable oxidation or grain growth. The object is then transferred to the second furnace, heated rapidly for a short time, and maintained at heat treatment temperature for minimum period. This practice reduces the total time of holding at the higher heat treatment temperature and thus the above mentioned problems are reduced. The temperature–time relationship for such a heating cycle is shown in Figure 2.

In addition to the mode of heating up to heat treatment temperature, the rate of heating is also of significance. The heating rate depends on the size and shape of the object and the thermal conductivity of the alloy. Almost all metallic alloys have good thermal conductivity and thus, in general, these parameters play only a marginal role. However, in the case of alloys like stainless steels, thermal conductivity is an important factor to consider while deciding the employable rate of heating. Secondly, low heating rates ensure better homogeneity of the structure and reduce the holding time at the heat treatment temperature. Complicated shapes, sharp cornered objects, and objects with variable sections are also heated slowly. Some alloys, such as high carbon steels and austenitic stainless steels, are subjected to slow heating rates. Smaller and simple shaped objects can be heated with higher heating rates and homogeneity of the structure can be ensured in such cases by increasing the holding time. Also, for the alloys that are prone to oxidation at high temperatures of heat treatment, faster rates of heating are recommended at high temperature range. Heat treatment temperature is governed mainly by chemical composition of the alloy, prior heat treatment, if any, and the final properties required. Heat treatment of steel is accomplished by heating it above upper critical temperature (Ac_3). This is known as austenitizing temperature, and can be determined from the iron–carbon equilibrium diagram. For plain carbon steel, Ac_3 temperature decreases with increasing carbon content. During heating, actual austenitizing temperature is raised above the equilibrium temperature. Similarly upon cooling the transformation temperature is depressed. Hence, during heat treatment practice, temperatures in excess of equilibrium temperature are employed. The austenite produced at these temperatures is homogeneous. In case of alloy steel, some alloying elements or their compounds do not dissolve easily in austenite and so they need to be austenitized for longer time at higher temperature. Unlike cementite which dissolves readily in austenite, the dissolution of alloy carbides is rather slow. For an object having variable section size, the soaking time is determined on the basis of largest section size. Lowering of heat treatment temperature has the implication of higher holding time. Generally soaking time of alloy steels is kept higher than plain carbon steels of low carbon content and the thinly enriched alloys. Heavy sections, complicated shapes, objects with variable section thickness, and highly enriched alloys should be cooled slowly. Extremely slow cooling results in the development of a structure as evident from the equilibrium diagram. The size, shape, distribution, and relative proportions of microconstituents can be controlled over a wide range by way of varying the cooling rates. Up to a certain limits, higher cooling rate results in a structure which is qualitatively similar to that in the equilibrium diagram. By increasing the cooling rate beyond this limit, structures produced will consist of either nonequilibrium transformation products or the high temperature phases retained by sudden quenching.

2.1.3.1 Austenitization

Austenitization is the first step of heat treatment of steel. Avoidance of microstructural gradient in the heat-treated part is very much necessary; else the final property will be different in different portion of the heat-treated part. The same strategy as discussed in the preceding section is applied during austenitization process. Formation of austenite from the initial microstructure of ferrite and cementite is a nucleation and growth process. It may be recalled that the austenitization process involves a polymorphic transition of BCC-ferrite to FCC-austenite and subsequent dissolution of cementite in austenite. The initial composition of austenite is the weighted average of those of ferrite and austenite in the intercritical region and the entire austenitization process is controlled by diffusion. The first nucleus of austenite will form above A_1 temperature at the high energy interphase boundaries (like ferrite–ferrite and ferrite–cementite) as available within the initial structural configuration. If the initial microstructure is lamellar pearlitic, the formation of austenite is quite rapid. Its nucleation will start at the ferrite–cementite boundaries as shown in the Figure 9.

On the contrary if initial microstructure contains globular cementite embedded in the ferritic matrix, nucleation of austenite will generally takes place in ferrite–ferrite boundaries, although cementite–ferrite interfaces are not excluded from being the potential nucleation sites. Evidently such situations of dispersed cementite within the ferrite matrix will take a longer time for the formation of homogenous austenite.

Figure 9 demonstrates the stages of formation of austenite from pearlite upon isothermal holding at a particular temperature. The time–temperature plot for such process is shown in Figure 10.

It is evident from the above isothermal transformation diagram that initiation of austenite formation from pearlite takes a definite incubation time which is a function of temperature. Upon formation of initial nuclei of austenite on ferrite boundary, the nuclei of austenite will gradually grow; concurrently cementite will dissolve in newly formed austenite as a demand of equilibrium. However equilibrium is not attained and dissolution of cementite lags behind the formation of austenite by polymorphic change of ferrite. A stage may be visualized when partially transformed austenite coexist

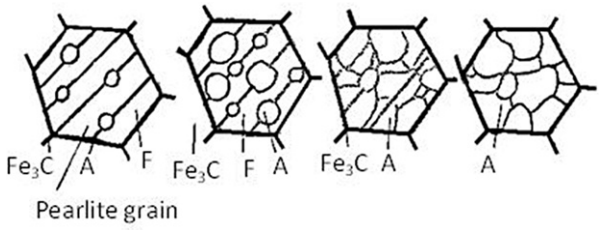

Figure 9 Stages in austenitization.

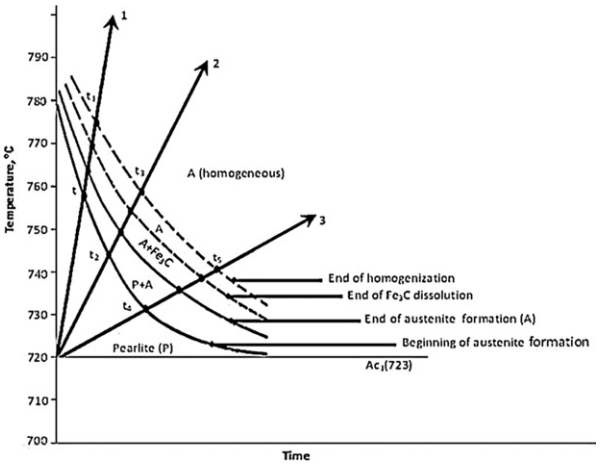

Figure 10 Time–temperature relationship in forming homogeneous austenite.

with pearlite. Upon further holding at the transformation temperature the entire pearlitic ferrite is converted to austenite with some cementite still remaining to dissolve in austenite. This cementite dissolution is a diffusional process and it takes some time to produce 100% austenite in the microstructure. However even after completion of austenite formation it does not immediately become homogenous. This is because the regions where the dissolution of cementite took place last will be of higher carbon concentration than elsewhere. Further holding for some more time will produce homogenous austenite, ready for subsequent heat treatment steps.

This process of achieving a homogenous single phase alloy is generic in the sense that for any initial multiphase microstructure, the sequence described above is followed by other systems, as for example, solutionizing of age hardenable alloy at elevated temperature.

2.1.4 Introduction of Alloying

Plain carbon steels are of limited use because of its deficiencies on many counts. They are unsuitable for applications where considerably higher strength and toughness properties are required. These steels are incapable to withstand highly corrosive environment, neither they are useful for high temperature or cryogenic applications. Plain carbon steels can be hardened only to a limited section and exhibit a marked tendency for softening at higher temperature. The above limitations of plain carbon steel are overcome by alloying steels with other elements. By definition, the elements that are deliberately added to achieve desirable properties in a metallic system are called alloying elements, whereas those elements that are inevitably present in steel without any deliberate intention to serve additional purposes are known as impurities. For example, the steel making operation cannot fully remove sulfur and therefore some amount of sulfur is always present in steel. Sulfur in such situation is called an impurity. Again the same sulfur when present in appreciable amount has the capacity to make chips brittle during machining. A particular variety of steel, known as free-cutting steel contains deliberately added sulfur. In this case sulfur, is an alloying element, even though in majority of cases sulfur is considered an unwanted element in steel due to its adverse effect on the properties of steel, for example, inducing hot-shortness to steel. Steels containing alloying element are called alloy steels. So long as the total alloying element content is less than 5 wt.%, the steels are considered as low alloy steels whereas the steels with alloying elements in excess of 5 wt.% is called high alloy steels.

2.1.4.1 Classification of Alloying Elements

The alloying elements in steel are classified in to two broad types. Some alloying elements stabilize the higher temperature phase austenite, which is of FCC crystal structure. The crystal structure of these austenite stabilizing elements is FCC. The other class of alloying elements is those which stabilize ferrite phase. These ferrite stabilizing elements are in general of BCC crystal structure. The majority of ferrite stabilizers are seen to be strong carbide formers. However at room temperature any alloying element in steel has to be present either in solution in ferrite or in carbide. The austenite formers do not in general form carbides. It is to be recalled that any element added to steel is partitioned between the two phases, carbide and ferrite. The austenite formers which partition to ferrite are not generally found in carbide. The austenite stabilizing elements are appreciably soluble in austenite by being of FCC crystal structure; these elements delay austenite to ferrite transformation, i.e., the basic lattice transformation in Fe–C system. However when austenite to ferrite transformation takes place, an austenite stabilizer can have altogether two options: either it goes in solution within ferrite or it gets precipitated in elemental form. Whether the austenite stabilizing alloying element will remain in solution within ferrite will depend upon how the concerned solute obeys the other rules of alloying. In the case of nickel, it is observed that nickel partitions to ferrite. The atomic radius of iron and nickel are very near to each other, as a result nickel goes in solution in ferrite at ease. On the contrary, one would find that copper with FCC structure is not soluble in ferrite. Moreover it is not carbide former; hence it is left with the lone option of being precipitated in element form. The precipitates of copper lead to hardening of steel.

Majority of austenite formers being non carbide formers are either present in ferrite or get precipitated depending upon the solubility of the concerned element in BCC ferrite. Manganese is the exceptional austenite stabilizer, which forms isomorphous carbide with cementite. Thus manganese gets partitioned between ferried and carbide, forming $(Fe,Mn)_3C$ type of carbide.

On the contrary, the ferrite stabilizers like Cr, Mo, Nb, etc. are generally carbide formers. In steel containing more than one carbide formers, the formation of carbides and partitioning between ferrite and carbide depend upon their relative affinities for carbon and solubility in ferrite.

The alloying elements have significant influence on the phase transformation behavior of steels. All the alloying elements influence the decomposition behavior of austenite and in the process, the alloying elements exert their characteristics effects on the equilibrium phase diagram, TTT or continuous cooling transformation (CCT) diagrams.

Some of the important purposes of alloying are:

1. To enhance strength and toughness at room temperature.
2. To improve strength, ductility, and impact properties at high as well as very low temperature.
3. To improve resistance to degradation under aggressive service condition.
4. To develop wear resistant steel for employment at ambient and elevated temperatures.
5. To develop magnetic properties with minimum hysteresis loss.
6. To improve the strength of steel without aid of quenching.

However, alloying elements cannot change the structure insensitive properties like stiffness of the steel. The stiffness is dependent on the elastic modulus, which is the slope of true stress–true strain (σ–ε) curve within elastic limit. Although alloying elements can improve elastic limit, it cannot appreciably change the modulus of elasticity which is a structure insensitive properties.

2.1.4.2 Effect of Alloying Elements

Alloying elements bring about changes in the Fe–Fe_3C equilibrium diagram. It is to be understood that by the addition of alloying elements, it is possible to alter the composition and properties of phases, without giving rise to the formation of entirely new phases in general. Since alloying elements are responsible for change in transformation temperature and the rate of decomposition of austenite, the properties of plain C-steel can be modified by alloying.

Addition of alloying elements changes the free energy of participating phases in phase transformation, either diffusional or diffusionless. Therefore the transformation temperature of austenite is changed by the addition of alloying elements.

The diffusional decomposition of alloyed austenite necessitates adequate movement of the atoms of alloying elements. Since such movement is generally sluggish the alloying element influences the kinetics of diffusional decomposition.

Solubility of C in austenite as well as in ferrite is modified by the addition of alloying elements. This is because the alloying elements dissolved in austenite or ferrite tend to induce lattice strain due to difference in size of solvent and solute; this directly influences the solubility of C in austenite as well as in ferrite.

The diffusionless shear transformation proceeds through stacking shifts of atoms on the habit planes. The presence of alloying elements changes the strain field distribution on the habit plane and thus influences the stacking shifts required for martensitic transformation. This leads to the stabilization of either the parent or the product phase and is characterized by depression or elevation of the characteristic transformation temperature. The general microstructure of steel at room temperature is comprised of ferrite and carbides. Alloying elements like Ni, Si, Al, Zr, P, S, and Cu dissolve at ease in austenite and also in ferrite at different degrees. Some of these elements like Si, Al, and Zr may form oxides and be present in steel in the form of nonmetallic inclusions. Similarly Mn and Zr may form sulfide inclusions. These elements however do not have appreciable tendency toward formation of carbides. The other elements like Cr, W, V, Mo, Ti, Nb, and Mn have tendencies for forming carbides. In the absence of carbon to react with, these elements should be in a ferrite solution. The increasing order of carbide forming tendency is Mn, Cr, W, Mo, V, and Ti. The alloying elements dissolved in ferrite increase the hardness due to solid solution effect and it is schematically shown in **Figure 11**.

As stated earlier, addition of alloying elements not only modifies the transformation temperature of austenite to ferrite, but also the eutectoid point. Thus both A_1 and A_3 temperatures are altered due to the addition of alloying elements. **Figure 12** shows the effect of alloying addition on the eutectoid transformation temperature. From the diagram, it can be seen that those alloying elements that are known to stabilize austenite would lower the A_1 temperature. Whenever ferrite stabilizers are added by a large amount, the austenite loop gradually becomes narrower due to the increase in upper critical temperature; beyond some specific concentration of ferrite stabilizers like Cr, the austenite may not form at all and the steel remains ferritic at both elevated and room temperature.

All the alloying elements except cobalt shift the TTT- and CCT-diagrams toward right. Austenite forming elements stabilize the metastable austenite and delay its diffusional decomposition. Therefore it is easy to understand that all

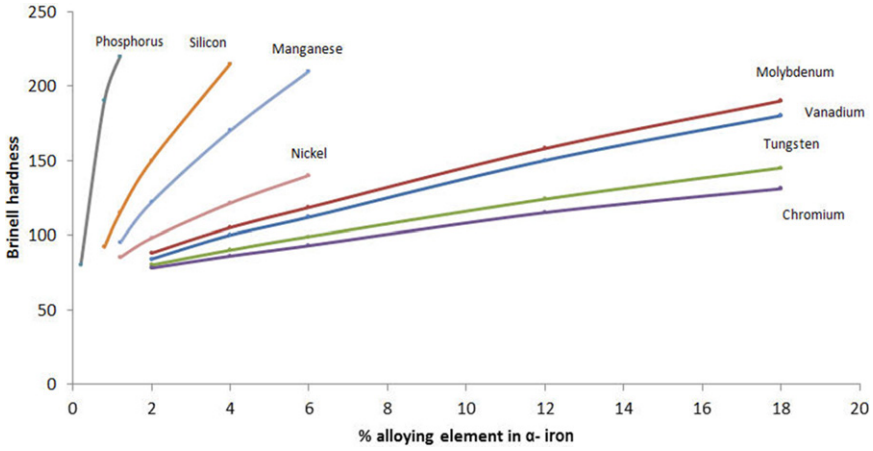

Figure 11 Effects of various alloying elements on hardness of steel.

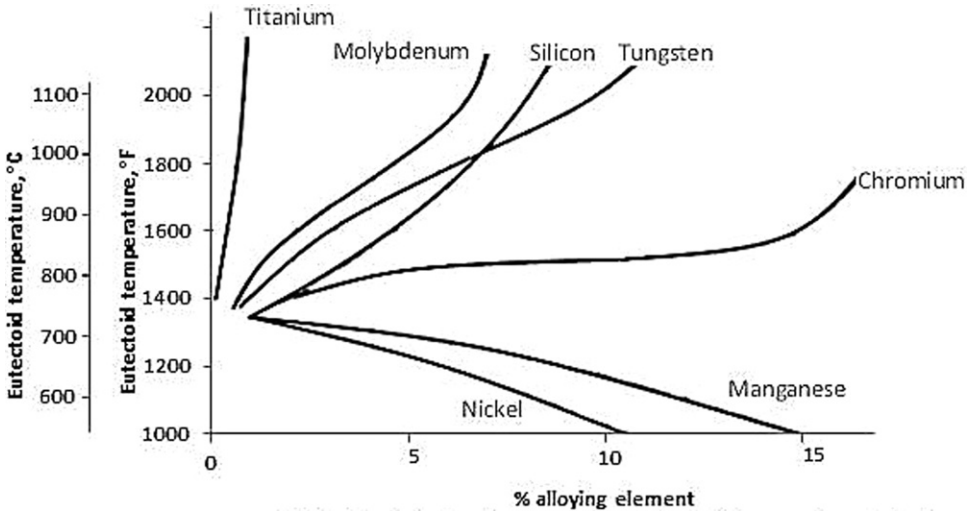

Figure 12 Effect of alloying element on eutectoid temperature of steel.

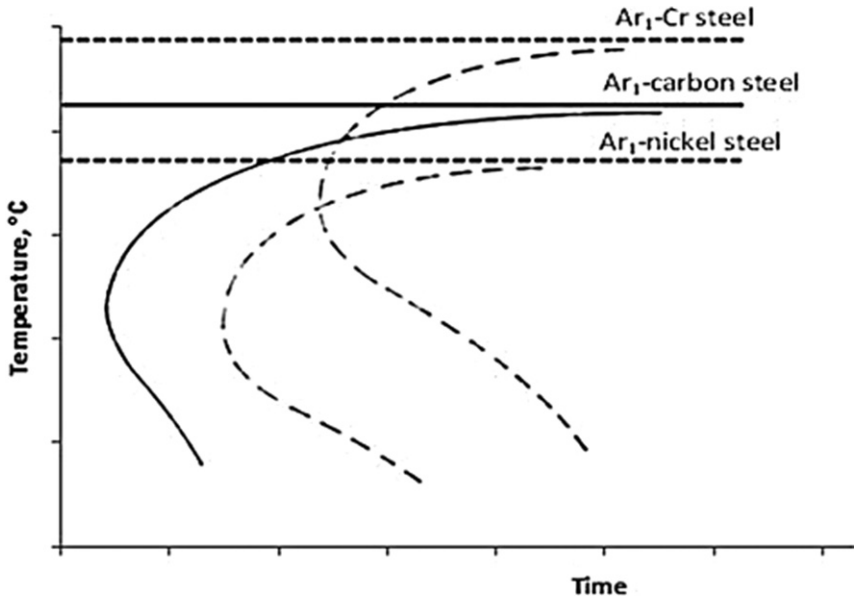

Figure 13 Diagram showing shift of TTT diagram due to alloying with nickel and chromium.

austenite stabilizers should cause a rightward shift of TTT- or CCT-diagrams. The ferrite stabilizers are in general carbide formers. It is known that nucleation of pearlite from austenite is initialized by the formation of Fe_3C. In the presence of strong carbide formers, the formation of Fe_3C at prior grain boundaries becomes more difficult. Strong carbide formers prefer to neighbor the C-atoms in austenite; the formation of cementite requires free C-atoms to react with iron. However getting away from the attraction of the neighboring atoms of carbide formers is a thermally activated process and hence time dependent. Thus more time is required for the carbon atoms to make them available for iron atoms to form cementite. This implies a shift of CCT- or TTT-diagrams toward right. The shift of TTT and CCT due to Ni and Cr is shown in Figure 13.

It is clear that diffusional decomposition of austenite is delayed due to the addition of alloying elements. The alloying elements influence the kinetics of both pearlitic and bainitic transformation. Any specific alloying element is liable to shift pearlitic reaction and bainitic reaction to larger times but by different magnitudes. A carbide forming element is expected to shift the pearlitic reaction to a larger extent than the bainitic reaction due to difference in the mechanism of these two transformations.

As seen from Figure 13 both nickel and chromium shift the TTT diagram toward right, but to different extent. If equal amount of chromium and nickel are added, it is expected that the shift of TTT diagram will be more toward right; the magnitude of shift may appear to be additive. However the actual shift of TTT diagram is more than the summed up shifts due to addition of either elements. This effect is called 'Synergism.' Chromium and nickel are known to shift TTT and CCT diagram synergistically toward right. Several such synergisms are

observed in Fe–C system and examples may be cited of molybdenum–boron and copper–boron, which depress the austenite to ferrite transformation temperature synergestically. However effect of each element on pearlitic and bainitic reaction is different and so the pearlitic and bainitic bays get retarded differently due to addition of alloying elements.

2.1.4.2.1 Effect of individual alloying elements in summarized form

- Manganese (Mn): manganese has got very high solubility in austenite because of its FCC structure, but its solubility in BCC-iron is less than 3%. Manganese is a medium carbide former, forming isomorphous $(Fe, Mn)_3C$ carbides. Manganese is a very good hardenability raiser, and is of highest multiplying factor in determining the hardenability of steels. It reduces hot-shortness by binding sulfur as MnS. Manganese is an austenite stabilizer.
- Molybdenum (Mo): it is a ferrite stabilizer, and is extremely soluble in BCC-iron, having solubility greater than 35% whereas it is soluble only up to 3 wt.% in FCC-iron. The solubility of Mo in FCC-iron is increased if carbon is added to the system. It forms intermetallic compound with iron and therefore causes precipitation hardening in Mo–Fe system. It is a strong hardenability raiser, stronger than most of other alloying elements. It gives rise to appreciable secondary hardening. As the dissolution of molybdenum carbide in austenite is a slow process, the grain coarsening temperature of austenite is significantly increased by molybdenum. It increases the high temperature strength and red hardness of steel. Molybdenum imparts resistance to pitting corrosion in stainless steels; further molybdenum increases abrasion resistance by forming hard molybdenum carbide particles in ferrite matrix. Molybdenum reduces temper embrittlement in a chromium bearing steel. It is not capable to inhibit the formation of chromium carbides, but slows down the kinetics of precipitation of chromium carbide, thereby putting a constraint to embrittlement.
- Nickel (Ni): nickel with FCC structure is an austenite stabilizer, with unlimited solubility in FCC-iron. Its solubility in BCC-iron is limited to 10 wt.%, irrespective of whether there is any carbon or not. Nickel strengthens and toughens iron by solid solution hardening. It is a moderate hardenability raiser but in combination with Cr and Mo, it increases hardenability significantly. Nickel is not carbide former but is a weak graphitizer. Nickel does not increase tempering resistance of steel to any appreciable extent. Nickel promotes grain coarsening at elevated temperature.
- Cobalt (Co): cobalt is soluble in FCC-iron, with unlimited solubility. It is extensively soluble in BCC-iron with the limit of solubility being 75 wt.%. It improves hardness of iron by solid solution hardening and is a significant contributor to raise hardness by way of hardening ferrite. Its carbide forming tendency is similar to that of iron and is the only alloying element which decreases the hardenability when dissolved in iron.
- Chromium (Cr): chromium is a ferrite stabilizer and has got unlimited solid solubility in BCC-iron. Limit of its solubility in FCC-iron is about 13 wt.%; however, this may be extended up to 20 wt.% with addition of carbon up to 0.5%. It is a strong carbide former; its carbide forming tendency is greater than Mn but less than W. Chromium increases the resistance to oxidation by forming a very thin layer of chromium oxide. Chromium is a moderate hardenability raiser; however, Cr and Ni increase the hardenability of steel synergistically. It imparts very good abrasion and wear resistance by forming chromium carbide in the microstructure.
- Silicon (Si): silicon is least soluble in FCC-iron, with solubility up to 2 wt.%. Silicon increases the activity of C in ferrite. Its solubility in BCC-iron is about 18 wt.%. Silicon hardens steels with loss in plasticity. Silicon is a very strong oxidizing element. Silicon segregates at basal plane of graphite crystal to prohibit inherent growth form of graphite. Thus silicon leads to the formation of graphite flakes. It increases the hardenability but quite moderately. Silicon influences tempering in low carbon steels through solid solution hardening. Silicon is generally used as a deoxidizer; however silicon as an alloying element up to 4 wt.% is capable of grain orientation. This makes the steel useful for transformers. Silicon improves the oxidation resistance of steel.
- Titanium (Ti): titanium is mildly soluble in austenite, with solubility less than 1%. However its solubility in BCC-iron is higher and around 6 wt.%. It is a hardenability raiser but it is generally added to steel in very low concentration for the formation of titanium carbide which enhances the material properties during thermo-mechanical treatment. It prevents formation of austenite containing high amount of chromium. It also inhibits sensitization in austenitic stainless steel by way of forming distributed titanium carbide.
- Vanadium (V): vanadium is very little soluble in FCC-iron, with solubility up to 1 wt.% whereas its solubility in BCC-iron is unlimited. It acts as hardenability raiser. It is strong carbide former but its carbide forming tendency is less than titanium and niobium. Vanadium is excellent in giving rise to secondary hardening. Similar to molybdenum, vanadium enhances the grain coarsening temperature of austenite, because the dissolution of vanadium carbide in austenite takes a longer time.
- Tungsten (W): tungsten is weakly soluble in FCC-iron; however its solubility in BCC-iron is quite high, around 33 wt.%. Tungsten is a strong hardenability raiser, and is also strong carbide former. Tungsten is capable of providing secondary hardening during tempering. Tungsten is able to provide very high wear resistance due to formation of hard particles of carbide in microstructure. It also improves the elevated temperature strength property of steel.
- Phosphorous (P): phosphorus is very weakly soluble in austenite (Avner),[3] whereas it is around 3 wt.% in alpha iron (maximum solubility in α iron at 950 °C). Phosphorus leads to hardening of steel by solid solution strengthening. It is also known to improve hardenability. It improves machinability of free-cutting steels, by way of making the chip brittle. It also improves corrosion resistance.
- Aluminum (Al): aluminum is extremely soluble in BCC-iron up to 36 wt.%, whereas its solubility in FCC-iron is around 1 wt.% (Avner).[3] It strengthens ferrite by solid

solution hardening. However it is a graphitizer. Aluminum is a very good grain refiner by way of dispersing its oxides and nitrides throughout the matrix of ferrite. Aluminum is alloyed in steels to be subjected to nitriding, because strengthening of nitrided steel is realized by the formation of aluminum nitride.

2.1.4.3 Effect of Alloying Elements on TTT and CCT Curves

Shift of pearlite reaction curve and that of bainite reaction curve are different due to addition of a single alloying element. This is because the pearlitic and bainitic reactions are mechanistically different; hence the same alloying element should be responsive to two reactions in different ways. Taking the instance of addition of a strong carbide former like molybdenum, it is recognized that initiation of pearlitic reaction is conditioned by carbon atom being freed from the influence of molybdenum atoms, which have high affinity for carbon atoms. Since this depends upon diffusion of molybdenum atoms and also since such movement is quite sluggish, the reaction is shifted to longer times. The same element will delay upper bainitic reaction in a different way. Upper bainite formation is conditioned by taking away carbon atom from the vicinity of iron atoms, so that the carbon-depleted austenite transforms martensitically to bainitic ferrite. The presence of molybdenum itself aids to this as it removes some carbon atoms from the influence of iron atoms by way of neighboring the carbon atoms it has affinity with.

Thus iron atoms populated regions, relatively free of carbon atoms, are now made available. So martensitic transformation of austenite to upper bainitic ferrite is accentuated. Therefore the addition of such alloying elements brings about differential shifts in pearlitic and bainitic bays, thereby separating the two bays; hence the alloy systems become amenable to bainitic transformation by continuous cooling. This is not possible for a plain carbon steel, where TTT curve is continuous with superimposition of pearlitic and bainitic bay as shown in Figure 14.

However, when the cooling rate is so fast as to bypass the nose of CCT diagram, neither pearlite nor bainite is possible to form; rather a diffusionless martensitic reaction takes place, else the metastable austenite phase remains as it is.

It is to be recalled that austenite undergoes phase transition only when it attains a finite degree of metastability. This means that stable austenite above A_3 or above A_1 for eutectoid steel does not undergo any transformation.

Supercooling of austenite below equilibrium temperature makes it metastable; this then acquires driving energy for transformation to product phase (for elaborate understanding any text book of physical metallurgy may be consulted).

In normal circumstances, finite cooling rate is applied to gain sufficient driving force for transformation to takes place. Thus as previously mentioned, the equilibrium phase diagram is of limited use in practical heat treatment. Equilibrium cooling is not generally practiced; nevertheless knowledge of equilibrium diagram of a system is extremely important to understand its heat treatment behavior. Equilibrium diagram

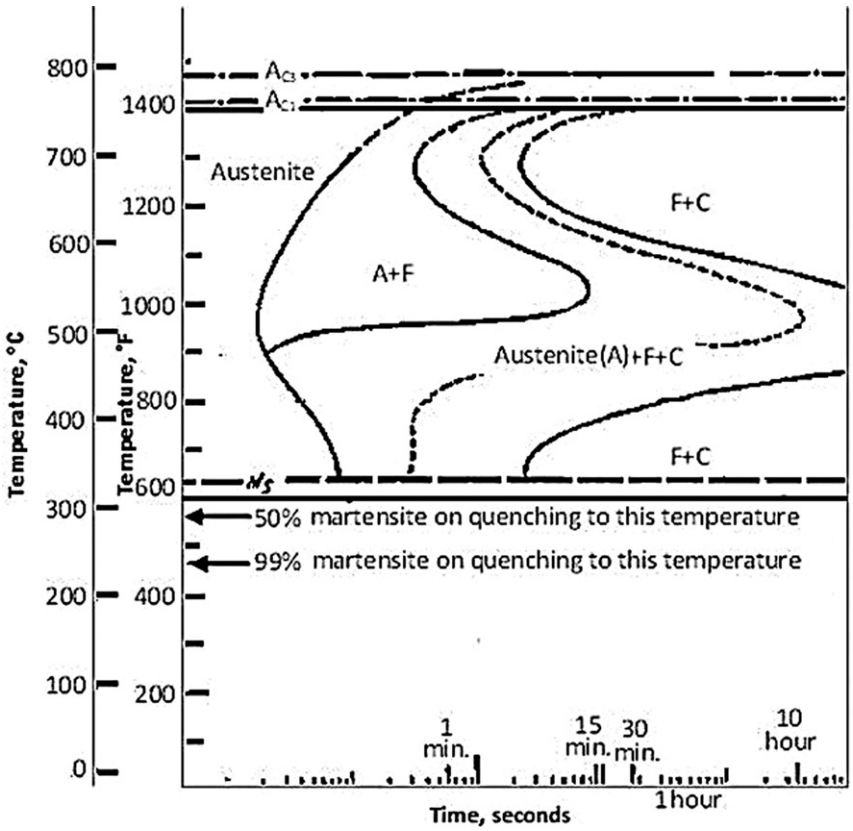

Figure 14 T–T diagram of a 0.33 wt.% carbon, 0.45 wt.% manganese, and 1.97 wt.% chromium steel (Austenitized at 870 °C).

provides information about which phase is stable at what temperature–composition combination.

From the information one can decide the temperature of heating to get a single phase alloy at higher temperature.

Equilibrium diagram denotes the stability of different phases at various temperature–composition combinations. It provides information of possible polymorphic transition, limit of solubility of a solute in a solvent as a function of temperature and also the amount of different phases present in an alloy at any particular temperature. However all these information are true only if equilibrium state exists all through. In practice equilibrium is not maintained in most of the time; at any finite cooling rate there is factually a deviation from equilibrium. A fast cooling puts constraints to attainment of equilibrium in a diffusional transformation which depends upon time. So, transformation must take place at temperature lower than the equilibrium temperature. It is also known that a phase transformation takes place only with a finite undercooling; the number of nuclei available for transformation depends upon the degree of supercooling and hence the temperature at which transformation is given to take place. This information however is not available from equilibrium diagram. Hence it is very important to get the information about the transformation characteristics at temperature lower than the equilibrium one. This necessitates the construction of isothermal transformation diagram; these are essentially temperature–time plot for various amounts of transformation, say transformation start, its finish or any other percentage of transformation. Such diagram for eutectoid steel is shown in **Figure 6**. It is found that pearlite and bainite transformation overlap and from the nose of the TTT curve at about 550 °C upward, pearlitic reaction takes place; below 450 °C, bainitic transformation is certain. From the very nature of TTT diagram it is apparent that if cooling rate is such that the time required to reach the temperature of the nose is less than or equal to its incubation time, diffusional decomposition of austenite is completely suppressed.

The time required to start the transformation at a temperature is the incubation time required by the system to overcome the activation barrier of the concerned diffusional transformation.

The TTT diagram of hypoeutectoid steel shows its similarity with that of eutectoid steel in the sense that:

1. The curves are 'C' shaped characterizing diffusional transformation.
2. Being asymptotic to the critical temperatures at long time, hint that undercooling is must for transformation to take place, else infinite time will be required to effect a transformation which is impossible.

However the dissimilarity between the two is the presence of a line 'ab' lying above and to the left of lines describing the austenite to pearlite transformation. This line 'ab' is asymptotic to A_3 temperature at infinite time and defines the formation of proeutectoid ferrite. From the cooling paths imposed on the TTT diagram of hypoeutectoid steel, it is apparent for path 1 that the proeutectoid ferrite forms between A_3 and A_1 temperature and holding for a long time it simply equilibrates to produce ferrite and unreacted austenite. However for path 2, the proeutectoid ferrite formation is followed by the complete transformation of remaining austenite to pearlite. In contrast cooling path 3 passes through the lines of TTT diagram below its nose and leads to the formation of bainite. Although isothermal transformation behavior is understandable by following the cooling paths drawn in **Figure 15**, these cooling paths are not possible to be realized in practice.

Superimposition of cooling curves on to an isothermal transformation diagram may be made to avoid the imaginary cooling path envisaged in the preceding paragraph. Cooling

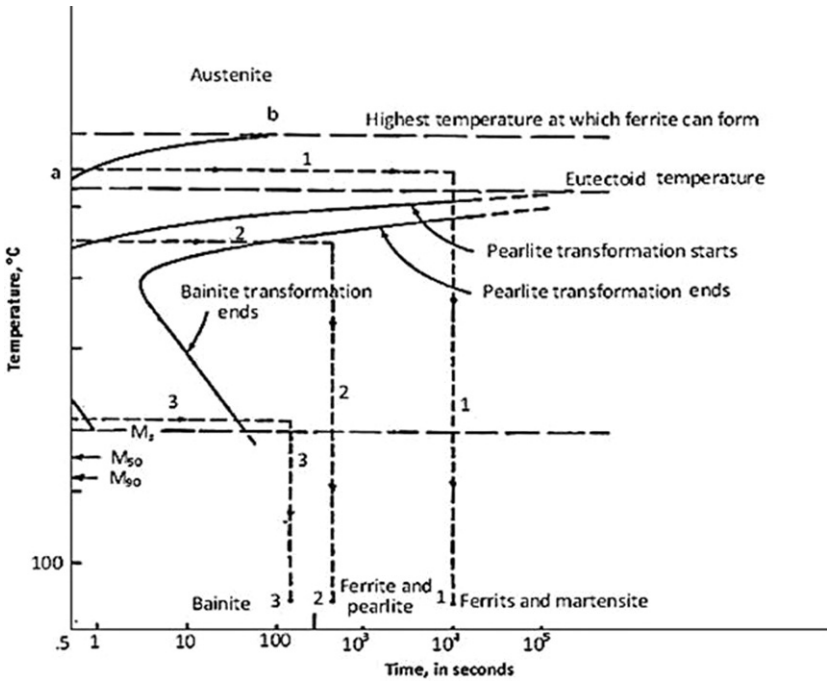

Figure 15 Arbitrary time–temperature paths on the isothermal diagram of a hypoeutectoid steel.[1]

curves are essentially a temperature–time recording continuous change of temperature of a cooling object with time. This superimposition is demonstrated in Figure 16. For a very slow cooling rate aiming to resemble full annealing, it is found that transformation is completed within a narrow temperature band just below the critical temperature A_1; the microstructure simulates that of annealed steel and consists of pearlite of large interlamellar spacing. The cooling path is however the one that demonstrates the entire transformation to take place at constant temperature due to isothermal holding for sufficient period of time. Relatively faster cooling rate (as in cooling path 3) has led to transformation occurring at lower temperature to yield fine pearlite. Cooling path 4 represents the CCR which when employed disallows diffusional transformation of austenite to pearlite. Any rate of cooling higher than the CCR will retain metastable austenite till a different mechanism of phase transformation without the aid of diffusion is realized by the system. A diffusionless shear transformation has to take place unless the metastability of austenite is enhanced so much so by alloying, that the temperature of martensite formation, M_s, goes below room temperature (readers may check up with text books on phase transformation). In that case metastable austenite will remain at room temperature as in the case with austenitic stainless steel.

Unfortunately superimposition of continuous cooling curve on a TTT diagram is not scientifically justified, although it gives a rough estimate of phase transformation in steel under nonequilibrium cooling (Figure 17).

That is why TTT diagram cannot be directly used for describing the transformation of austenite in practical situation. For this purpose CCT diagrams are needed to be constructed. Incidentally it is possible to derive the CCT diagram from the corresponding TTT diagram.

As evident from Figure 18 the supercooled austenite under a state of continuous cooling transforms over a range temperature. On the contrary TTT diagrams are drawn by monitoring time dependent austenite decomposition at constant temperatures.

The approximate CCR from a TTT diagram is obtainable by the use of Grange–Kiefer formula:

$$\mathrm{CCR} = (\mathrm{A}_1 - T_{\mathrm{nose}})/1.5t_{\mathrm{min}}$$

where, t_{min} = minimum incubation period at the nose of the TTT diagram, T_{nose} = temperature at the nose where incubation period is minimum.

Moreover commercial heat treatment is hardly accomplished isothermally at constant temperature. Therefore one needs to understand the difference between TTT and CCT diagram. From Figure 18, it is noticed that continuous cooling from a temperature above eutectoid temperature reaches the line for austenite–pearlite transformation after a time say t_1 second. Let it be taken that after a lapse of t_1 second while cooling the stock at the cooling rate C_1, the temperature attained by the stock is T_1°C. It may now be presumed that entire stock had been at T_1°C for a time of t_1 second with in

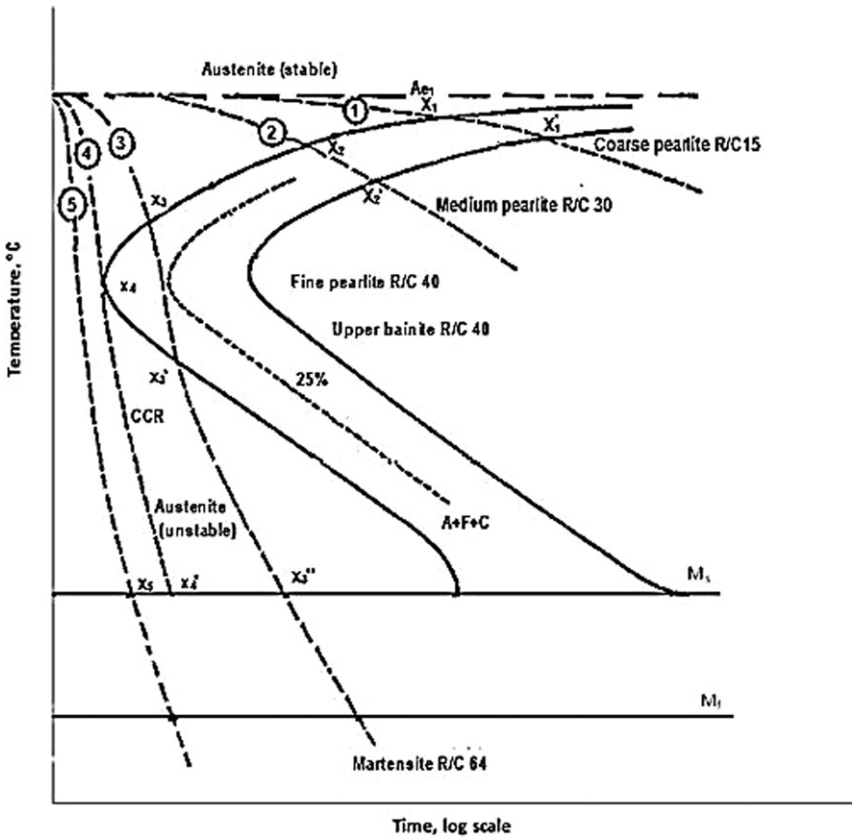

Figure 16 Superimposed cooling curve on TTT diagram.

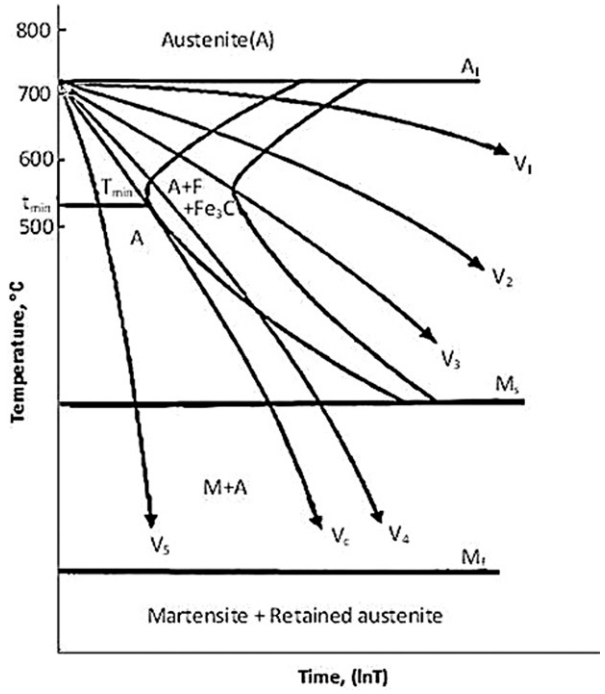

Figure 17 Superimposition of cooling curves on a TTT curve (austenite decomposition). Cooling rates $V_1 < V_2 < V_3 < V_4 < V_5$.

the metastable austenite region. This is as tenable as at any temperature higher than T_1°C; the stock requires more than t_1 second to reach the line for pearlite start temperature. The continuously cooled sample is not ready to form pearlite after t_1 seconds, rather it will take a slightly higher time to initiate the reaction. Thus the point '*a*' is shifted toward right. Again higher time implies a greater drop in temperature. This means the actual position of pearlite start point '*b*' is toward right of '*a*' as well as depressed. Similarly at the γ-pearlite finish point may be found lie at '*d*' to mean that the '*c*' point on TTT diagram is shifted toward right and downward.

TTT diagram is therefore quite useful in predicting the cooling rate required to avoid soft pearlitic transformation of austenite. From the foregoing discussion it is very clear that if a rate of cooling is faster than the CCR in accordance with TTT diagram, it is certain that in actual case of prediction made on the basis of corresponding CCT diagram, the same cooling rate will always give rise to non-diffusional products of transformation.

CCT diagram can be obtained quite accurately by a number of techniques. Differential dilatometric technique is generally employed to construct the CCT diagram of any steel under preprogramed cooling schedule. **Figure 19** shows the CCT diagram drawn in Gleeble machine which makes use of dilatometry to accomplish the task.

From the curve in **Figure 19**, it is clear that transformation under continuous cooling takes place over a range of temperature. Since structure and morphology of phases formed

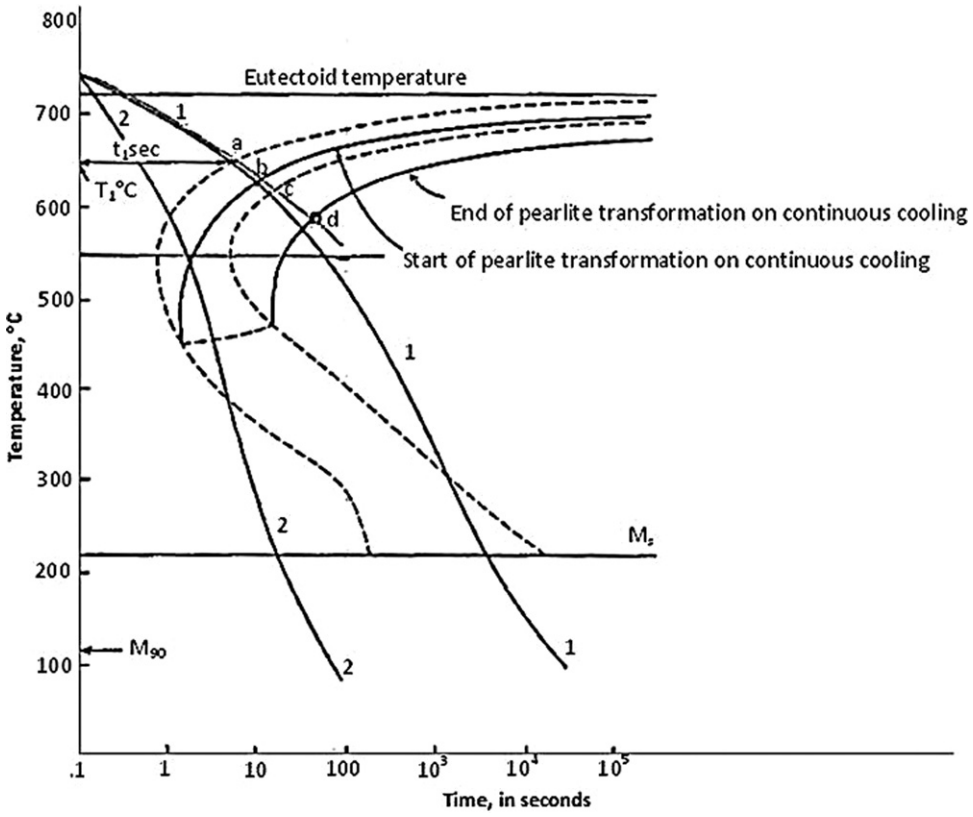

Figure 18 The relationship of the continuous cooling diagram to the isothermal diagram for an eutectoid steel (schematic). After Atlas of Isothermal Transformation Diagram; United States Steel Corporation: Pittsburgh, 1951.

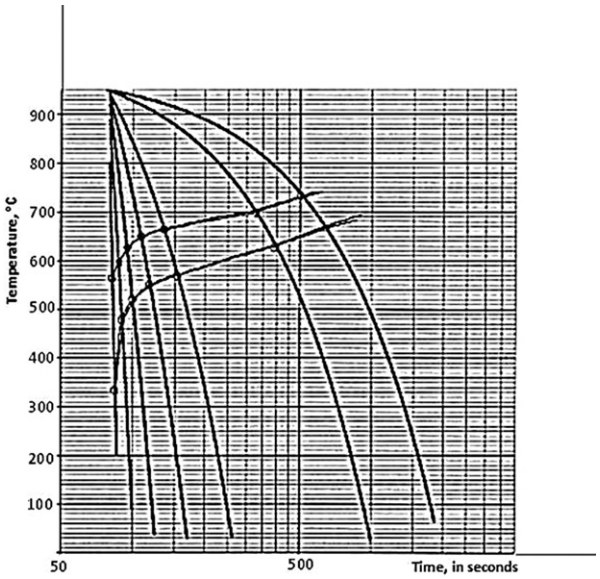

Figure 19 Continuous cooling transformation diagram of a low carbon steels constructed by dilatometric method.

due to phase transformation depend upon the transformation temperature, it is imperative that there will be a structural gradient in steels cooled continuously. Moreover it is pertinent to remember that phase transformation in many steels is mechanistically transient over a range of temperature, the complete transformation of parent phase takes place. This is particularly important for low carbon steels, where the mechanisms of austenite to ferrite transformation are different at different temperatures. Thus quite often a multiphase microstructure is obtained by continuous cooling of low carbon steels. However microstructural gradient is not desirable in respect of deriving uniform properties in the heat treating object. The shape of the CCT diagram determines if there will be uniformity of microstructure. In some alloy steel it is possible to get flat CCT diagram in both cases of transformation start and finish, which represent low carbon bainite and hence chances of microstructural gradient is least in this case. Whenever a decomposition of austenite takes place under continuous cooling, a number of mechanisms are operative for austenite to ferrite transformation depending upon the temperatures of transformation. For example, in low carbon high strength low alloy steel (HSLA) steel, progressively decreasing transformation temperature or equivalently the increasing cooling rate, envisages the transformation of austenite in the following sequence.

$$\text{Austenite}(\gamma) \rightarrow \text{Equiaxed ferrite}(\alpha_P) \rightarrow \text{Quasipolygonal ferrite}(\alpha_q) \rightarrow \text{Widmanstatten ferrite}(\alpha_w) \rightarrow \text{Massive ferrite}(\alpha_{\text{massive}}) \rightarrow \text{Granular bainite}(\alpha^0 B) \rightarrow \text{Acicular bainite}(\alpha_B) \rightarrow \text{Martensite}(\alpha_M)$$

However in the regime of CCT diagram where acicular bainite or martensites are formed, the transformation mechanism is practically same at all transformation temperatures, viz. martensitic transformation. This situation of microstructural gradient is of much greater concern for finite-sized samples. Whenever a finite sized sample is cooled from the austenite state to effect

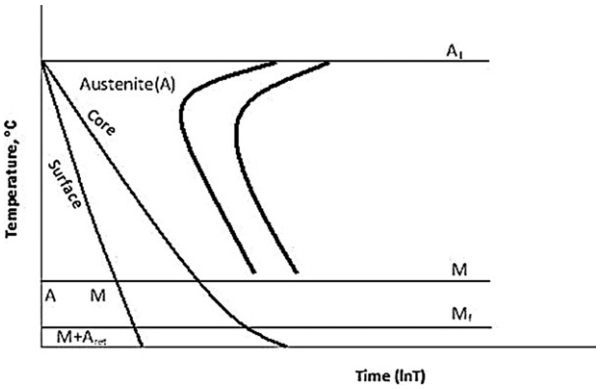

Figure 20 Diagram showing different cooling rates at surface and center of the workpiece.

phase transformation, the cooling rate at the surface and at the center of the sample ought to differ as shown in Figure 20.

The temperature difference at each time during cooling is dependent upon two important factors. One is the material and other is the external media used to cool the object. For the same material, cooling from the same austenitizing temperature but in different media like water and oil will result in different temperature differential between surface and center of the sample. So whenever it is required to avoid the nose of a TTT or CCT diagram in a heat treatment process, it is required to decide the cooling media for the same due to following reasons:

1. Different cooling media has different heat extracting ability from a specific stock of definite size, that is different quenching media have different severity of quench; it is further important to note that the cooling rate achievable from a quenching medium varies with the changing temperature of the sample during cooling. Thus severity of quench is a sole property of the quenching medium.
2. By virtue of heat transfer ability, different materials exhibit different responses to cooling in various quenching media. Also each material has its characteristic section sensitivity (i.e., variation of cooling rate at different places at any time). This implies that there is a sole material property which defines the ability of a material to avoid diffusional decomposition of the metastable parent phase. To get a reach to this material property, it is necessary to remove the effect of cooling rate on the ability of material to avoid the nose of TTT diagram of a material.

This inherent property of steel is called hardenability which describes the depth up to which a steel component is able to avoid soft pearlite transformation. The term hardenability originates from the fact that avoidance of the nose of CCT curve by a cooling rate higher than the CCR leads to the hardest possible phase in steel, which is martensite. This definition of hardenability is not universal. The idea of increasing the hardness of a material by avoidance of diffusional decomposition of high temperature parent phase is not generic. It is true that if a metastable solid solution is not allowed to undergo its due decomposition by way of diffusional means at relatively high temperatures, the solid solution will take chance to form more thermodynamically feasible alternative phase, through diffusionless shear transformation

mechanism. This type of transformation, martensitic transformation, takes place in a number of systems. For steel, the martensites are extremely hard. There are many systems like Cu–Zn–Al, Cu–Al–Ni, Ni–Ti, In–Th, where the martensite phase is very soft. The high hardness of iron–carbon martensites is ascribed to (1) solid solution hardening due to it being a supersaturated solid solution of carbon in body centered tetragonal structure, (2) dispersion hardening due to fine-scale precipitation of carbide due to auto tempering, (3) dislocation hardening due to martensite being internally faulted with dislocations, (4) hardening due to interaction between dislocations and distortion dipole produced in martensite due to asymmetric alignment of carbon atoms in the unit cell and finally due to fine crystal size. The suppression of solid state diffusional transformation by fast quenching is quite common in many systems; it is true that a rapid cooling to bypass the diffusional transformation (hence the nose of corresponding CCT diagram) results in the formation of a supersaturated solid solution. The supersaturated solid solution in iron–carbon system is hardest and hence this process is called hardening heat treatment. In other systems, the supersaturated solid solution may not be the hardest (e.g., Al–4 wt.%Cu) constituent, but this may give rise to hardening when heated to slightly higher temperature and held for preselected period of time.

However hardening of hypoeutectoid steel is carried out 50 °C above A_3 temperature and then it is soaked there for sufficient period of time as discussed earlier. The homogeneous austenite is then rapidly cooled with the aim to produce 100% martensite in the structure. In case of eutectoid steel, the steel requires a temperature of 780–800 °C for production of homogeneous austenite and then it is quenched.

An empirical relationship between the M_s temperature and alloying element content may be written as,

$$M_s(^\circ C) = 561 - 474(\text{wt. \%C}) - 33(\text{wt. \%Mn}) - 21(\text{wt. \%Mo}) - 17(\text{wt. \%Ni}) - 17(\text{wt. \%Cr}) \quad [1]$$

It is evident that carbon has the maximum effect to lower the M_s temperature. Thus for high carbon austenite in hypereutectoid steel, the depression of M_f temperature below room temperature will always yield some retained austenite in the quenched microstructure. This retained austenite will make the material softer at specific location, thereby rendering it to an inferior quality material.

2.1.5 Annealing

Annealing is the process of heating the object to single phase field followed by equilibrium cooling to aim at achieving equilibrium microstructures. Depending upon the purpose, various annealing types are carried out at different temperature. The temperatures used for various types of annealing operation are shown in Figure 21.

2.1.5.1 Full Annealing

Full annealing is carried out to achieve a microstructure predicted by the equilibrium phase diagram of the alloy system. Full annealing process involves heating hypoeutectoid and eutectoid steels 50 °C above Ac_3 and Ac_1 temperatures, respectively. The

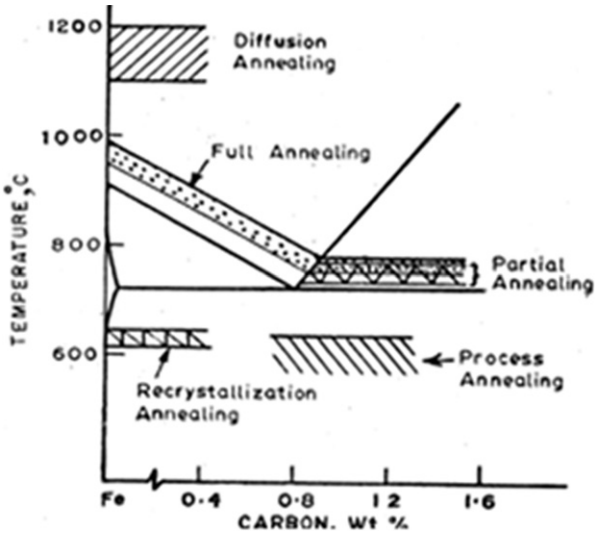

Figure 21 Diagram showing temperature ranges of different annealing process.

component is held for 1 h per 25 mm of section size and then subjected to very slow cooling. The rate of cooling should be as slow as possible and an example of industrially acceptable cooling rate to obtain near-equilibrium structure is 50 °C h^{-1}. Again, care must be taken to avoid decarburization especially in case of annealing high carbon steels. The aim of full annealing is to effect diffusional decomposition of parent phase, viz. austenite in case of steel, at as low an undercooling as is possible to be provided by the furnace. The microstructure in annealed hypoeutectoid steel consists of proeutectoid ferrite and pearlite whereas it is full pearlite in eutectoid steel (Figures 22(a) and 22(b)). Hypereutectoid steels are not ordinarily put to full annealing. The A_{cm} line is quite steep and full annealing of hypereutectoid steel attempting to produce completely homogeneous austenite necessitates heating the steel to a very high temperature, with associated risk of grain coarsening and decarburization. However full annealing of hypereutectoid steel is required if prior hot working is done at a very high temperature causing overheating and gain coarsening. Under such situation a judicious full annealing may result in partially refined grain structure. If cooling rate is high, network of proeutectoid constituents around the grain boundaries is likely to form; a slower cooling on the other hand may lead to the formation of separate ferrite regions in full annealed hypoeutectoid steel.

2.1.5.2 Isothermal Annealing

In case of isothermal annealing, steel is heated in the same manner as that in the case of full annealing. After austenitization the steel is rapidly cooled at a predetermined temperature and it is held there for sufficient period of time so that transformation of austenite becomes complete. A prior knowledge of TTT diagram enables to determine the time of holding at the isothermal annealing temperature. Isothermal annealing is advantageous as the total heat treatment time is considerably reduced yet obtaining comparable microstructure and properties. Isothermal annealing is particularly suitable for alloy steels which otherwise require at extremely slow

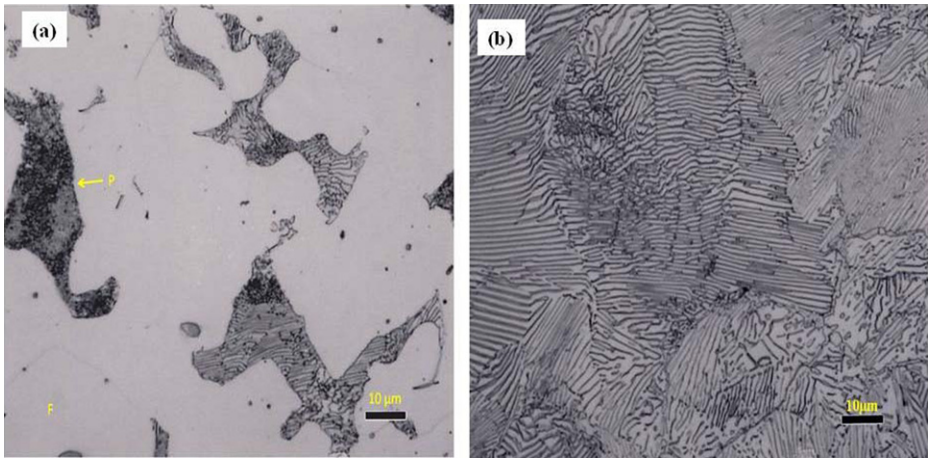

Figure 22 (a) Ferrite–pearlite microstructure of 1018 carbon steel annealed at 900 °C, (b) fully pearlitic microstructure of 1095 carbon steel annealed at 900 °C. Courtesy of George Vander Voort, USA.

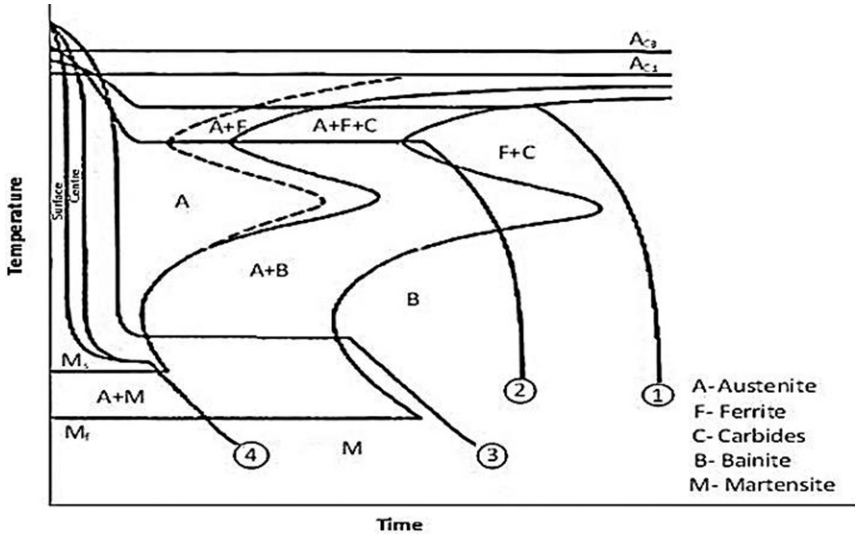

Figure 23 Isothermal annealing of alloy steel.

cooling in order to effect transformation involving the long range of migration of slowly moving atoms of the alloying elements. As evident from the **Figure 23**, object being heat treated is cooled rapidly after austenite is completely transformed to the desired phase that is pearlite.

Patenting is a specific isothermal annealing where the transformation of metastable austenite is effected just at the nose of the TTT diagram of the material under heat treatment. Normally patenting is carried to impart high strength to musical wires. A high carbon steel of nearly eutectoid composition is austenitized 15 °C above Ac_3 for hypoeutectoid and above Ac_1 for eutectoid composition (0.65–0.80). After producing homogeneous austenite rapid cooling is done in a salt bath kept at about 450–550 °C and held for complete transformation of austenite to fine ferrite–carbide aggregate. In accordance with the possible mechanism of transformation of austenite to fine ferrite–carbide aggregate, the microstructure may comprise of either fine pearlite or a mixture of fine pearlite and upper bainite. The patented rod is cold drawn to fine wire, to be used in musical instrument as combined microstructural and strain-hardening results in a very high strength of the wire.

2.1.5.2.1 Patenting

'Patenting' is a process of annealing which is generally employed in wire and rod manufacturing process. Patenting is normally carried out when extra toughening is required in steels containing 0.5 wt.% or higher amount of carbon. The annealing process in the name of patenting involves isothermal annealing of steels in a suitable salt bath at temperature near the nose of the TTT diagram. After austentizing the steel is cooled rapidly to the isothermal holding temperature viz. 550 °C. The object is kept at that temperature for sufficiently time so that complete transformation of austenite to fine pearlite is possible.[4] The objective of patenting is to produce very fine pearlite in the microstructure (**Figure 24**); since smaller inter lamellar spacing of pearlite envisages high toughness of steel it is applied to medium- and higher-carbon grades of steel, rod, or wire products.[5]

Figure 24 1080 steel isothermally annealed at 482 °C (patenting). Courtesy of George Vander Voort, USA.

Sometimes drawing and patenting steps are successively repeated for obtaining the desired size and strength level. Appropriate tailoring of composition may enable complete transformation of austenite to fine pearlite by air cooling; this alleviates with the use of salt bath or molten lead bath which is health hazardous. Air patenting is less expensive than lead patenting but results in pearlite of varying inter lamellar spacing which is not desirable. For a less, hardenable steel possibility of formation of proeutectoid ferrite may not even be precluded.

The steels to be used for manufacturing suspension bridge wires demand extra strengthening after patenting; for this hypereutectoid steel with minor addition of chromium ~0.5 wt. % is now a day's employed. Chromium induces a higher degree of refinement in interlamellar spacing of pearlite in hypereutectoid chromium bearing steel, even down to 70 nm.[6–8] Also the carbide lamella becomes shorter and discontinuous. When steel with such fine pearlitic microstructure is subjected to heavy deformation during wire drawing cementite particles decompose. The ferrite crystals get supersaturated with carbon. Complete decomposition of cementite is envisaged in chromium bearing hypereutectoid steel. Excess carbon precipitated on dislocations within the resulting ferrite not only increases the strength of the steels but also its work hardening rate quite significantly. This aids in suppression of delamination. Heavy drawing of such steels reportedly leads to a super saturation of ferrite up to 0.5 wt.% carbon with consequent UTS being about 1500 MPa. The degree of decomposition of cementite depends upon the rise in temperature during wire drawing; the adiabatic heating in heavily drawn wire causes decomposition of cementite with concurrent deposition of carbon atoms at the dislocations which are pinned by the carbon atoms; as a result of consequential strain aging effect yield strength of the steel is significantly increased. The microstructure of a 1080 carbon steel is in Figure 24.

The decomposition of cementite phase, θ during heavy drawing has been ascribed to elastic interaction between dislocations and C-atoms.[4,8] It is postulated by one school of thought that heavy deformation during wiredrawing leads to refinement of cementite. Upon continued deformation, the slip steps is formed in θ; these two events lead to increase in interfacial areas and hence the surface free energy. The dictates of Gibbs–Thomson effect in respect of urge to lower surface energy results in ultimate decomposition of cementite. The state of C-atoms in α, may provide clues to such decomposition of cementite; if carbon is present at dislocations, strain aging effect will enhance the yield strength quite significantly. On the contrary, if carbon is assumed to cause super saturation of ferrite solid solution hardening shall be the chief hardening mechanism with concurrent change in the lattice parameter. Equally the other proposals that carbon segregates at the prior α–θ interfaces,[5] or that carbon precipitates out in the form of carbide on to the dislocations[9] have grounds to attract due attention. The observation that no significant change in lattice parameter in noted in the process may cast doubt on the ferrite super saturation model.

There are reports[10] that heavy deformation during forging of white cast iron led to collapse of cementite lattice and that elemental carbon released in huge quantity leads to graphitization. High carbon steel for wire drawing contains much less proeutectoid cementite as compared to ledeburitic cementite in white cast iron grown further in size due to precipitation of proeutectoid cementite. The author hypothesizes that heavy deformation during wire drawing leads to collapse of cementite and the concurrent diffusion of carbon atoms from cementite–ferrite boundary to intragranular dislocations in ferrite takes place at high temperature due to local adiabatic heating. However, being energetically cheaper, the carbon atoms prefer to segregate at the dislocations in the form of metastable cementite and not in elemental form. In this case one will find that carbon content of ferrite is high without tangible rise in lattice parameter. All observations made so far are also compatible to the hypothesis. Nevertheless it is of paramount importance to study the nature of particles present at the dislocations within ferrite; the possibility of formation of ε-carbide and/or chromium bearing carbide of higher carbon content must not be ruled out especially in situation of high strain rate deformation.

2.1.5.3 Incomplete Annealing or Intercritical Annealing

Incomplete annealing aims at relieving internal stresses thereby improving machinability of the steel. Normally this type of annealing is carried out by heating the stock just above Ac_1 and then holding there for sufficient time. Finally it is cooled slowly within the furnace. It must be understood that this type of annealing does not eliminate proeutectoid ferrite or cementite from the microstructure at the annealing temperature. Mainly incomplete annealing of such type is applied to hyper eutectoid steel. Annealing of hypereutectoid steel produces the microstructure with cementite network enclosing the pearlitic region. Whenever incomplete annealing is carried out in eutectoid steel, the effect of full annealing is realized because the annealing temperature lies in the austenite phase field.

Intercritical annealing of hypoeutectoid steel followed by rapid cooling gives rise to a duplex ferrite–martensite structure. This type of heat treatment for low carbon micro-alloyed steel is quite popular in recent years. The steel is held at a convenient intercritical temperature till the time it is equilibrated between higher carbon austenite of low volume fraction and low carbon ferrite. Upon rapid cooling from the intercritical

Figure 25 (a) Microstructure of intercritcally annealed 4140 alloy steel showing ferrite and martensite (Courtesy of George Vander Voort, USA) and (b) microstructure of hypereutectoid steel annealed above A_{cm} temperature followed by slow cooling.

annealing temperature, austenite transforms to martensite. This biphasic structure, where martensitic island are interspersed with in soft ferrite matrix strengthens the material significantly. Figure 25(a) delineates ferrite–martensite structure in 4140 steel intercritically annealed at 775 °C within $\gamma + \alpha$ phase field followed by water quenching.

The yield–tensile ratio of this steel is about ~0.5; this HSLAs possess excellent deep drawability and is considered to be a very good automotive material.

Again annealing of hypereutectoid steel is essentially an intercritical annealing as it is austenitized above A_1 temperature in the two-phase field γ + cementite and then furnace cooled. This makes the proeutectoid cementite agglomerated or spheroidized. On the contrary if it is annealed by austenitizing at temperature above A_{cm} and then slow cooled to room temperature, proeutectoid cementite forms a network along prior austenite grain boundaries. These types of microstructures promote intercrystalline fracture and thus make it brittle (Figure 25(b)). Annealing of hypereutectoid steel in two-phase field breaks the continuous cementite network by agglomeration into spherical carbide particles. The associated reduction in austenite–cementite interfacial area acts as the driving force for the process.

2.1.5.4 Spheroidizing Annealing

Spheroidizing annealing is meant for obtaining granular cementite in a ferrite matrix. The lamellar pearlite of high carbon steel is converted to granular morphology by way of heating the steel just above the critical temperature, 740–750 °C and then holding at that temperature for considerable period of time. This is followed by a slow cooling of the order of 25 °C per hour down to a temperature of 600 °C. To obtain granular cementite the annealing temperature should not be too high above Ac_1 and cooling rate should be so slow as to allow decomposition of austenite to be completed at a low degree of supercooling. This enables the cementite particles to attain globular morpohology. High carbon steels are conducive to such spheroidizing annealing temperature when heat treatment is carried at a temperature slightly above Ac_1 temperature; however spherodization of cementite particles is also aimed in relatively lower carbon containing alloy steels as a pretreatment for facilitating production of homogeneous austenite during the subsequent autenetization. Instead of holding the steel just above Ac_1 temperature, thermal cycling across Ac_1 temperature for a number of times may also give rise to spheroidization of carbides. During thermal cycling across Ac_1 the steel is held at a temperature just below Ac_1 for predetermined period of time followed by gentle heating. Repetition of isothermal cycles will produce the desired spheroidized morphology. In the heating stage of thermal cycling carbides tend to dissolve but reappear in the following cooling cycles. Attempts to effect phase transformation with such a low driving energy entices the system to assume spheroidal morphology; spheroidization diminishes the specific surface area and thus overcome the constraint due to surface free energy term in the target phase transformation. Implicitly the spheroidal structures are softer with good machinability. As stated earlier a microstructure with spheroidal cementite aids in production of homogeneous austenite. Figure 26 exhibits spheroidized cementite in hypereutectoid steel containing 1.05 wt.% carbon steel.

Figure 26 Microstructure of steel after spheroidizing annealing. Courtesy of George Vander Voort, USA.

Inter critical annealing of hypereutectoid steel gives rise to globular cementite and thus leads to the formation of granular

pearlite. Within the intercritical region, undissolved cementite particles tend to globularise due to prolonged heating at the annealing temperature. Spheroidization of particles held at elevated temperature is a natural event. Spheres have minimum specific surface area as compared to other shapes and hence spherodization of a micro-constituent leads to the diminution of its surface free energy. Thus the process of spherodization enables the system to lower its overall energy. At the temperature of inter critical annealing diffusion is not a constraint; this favors the kinetics of spheroidization. During slow cooling the carbon content of austenite will gradually decrease down the A_{cm} line. So rejection of carbon in the form of cementite may take place on to the existing cementite particles as this will reduce the requirement of supply of energy for nucleation of new phase. When austenite is cooled just below the Ac_1 line, austenite needs to undergo eutectoid reaction which is essentially a discontinuous precipitation where cementite is the leading nucleating phase.

Eutectoidal cementite will form mostly through deposition on the existing cementite particles although nucleation of new cementite on the prior austenitic grain boundaries is not excluded. In any case this cementite will have a better scope of equiaxed growth and hence the overall microstructure will consist of globular pearlite.

Spheroidization is also carried out by holding the object under heat treatment just below A_1 temperature. Prolonged holding at this temperature effects spheroidization of cementite particles, embedded in ferrite matrix. However this method of spheroidization is rather slow. It is not out of place to mention than the equilibrium shape of the particle is not strictly spheroid but ellipsoidal. Particles assume spheroidal morphology due to the urge to attain low energy state is reasoned out by the fact that in solid state transformation strain energy is equally important.

Maximum reduction in strain energy is not concurrent with spheroidal growth of the particle. Rather growth of particles along specific direction reduces the lattice disregistry, and hence the strain energy. However continued nonspherical growth to reduce strain energy is in opposition toward attainment of stability in a system; this is because the nonspherical growth increases the surface area and hence the surface free energy. Thus a situation comes, when urge to reduce surface energy takes over and a spheroidization process sets in. This continues till strain energy term prohibits spherical growth and thus the aspect ratio of the particle swings across a value near to but less than unity.

2.1.5.5 Homogenization or Diffusion Annealing

Homogenization or diffusion annealing is usually carried out for heavy and intricate castings which are prone to significant intercrystalline segregation. Homogenization annealing is carried out to remove the inevitably occurring chemical inhomogeneity in heavy alloy steel casting. In reality most of steel casting produced under moderate cooling rate as in sand molds experience segregation of alloying elements along the cell boundary of the cellular dendritic structure. To ensure microstructural homogeneity diffusion annealing is carried out at high temperature as 1150 °C so that appreciable diffusion of atoms of the alloying elements takes place easily. This entails the possibility of achieving austenite of uniform composition. However homogenization annealing as demanded to be carried out at such a high temperature is liable to produce coarse-grained microstructure along with formation of scales at the surface of the casting. Therefore homogenization annealing is followed by subsequent heat treatment process to incorporate the desired set of properties in the steel castings. These heat treatments may be conventional full annealing, normalizing or normalizing followed by tempering depending upon the specified property requirement.

2.1.5.6 Recrystallization Annealing

Recrystallization annealing is a process of heating cold-worked steel above the recrystallization temperature, holding at that temperature for a predetermined time and then followed by normal air cooling. Recrystallization annealing is carried out for removing strain-hardening effect of multipass cold-working operation. In such case, recrystallization annealing is an intermediate process to facilitate further deformation by cold working. On the contrary, recrystallization annealing is also employed as a final heat treatment where removal of cold-working effect with replacement by fine equiaxed strain-free grains is derived. Proper selection of time and temperature of annealing enables to achieve fine-grained uniform microstructure comprised of recrystallization. Sometimes a cold-worked structure is subjected to annealing at a temperature less than the recrystallization temperature with the purpose of rearranging dislocations to some low energy configurations. This is known as a recovery process and is accomplished by suitable annealing process.

When metals and alloys are cold worked, that is when these are subjected to plastic deformation at a low temperature, say, less than 0.4 T_m (T_m is the melting point of the concerned metal or alloy in degree Kelvin), a portion of energy spent for cold-working remains stored within the material in the form of crystal defects. The amount of stored energy ranges from a low value to around 10% of the total energy spent in a deformation process. The work of deformation leads to generation of point defects and dislocations. These crystal defects are associated with strain energy and the creation of crystal defects during deformation is the manifestation of stored energy in cold-worked materials. Obviously the magnitudes of stored energy increases with increasing amount of deformation up to a certain saturation value which is different for different materials and deformation condition; however in most practical cases, the maximum of stored energy does not exceed 15% of the energy spent in cold working and the rest energy is dissipated in the form of heat.

The above stated stored energy drives the relaxation processes during subsequent annealing. Upon annealing, the stored energy is released through different recovery processes which may occur in steps. The process involved during the release of stored energy is called recovery, recrystallization, and grain growth. During recovery process the point defects viz. vacancies are annihilated at the sinks like grain boundaries, or it may annihilate at edge dislocation affecting its climb. The reduction in density of point defects due to recovery process leads to reduction in resistivity of the metals and alloys. Resistivity is due to incoherent scattering of electrons at the

scattering centers like point defects. Also during recovery process, the dislocations generated by cold working either get annihilated or reorganize themselves into low energy arrays. Annihilation of dislocations takes place where dislocations of opposite sign come together either through slip or through climb. Normally the dislocations remaining in excess after annihilation would try to reorganize themselves into low energy array for the purpose of lowering the overall energy of the system. One example of such process is what is termed as polygonization. When a crystal is bent, the excess positive edge dislocation may lie along the active slip planes in disorderly fashion. When a row of edge dislocation lie on a specific plane, its total strain field in quite high; if the dislocations lying on different vertical planes are arranged in disorderly fashion, the overall strain energy due to dislocations in bent crystal becomes quite high. However, if the bent crystal is heated, the dislocation climb is possible and a regular arrangement as shown in Figure 27 is realized.

When the dislocations are rearranged in the manner as shown in Figure 27, the tensile and compressive component of strain field due to adjacent dislocations will tend to cancel each other; as a result total strain energy of the system will be reduced. The region of crystal in between any two lines of dislocations is essentially devoid of dislocations and thus becomes a strain-free region. These strain-free regions within the crystal are bound by thin arrays of dislocations, describing a small degree of misorientation across the regions; considered as boundary, it is called a sub grain boundary. During recovery of cold-worked crystals, mechanical and physical properties are changed. The resistivity decreases with increase in time or temperature till a saturation value is attained (Figure 28).

A typical microstructure containing sub grain boundaries is shown in Figure 29.

When annealing is carried out at temperatures above 0.4 T_m a different recovery process takes place. During this process, highly strained grain within cold-worked material (characterized by high dislocation densities) is replaced by the strain-free grains. This process of relaxation is called recrystallization. Recrystallization is a nucleation and growth type process as initiated by the formation of nuclei of strain-free grains which, subsequently, grow by migration of its high angle boundaries. The growth of strain-free crystals continues in all directions until there is impingement from the surrounding crystals. Being a thermally activated process, recrystallization is temperature and time dependent; also the process is influenced by

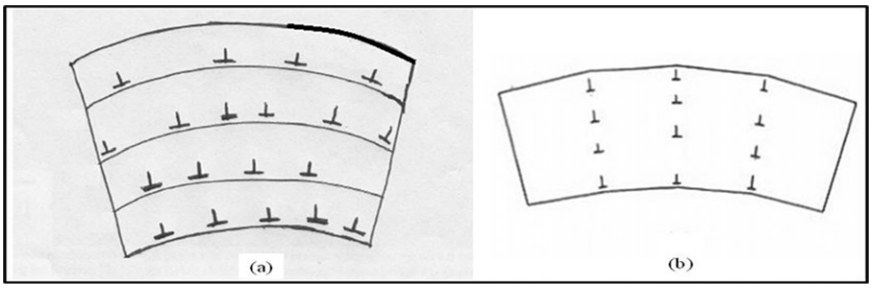

Figure 27 Recovery of crystal showing rearrangement of dislocations in bent crystal (polygonization); (a) shows irregular arrangement of dislocations and (b) shows rearrangement to low energy array.

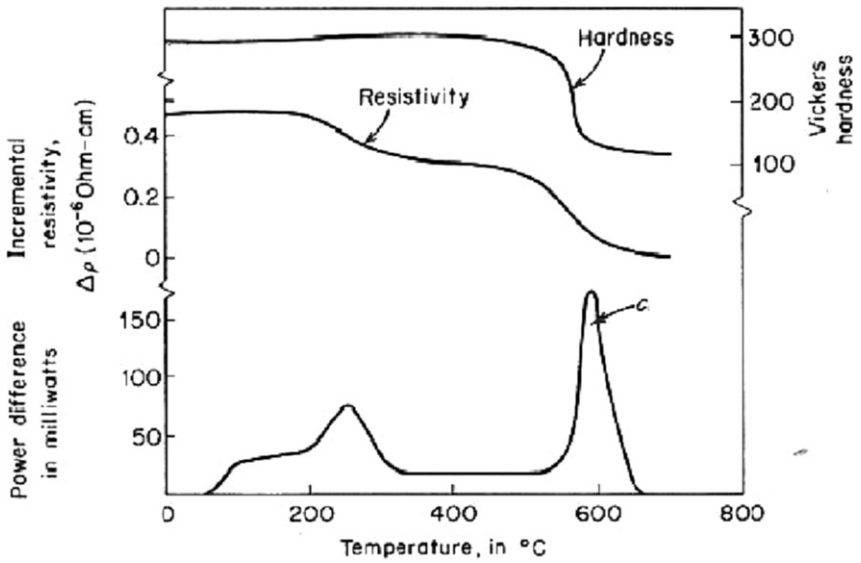

Figure 28 Variation of properties for cold-worked nickel due to recovery annealing. Courtesey of J.E. Indacochea University of Illinois at Chicago, USA.

the amount of deformation. The following observations can be made in any recrystallization process.

1. A minimum amount of deformation is required to effect recrystallization at a particular temperature.
2. Time required to complete recrystallization increases as the temperature of recrystallization is lowered.
3. With increasing deformation percent, the temperature to start recrystallization is decreased.
4. Recrystallized grain size becomes smaller with larger percentage of deformation at a particular temperature.
5. New strain-free grains don't grow into deformed grains.
6. A metal or alloy with fine initial grain produces smaller recrystallized grain.

The recrystallization kinetics in metals and alloys shows typical sigmoidal behavior as shown in **Figure 30**.

The same figure demonstrates that increase in recrystallization temperature reduces the time to complete recrystallization. It also takes less time to initiate the process of recrystallization.

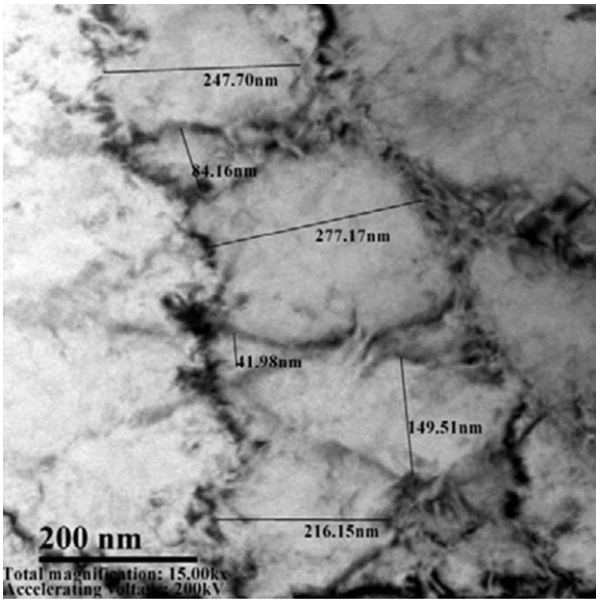

Figure 29 TEM of 0.05C–1.5Cu–1.5Mn steel showing subgrain boundaries. Courtesy of Material Research Centre, MNIT Jaipur, India.

Several mechanisms of recrystallization are proposed. There can be different dislocation density across a grain boundary; the grain boundary is not strictly planar but it is perturbed with transient wavy character. A small bulged-type region at grain boundary may move into region of high dislocation density. Grain boundary acts as sinks for dislocations and annihilates them; the creation of such small dislocation free region lowers the local free energy and hence becomes a stable nucleus. The nucleus then grows to form a strain-free grain (**Figure 31**).

The other mechanism of recrystallization is the coalescence of sub grains to form a region bound by high angle boundary and hence a strain-free grain is formed under the driving force of lowering of strain energy due to replacement of a number of sub grain boundaries by a single boundary of large misorientation.

While recovery process reduces the electrical resistivity, recrystallization leads to reduction of hardness values with progressive diminution of dislocation density. For a fine recrystallized grain structure both strength and ductility are simultaneously improved. The change in properties of a heavily cold-worked metal subjected to isothermal annealing above recrystallization temperature is shown in **Figure 32**.

Further annealing at still higher temperature leads to grain growth. The driving force for grain growth is lowering of

surface free energy. Anything which aids grain boundary movement shall accelerate grain coarsening.

During recrystallization annealing proper control of recrystallization temperature and time is required. After the completion of recrystallization, the process must be stopped; else grain coarsening will set in.

2.1.5.7 Subcritical Annealing

Subcritical annealing is generally carried out at a temperature below the lower critical temperature, A_1. There are a number of purposes for which subcritical annealing is considered to be a useful heat treatment operation. Apparently subcritical annealing is not liable to cause any phase transformation. However it will be demonstrated in the following discussion that in certain cases phase transformation may be realized in subcritical annealing.

1. Indirect second stage graphitization of cast iron is a subcritical annealing process, where cast iron with pearlitic matrix is heated to an elevated temperature below A_1 temperature. Upon holding for a prolonged time, the pearlitic cementite may undergo decomposition to form graphite, leaving behind ferrite in the matrix. Thus complete second stage graphitization will lead to the formation of ferritic cast iron, which is a cast iron where graphite particles (flakes or other shapes) are contained in a ferrite matrix; this makes the cast iron soft and ductile.
2. Subcritical annealing is carried out in large and intricate castings to get rid of internal stresses. It is also carried out after welding of some steels where there is a chance of formation of martensite at the heat affected zone. The welded joints are subjected to both thermal stress and stress due to volume change accompanying martensite transformation.

Subcritical annealing relieves the thermal stress by dislocation annihilation at the grain boundaries and as well it removes transformational stress by way of tempering martensite to make it decompose to fine ferrite–carbide aggregate. The microstructure of 0.10C–2Mn steel subjected to subcritical annealing at 710 °C is shown in **Figure 33**.

Sometimes subcritical annealing is employed to drive away the dissolved harmful gases within the steel component. For example, in cases where hydrogen is known to remain dissolved in steel in excess of limit of tolerance, subcritical annealing at 400 °C is carried out. Diffusivity of hydrogen is quite high at this temperature, and so it diffuses out quite easily; thus chances of hydrogen embrittlement is greatly reduced.

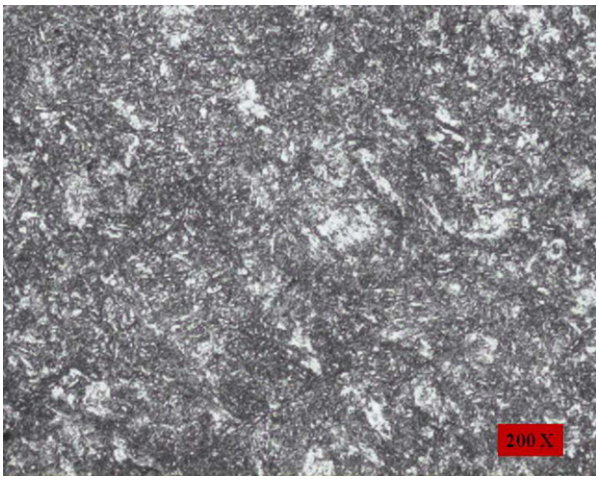

Figure 33 Microstructure of subcritically annealed steel. Courtesy of George Vander Voort, USA.

In certain cases subcritical annealing or high temperature tempering just below the lower critical temperature is employed to improve upon the sub-ambient impact strength.

2.1.6 Normalizing

Normalizing is the heat treatment process, which consists of heating the object to the austenitization temperature, holding it to produce homogeneous austenite and then allowing to be cooled in still air. Normalizing tends to imply a normal cooling of austenite to produce stronger steel in much shorter time than what can be obtained by full annealing. Due to the fact that normalizing refines the microstructure of the steel thereby improving its toughness, it is quite often employed as the final heat treatment. Normalizing is carried at a temperature 50 °C above upper critical temperatures (A_3 and A_{cm}). Being austenitized at higher temperature (20 °C) than annealing, normalizing produces greater homogeneity of austenite but at a lower temperature than homogenizing annealing and in shorter time. Quite often grain size becomes rather large after hot working; normalizing of such coarse-grained hot work material gives rise to formation of fine-grained austenite which upon air cooling produces small ferrite grains and fine pearlite in the microstructure of hypoeutectoid steels. This type of microstructures of greater uniformity helps to achieve superior mechanical properties. For example, when medium carbon steels are forged high temperature like 1100 °C, the size of recrystallized austenite grains is quite large due to adiabatic heating; the final microstructure is also very coarse (**Figure 34(b)**). Moreover distribution of pearlite and ferrite in its microstructures is nonuniform and thus the forged steel may not possess good and uniform mechanical properties. Hence it is imperative to suitably heat treat the forged product for refinement of its microstructure;

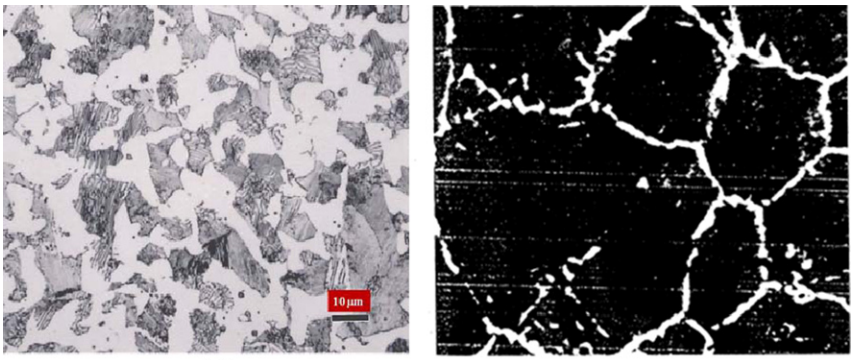

Figure 34 Microstructure of (a) 0.4 C–0.6Mn steel under normalized condition (Courtesy of George Vander Voort, USA) and (b) microstructure of 0.5 wt.%C steel forged at 1100 °C and cooled in air.

normalizing of forged steel can lead to desired structural refinement thereby enabling to produce fine uniform ferrite–pearlite structure. Due to relatively rapid cooling, the transformation of austenite takes place at a lower temperature, around 600 °C. The cooling rates superimposed on a CCT diagram of eutectoid steel qualitatively describe the difference in transformation behavior between annealing and normalizing. The properties of the steel casting are made improved by normalizing operation. It is used to remove micro-segregation in steel castings producing thereby a homogeneous structure. In hypereutectoid steel normalizing is carried out above A_{cm} temperature; this insures dissolution of carbides which aids in removal of carbide network which might have developed in prior processing. Normalized structure is highly responsive to spheroidizing treatment. Quite often normalizing is used as a preceding treatment to hardening operation, which requires a uniformly homogeneous structure without any structural gradient. If there is a structural gradient in steel before being subjected to hardening operation, the hardened steel will yield nonuniform hardness consisting of localized soft and hard spots. Well-normalized steel enables to overcome this difficulty. Air cooling is faster than furnace cooling and so normalizing heat treatment envisages austenite decomposition at a lower temperature. The resultant microstructure is significantly different from that obtained by full annealing. A lower temperature of transformation during normalizing reduces the critical nucleus size and the energy of nucleation of proeutectoid ferrite. So grain size of ferrite formed due to normalizing is smaller than the annealed steel. Again due to faster cooling formation of equilibrium amount of ferrite is not tenable. Thus the amount of proeutectoid ferrite is less than its annealed counterpart. In contrast with furnace cooling, equilibrium is not attained at any stage of air cooling during normalizing. So ferrite contains carbon in excess of equilibrium amount. Similar reasoning applies to austenite to pearlite transformation. Lower transformation temperature envisages higher density of operating nuclei for pearlitic transformation. This leads to decrease in the size of pearlite colonies. At the same time the interlamellar spacing of pearlite is reduced due to lower transformation temperature. Since amount of proeutectoid ferrite is reduced, the amount of pearlite is correspondingly increased as a consequence of shift of eutectoid point toward left upon faster cooling. Thus when compared with the achievable microstructure by annealing hypoeutectoid steel, normalizing results in decrease of ferrite grain size, increase of carbon content of ferrite, decrease in its amount. All these factors increase the hardness and strength of the steel. Again normalizing is liable to produce higher amount of pearlite with smaller colony size and interlamellar spacing. All these increases strength and hardness of the steel. Thus normalized steel is structurally finer than annealed steel and is stronger than the annealed variety. Strengthening of hypoeutectoid steel due to normalizing improves the machinability. The microstructure of normalized 1045 carbon steel is shown in Figure 34.

Low carbon mild steel is quite soft and ductile in the annealed state. Therefore chips of this ductile material get adhered to the tool tip making the machining quite difficult. Higher becomes the depth of cut, more would be the removal of material and the chances of tool tip jamming with adherent ductile chip will increase. On the contrary, normalizing makes the steel strong and relatively less ductile; this entails the scope of relatively brittle chip formation and chips can easily get away from tool tip. This ultimately improves machinability. Steel compositions may be suitably tailored so that normalized itself can harden the steel or can even alleviate with the conventional hardening and tempering heat treatment, yet achieving equivalent or better mechanical properties. For the advantages which can be accrued from normalizing steel the recent efforts to make use of normalizing as the final heat treatment process of new generation steels is noteworthy.[11–13]

2.1.6.1 Distinctions between Annealing and Normalizing Purpose

Annealing is a widely used heat treatment operation and is generally carried to refine the microstructure of materials and hence to improve its ductility. Annealing also aims to relieve internal stress, to eliminate micro-segregation in cast material for obtaining uniform grain structure, and to suitably modify the microstructure when needed for a subsequent heat treatment processes.

In case of annealing, cooling rate is extremely slow and almost equilibrium microstructure is obtained. In contrast, normalizing heat treatment employs air cooling which also produces near-equilibrium microstructure but of a smaller grain

size compared to annealing. Thus for the same composition of steel, normalizing produces stronger and tougher steel than what can be obtained by annealing. In certain cases of high hardenability steels, normalizing may lead to the formation of nonequilibrium martensite phase and in that case, the steel is said to have been air hardened.

Annealing serves identical purposes for both ferrous and nonferrous metals and alloys. Air cooling may be done in nonferrous metals and alloys to avoid the possibility of grain coarsening due to slow cooling in annealing operation; however, air cooling of nonferrous materials is not termed normalizing. Air cooling may be carried out in nonferrous alloys only when there is no chance of precipitation of solute-rich phase. If an alloy contains high amount of solute dissolved at elevated temperature, and if the solubility of solute is appreciably lower at room temperature, the alloy ought to be cooled quite fast after annealing; this is because, the slow cooling say in air may lead to precipitation at the grain boundaries of matrix alloy; these grain boundary precipitates, enriched with solute make the alloy vulnerable to premature intercrystalline failure.

In case of annealing the cooling rate is extremely slow and the rate of cooling may be same at all points across various section of the component under heat treatment. This implies that annealed material is structurally isotropic. This insures better uniformity in mechanical properties in annealed components. On the contrary, in normalizing the nonequilibrium cooling rate is experienced and hence in this case, microstructure may be different at different locations of the same component. This in turn results in nonuniformity in mechanical properties across various sections of the same component. Annealing employs a slower cooling rate; this implies higher residence time of the components at higher temperatures. Therefore the chances of grain coarsening is rather high during annealing; however, chances of grain coarsening is relatively less in normalizing due to its higher cooling rate which insures that less time is available for grain growth. Hardness of normalized components is higher than its annealed counterpart; this aids in improving machinability for very low carbon steel. However medium and high carbon steels have better machinability in annealed conditions. Due to discontinuous chip formation in normalized low carbon steel, the surface finish after machining of normalized component is better than when it is annealed. In a nutshell the similarity and difference between annealing and normalizing is summarized as:

Similarities

- Both the process are carried out in fully austenite state for hypoeutectoid and eutectoid steel.
- Heating rate and soaking time for both the process are identically selected.
- Microstructures consist of diffusional transformation product of austenite but finer in normalized steel.

Differences

- For hypereutectoid steel complete austenitization is needed in normalizing treatment whereas its annealing requires holding within $A_1 - A_{cm}$ but for which cementite network may form around austenite grain boundary making the steel very brittle.
- Annealing employs equilibrium cooling whereas cooling due to normalizing is nonequilibrium.
- Normalizing temperature of hypoeutectoid and eutectoid steel is 20 °C higher than the corresponding annealing temperature; this insures structural fineness and compositional uniformity in normalized steels.

Moreover, the microstructural distinction between normalized and annealed plain carbon steels reveals the difference between mechanical properties achievable in them.

It is understood that when hypo eutectoid steel of low carbon content, say 0.20 wt.%, is annealed, its microstructure consists of about 25% pearlite and 75% ferrite; as evident from equilibrium diagram, the carbon content of ferrite is very small. When the same steel is subjected to normalizing the following microstructural changes take place.

1. The grain size of ferrite becomes smaller due to lower temperature of transformation of austenite. This results in higher magnitude of undercooling; hence less critical nucleus size is envisaged. This leads to the formation of higher number of effective nuclei and hence fine-grained ferrite is achieved in its microstructure.
2. The carbon content of ferrite will be higher than that in the annealed samples. This is due to the fact that a fast cooling provides less time for diffusion of carbon. Hence equilibrium is not attained. This retains more carbon in ferrite.
3. The amount of ferrite is less than that in the annealed sample owing principally to less time available for the formation of proeutectoid ferrite, which is a diffusional process and is time dependent.
4. The amount of pearlite is higher than the annealed sample.
5. The colony size of pearlite is less than that in annealed sample because a lower transformation temperature aids in formation of higher number of pearlite nuclei.
6. The interlameller spacing of pearlite is smaller in normalized steel sample than that in annealed sample. The changes in the microstructures are shown in **Figures 35(a)** and **35(b)**.

Each of the above changes in microstructure is brought about by faster cooling in normalizing; this results in enhancement of strength and toughness. Thus normalized component is always stronger and tougher than the annealed component. The difference between the properties of annealed and normalized steels are furnished in **Table 1**.

2.1.7 Hardening

Hardening is the heat treatment process by which the hardness and hence the strength of a material is increased. Different types of hardening processes are employed in different situations. There are cases of age hardening where the material is heated to get a homogeneous single phase solid solution which is cooled very fast from the high temperature and in the process a supersaturated solid solution is obtained. The super saturation is relieved by precipitation of solute-rich phase mostly in certain sequences where coherent GP zone formation is followed by a series of precipitate formation; the precipitates in their initial stages of formation are either coherent or semicoherent with the matrix. Equilibrium incoherent precipitate is

formed only at later stages. The process is halted before that and the coherent or semi-coherent metastable phases give rise to precipitation hardening through dislocation particle interaction. Many aluminum alloys harden by such age-hardening treatment. So hardening in such situation is a quench-aging process. There are many single phase systems like austenitic stainless or aluminum magnesium alloys which cannot be hardened by any method other than cold working where dislocation density created due to cold working without recrystallization hardens the material. This is a typical work hardening process. More discussion on the heat treatment of nonferrous systems are narrated in later section.

However in case of steels, hardening is possible by quench-hardening means; in this case rapid cooling of homogeneous

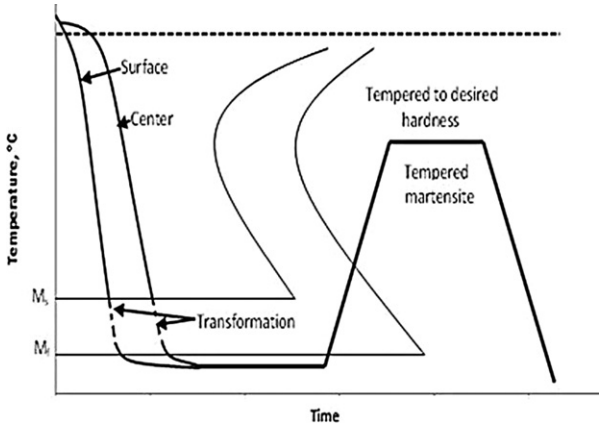

Figure 36 Diagram showing the hardening and tempering of euctectoid steel.

austenite leads to the formation of martensites as discussed earlier. This martensite is very hard in steel. So hardening in steel is a typical quench-hardening process. In this process the steel is heated to austenitization temperature; the temperature up to which the steel is to be heated is also decided by whether a homogeneous austenite can be achieved in reasonable period of holding or not. Normally, for hypoeutectoid steel the heating temperature is 50 °C above A_3 temperature and that for eutectoid steel it is 50 °C above A_1 temperature. From this high holding temperature, the steel sample is quenched at a rapid rate. The rate of cooling which is to be applied without formation of quench crack is judiciously decided as it is dependent on the composition of the steel. The severity of quench of individual cooling medium is different and the steel under hardening is cooled from high temperature in water, oil, air, or molten salt baths. The process of hardening is schematically shown in **Figure 36**.

The hardening process thus consists of three steps: First step is the production of homogeneous austenite in hypoeutectoid and eutectoid steel while austenite plus undissolved carbide in case of hypereutectoid steel. The heating temperature may range from a very high magnitude for alloy steel ~1200 °C to quite a low value like 750 °C for hypereutectoid steel. For hypoeutectoid and eutectoid carbon steels it varies between

780 and 880 °C. The heating is followed by holding for predetermined time for dissolution of carbide and production of homogeneous austenite; in case of hypereutectoid steel, however, undissolved carbide is deliberately kept in the microstructures for reasons stated earlier. Finally, the workpiece is cooled at a cooling rate that produces martensitic structure with minimum residual stress. The heat treatment is required to be carried out in a protective atmosphere so that chemical degradation due to decarburization can be avoided as far as practicable. Cooling is performed in different media viz. water, saline water, hardening oils, polymers, salt bath, and nitrogen or argon gas. Individual cooling medium has its own characteristic advantages and disadvantages; however, salt bath quenching reduces chemical degradation as well as minimizes the chance of warpage due to fact that the objects immersed in liquid bath experiences Pascal pressure which is same along all directions. Moreover the inert gas quenching like nitrogen or argon minimizes oxidation and decarburization. The hardened steel is extremely brittle and cannot be put to use unless it is toughened suitably.

Thus the salient features of hardening of steels are:

1. Selection of proper quenching medium should be made so that thermal stresses can be kept to minimum.
2. Alloy steels having high hardenability and low CCR should be subjected to air cooling to avoid warpage or cracking.
3. High carbon steels have slightly higher CCR and has to be hardened by oil quenching.
4. Medium carbon steels with relatively high CCR may require judicious selection of quenching medium; many a time oil quenching or polymer quenching is preferred to avoid heat treatment defects.

2.1.7.1 Factors Influencing Hardening Process

The hardening process of steel is appreciably influenced by the following:

2.1.7.1.1 Adequate carbon content to produce hardening

As stated earlier the alloying elements with the exception of Co and Al depress the martensite reaction temperatures and carbon exerts the strongest effect to lower both M_s and M_f temperatures. As shown in Figure 37, carbon in excess of 0.7 wt.%C lowers the M_f temperature to below room temperature and so, higher carbon steels quenched into water often contain appreciable amounts of retained austenite in the microstructure.

2.1.7.1.2 Austenite decomposition to produce pearlite, bainite, and martensite structures

Steels must have adequate hardenability to avoid soft pearlitic transformation for producing fully martensitic structure throughout the section. For this purpose, the alloying elements having good ability to shift TTT or CCT diagrams toward right are often added in steels, meant for quench hardening. The microstructure of hardened steel containing martensite and some retained austenite is shown in Figure 38. During martensitic transformation some austenite remains untransformed. The amount of retained austenite depends upon the chemical composition, cooling rate, and mechanical treatment. Stabilization of austenite in quenched steel is discussed in subsequent section.

Another way of forming martensite is by fast cooling in the softer region, i.e., the pearlitic and the bainitic region and then

Figure 38 Microstructure showing martensite.

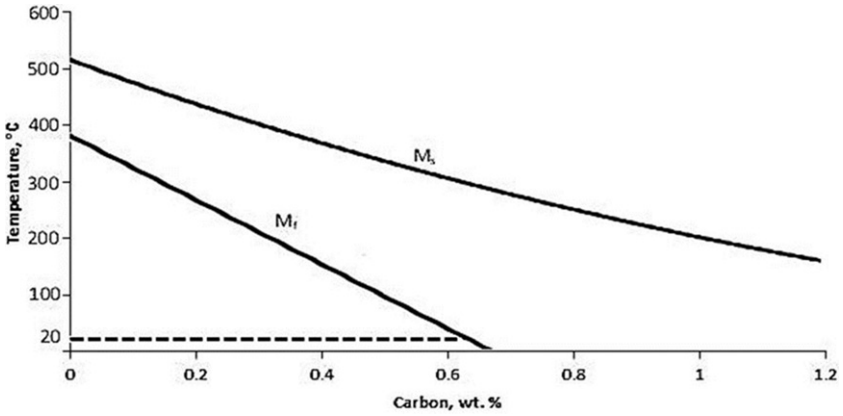

Figure 37 Carbon content vs. martensite start (M_s) and martensite finish (M_f) temperatures in unalloyed steels.

a comparatively slow cooling rate can be employed to produce martensite.

2.1.7.1.3 Temperature of heating, rate of heating, and the time of holding

2.1.7.1.3.1 Temperature

Proper selection of temperature is essential for successful hardening operation. For hypereutectoid steels the heating is done below the A_{cm} line, has the unique benefit of retention of undissolved cementite in the microstructure which apart from inhibiting grain growth provides high wear resistance to the heat-treated parts.

2.1.7.1.3.2 Heating rate and soaking time

The heating rate is so selected that there should not be any decarburization or grain growth. For this the heating is done in steps. For an example heating to 800 °C and soaking for some time to homogenize the structure and then heating the material rapidly to the peak temperature; this process necessitates a low soaking period at the high austenitizing temperature. This leads to complete homogenization of austenite without appreciable grain growth. The soaking period and heating rate depend on the size and shape of the part being heat treated.

In order to avoid defects due to hardening of steels the following guidelines are useful:

- The properties required in the heat-treated part are obtained without the parts being distorted beyond acceptable limits.
- The ideal design for a heat treatable part should be such as to attain the same temperature at its every point with minimal chances of abrupt change in thermal stresses. This necessitates the avoidance of abrupt change in the section sizes.
- Long thin parts like connecting rods should be as symmetrical as possible to reduce stresses.
- The holes in a part should be kept centered such that metallic mass around these holes are nearly same; this insures balanced mass around and hence less chance of cracking.
- The internal corners in a part should be provided sufficient fillets and regions prone to lead to stress concentration should be avoided.

2.1.8 Heat Treatment Fundamentals of Nonferrous Alloys

A variety of heat treatment processes are practiced to control the structure and properties of nonferrous alloys. Most of these processes have their characteristics features that are common to the alloys undergoing such treatment; the general principles of individual processes adopted for heat treating nonferrous alloys are briefly reviewed in this section.

2.1.8.1 Age-Hardening Treatment

A number of nonferrous alloys exhibit sloping solvus in their phase diagrams. This makes the concerned alloys amenable to age hardening; age hardening is the heat treatment that envisages formation of a single phase by heating the alloy to a high temperature which insures complete dissolution of second phase particles. Upon being quenched to room temperature the solid becomes supersaturated with respect to solute concentration. Supersaturation is a state of thermodynamic instability and hence the system becomes prone to be relieved of supersaturation through what is called precipitation.

However a homogenous solid solution becomes heterogeneous if it is cooled rapidly from a high temperature to the room temperature. All quenched alloys contain vacancies in excess of equilibrium number. The presence of excess vacancies entices the solute atoms for small-scale migration. This has the implication that perceptible chemical heterogeneity is created in a local scale. If the composition of the alloy lies within its spinodal points, the alloy decomposes spontaneously without regard to chemical potential barrier. This fine scale solute-rich region created within the system is known zone, more customarily Guinier–Preston (GP) zones. The aging sequence in age-hardening alloys can be obtained in text books on light alloys and in *ASM Metal Hand Book Volume 4*.[14]

Quite often the heat treatment cycle is so designed as to maximize the density of GP zones by a low temperature aging treatment just after solutionizing followed by quenching. Following this, a second step of aging treatment is carried out at a high temperature. The preexisting GP zones dissolve (above GP solvus) and give way to the formation of a series intermediate precipitates which are mostly coherent or semicoherent with the matrix. The first step of aging at low temperature (below GP solvus) is called natural aging and the aging at temperatures above GP solvus is known as artificial aging. The overall aging process is referred to as duplex aging; duplex aging has the advantage of achieving precipitates of varying sizes which when suitably designed may lead to the formation of duplex precipitate structure which is extremely beneficial in simultaneous improvement of both yield strength and fracture toughness of the heat-treated alloy. It is to be noted that during artificial aging a series of metastable phases are formed and the formation of equilibrium precipitate may not even occurs in many cases.

A few nonferrous alloys exhibit precipitation hardening behavior due to the formation of fine coherent precipitates of the intermetallics during aging. In this way it resembles aging in maraging steel where coherent precipitates of types Ni_3Mo, Ni_3Al are formed. Cu–7.5Ni–1.5Si–1.2Cr is one such alloy in which the quenched-aged microstructure exhibits nanometer scale precipitates of β-Ni_3Si and δ-Ni_2Si.[15] However it may be noted that when transition metals like chromium is alloyed with a full metal like copper, the as solidified alloys are normally heterogeneous with preferential segregation of chromium.[16] In conventionally cast alloys the microstructure exhibits large chromium rich phases. The segregation of chromium in as cast condition is ascribed to high Chromium–Chromium coordination in the liquid state due to differential mobility of the solute and solvent atoms at the conventional temperature of molten alloy.[16] This type of micro-segregation is the main reason why these alloys containing appreciable amount of chromium is solution treated for as long a time as 10 h at high temperatures like 970 °C. In this connection special mention must be made of nickel-based superalloys like Inconel, Hastalloy, Nimonic, Udimet, and Waspalloy which are subjected to quench and aging heat treatment, where diffusion of solute atoms plays a vital role. These superalloys need to possess high creep resistance and hence its microstructure should be such

that it is not only very hard at room temperature but also can retain its hardness at high temperature. Hard refractory compounds embedded in strong and tough matrix enable the material to attain good high temperature strength. Thus all the superalloys are dispersion-strengthened and or precipitation-hardened alloy. Since these superalloys contains refractory elements like Mo, W, Cr along with some carbon and alloying elements the hardened phase are generally intermetallic compounds and carbides of refractory material.[17–19] The diffusion of these high melting refractory metals are very sluggish at the average tempering temperature of 600–700 °C unless it is aged for a prolonged period of time. A long holding time at the aging temperature makes it possible to precipitate all the solute atoms in the form of refractory intermetallics or carbides.

A sloping solvus in equilibrium diagram of a system is a necessary but not sufficient condition for any alloy system to be age hardenable. Example may be cited of Al–Mg system which possesses a sloping solvus in its equilibrium diagram, but does not exhibit age hardening. It is postulated that GP zones are not formed in Al–6Mg alloy due to GP solvus lying below room temperature and that the alloy in solidified condition contains coarse Mg_2Al_3-type intermetallic. However it is found that trace additions of different elements in several nonferrous alloys impact their aging response quite significantly.[20–23] Different trace element additions exert different types of effects. Some trace additions in some systems stimulate formation of GP zones; for example, addition of silver in Al–Mg alloy leads to formation of GP zones in the alloy; it is not certain if these zones are magnesium atom dominated zones or are of the same type of zones as is known to form in binary Al–Ag alloys. Al–Ag alloy forms spherical GP zones; hence the possibility that stimulation in GP zone formation in Al–Mg alloy is due to silver rich GP zone formation cannot be over ruled. On the contrary minor addition of scandium leads to very prominent age-hardening effect in Al–6Mg alloy.[24,25] Scandium in aluminum forms Al_3Sc precipitates and strengthens the alloy. Recent investigation through position annihilation and coincidence Doppler boundary spectroscopy has confirmed that GP zones are not formed in Al–Mg (Sc) alloy even though it shows excellent age-hardening behavior.[26,27] It implies that for precipitation hardening to take place, the formation of GP zone is not mandatory (**Figure 39**).

Moreover, the observation that scandium treated Al–Mg alloys age harden but do not form GP zones while silver added Al–Mg alloy records GP zone formation, raises a doubt on the common belief that binary Al–Mg alloy does not exhibit age hardening because its GP solvus lies below room temperature. There is another class of alloys which have the sloping solvus in their phase diagrams but are nonresponsive to age hardening due to quench sensitiveness. The ideal example of this class is aluminum – transition metal alloys viz. Al–Cr alloy which is highly quench sensitive. These alloys are highly prone to form coarse intermetallics in microstructure and do not exhibit age hardening in general.[28] It is surmised that density difference between solvent and solute leads to prevalence of biased neighboring of like atoms. Treating these alloys with rare earth elements makes the liquid alloy more homogenous and as a result homogenous supersaturated solid solution is likely to form after solutionizing treatment followed by rapid quenching. It is further demonstrated that the alloys which

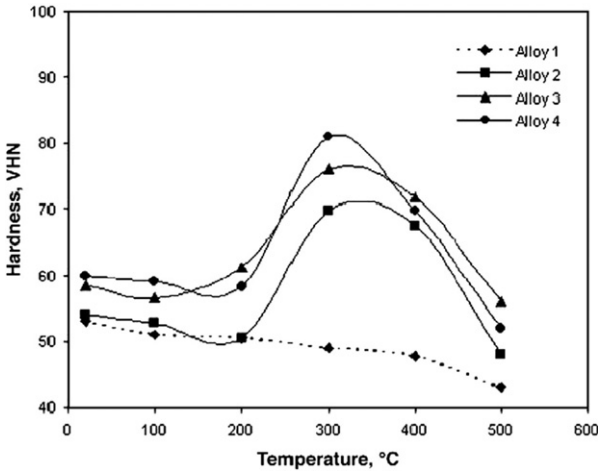

Figure 39 Age-hardening curves of Al–6Mg alloy containing 0.2, 0.4, 0.6 wt.%Sc. Dotted curve is for the base alloy.[19]

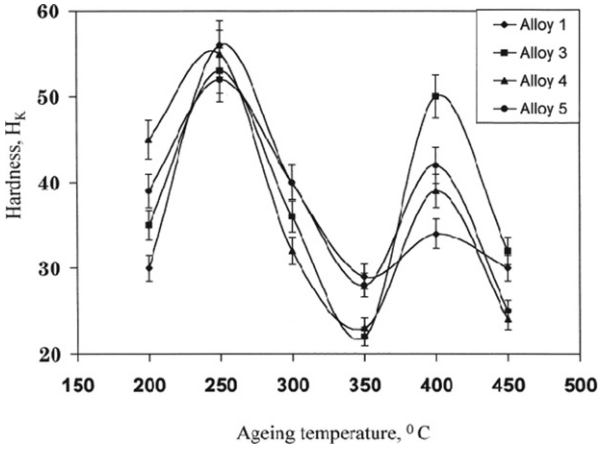

Figure 40 Variation of hardness with aging temperature for cold-worked Al–Cr (Zr) with trace rare earth addition.[23]

become responsive to age hardening due to trace addition are those for which cold-working accentuates age hardening. The aging curves in **Figure 40** demonstrate that cold-worked Al–Cr alloy is highly age hardenable even though it is otherwise a quench sensitive alloy. It is described earlier[28] that the first peak is due to the formation of $CrAl_7$ phase which is the chief hardening phase. At high temperature the $CrAl_7$ phase dissolves and the new precipitate of Cr_2Al_{11} appears. The volume fraction of this precipitate is less due to paucity of flux of chromium atoms against the need to form higher aluminizes, Cr_2Al_{11}. Also recrystallization takes place partially due to high temperature aging and so, the number of dislocations available as nucleation sites for Cr_2Al_{11} becomes quite low. As a result the extent of age hardening is less after geeing at 350 °C.

Quench-sensitive alloy contains coarse insoluble in its quenched state (**Figure 41**). The incoherent insoluble – matrix interface acts as the sink for vacancy annihilation. As a result, availability of vacancy in its quenched structure is limited. So solute diffusion becomes restricted; neither GP zone formation nor formation of intermetallic precipitate is encouraged.

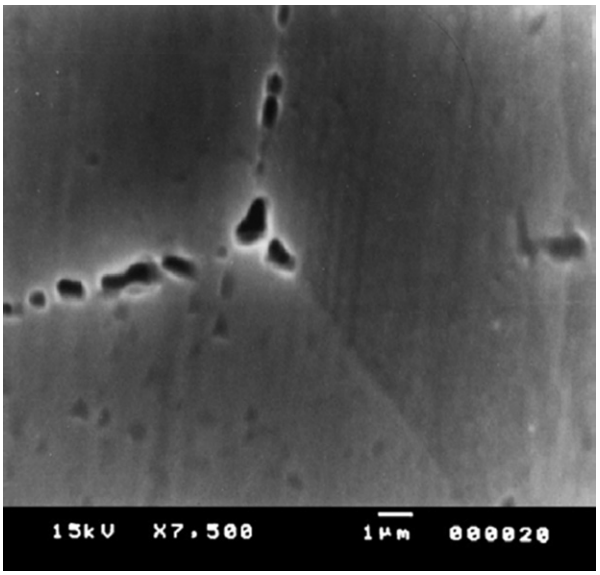

Figure 41 SEM micrograph of Al–6Mg–0.6Sc alloy.[19]

It is known that precipitation phenomenon involves long-range transport of atoms. Cold-worked alloy provides dislocations as the nucleation sites for precipitates and punched out vacancies from dislocations also make solute diffusion easy thereby aiding in precipitate formation in many quench sensitive systems.[29] However dislocation-induced precipitation is not generic of age-hardening alloy systems. Vacancy solute atom complex formation and its easy transportation to nucleation sites is the chief controlling factor of precipitation of Al_3Sc in Al–6Mg (Sc) alloy. This alloy does show any benefit in aging response after cold working following quenching.

2.1.8.2 Annealing of Nonferrous Alloys

The other common heat treatment processes applied to nonferrous alloys are homogenizing, conventional annealing and stress reliving. For example, many copper alloys are single phase solid solution and therefore can be heat treated only by the above mentioned processes.

In general the alloy castings are subjected to homogenization annealing heat treatment by heating the cast alloys to a high temperature where rapid diffusion of substitutional solute atoms is possible. The selected temperature should not be so high as to promote unwarranted grain growth. The alloy like Cu–Sn which shows a wide gap between solidus and liquidus temperature is prone to coring or micro-segregation. These alloys are normally homogenized at high temperature.

In order to relieve internal stresses and to restore the original structure and properties that are affected during cold working, the nonferrous alloys are subjected to recrystallization annealing as usual. High solute alloy like α brass are recrystallization annealed appreciably above the recrystallization temperature to assist diffusion of solute atoms. Stress relieving annealing treatment of nonferrous alloys is carried out as usual to relieve internal residual stresses those are introduced during the welding, brazing, casting, machining, or the fabrication processes. Stress relieving treatment may also be carried out for the purpose of securing partial recovery in cold drawn alloys. When extremely deformed alloys are subjected to low temperature annealing treatment, point defects are eliminated in particular and the excess lattice defects in general. Such stress equalizing treatment as it is called, is commonly practiced in the case of cold-worked Monel alloys by annealing it at 300 °C. Sometimes propensity to stress corrosion cracking as in the season cracking of α brass (>15 wt.%Zn) is minimized by annealing the cold-worked material below recrystallization temperature. This retains strain-hardening effect with some loss in hardness. In this condition, the strain-hardened components do not get softened. However some hardness drop inevitably accompanies this process.

Figure 42 Self accommodating thermoelastic martensite in Cu–Zn–Al alloy.[27]

2.1.8.3 Martesite Formation in Nonferrous Alloys

Although many nonferrous alloys including α–β brass are strengthened by precipitation hardening, copper zinc alloys are not always meant for precipitation hardening. Ternary addition of aluminum in Cu–Zn alloys produces thermoelastic martensite,[30–33] capable of exhibiting shape memory effect (Figure 42). If the alloy is deformed in martensitic state to assume a different shape, the high temperature shape can be regained by the original article upon being heated beyond a certain temperature, called recovery temperature.

When Cu–xZn–yAl or Cu–xAl–yNi is quenched from high temperature in β-phase field, martensites are formed. These martensites are very soft and are amenable to shape change with the application of small force.

The volume change 'ΔV' accompanying martensitic transformation is quite small and the lattice invariant deformation mode is either twin or stacking faults (Figure 43).

The reversible internal faults enable the reverse transformation of martensite to parent phase to take the same path as that of the forward transformation (β-M). The inherent reversibility characteristics of martensitic transformation in Cu–Zn–Al and Cu–Al–Ni alloy are envisaged due to low thermal hysteresis.[34–37]

The repetitive use of these shape memory alloys exhibit degradation in shape memory behavior due to cumulative

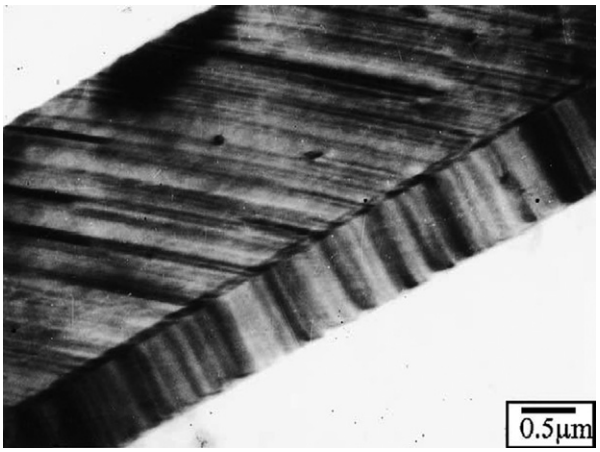

Figure 43 Internal twins in Cu–Zn–Al shape memory alloy with trace Zr add.[26]

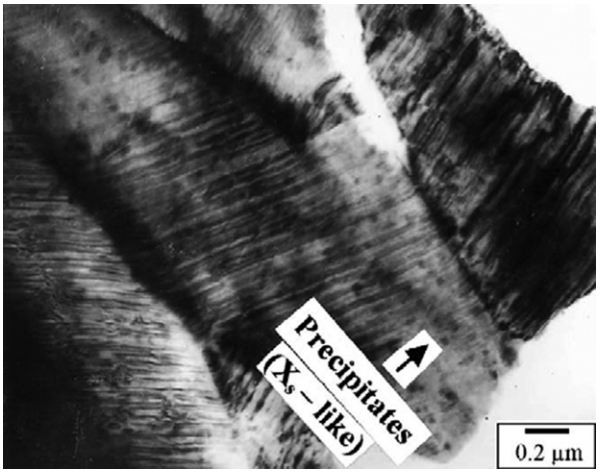

Figure 44 Microstructure of Cu–Zn–Al (Ti) alloy showing fine precipitates after repeated shape memory cycling.[32]

aging effect. Repetitive shape recovery cycling leads to precipitation of inter metallic compounds on to the twin boundaries and make them immobile. Thus de-twinning during reverse transformation is inhibited thereby, resulting in a loss of shape memory effect.[38,39] The effect of aging precipitates on the SME is elaborately studied elsewhere.[40,41] Excepting a few cases, formation of precipitates due to aging, in general degrade shape memory behavior, with concurrent rise in hardness (**Figure 44**).

In view of apparent differences in heat treatment of some technologically important nonferrous systems, a brief review of fundamentals underlying principles of heat treating a few such systems is done in the following paragraphs.

2.1.8.3.1 Heat-treat principles of nonferrous alloys exhibiting polymorphic transition

Unlike aluminum, copper or nickel, titanium undergoes polymorphic transition at 882.5 °C; high temperature β-phase is BCC and this phase undergoes phase transition through formation of hcp α below the transition temperature. This makes it possible to produce α, β, or $\alpha+\beta$ alloy of titanium. Therefore evolution of different kinds of phases due to various types phase transformations accompanying heat treatment of titanium alloys is noticed. This enables to achieve specified set of properties in titanium alloys suiting the needs of target applications.[42–45] Being low temperature single phase system, α-alloys are generally cold worked and annealed to achieve grain refinement while it is in fully α-phase state. However if fully 'α' alloy is quenched from β-phase field, α' martensite may form, with very little change in properties. Similar to many ferrous and nonferrous systems a relatively slower cooling from β-phase field (say air cooling) produces Widmanstatten α with a consequent deterioration in fatigue strength. If α-alloy of approximate composition, Ti–11Sn–2.25Al–5Zr–1Mo–0.2Si is equilibrated at temperature within $\alpha+\beta$-phase field, evolution of microstructure takes place in the same way as in duplex ferrite–martensite steel. When the alloy is annealed at 900 °C within $\alpha+\beta$-phase field and then cooled fast, the β-phase transforms to α' martensite; on the contrary a relatively slow cooling like air cooling produces fine equiaxed primary α and Widmanstatten α obtained from β.

In α/β-alloys several heat treatment processes may be adopted. The most common α/β-alloy is Ti–6Al–4V alloy. In such α/β-alloy 4–6% β-stabilizing (V) elements are added to retain some β even after quenching from β- or $\alpha+\beta$-phase.[46–48] Annealing of the alloy can be done from β-phase field as well as from $\alpha+\beta$-phase field. When it is annealed at β-phase and then cooled to room temperature, Widmanstatten 'α' is formed in a β-matrix or β may partially or wholly transform to α' martensite depending upon the cooling rate. When annealed from $\alpha+\beta$-phase field the microstructure consists of equiaxed α and transformed β. Transformed β may be Widmanstatten 'α' or α'. The strength of annealed alloy increases with increasing alloy content.

β-quenching: the α/β-alloy may be betatised at elevated temperature, where single phase β is present. The β-phase is then quenched. In case of dilute alloy, β may convert to α' (hcp) martensite; α' martensite may finally convert to lath martensite α'' or twinned martensite α'''. However in a concentrated alloy 'β' phase is retained as metastable 'β' which is then subjected to aging heat treatment as is done in a typical precipitation-hardened stainless steel. In dilute alloys β-phase may directly convert to laths of orthorhombic α' to α'' martensite and face-centered orthorhombic α''' martensite. The transition from α' martensite to α'' martensite takes place with increasing solute content. Thus,

$\beta \rightarrow \alpha''$ with retained β

i.e., $\beta \rightarrow \beta_{(\text{lean})} + \beta_{(\text{rich})} \rightarrow \alpha'' + \beta_{(\text{rich})}$

When the alloy is very rich in β-stabilizing elements, a fast quenching from β-phase field may give rise to metastable β. Aging of metastable β decomposes differently at different temperature regime.

In a medium alloy aged within 100–500 °C $\beta_{(\text{metastable})} \rightarrow \beta + \omega \rightarrow \beta + \alpha$

In concentrated alloy β metastable $\rightarrow \beta + \beta_1 \rightarrow \beta + \alpha$

ω-phase leads to severe embrittlement of the alloys. Formation of ω-phase takes place through displacive mode of transformation; ω particles are cuboidal and maintain specific orientation relationship with β-phase.

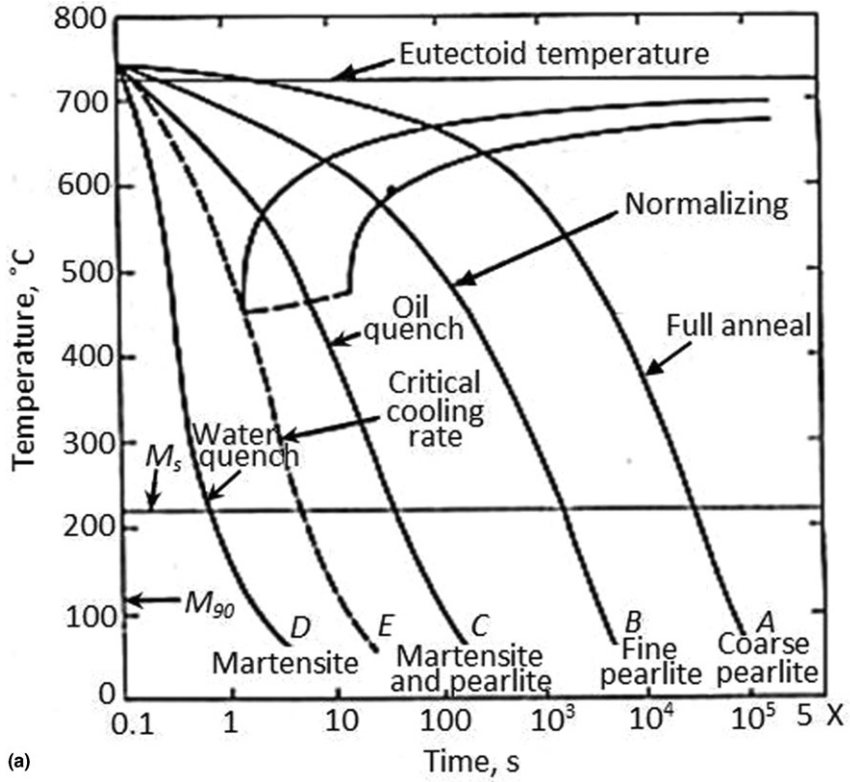
Within the group of β-alloys, a relatively lean solute content produces metastable 'β' upon fast cooling; whereas above a critical value of the concentration of β-stabilizers stable 'β' remains present in the microstructure. The alloys are cold formed and aged to secure high strength.

2.1.8.3.2 Application of heat treatment principles in Mg-alloys

In view of recent interest in commercial use of magnesium alloys due to its advantage of low specific weight, more elaborate discussion is made to know about the heat treatment of Mg-alloys. Cast magnesium alloys are quite often subjected to solutionizing followed by aging. The solutionizing is carried out to attain a single phase from where it is cooled fast to form supersaturated solid solution. The cast alloys show microsegregation and quite often cast magnesium alloys contain intermetallic precipitates of the form AB, AB_2 (laves phase), or CaF_2 (BCC) in the microstructures. Mg–(8–10)Al–0.5Zn–0.3Mn alloys are subjected to natural aging after solutionizing or first solutionizing and then artificial aging to effect intra granular precipitation of magnesium aluminides. On the contrary Mg–(4–6)Zn–0.7Zr (RE) is directly subjected to T_5 tempering, that is artificial aging[49]; this leads to the formation of Mg_2Zn type precipitates. In general, magnesium alloys form three different types of precipitates. These precipitates form at grain boundaries if the alloys are cooled at moderate cooling rate as in sand casting. In order to improve strength and corrosion behavior of magnesium alloys, it is required that these intergranular precipitates are dissolved during solutionizing heat treatment. Subsequent aging to form intragranular precipitates of intermetallic phases gives rise to significant improvement in mechanical and mechano-chemical properties. A large number of magnesium alloys are precipitation hardenable; the precipitate phases forming in different magnesium alloys with their precipitation sequences in furnished in the **Table 2**.

In observance of the aging sequence in important magnesium alloys, it may be understood that most of these alloys are subjected to age-hardening heat treatment and in most of the cases combined T_4 and T_6 is recommended so that a duplex precipitates structure may result in the microstructure. In Mg–RE system, maximum strengthening is obtained due to the formation of β'' phase which exhibits DO_{19} ordering. But aging at higher temperature till 250 °C leads to loss of coherency and the semi-coherent β'-phase with hcp structure forms, mainly on to the existing dislocation. This drastically reduces creep resistance. Solution treatment temperature for this alloy is judiciously selected and is normally around 420–450 °C for most of the commercially important alloys because it can avoid both grain coarsening and chemical degradation.

2.1.9 Quenching and Quenching Medium



In case of age hardening the supersaturation is relieved by fine-scale precipitation through a definite sequence. However the alloy becomes hardest at particular time and temperature of aging. As stated earlier in case of the Fe–Fe_3C system the supersaturated solid solution is the strongest phase but is extremely brittle. Heating it to some elevated temperature below A_1 temperature decomposes the supersaturated solid solution leading to ductilization of the alloy. As in contrast with the previously stated age-hardening phenomena, the decomposition of the alloy leads to toughening of the alloy. As described earlier hardening of steel is conditioned by a CCR as defined earlier. It is to be further noted that whether the cooling rate offered by a particular cooling medium is able to give rise to the formation of 100% martensite throughout the section or not depends upon the section size of the stock being cooled.

Figure 45(a) shows the effect of various cooling medium on a round-eutectoid steel bar. It is apparent that water having more severity of quench can bypass the nose of CCT diagram up to a greater depth then oil and air of lower severity of quench. Hence to gain idea about the inherent ability of a material to avoid soft pearlitic transformation, it is required to alleviate with the influence of severity of quench while determining the achievable depth of hardening. This is done by imagining an ideal quenching medium with infinite severity of quench.

By definition the ideal quenching medium will take away the heat from the surface at the same rate as it flows to the surface from inside the bar which is being quenched. The cooling efficiency of the usual quenching media such as water, oil, brine, etc., relates with that of the ideal quenching medium. If round bars of varying diameters are quenched in a medium from an austenitizing temperature, there will be a particular diameter of which 50% martensite and 50% pearlite will be formed at the center. Conventionally this diameter is called critical diameter and is usually taken as the measure of hardenability. It must be noted that reckoning hardenability of steel on the basis of existence of 50% martensite and 50% pearlite in the structure is not mandatory. Depending upon the design requirement of steel, on the basis of strength and toughness parameter, it is possible to describe hardenability as the depth up to which 100% martensite is formed; however the classical definition of hardenability, as the depth up to which 50% martensite and 50% pearlite is formed, owes its origin to the easy identification of a structure with 50% martensite and 50% pearlite. The fracture of such a material will show a transition from ductile to brittle type and a plot of hardness versus the depth from the center shows a point of

Table 2 Heat treatment of Mg-alloys

System	*Precipitates process*
Mg–Al	SSSS → BCC equilibrium precipitate $Mg_{17}Al_{12}$ (β-phase) with $(011)_\beta$//(0002)Mg and faceted with lath morphology
Mg–Zn–(Cu)	SSSS → GP zone (coherent, disk) → $MgZn_2$ (rods, coherent) → $MgZn_2$ (disk, semi-coherent) → Mg_2Zn_3 (incoherent)
Mg–RE	SSSS → GP zone (coherent, disk) → β'' Mg_xNd ($x>1$) (Do_{19} ordered) → β' Mg_3Nd (semi-coherent) → $Mg_{12}Nd$ (incoherent)
Mg–Y–Nd	SSSS → β'', Mg_3Nd, GP zone rods coherent Do_{19} → β' $Mg_{12}NdY$ globular + β_1 (plates) $Mg_3(NdY)$ FCC → incoherent $Mg_{14}Nd_2Y$ FCC

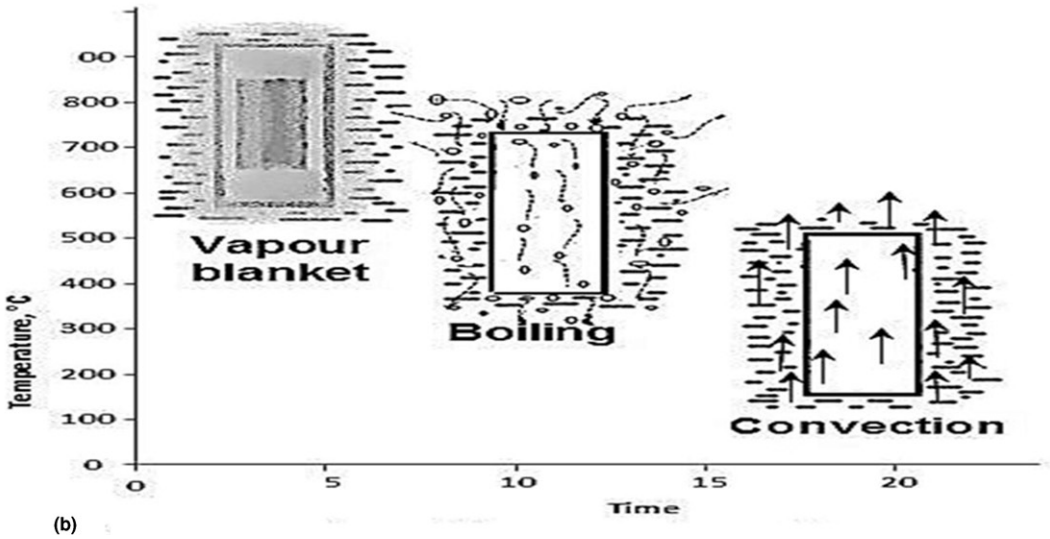

Figure 45 (a) Effect of cooling medium on microstructure evolution in eutectoid steel and (b) different stages in quenching.

inflexion denoting the change in curvature from positive to negative. As stated earlier hardenability is an inherent material property measuring the depth up to which the material can be hardened with a predefined percentage of martensite in the microstructure. The critical diameter of steel for a definite quenching medium of a particular H-value can be made co-related to the ideal critical diameter quenched in an ideal quenching medium (the details of hardenability of steel and methods for its determination can be obtained from physical metallurgy books of steel).

Once hardenability is defined as the depth to which a definite percentage of martensite can be formed, it becomes obvious that all the factors which delay the diffusional decomposition of austenite will improve hardenability. If austenite grain size is large, the nucleation sites for pearlite formation will decrease and hence CCT diagram will shift more toward right, thereby increasing the hardenability. Likewise all alloying elements except cobalt shift the CCT diagram to right and improve hardenability. However individual alloying elements has characteristic influence on degree

of shift of CCT diagram and so a multiplying factor is assigned for each alloying elements to describe the quantitative effect of individual element in increasing the hardenability of steel. From the forgoing discussion it is clear that the microstructure in continuously cooled steel depends on the cooling media employed for the concerned material.

During the cooling operation, a hot object is immersed in a quenching medium – this is a complex process consisting of two major stages:

- Stage 1: vapor blanket stage

  The temperature at the surface of the stock is initially very high and so the cooling medium gets vaporized and forms a thin layer of vapor around the immersed part. Under such circumstances the mode of heat transfer is radiation through vapor blanket which acts as insulating layer. This insulating layer puts a restraint to rapid flow of heat and hence cooling of the object. Thickness of vapor blanket around the object is determined by the quenching efficiency of the medium. The duration up to which this vapor blanket stage prevails around the object is different for different quenching medium. It further depends upon the ratio of the weight of object being heat treated and that of the quenching medium being used. Further the specific surface area and the distance between any two object put inside the quenching media also influence the vapor blanket stage. **Figure 45(b)** shows the formation of vapor blanket around the bar.
- Stage 2: the boiling stage

  In the course of cooling, the temperature at the surface of the stock becomes low enough to reduce the rate of radiation, resulting in the loss of vapor blanket stability. The disappearance of vapor blanket at any region around the object will immediately supply liquid to come in contact with the hot surface of the object. The liquid start boiling and the bubbles emanated thereof create turbulence near to the metal surface; this enhances the rate of heat extraction. Since the quenching media have high latent heat of vaporization, the boiling stage experiences the fastest cooling of the object. After the lapse of some more time with continued heat extraction from the surface of the stock, the temperature at the surface goes down below the boiling temperature of the quenching media. Boiling stops and the mode of heat transfer at this stage becomes only convection. Thus the rate of cooling continues to reduce with falling temperature of the quenching medium. It is important to note that the progressive lowering of temperature of the heat-treated stock and hence that of the liquid surrounding the object leads to increase in the viscosity of cooling medium; this reduces the rate of convection and hence the cooling rate. These stages of quenching are shown in **Figure 45(b)**.

Because of the fact that the thermal property of the liquid is a function of temperature, rate of cooling by any quenching medium would automatically depend upon its temperature dependent thermal properties. Qualitative information on commonly used commercial quenching media is provided in **Figure 46**.

From **Figure 46** it appears that the major feature of water quenching is defined by the extended vapor blanket stage over a wide range of temperature. Its implication is that the cooling rate at the initial stage where diffusional decomposition of austenite is supposed to takes place is rather slow. Thus the formation of diffusional decomposition product takes place with nonuniformity. The cooling capacity is of water at high temperature is sharply reduced and with increase of temperature of water the vapor blanket stage extended. This gives rise to a very nonuniform cooling rate at high temperature region, while quenching in water. The curve further shows that water offers its maximum cooling rate at a temperature between 250 and 300 °C which belongs to the temperature range of martensite transformation in many commercially important steels. The high cooling rates within Ms–M_f range is a great concern for distortion, warpage, and even quench cracks. It may be noted that increasing the temperature of water cannot solve the problem by the way of reducing the rate of cooling during martensite transformation. On the contrary increased

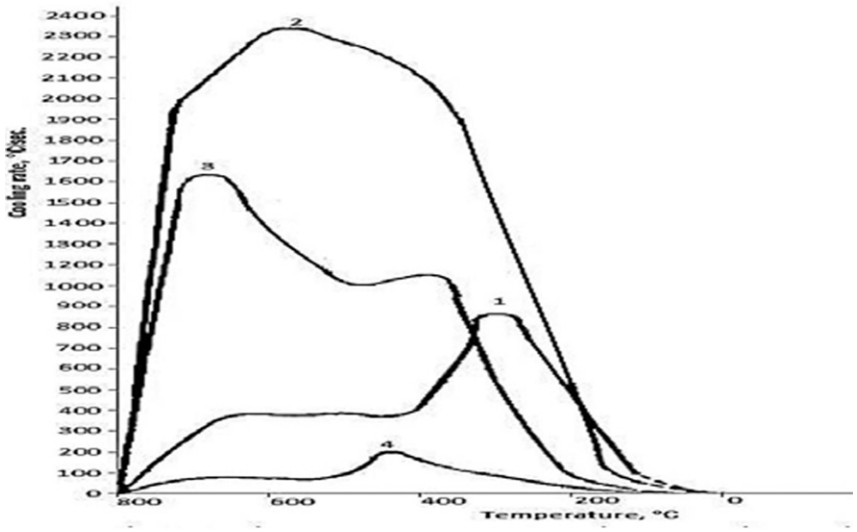

Figure 46 Cooling rate vs. temperature for various quenching media 1-H_2O; 2-H_2O + 10%NaCl; 3-H_2O + 50%NaCl.

water temperature may increase the cooling rate at certain temperature. That is why quench cracks are frequently observed in case of quenching of steel in hot water. In contrast a brine solution containing 10% NaCl in water appreciably changes the situation; the cooling capacity is increased to a high value even with exclusion of first stage of cooling, i.e., the vapor blanket stage. Moreover the cooling by brine solution is found to be uniform, although it is expected to decrease with decrease in temperature. Because of high cooling rate at high temperature where a vapor blanket is expected to form, the temperature of the metal surface decreases fast; this causes the vapor blanket to become unstable and gets destroyed right at the initial stage of cooling. Moreover, the NaCl salt spalling out may accentuate the destruction of vapor blankets. The brine solution is known to be relatively less responsive to heating. Moreover the cooling rate within the M_s–M_f range can be brought down to low value by the use of concentrated brine solution, 40% NaOH in water is a very good quenching medium which greatly minimizes the warpage and ensure a clean surface after heat treatment. Unlike brine solution, NaOH in water is a rapidly degradable quenching medium. This absorbs CO_2 from air and loses its properties within a day or so. The low cooling rate between M_s and M_f range is an important consideration in the evaluation of efficacy of quenching medium. A fast cooling down to M_f temperature induces high thermal stress, also called macro-stress. Micro-stress due to martensite transformation is quite severe and is to be inevitably developed during martensite formation. Therefore a slow cooling rate within the M_s–M_f temperature range is always advantageous in terms of reduction in cumulative stresses developed in the quenched stock. Examples may be cited of a solution of 5% $KMnO_4$ with 3% glycerin in water which decreases the cooling rate in the martensite transformation region to a significant extent. On the average this is around 50 °C s^{-1} as against 600 °C with pure water and 100 °C in water with 50% NaOH.

The other important quenching medium is considered to be mineral oil which has a number of advantages over water as a quenching medium.

- Boiling point of quenching oil is around 250 °C and this mineral oil provides a very low cooling rate within the M_s–M_f range. At a temperature around 200 °C the cooling rate provided by the oil is at least 25% less than that provided by water. As evident from **Figure 46**, the rate of cooling provided by the oil remains more or less unchanged from 150 °C to room temperature.
- However the oil quenching provides a low cooling rate in the intermediate range of transformation temperature, where austenite decomposes in to pearlite. Thus the effective hardenability significantly decreases due to oil quenching.
- Most of the commercial quenching oil is highly inflammable and its flash point is around 128 °C. However oil with higher flash point around 170 °C is also available in the market.
- The cooling rate provided by the oil is rather small at low temperature. Oil preheated to 80 °C provides good fluidity of oil, so that effective convection occurs. Being well below the flash point of oil at 80 °C does not set to fire and continuously provide a slow cooling rate within the M_s–M_f temperature range and thereby reduces the chance of warpages.
- In the recent time, the new generation steels have been developed which are hardenable by cooling in the still air. The air hardening steels are particularly suitable for minimizing the distortion and warpage as the thermal stress induced during quenching is minimum. Also air–water mixtures at a pressure of 2–3 atmospheric pressure is sometimes used for hardening heavy articles made up of alloy steel and are prone to crack on quenching. On examination of the values of severity of quench for air and oil it would appear that air with low moisture contains is able to provide a cooling rate which is nearly same as oil.
- It is possible to increase the efficiency of hardening alloy steels for water quenching is generally prohibitive due to proneness of quench cracking. A leaner alloy steels, which otherwise cannot avoid the nose of CCT diagram for the entire section, may first be subjected to more severe quenching in water down to the level of 450–400 °C (assuming nose to exist between 500 and 550 °C), and then quickly withdrawing the same from water and quenching it in oil which is quite efficient a quenchant within M_s–M_f range. By this technique it is possible to make use of lower alloying element content in steel yet achieving the same strength and toughness properties.
- Apart from what are stated above, proper immersion of the articles in to quenching medium is very important to avoid warpage and cracking due to hardening. The general recommendation in this regard is that longer articles should be immersed with its main axis perpendicular to the surface of quenching bars. Flats and sheets are immersed on their edges. For a better heat transfer it is advisable to create a relative movement between the article and cooling liquid. The lighter articles should normally be moved along the direction in which they are inserted in to the quenching medium. But the heavy stocks may be held stationary and creating agitation in the quenching bath.

2.1.10 Tempering

As stated earlier the hardened steels with full martensite in microstructure cannot be employed for useful purposes because martensite is extremely brittle; martensite formed by quenching produces high internal stresses in the hardened steel. The hardened steel need be heated to higher temperature to reduce its brittleness; this process is called 'Tempering.'

Tempering is generally carried out by heating the hardened steel to temperatures below A_1; it is held there for some preselected period of time and then followed by cooling to room temperature.

The selection of tempering temperature depends upon the composition of the steel and the final properties desired after tempering; this however depends upon the exact microstructure and the hardness of the component at various points across its section. High carbon and high alloy steels are normally tempered at as high temperature range as 550–650 °C (**Figure 47**). In order to achieve good combination of strength and ductility commensurate with the demands of service

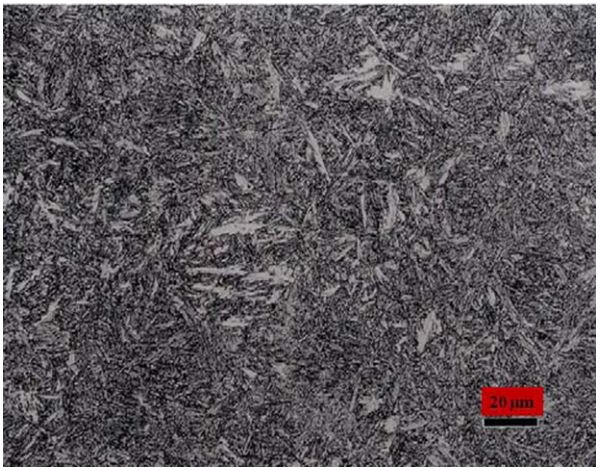

Figure 47 Tempered high carbon plate martensite in 0.9C–0.4Mn steel water quenched from 900 °C and tempered at 538 °C. Courtesy of George Vander Voort, USA.

conditions, proper selection of process parameters for tempering operation is necessary. The concerned process parameters are:

- tempering temperature,
- time to spend at tempering temperature, and
- cooling rate from the tempering temperature.

In some alloy steels, the hardness increases during tempering at high tempering temperature. This is known as secondary hardening. It occurs due to the formation of transition phases which are coherent with the matrix.

Secondary hardening is sometimes termed as fifth stage of tempering as it takes place normally beyond the tempering temperature for globularization of cementite in plain carbon steels. Some workers have termed this process of globularization during tempering as the fourth stage of tempering and so secondary hardening in alloy steels are sometimes referred as fifth stage of tempering. In case of chromium bearing steel the first formed carbide is cementite at low tempering temperature when the diffusion of chromium atoms are very slow. However with increasing tempering temperature the diffusivity of chromium is enhanced and cementite gives way to the formation of alloy carbides. The equilibrium carbide phase forms through the formation of a series of transitional carbide phases. In chromium steel, the sequence is: $Fe_3C \rightarrow Cr_7C_3 \rightarrow Cr_{23}C_6$.[50–52]

The situation becomes more complex in case the steel contains more than single strong carbide formers; in these cases normally more than one carbide may form and the sequence and amount of individual carbide phase depends upon the relative strength in carbide forming ability of the concerned elements.[53–55]

The alloying elements effect carbide formation during tempering at temperatures when their diffusion becomes perceptible. If both molybdenum and tungsten are present, the sequence of carbide formation may be: Fe_3C–M_2C (M ~ Mo&W)–$M_{23}C_6$–M_6C.

Since tempering is the process where the hardened steel is reheated to an intermediate temperature, it must take place in a number of stages that may overlap considerably with characteristics reactions occurring simultaneously as the steel is heated to higher and higher temperatures. The microstructural changes accompanying tempering at different temperatures following hardening of a medium carbon steel may be followed from Figures 48(a)–48(d).

2.1.10.1 Stages of Tempering

During first stage of tempering, formation of transition carbides occur, which can be η carbide (eta carbide) and/or ε carbide (epsilon carbide). The crystal structure of η carbide is orthorhombic and bears composition formula Fe_2C. However no authentic proof about formation of the same has been presented by researchers. The formation of ε carbide of closed pack hexagonal structure with approximate formula $Fe_{2.4}C$ is already ascertained. The first stage of tempering experiences segregation of C atom at the internal fault within martensite. The carbon in excess of 0.2 wt.% is rejected in the form of ε carbide. This converts high carbon martensite to a low carbon matensite of about 0.2%C, with a low tetragonality, as characterized by a c/a ratio of 1.02, against 1.08 of a 0.8%C containing martensite. Formation of low carbon martensite is a softening process, whereas ε-carbide formation is a process of hardening. The opposing action of these two phases results in the hardness of the quenched steel more or less constant (in fact, the reduction in hardness if there is any, is only just marginal).

The second stage of tempering takes place within approximate temperature range of 200–300 °C. During this stage retained austenite is transformed to bainite. However the second stage of tempering is not very important in any ordinary steel, as the quantity of retained austenite present in microstructure is not appreciable. On the contrary in case of alloy steel, retained austenite content is quite large and hence second stage of tempering becomes an important phenomenon. It is associated by rise in hardness as bainite is harder than the austenite.

The third stage of tempering takes place at 300 °C and above; low carbon martensite reduces its tetragonality by way of diffusing out the C-atoms, which further leads to the formation of elliptical ferrite of BCC crystal structure.

The ε carbides dissolve and low carbon martensite loses tetragonality be rejecting carbon. Finally in the third stage of tempering taking place at 300 °C, the microstructure consist of ferrite and cementite; there is an overall contraction in volume because low carbon martensite becomes cubic at extreme rapidity at temperature near 300 °C.

During third stage of tempering the ferrite phase undergoes recovery; dislocations migrate to grain boundaries, resulting in the formation of acicular ferrite structure of low dislocation density. Upon further heating to above 600 °C, acicular ferrite recrystallizes to equiaxed ferrite. However for high carbon concentration, the ferrite boundary may be pinned and thus recrystallization may take place with difficulty. The final microstructure after third stage of tempering consists of equiaxed ferrite with dispersed spheroidal cementite particles.

However it is to be remembered that rapid heating to the third stage tempering temperature range, may allow the changes to take place in the same sequence as described earlier. Due to paucity of time, for example, ε carbide may not even be

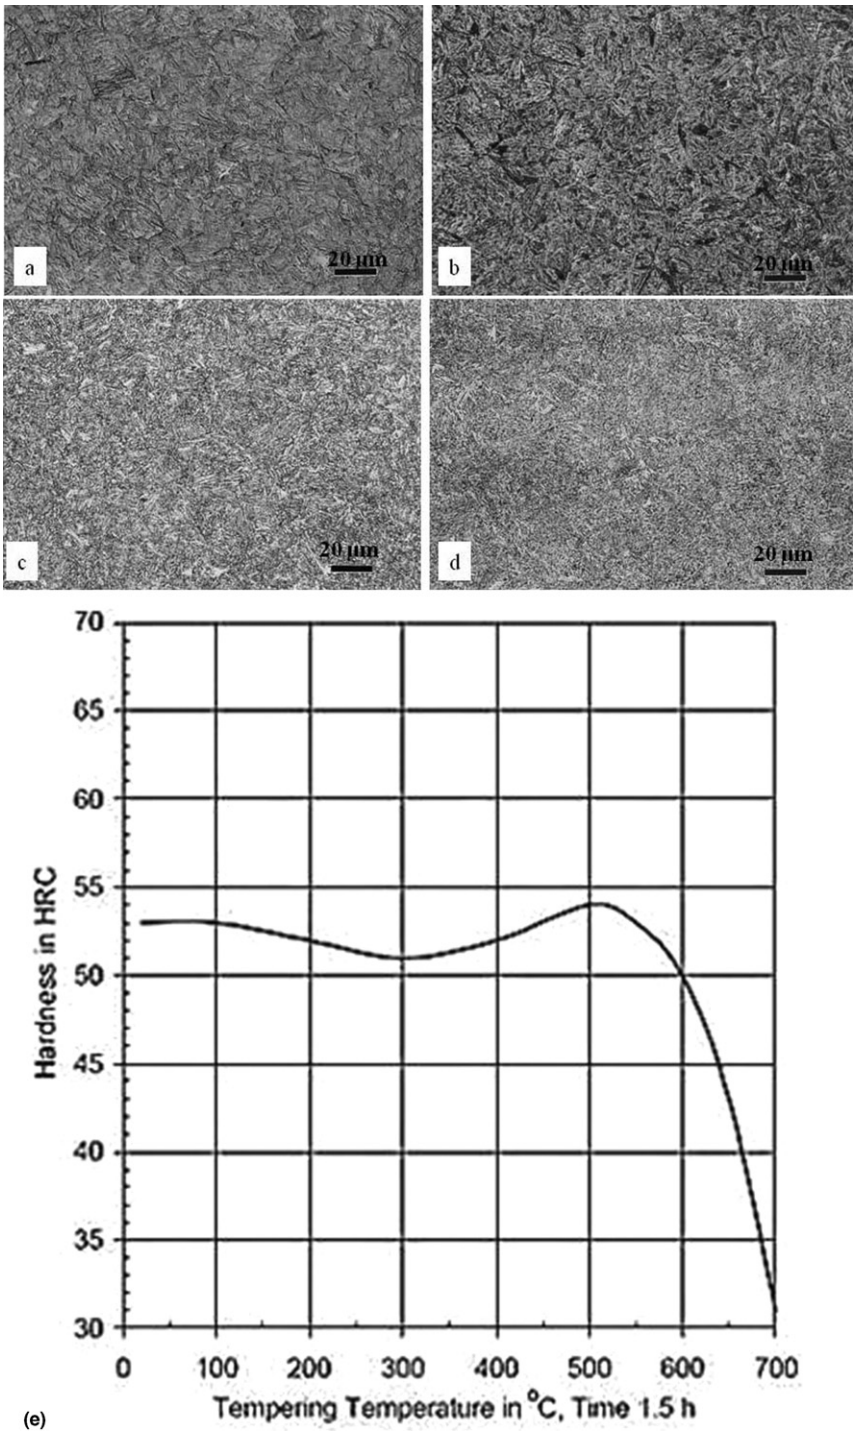

Figure 48 Changes in microstructures and corresponding hardness during tempering of 4140 steel after oil quenching from 870 °C. (a) Quenched (55RC), (b) tempered at 204 °C (53RC), (c) tempered at 427 °C (45RC), (d) tempered at 649 °C (26RC) (Courtesy of George Vander Voort , USA), and (e) tempering curve of AISI H13 steel.

formed and the tempering may result into direct formation of cementite particles.

At the same time it is noted that the retained austenite present in the microstructure may not undergo isothermal transformation to bainite, if the tempering is carried out at temperature 600 °C, by reaching the tempering temperature through rapid heating. If the tempering temperature lies above the nose of CCT diagram, the transformation of austenite to pearlite will occur by diffusional means.

Upon continuation of tempering beyond 600 but below 700 °C, the spheroidal cementite particles grow. The driving force for particle coarsening is the lowering of free energy due

to overall reduction of surface energy. In alloy steel containing elements like Cr, Mo a phenomenon called 'secondary hardening' takes place at higher tempering temperature. If tempering is carried out at a high temperature, where these substitutional alloying elements have sufficient mobility, their carbides are formed at the expense of cementite, which dissolves and supplies the flux of carbon atoms for formation of alloy carbides.

If we follow the tempering curve in Figure 48(e), we observe that during the first stage of tempering there is no significant change in the hardness values due to reasons already stated.

Possible hardening of small magnitude in second stage tempering, due to retained austenite to bainite transformation is masked by the softening due to loss in tetragonality of martensite and so there is a continuous softening during third stage of tempering. Spheroidization followed by coarsening of cementite called fourth stage of tempering also experiences softening.

However as the tempering temperature increases to 600 °C and above, the cementite particles dissolve and alloy carbides start to emerge. The formation of alloy carbides is a sequential event, where a number of transitional carbide phases are formed before the formation of equilibrium carbides.

The transitional carbides are initially coherent with ferrite matrix thereby making the steel stronger through secondary hardening. Secondary hardening is essentially an age-hardening phenomenon where sequential change in precipitation structure and composition occurs; thus secondary hardening follows mechanism of precipitation hardening. In the case of secondary hardening initially formed precipitates are coherent with the matrix and strong interaction between dislocations and coherency strain gives rise to the strengthening.

2.1.10.2 Formation of Bainite in Steels

It is seen that diffusional transformation of austenite produces pearlite whereas transformation of austenite under complete suppression of diffusional process takes place through diffusionless shear transformation mode resulting in supersatured solid solution of carbon in body centered tetragonal ferrite that is martensite. However there can be a situation where the driving energy for martensitic transformation is not available and diffusional mode of transformation of austenite is also improbable due to sluggishness of atomic mobility within the temperature range intermediate to nose of TTT diagram and the martensite start temperature. Under such circumstances a mixed mode of transformation, in the form of bainitic reaction takes place. The character of transformation is partly diffusional and partly shear. Again depending upon the transformation temperature and hence the available driving force the diffusion of solute carbon atoms may take place before or after the FCC–BCC polymorphic transition through shear mechanism. Accordingly the transformation products are called upper or lower bainite.

2.1.10.2.1 Mechanism of bainite formation

Below the nose of TTT diagram, lamellar product of decomposition of austenite is no longer seen to form; rather discrete particles of ferrite and cementite with different morphologies are observed in the microstructure. When austenite is given to transform at various temperatures below the nose of TTT diagram, phase transformation of austenite follows different mechanisms. The evidence of change in the manner of association as well as the composition of carbide and ferrite phases in the microstructures of low carbon steels under situation of continuous cooling, has enticed the scientists to advocate for mechanistically transient character of austenite transformation down to martensite transformation temperature. Study on the isothermal decomposition of austenite in these steels, provides good information about the possible mechanism of phase transformation. It has long been known that below the nose of TTT diagram, broadly two different classes of microstructures are formed. The first one forming just below the nose of TTT diagram and above 300 °C is called upper bainite; upper bainite appears feathery under optical microscope. In contrast, the decomposition product forming below 300 °C looks acicular or needle shaped; this phase mixture is called lower bainite. In upper bainite the sheaves of fine elongated ferrite laths are formed. The cementite particles lie along the boundaries between the laths of ferrite. In case of lower bainite, ferrite becomes more acicular and is appreciably supersaturated with carbon. This needle-shaped ferrite crystals exhibited the presence of intra lath carbide particles. The composition of this carbide phase is also different from that in upper bainite, which is orthorhombic cementite, Fe_3C of 6.67 wt.% carbon. In contrast, the lower bainitic carbide phase contains 8.4 wt.% carbon with a stoichiometric formula $Fe_{2.3}C$. The microstructure of upper bainite in 0.8%C steels is shown in (Figure 49); the transmission electron microstructure gives evidence of bainitic ferrite with carbide at the lath boundaries. A high dislocation density within the ferrite is also noticed. Ferrite lath in upper bainite also shows evidence of dislocations generated presumably due to lattice invariant deformation. Similarly the optical and transmission electron microstructure of lower bainite formed during isothermal transformation of austenite in 0.8%C steel show needle-like ferrite crystals with intra granular carbides (Figure 50).

In case of formation of upper bainite, diffusion of carbon in austenite takes place at relatively higher transformation temperature 400 °C; this leads to creation of the localized carbon-depleted regions within the metastable austenite. The preceding carbon diffusion followed by the creation of the above stated carbon-depleted regions result in rise of M_s temperature and since a highly metastable austenite below the nose of TTT diagram seeks for a suitable mode to undergo rapid transformation for its urge to lower overall free energy of the system, the diffusionless martensitic transformation is called for just when adequate driving energy commensurate with martensite formation temperature becomes available.

This behavior is logically consistent with proposed transformation mechanisms of lower bainite; the low transformation temperature of lower bainite tantamount to a much higher available driving forces and hence austenite can undergo polymorphic transformation without regard to prior diffusion of carbon. However one school of thought has proposed that upper bainitic transformation is entirely diffusional and is nothing more than a nucleation and growth type process where the ferrite crystal grow by ledge mechanism; bainitic ferrite sheaves are formed by sympathetic nucleation of new crystals at the boundary of prior crystals; according to this school of

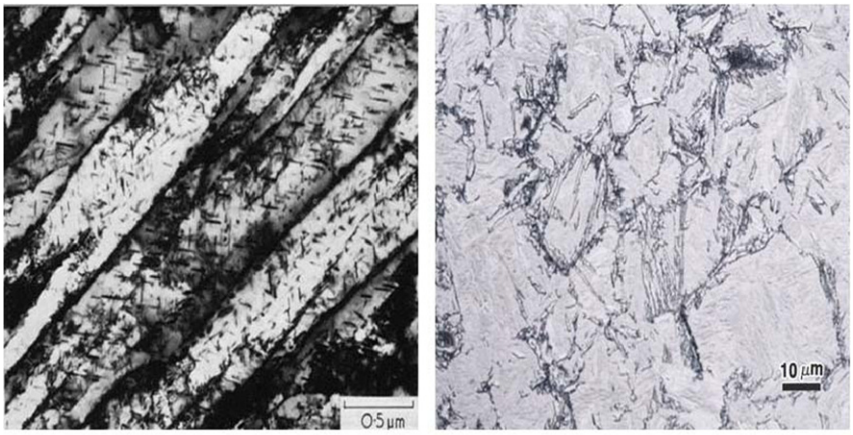

Figure 49 TEM and optical photomicrograph of upper bainite (dark) and martensite (white) in 0.6%C–0.85%Mn–0.25%Si–0.8%Cr steel (austenitized at 830 °C and partially transformed to upper bainite at 530 °C). Courtesy of George Vander Voort, USA. http://cml.postech.ac.kr.

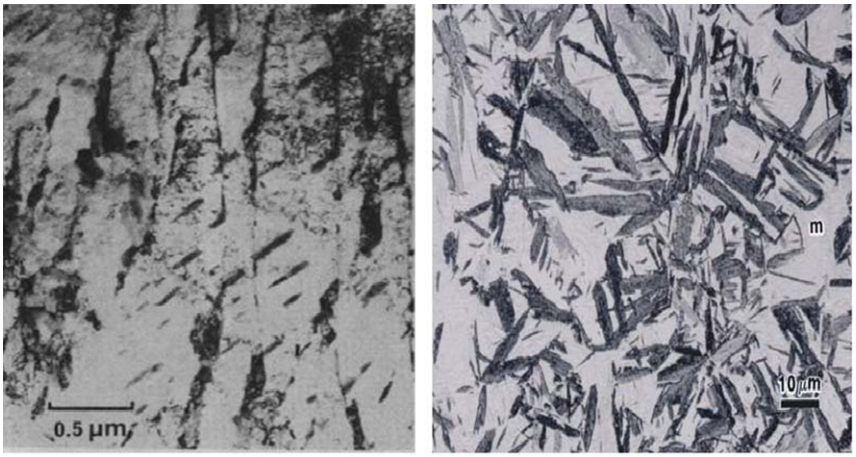

Figure 50 TEM and optical micrograph of lower bainite (dark) and martensite (white) in 0.6%C–0.85%Mn–0.25%Si–0.8%Cr steel (austenitized at 830 °C and partially transformed to lower bainite at 350 °C). Courtesy of George Vander Voort, USA. http://cml.postech.ac.kr.

thought, upper bainite formation can no longer be considered to be a 'partly diffusional and partly diffusion less shear transformation.' In this context it may be recalled that transformation of undercooled austenite is mechanistically transient and different transformation mechanisms operating at various degree of undercooling are distinguishable in continuously cooled low carbon steel. As one increases the degree of under cooling in a pool of transforming austenite, the phase transformation of austenite to ferrite is reported to take place in the sequence: polygonal ferrite–widsmanstatten ferrite–massive ferrite–granular ferrite (bainite)–acicular bainite–martensite. Each transformation type takes place within specific temperature region as decided by the chemical composition and defect structure of the transforming austenite. It has been demonstrated earlier that granular bainite forms by ledge mechanism; there is therefore reasons to believe that for any specific condition of under cooling, the driving force for polymorphic transition of austenite typifies a definite mode of transformation to operate. In extreme circumstances the mechanism of basic transition of austenite to ferrite may be non-diffusional, notwithstanding if diffusion of carbon atoms, required to form bainitic carbides takes place before (upper bainite) or after transformation (lower bainite). Although the proposition of ledge mechanism in formation of some form of bainite must not be reasoned out, it is wiser to dispense with dogmatic documentation in favor of fully diffusional nature of any bainitic transformation. The transient transformation behavior has its origin to the compromise between degree of metastability of austenite and feasibility of any specific transformation mode to operate within the scope of available driving energy with insurance of the most favorable transformation kinetics for FCC austenite to BCC ferrite formation.

2.1.10.3 Martempering

It is stated earlier that hardening of steel gives rise to severe thermal stresses over and above the inevitable transformational

stresses. These two stresses together, quite often lead to warpage or cracking of the heat treating stock. 'Martempering' is a process, which can minimize the chance of cracking during hardening of alloy steels. In this process, the steel after being suitably austenitized, is rapidly quenched in suitable medium, i.e., preferably a salt bath, which is maintained at constant temperature above the M_s temperature and held there for preselected period of time as shown in Figure 51.

Temperature of holding is decided by the M_s temperature of the material being quenched that is the chemical composition of steel. On the contrary, the holding time must commensurate with the time required to equalize the temperatures between the surface and center of the heat treating stock, which further is a function of the geometry of the stock. Too low a holding time will not secure the basic purpose of this process; again too high holding time will bring about decomposition of austenite through diffusional means, which the process of hardening of steel does not aim at. Holding the steel above M_s temperature for sufficient period of time, equalizes the temperature between center and surface of the stock. Thus the thermal stresses generated due to differential volume contraction across the section of the stock are removed; also quenching from low temp to trigger martensite formation will eliminate thermal shock and hence reduce overall thermal stresses. Stresses originated from volume change accompanying martensitic transformation only exist. This leads to minimization of warpage and lessens the chances of formation of quench cracks. Thermal stresses is dependent on section size and if there is sharp change in section size in a component, stress localization may occur at the transition region; failure may initiate from this weak region. A larger section implies a higher magnitude of difference in cooling rate between surface and center; therefore thermal stress becomes quite high. Along with this, rapid change in cross section aggravates the situation and tendency to form quench cracks increases.

2.1.10.4 Austempering

Many medium carbon low alloy structural steels achieve their optimum properties with a microstructure similar to that of lower bainite. This type of structure can be obtained by a heat treatment called 'Austempering.' 'Austempering' is the process of heat treatment where the steel is heated to austenitizing temperature, held there for sufficient period of time to produce homogeneous austenite. The selection of austenitizing temperature and time follows from the same principles as that in the case of conventional quench-hardening process. After austenitization the steel is rapidly cooled to a temperature above M_s temperature and preferably in the region of lower bainite transformation. The severity of quench must be such as to be able to overcome the hardenability constraint if any. A salt bath kept at the quenching temperature say 300 °C, is used for isothermally holding the component for sufficiently long period so that complete decomposition of austenite may take place as shown in Figure 52.

Holding at the austempering temperature eliminates thermal stresses and isothermal transformation of austenite to lower bainite in a salt bath also protects the steel from oxidation due to neutral atmosphere and from distortion due to prevailing situation of hydrostatic pressure. Austempering produces lower bainite which is composed of supersaturated ferrite and ε carbide (Figure 53). Needless to say that after completion of bainitic transformation no other transformation takes place during cooling to room temperature from bainitic reaction temperature.

The low temperature tempering of hardened steel also produces low carbon martensite (i.e., ferrite of low supersaturation) and ε carbide. However strength and toughness properties of austempered material are much better than the hardened and tempered material.

During austempering lower bainitic transformation is envisaged. This means that quenching to austempering temperature leads to the formation of supersaturated ferrite by

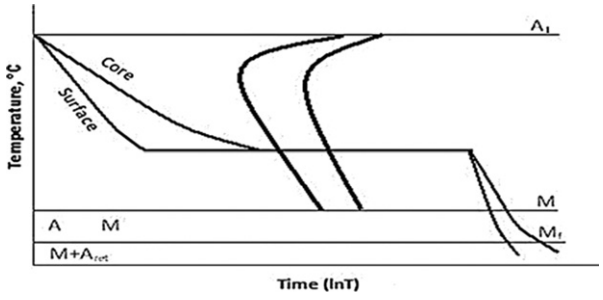

Figure 52 Austempering.

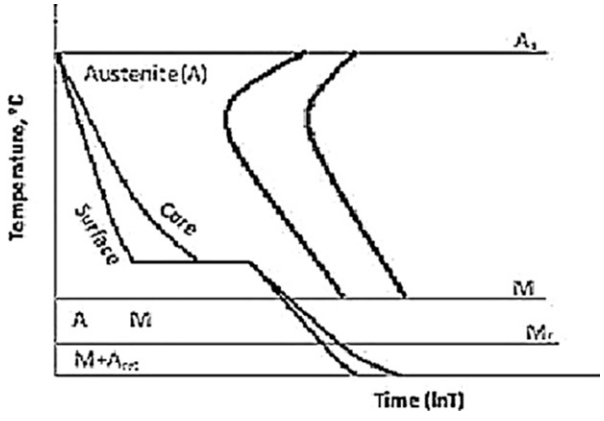

Figure 51 Martempering.

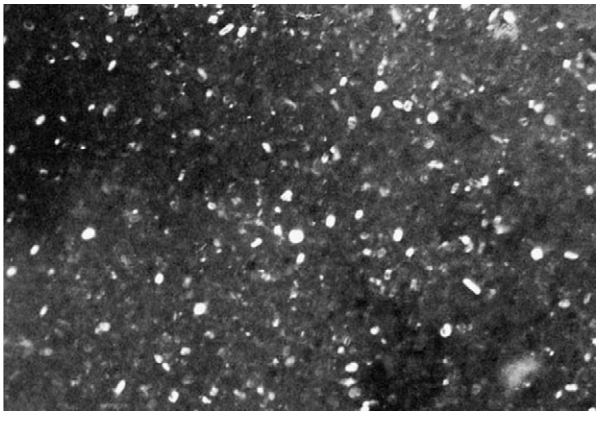

Figure 53 Microstructure showing supersaturated ferrite and ε carbide. Courtesy of George Vander Voort, USA.

diffusionless shear transformation mechanism; but due to the high temperature and also due to great urge for getting relieved from super saturation, the ferrite rejects carbon quite quickly in the form of ε carbide of 8.3 wt.%C (Reed-Hill).[1] Lower bainitic ferrite is much lean in carbon content as compared to the austenite and so excess carbon is rejected by the growing bainitic ferrite crystals ahead of the interface between the product ferrite phase and the parent austenite phase. Thus austenite ahead of bainitic ferrite becomes enriched with carbon; this process of formation of bainitic ferrite and continuous carbon enrichment of austenite ahead of interface continues, till a time is reached when high carbon austenite ahead of growing ferrite crystal cannot give way to the formation of bainite; at this time, growth of bainitic ferrite stops and there remains high carbon austenite, which cannot even transform to martensite during subsequent cooling to room temperature, owing principally to its increased metastability. Such a large amount of austenite retained inevitably due to incomplete bainitic reaction provides adequate ductility to the alloy. Thus austempering enables to achieve a good combination of high strength and high toughness, which otherwise would not have been possible, if the same steel was fully hardened and then tempered at the same austempering temperature (Figure 54). Austempering can harden complicated steel components without causing distortion and cracking. It can impart excellent toughness and ductility in thin sections of plain carbon steel. However, the entire cross section of the steel must be cooled rapidly enough to miss the nose of the IT curve. It is to note that thicker sections (>3 mm) of plain carbon steels are difficult to be austempered because of the short incubation period at the nose of TTT diagram. So, only thin sections are subjected to austempering. However larger sections of alloy steels can be austempered where the time to start the transformation is quite high.

2.1.11 Retained Austenite

In majority of cases the transformation of austenite to martensite does not go to completion. Presence of some untransformed austenite called 'retained austenite' is inevitable although its amount and quality depends upon composition of steel and its initial microstructure. Figure 55, shows that the amount of martensite formed from austenite increases as the transformation temperature is decreased within the M_s–M_f range. Martensite starts to form at M_s and its amount increases with decrease in temperature till the M_f temperature, which denotes completion of transformation. This follows from the typical characteristics of athermal transformation. At this point the transformed phase may contain some retained austenite. Figure 56 gives evidence of retained austenite in 0.9C steel after water quenching from 900 °C

Retained austenite is highly unstable and can be subsequently transformed to bainite or martensite depending upon the parameters of tempering operation. Sometimes a small amount of retained austenite is deliberately kept in the final microstructure. Not only it imparts toughness to the hardened steel but also if it transforms to martensite during post tempering cooling operation, some residual compressive stresses may be developed which is quite helpful to improve fatigue resistance.

Retained austenite is very soft and so if it is present in large quantity, say, by more than 15–20 vol.% in the microstructure, there will be a considerable reduction in the hardness of the quenched steel. As martensite forms, its volume strain is accommodated both by product martensite by lattice invariant deformation and by matrix austenite through plastic deformation. Continued growth of martensite plates lead to small pool of austenite entrapped between adjacent plates of martensite. This austenite contains a high density of crystal imperfection

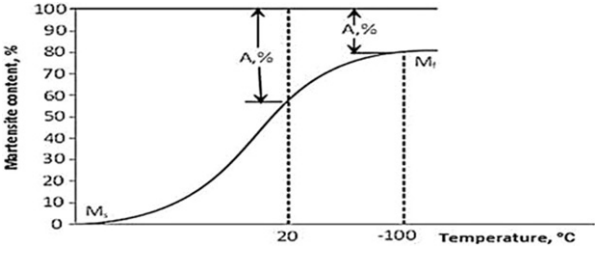

Figure 55 Martensite transformation curve.

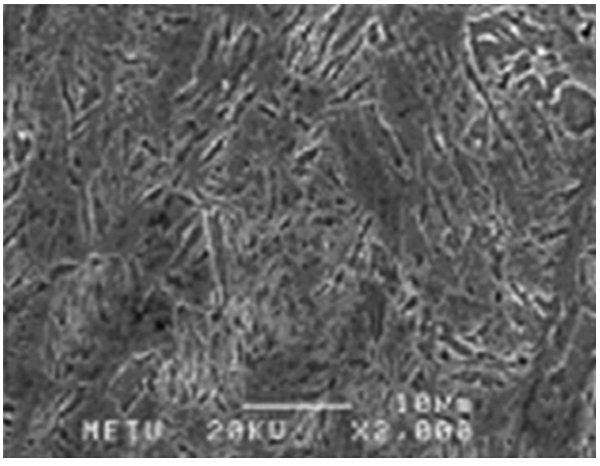

Figure 54 Microstructure of 0.37C–0.48Mn–1.3Cr austempered steel.[56]

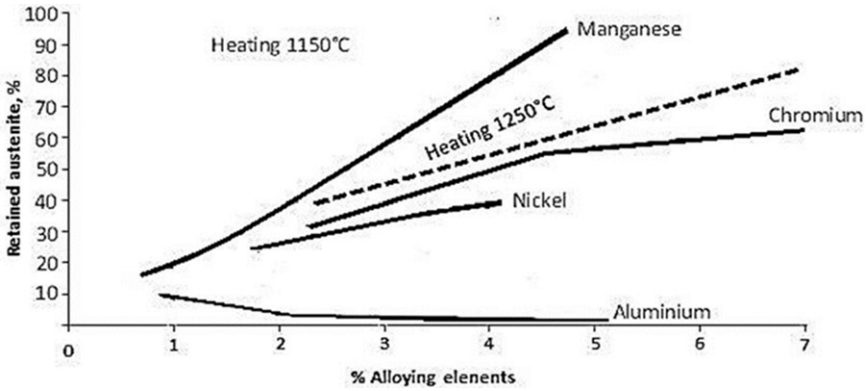

Figure 57 Effect of the alloying elements on the amount of retained austenite in quenched steel (1 wt.%C).

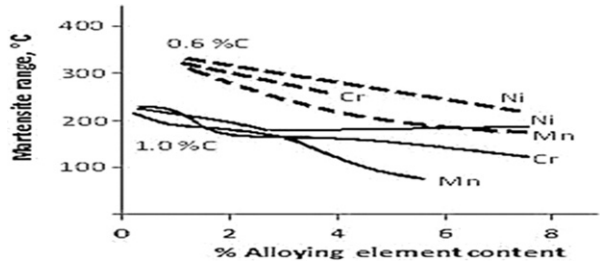

Figure 58 Effect of alloying addition on martensite range.

viz. dislocation and is not amenable to further martensite transformation. So they remain present in the microstructure as retained austenite.

Both M_s and M_f temperature are functions of alloying element content. When M_f goes below room temperature, the amount of retained austenite in the microstructure will expectedly be higher. The amount of austenite to be retained is mainly decided by the M_s–M_f temperature range. The effect of various alloying elements on the amount of retained austenite formed during quenching of steels is shown in Figure 57. The alloying elements which depress the M_s temperature are those which increase the percentage of retained austenite in the microstructure.

In alloy steels, the martensite start point M_s is lowered by most of the alloying elements and the martensite range narrows under the influence of carbon. The influence of carbon on austenite content is stronger than that of other alloying elements as shown in Figure 58.

In addition to the carbon content and alloying elements, the other factor which can influence the amount of retained austenite formed during quenching of steel is the rate of cooling between the martensite start point M_s and the final quenching temperature.

However at temperature just below M_s temperature a slow cooling may affect isothermal transformation of martensite formation. Here a phenomenon called the stabilization of austenite takes place. Holding the transforming austenite after appreciable amount of athermal martensite has formed, makes it prone to stabilization due to, relaxation of stress. Austenite stabilization takes place due to stress relaxation which leads to permanent loss of coherence between parent and product phase. The longer the holding time, the greater would be stress relaxation and thus greater will be stabilization. If martensitic transformation is interrupted between M_s–M_f ranges, then for further transformation to take place, much higher driving force will be required by intensive cooling.

The effect of quenching temperature is linked to the magnitude of thermal stresses due to transformation of austenite to martensite. When steel is heated substaintially above A_3 temperature, grain coarsening of austenite takes place, which further results in the formation of larger martensite plates. This leads to higher volume fraction of retained austenite in the microstructure. Higher austenitizing temperature lowers the martensite start temperatures (M_s), due to complete dissolution of carbide. When hypereutectoid steels are quenched from the region of pure austenite, i.e., after heating the steel above the A_{cm} temperature for complete dissolution of carbides (which is not usual), the quenched microstructure consists of martensite and retained austenite; the hardness is reduced due to high amount of retained austenite. The initial retained austenite amount (after quenching) is dependent on the austenitizing (hardening) temperature to a large extent. The higher the hardening temperature, the greater the amount of retained austenite, but this retained austenite can be made transformed to martensite by subzero treatment.

2.1.11.1 Subzero Treatment

Subzero treatment consist of cooling the metal to a temperature below 0 °C, but in general subzero treatment temperature may range from -130 to -30 °C with holding time around 1 h. In some cases the subzero treatment temperature can be as low as -190 °C in accordance with the M_f temperature of the steel which in turn depends on its chemical composition. If austenite stabilization takes place at room temperature, it will be difficult to transform retained austenite to martensite by subzero treatment.

Subzero treatment should to be done in continuation with the original quenching, without much residence time at room temperature. If we wish to convert retained austenite to martensite at room temperature, it must be heated to higher temperature in a region of metastable austenite. Cooling from that temperature down to room temperature will enable austenite to transform to martensite. Multiple tempering may

effect transformation of retained austenite to martensite during post tempering cooling and repetition of the process may ultimately eliminate the retained austenite from the structure.

Subzero treatment is normally employed in high alloy steels which are prone to form high amount of retained austenite after quenching to room temperature. However in case of industrial scale operation, subzero treated steel is reported to have suffered from a loss in bending strength. There are reports confirming the enhancement of wear resistance in ledeburitic steels. It is also observed that the bending strength of the steel can be recovered by tempering above the secondary hardness peak temperature. Reportedly, the three point bending strength of material undergoing subzero processing is lower than the non-subzero processed one. However the reason for this apparently anomalous behavior requires further investigation.[57] It is further reported that accelerated rate of precipitation due to subzero treatment contributes significantly to the enhancement of wear resistance; the high wear resistance of steel subjected to subzero treatment is ascribed to the formation of carbides of size less than 0.5 μ; also the improvement in wear resistance outweighs the marginal loss in bending strength. Because of the fact that the quenched hardness of the subzero treatment is higher than that of the non-subzero treated steels, a greater latitude in decrement of hardness due to tempering is available. This ensures better mechanical property of subzero-treated steel after low temperature tempering.[58]

2.1.12 Heat Treatment Defects

2.1.12.1 Quench Cracks

When hardening is accomplished with a martensite transformation, evolution of large residual stress is inevitable. Such stress owes its origin to differential thermal contraction of a material cooled rapidly from a high temperature and stress due to transformation.

When the steel sample is quenched rapidly from a high temperature to the room temperature for hardening two types of stresses are developed; one is due to volume change accompanying phase transformation and the other is due to differential coefficient of contraction of different phases present in the material. Also thermal stress due to temperature difference between surface and center of the component is superimposed. When the cumulative value of these stresses becomes large enough, plastic deformation of the steel sample may take place. This plastic deformation may lead to warpage of the component; whenever plastic deformation is unable to take care of all the quench stresses, there would be accumulation of the residual stress which when exceeds the fracture stress of the material will lead to quench crack.

When a round steel bar is quenched, the surface undergoes martensite transformation before the center. It is known that martensite transformation leads to expansion whereas rapid cooling leads to thermal contraction. When expansion at the surface is larger than thermal contraction, the surface will be in a state of tension whereas center is at the state of contraction as shown in Figure 59.

If contraction exceeds expansion at the surface the reverse stress pattern with surface under residual compressive stress and center with tension will prevails. Which of these two will

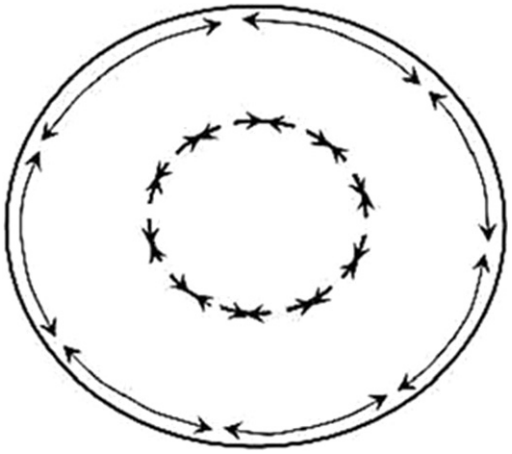

Figure 59 State of stresses due to quenching of a round bar.

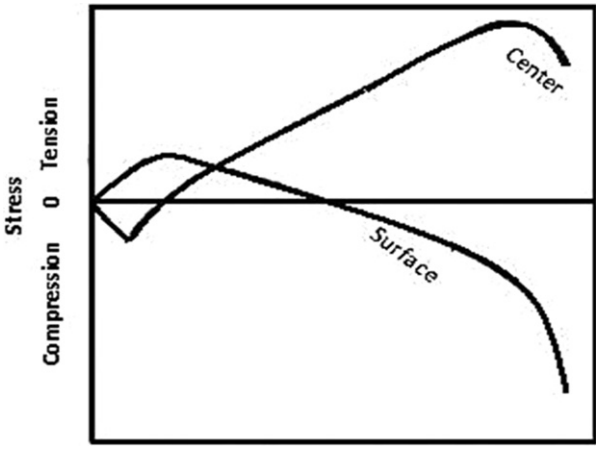

Figure 60 Residual stresses in a steel cylinder quenched to form martensite as computed by Scott. Scott, H. Origin of Quenching Cracks. *Sci. Pap. Bur. Stand.* **1925**, *20*, 399.

actually be present is decided by the relative cooling rate at the surface and at the center of the bar; this is a function of both size of the bar and severity of quench. For large diameter and fast cooling, the surface will form martensite while the center is still at high temperature. Under such circumstances thermal stress will be quite large and it will determine the pattern of volume change. Usually thermal contraction will exceed expansion due to martensite transformation. On the other hand for a thinner object, the difference in cooling rate between surface and center is small the thermal contraction after hardening of surface is still smaller as compared to expansion due to martensite transformation. The variation in stress due to temperature difference between center and surface of the bar is shown in Figure 60.

In many cases the tensile stress persists at the surface. Initially over a large range of specimen diameter tensile stress is seen to increase with cooling rate differentials. Those steel which have high carbon content, transform to martensite with higher degree volume expansion and hence in such case the tensile stress prevails at surface. Since quench crack is formed

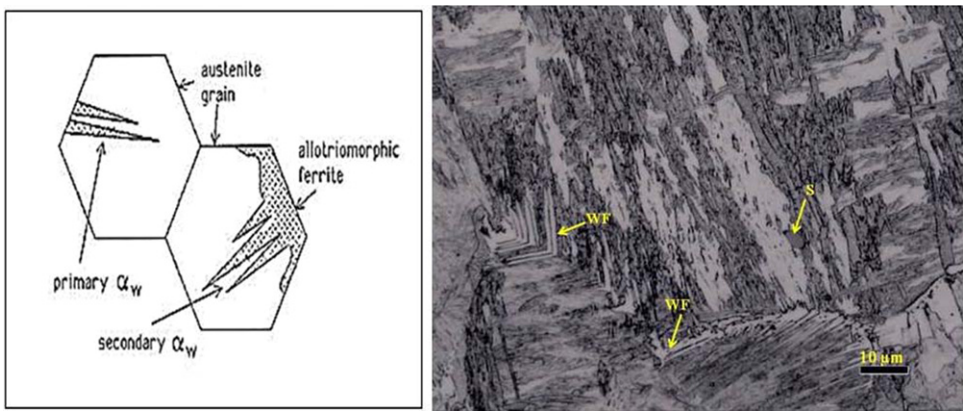

Figure 61 Widmanstatten ferrite in water quenched 1018 steel. Courtesy of George Vander Voort, USA.

as a result of tensile stress high carbon steel with high volume change put to a very fast quenching, results in quench crack.

2.1.12.2 Overheating

If a steel specimen is heated for a very long time far above the stipulated temperature, over heating may occur with the result of getting coarse grains. Structure of the overheated steel sample with Widmanstätten ferrite is shown in **Figure 61**. If a prolonged heating at a temperature is carried out in a furnace where no control of atmosphere is existent or if the material is heated to a temperature near to its melting point, the damage of the specimen is visualized as burning. In this case carbon atoms segregate at the grain boundaries and lead to intercrystalline fracture. A lot of cavities can form including the formation of iron oxide which will be present as inclusion and this leads to stone like fracture at a low ductility level. Quite often in an uncontrolled furnace a high austenitizing temperature leads to decarburization of the surface and the hardness of the surface is decreased, and it misleads the heat treater. Excessive decarburization is associated with the formation of thick scale that acts as an insulating blanket and does not allow heat extraction to desired level. This makes the entire heat treatment process uncertain and undesirable.

2.2.1 Introduction

The term hardenability, as associated with steels, is closely related to hardening by heat treatment. Hardenability of steel is a material property describing the ability of steel to avoid diffusional transformation of austenite to equilibrium products which includes pearlite. Hardening of steels occurs due to the formation of martensite – a nonequilibrium phase formed by diffusionless shear transformation of austenite. For the formation of martensite in steel, the specimen is heated to the single phase austenitic region of Fe–C phase diagram. The steel specimen is held at austenitizing temperature for specified period of time in order to homogenize austenite; homogenization of austenite insures uniformity in chemical composition of austenite at all locations. After homogenization, the specimen is cooled at such a rate that equilibrium phases do not form. Such a cooling rate is generally achieved by immersing the steel sample from austenitizing temperature into water or oil. In order to produce martensite the applied cooling rate must exceed a critical value. This critical value depends upon the composition and other structural features of the steel. Figure 1 illustrates the critical cooling rate.

Any rate of cooling higher than this will produce martensitic structure in steel. In contrast, a cooling rate slower than this will produce pearlite. When a steel specimen of appreciable diameter is immersed in water or oil, the cooling rate at the surface is vastly different from that at the center. This is because of large thermal gradient across the section of the steel section. This difference increases with severity of quench. As soon as the specimen is immersed in the cooling medium from austenitic temperature, cooling starts immediately over the entire surface area surrounded by the coolant. The cooling rate is very high at the surface of the specimen but it decreases toward the center and reaches to minimum there. So long as the cooling rate at any location within the sample is greater than or equal to critical cooling rate, 100% martensite is formed. Thereafter, at increasing depth, the cooling rate remains less than the critical cooling rate and so, equilibrium products such as pearlite or ferrite are formed. At an intermediate cooling rate a mixture of fine pearlite and martensite may form due to split transformation. This effect is demonstrated in Figure 1, where cooling rate curves corresponding to surface and center of a sizable eutectoid steel bar quenched rapidly in a quench medium are superimposed on partial IT curves. In addition, two more cooling rate curves corresponding to critical cooling rate and one at intermediate cooling rate are also shown in the same diagram. The intermediate cooling rate curve is assumed to give a structure

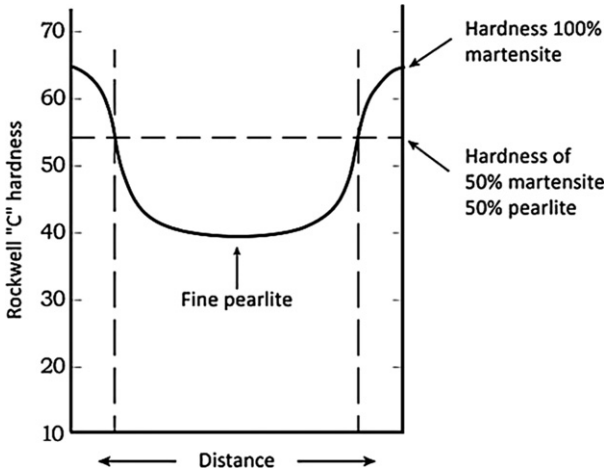

Figure 2 Hardness traverse along a diameter on cross-section of a cylindrical steel specimen from surface toward the center.[1]

comprising of 50% martensite and 50% pearlite. Thus the specimen is expected to have 100% martensite at its surface while 100% pearlite at its center. Since microstructure is varying from surface to core, the corresponding variation in hardness is obvious. The hardness test is performed on the circular cross-section along a diameter at number of locations and the results are plotted as function of distance from center toward the surface of the specimen, as shown in **Figure 2**. The martensite formed at the surface produces high hardness of 65 HRC whereas the pearlite formed at the center gives lowest hardness of 40 HRC. The horizontal line represents the hardness corresponding to 50% martensite and 50% pearlite (which has been estimated from the microscopic measurement. In the microstructure pearlite etches darker than martensite). Surface hardness, depends on the carbon content of

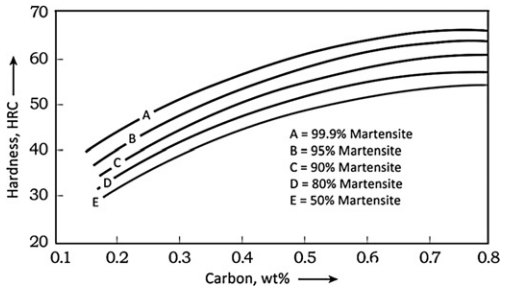

Figure 3 Relationship between hardness, carbon content, and percentage of martensite in steels.[2]

the steel more precisely the carbon content of the transformed martensite. Undissolved carbide, if present in austenite may promote formation of pearlite. The hardness of quenched steel is maximum if all carbon goes into solution in austenite, critical cooling rate is attained during quenching, no austenite is retained after quenching, and no autotempering occurs during quenching. **Figure 3** illustrates the effect of carbon content on hardness of martensite and the amount of martensite formed. It can be noted from this figure that for any percentage of martensite, hardness increases with increasing carbon content.

If the thickness or diameter of the specimen is so small that cooling rate up to its center is greater than the critical cooling rate, martensite will form throughout the specimen. The specimen is said to be fully hardened. The depth up to which the desired hardness in the specimen is achieved is a measure of hardenability of steel. Thus, hardenability of steel can be defined as the depth of hardening achieved in a steel sample after being quenched from the austenitizing temperature. It is the ability of steel to harden (by formation of martensite) throughout its cross-section. Hardenability sometimes is also defined on the basis of microstructure produced by quenching to a certain depth such as 50% martensite and 50% fine pearlite or other equilibrium transformation product. The steels which exhibit hardness to a greater depth below the surface are said to have high hardenability. On the contrary, the steels which harden to a shallow depth are said to possess low hardenability. Plain carbon steels are shallow hardening type. In deep hardening steels, uniform hardening is possible throughout the section depending on its thickness. This is illustrated in **Figure 4** for plain carbon steel 1060 and steel 5160 (an alloy steel containing 0.8% chromium) bars of 25 mm diameter quenched in oil. The hardness at the surface is same for both the steels having same carbon content but the hardness in the central region of 1060 steel is much lower due to formation of pearlite in this region. In contrast, steel 5160 exhibits nearly same hardness from surface to center. The word 'hardenability' does not mean the magnitude of hardness rather it is the depth of useful hardness and the usefulness is a user criterion. The basic purpose of quenching a steel article from austenitic temperature is to attain desired value of hardness up to the required depth. Each grade of steel has its own transformation behavior and therefore its own depth of hardening; hence hardenability is an important factor in the selection of steel for heat treated parts.

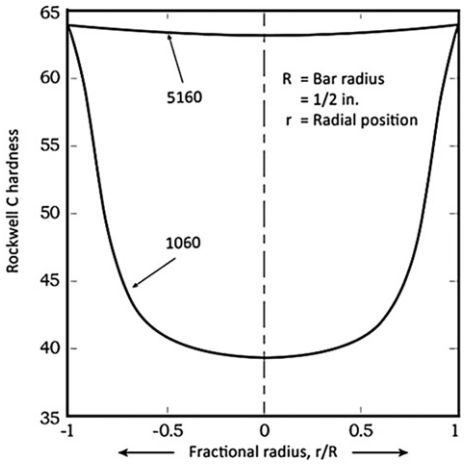

Figure 4 Rockwell hardness as a function of radius of 25 mm diameter bars of oil quenched 1060 and 5160 steels.[3]

2.2.2 Hardness versus Hardenability

Hardness of a material is the resistance offered by it against indentation or penetration of an indenter under a definite load as measured by Brinell, Rockwell, or Vickers tests. Hardness of steel is the maximum hardness that can be developed in it by the formation of martensite which in turn is a function of carbon content. Hardenability, on the other hand, is the depth up to which this hardness is developed from the surface of steel after hardening treatment. The maximum hardness that can be developed in steel depends on several factors stated previously in context of Figure 2. In contrast, carbon content has only minor effect on improvement of hardenability as explained in detail in Section 2.2.6.3. Plain carbon steels are characterized by low hardenability due to short incubation period for diffusional transformation during quenching. Hardenability is principally governed by the presence of alloying elements in steel and its grain size. Moreover, the depth of hardness is affected by the characteristic of the coolant used, the method of quenching, the massiveness of the steel specimen, and the criterion of hardenability set by the user. Hardenability is of considerable significance as it correlates to many of the mechanical properties of steels including yield strength, tensile strength, toughness, and fatigue strength.

2.2.3 Criterion for Measuring Hardenability

One of the most widely accepted criterion of measuring hardenability is the depth from the surface of steel where 50% martensite and 50% pearlite is produced during quenching. It is easy to distinguish a microstructure consisting of 50% martensite and 50% pearlite in a steel sample of finite size, which has been quenched from austenitization temperature. The diameter of the sample must be sufficient to prevent through hardening. The sample is generally fractured in the middle of its length. The visual examination of the as fractured surface shows two distinct regions.[4] The outer region appears smooth, bright, granular, and faceted, characterizing brittle type of fracture due to hard and brittle martensite formed in

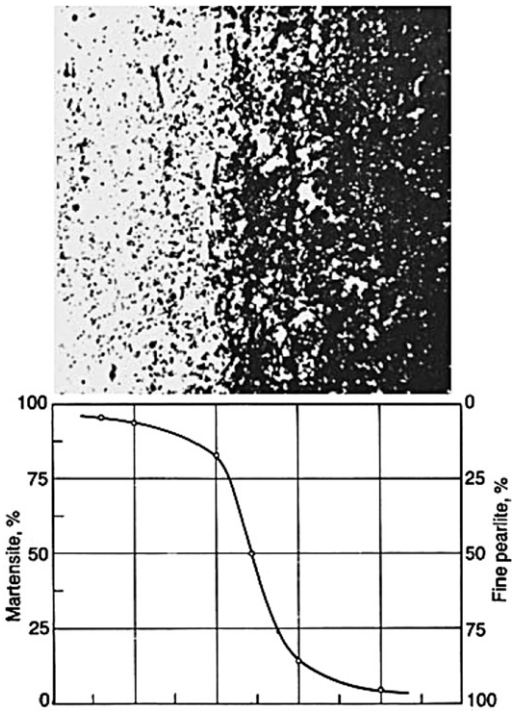

Figure 5 Transition from martensite (top left) to pearlitic (top right) microstructure between hardened and unhardened zones of a quenched steel.[5]

this region. The inner core region appears somewhat rough, fibrous, and dull in color characterizing ductile or tough type of fracture due to soft equilibrium product. The 50% martensitic structure delineates the boundary of two types of fracture. If the fractured surface is polished and etched in nital and examined microscopically, dark and light color regions are delineated. The outer lighter region is due to martensite which etches light whereas the inner region is due to pearlite which etches dark as illustrated in Figure 5. The color change occurs from lighter region to dark at 50% martensite. That is, 50% martensitic structure is the transition of this color change. These findings are generally confirmed from hardness measurement carried out on polished section along with one of the diameters from outer surface toward the inner core. The hardness data are then plotted against distance from surface to center as illustrated in Figure 2. It can be seen from this figure that the hardness is high at the surface and is constant a little up to certain depth where the microstructure 100% martensite. Thereafter, the hardness decreases with distance somewhat rapidly, passes a point of inflection, and then decreases slowly. At the point of inflection the proportion of martensite is 50%. Thus, at 50% martensite, there are abrupt changes in fracture behavior, etching, and also in the curvature of distance versus hardness plots; all the changes are easily detectable. This is why; the depth up to which 50% martensite is present in microstructure of quenched samples is taken as criterion for measuring hardenability.

The foregoing discussions show that the proportion of martensite and the corresponding hardness (Figure 3) at a certain depth below the surface of quenched steel of specific composition is a function of cooling rate (Figure 1) at that

point. However, the cooling rate at any point during quenching from austenitizing temperature may not be the same. It varies with the temperature at that point which in turn depends on severity of quench and section size of the steel sample. The effect of section size on surface hardness of a plain carbon steel quenched in water is shown in Figure 6.

2.2.3.1 Mechanism of Heat Removal During Quenching

To understand the mechanism of heat removal during quenching, consider a typical cooling curve for a small steel cylinder quenched in water as shown in Figure 7. The cooling curve is divided into three stages based on the rate of change of temperature with time.

In Stage I, which is known as Vapor Blanket Stage, the hot metal part immersed in a cooling (quenching) medium, leads to vaporization of liquid and forms a thin uniform film of vapor that is a vapor blanket around the metal. The vapor blanket is maintained for some time because the heat supplied from the interior of the part to its surface exceeds the amount of heat needed for vaporization of the quenching medium. Due to insulating nature of the vapor film, the cooling rate is relatively slow in vapor blanket stage. The vapor blanket formed is continuously washed off by the surrounding layers of the liquid, and this effect is intensified if the viscosity of the liquid is less, i.e., the greater its fluidity.

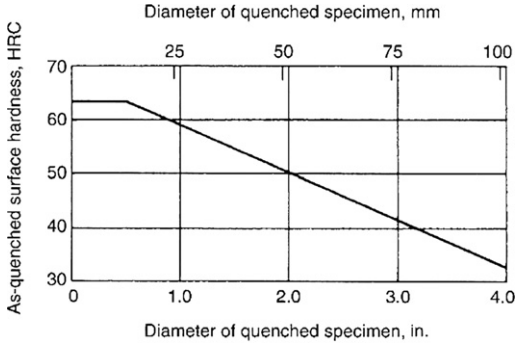

Figure 6 Effect of section size on surface hardness of 0.54% carbon steel quenched in water.[6]

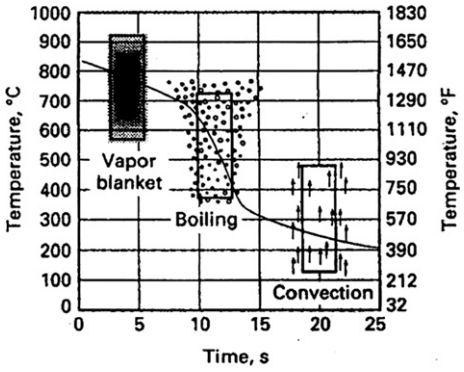

Figure 7 Three stages of heat removal during quenching of a small steel cylinder in water.[7]

Stage II is Vapor-Transport Cooling stage, in this stage as the metal surface cools down, the vapor film becomes unstable and collapse. At this instant the metal surface comes in direct contact with the quenchant and as a consequence, heat extraction from the metal part occurs rapidly and causes violent boiling of quenching medium (Figure 7). Due to this vigorous boiling, the second stage of cooling is also called vapor transport cooling or nucleate boiling stage. Latent heat of vaporization is responsible for rapid heat extraction from the hot metal during the boiling stage.

Third stage of cooling, known as liquid cooling stage, begins when the temperature of the metal is reduced below the boiling point of the quenchant; boiling stops and liquid vapor no longer forms. Cooling occurs by conduction and convection into the liquid quenchant. This stage is also called as convective stage.

If either the quenchant is agitated (e.g., by circulation of the quenchant) or the article is moved relative to quenching medium then mechanical disruption of the vapor blanket takes place which in turn results in faster transition to boiling stage of cooling. Agitation causes cooling of the part more or less uniform and usually produces faster cooling rates in all the three stages of quenching. In the absence of agitation quenching is mostly nonuniform due to uneven heat removal from the metal part, in particular, in the first stage of quenching.

2.2.3.2 Quenching Media

High hardenability is wanted to insure formation of martensite up to a higher depth of a metal part subjected to hardening. In order to obtain martensitic structure in a given steel, quenching medium must be such as to provide a cooling rate faster than the critical cooling rate. This enables to avoid soft diffusional transformation product of austenite, viz. pearlite and ferrite. On the other hand, it is desirable to cool the steel part at a considerably slower rate during martensitic transformation (300–200 °C) so as to minimize residual stresses accompanied structural change. For given steel, the required depth of hardening depends on the quenching medium used. The quenching rate varies vastly in different quenching media. The cooling rates for small specimens of steel in various quenching media are shown in Table 1 and Figure 8 gives cooling curves comparing the cooling characteristics of several quenching media. Some important quenching media are described in the following paragraphs.

2.2.3.2.1 Water

Water, by far, the most popular quenching medium used commercially, principally because of its ease of availability, low price, ease of handling, free of pollution, and produces fast cooling rates. Among all quenching media, water is next to aqueous solutions with regard to quenching rate (Table 1) not only in the metastable austenite region (which is excellent) but also during martensitic transformation temperature range (which is bad). However, drastic quenching during martensitic transformation temperature range, lead to danger of warpage and quench cracks, especially in complex shaped steel articles. Warming of water greatly reduces the cooling rate (Table 1) within the metastable austenite range and has very little effect

on cooling rate in the martensitic transformation range. This suggests that in most cases, preheating of water is not advisable.

Gases dissolved in water also reduce its cooling rate to a considerable extent. This explains why fresh water cools the hot steel part less drastically than already used water which has lost part of the gases dissolved in it. Similarly scum-forming (e.g., soap) drastically reduce the cooling rate. Optimum cooling power is achieved in water when its temperature lies in the range 20–40 °C. Cooling power of water rests in between those of aqueous solutions and oils.

Table 1 Cooling rates for small specimens in various quenching media

Cooling medium	*Cooling rate (°C s^{-1}) in the temperature range*	
	650–550 °C	*300–200 °C*
Water at 18 °C	600	270
Water at 30 °C	500	270
Water at 50 °C	100	270
Water at 75 °C	30	200
10% NaOH aqueous solution	1200	300
10% NaCl aqueous solution	1100	300
10% Na_2CO_3 aqueous solution	800	270
Distilled water	250	200
Water saturated with CO_2	100–200	200
Soap suds	30	200
Oil emulsion in water	70	200
Mineral oils (average)	100–150	20–50
Compresses air	30	10
Still air	3	1

Source: Ref. [9].

Investigation carried out by Mehmet Cakir and Abdullah Özsoy[8] on AISI 1050 steel quenched from austenitizing temperature (860 °C) with air–water mixture in Jominy end-quenched test showed that the cooling rate achieved was surprisingly higher as compared to cooling rate provided by water alone. In the quenching operation, water pressure at 22 mm water column and air mixture (0.40 bar) at about 18 °C (this condition is equivalent to the standard Jominy water pressure at 65 mm water column) was maintained. The reason for improved hardenability is that the air–water mixture spreaded the vapor phase formation and improved heat transfer and thus to enhanced hardenability.

2.2.3.2.2 Aqueous solutions

Aqueous solutions of 10 wt% of NaCl and $CaCl_2$ called brines and 10 wt% NaOH called caustic are widely used in industries. These solutions extract heat from the hot steel part very rapidly. Salts reduce the absorption of atmospheric gases that, in turn reduce the amount of bubbles. The salt elevates the boiling temperature and aid to quick collapse of the vapor blanket formed during stage I. As a result, the solution wets the surface of hot metal and cools it more rapidly than water. The consequent effect is the shortening of stage I (of relatively slow cooling) to appreciable extent. In addition to rapid and uniform cooling, the aqueous solution removes a large percentage of scale if present on the surface of hot metal. These aqueous solutions are of particular use for shallow hardening grade steels. The notable point with these quenching media is that, though the cooling rates are high (highest among all quenching media), the distortion is less severe in contrast to water quenching. Just like water, these solutions are used at room temperature. The disadvantages these solutions offer over water are high price due to the added cost of salts, and these solutions are corrosive in nature.

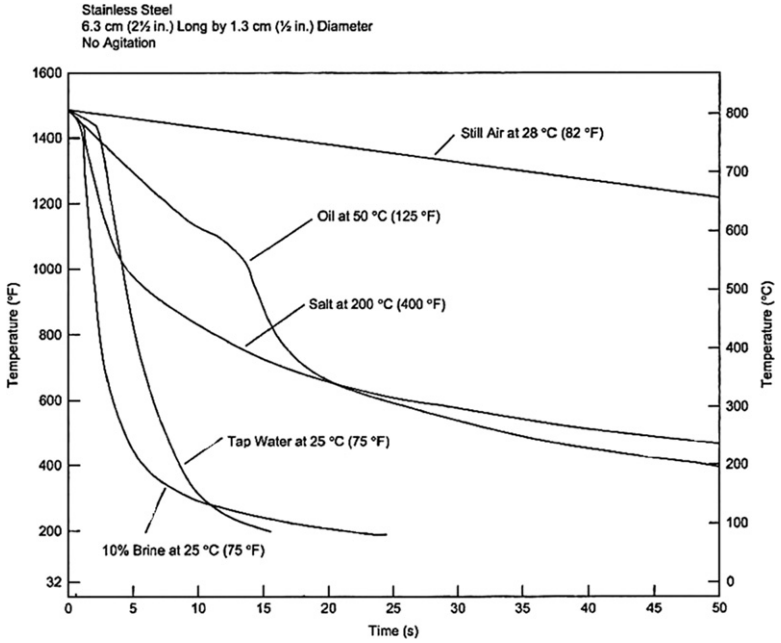

Figure 8 Comparison of some quench media.[7]

2.2.3.2.3 Oils

Oils are classed as an intermediate quench media because they have cooling rates slower than water or brine but faster than air. Oils are widely used as a quenching media in industry because it results in much lower residual stresses, distortion and very little probability of cracking. The cooling rates obtained by oils during first and third stages are much slower to suppress the transformation of austenite in carbon steels into a ferrite–cementite aggregate, as well as within the martensitic transformation range which is considered as a fairly favorable condition. Cooling rates of oils can be controlled by adjusting certain variables such as type of the oil used, bath temperature and degree of bath agitation. Major kind of oils used as quenching media includes animal oils, fish oils, vegetable oils, and mineral oils. The main drawbacks of mineral oils as quenching medium are limited range of cooling rate, water contamination of quenching oil tanks and hazards from smoke, fume and fire.

Molten salt and lead baths are used as quenching media when it is desirable to quench in the temperature range of 150–500 °C. These baths are used in austempering and isothermal treatments.

2.2.3.2.4 Polymer quenchants

Polymer quenchants are used to reduce or eliminate many of the problems encountered with water or oil-based quenchants. These are organic chemicals of high molecular weight and dissolve in water at room temperature to form a solution. The important property of such polymer quenchants is reverse solubility which imparts them a unique cooling mechanism as compared to oil quenchants. As this solution is heated by the immersion of hot metal into the quenching tank, the polymer becomes insoluble at temperatures greater than 70 °C, as the quenching medium cooled again; the polymer goes back into a fully miscible solution.

2.2.3.2.4.1 Mechanism of quenching in polymer quenchants

Cooling in polymer involves three stages:

Stage I: When the hot metal part is immersed into the polymer quenchant, the solution in contact with the metal is heated to above the inverse solubility temperature (65–85 °C). The polymer immediately becomes insoluble in the water and a thin polymer layer is deposited on the surface of the part. This stage is one of slow cooling, similar to the vapor blanket stage in water quenching.
Stage II: After a certain period of time this polymer layer becomes active and the cooling rate increases, equivalent to boiling stage in water quenching. The beginning of stage II depends upon the thickness of the deposited layer.
Stage III: The local temperature falls below the inversion temperature of the polymer, the layer redissolves and the heat is conducted away by the liquid solution. This stage is analogous to that of liquid cooling.

All the above three stages are illustrated by pictures in **Figure 9** for an austenitized steel rod quenched into an aqueous PAG polymer solution.

Cooling rate of a polymer quenchant can be varied by changing the polymer concentration as per the requirement for a particular operation. Many types of polymer quenchants have been developed and are commercially available as replacements for quenching oils to avoid flammability and pollution.

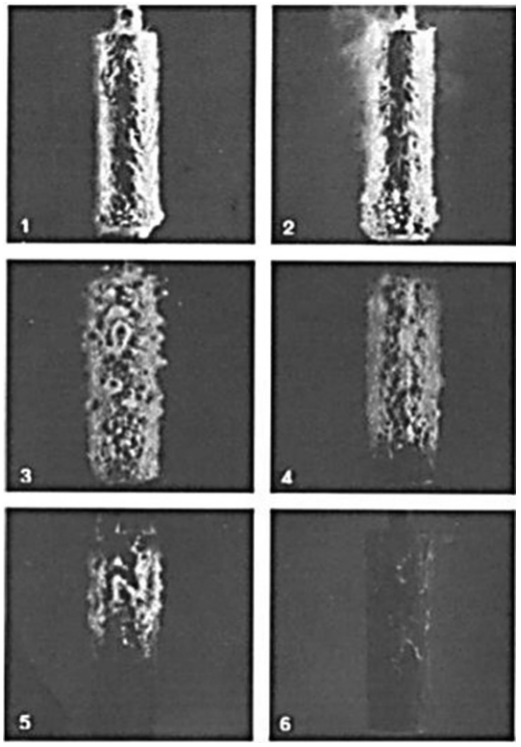

Figure 9 Sequence of photographs of a hot steel rod being quenched in a 25% PAG polymer in water solution. (1) When a rod is immersed, a polymer film forms on its surface, (2) After 15 s, polymer activates and begins to boil, (3) After 25 s, boiling occurs over the entire rod as the cooling rate increases, (4) After 35 s, boiling collapses and the convection stage begins, (5) After 60 s, the polymer starts to redissolve, (6) After 75 s, polymer film has completely redissolved and the heat removal is achieved entirely by convection.[10]

Elimination of smoke or fume during quenching clearly offers improved working conditions. Elimination of fire hazard removes the need for protective equipment.

Three prominent commercially available polymer quenchants are: polyalkylene glycol (PAG), polyvinyl alcohol (PVA) and polysodium acrylate (PA). PVA used to be very popular quenchant in early days and still in use in some countries. Proper PAG quenchant can provide an accelerated wetting so that the cooling rates achieved are faster than water and even approach those of brines. Thus brine like quenching is possible without the problems of hazards and corrosiveness associated with brine or caustic solutions.

Quench severity of aqueous solution of polymer can be controlled by the following parameters:

- Concentration of polymer in water,
- Quenchant temperature, and
- Quenchant agitation.

Higher the concentration of polymer in aqueous solution more is the thickness of the polymer layer formed on the hot metal during quenching and lower is the cooling rate.

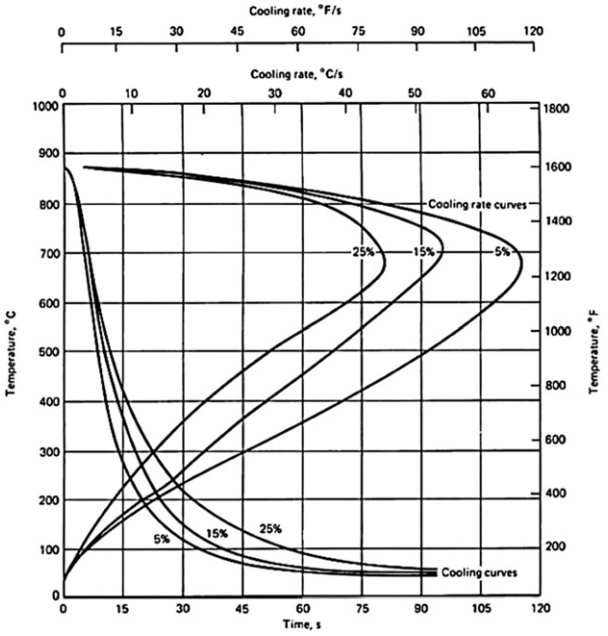

Figure 10 Cooling curves and cooling rate curves for a 25 mm (1″) diameter stainless steel probe quenched 5, 10, and 15% polyalkylene glycol (PAG) at 45 °C that is flowing at 0.25 m s^{-1}.[10]

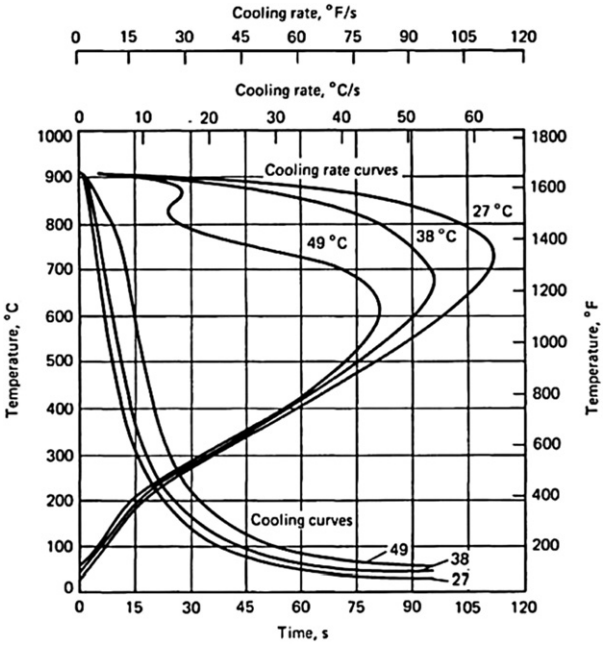

Figure 11 Cooling curves and cooling rate curves for 25 mm (1″) diameter stainless steel probe quenched in 10% PAG at 27, 38, and 49 °C that is flowing at 0.25 m s^{-1}.[10]

Figure 10 is an illustration showing the effect of PAG concentration on cooling rates in a 25 mm diameter steel probe. Any increases of temperature of the polymer quenchant results in a marked decrease in cooling rate of the quenchant. Effect of bath temperature on cooling rate of PAG quenchant is apparent from Figure 11. In general, low to moderate degree of agitation of the polymer quenchant is recommended to ensure adequate replenishment of polymer at the hot metal surface. This also provides uniform heat transfer from hot metal part to the surrounding quenchant. In case of shallow hardening steels it is recommended to use vigorous agitation of polymer quenching bath to avoid formation of undesirable transformation products. The effect of agitation on cooling rate is illustrated in Figure 12.

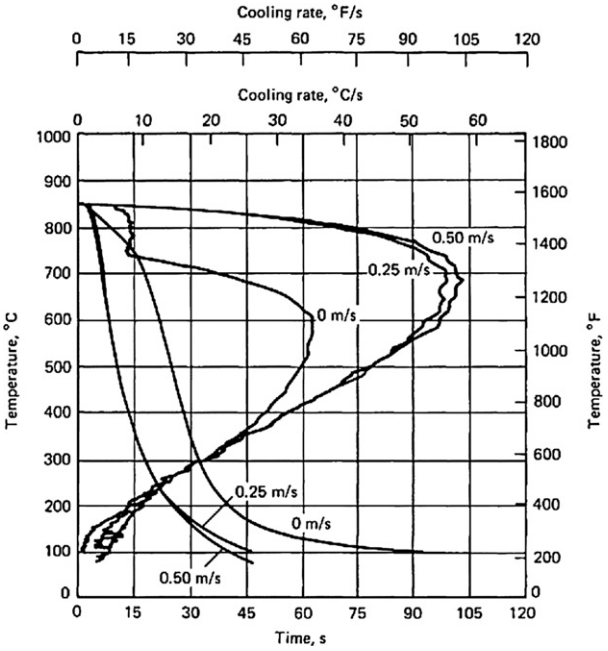

Figure 12 Cooling curves and cooling rate curves for 25 mm (1″) diameter stainless steel probe quenched in 20% PAG at 45 °C that is flowing at 0, 0.25, and 0.50 m s^{-1}.[10]

2.2.4 Quantitative Methods of Measuring Hardenability: Grossman's Method

2.2.4.1 Critical Diameter

It is more convenient and useful to express hardenability as the depth of penetration of hardness. The hardenability of a steel can be obtained by determining the diameter of a bar sample that will just hardened through to the center. M. A. Grossmann has devised a direct method in which hardenability is measured in terms of critical diameter. In this method, several round bar samples of different diameter are heated to austenitizing temperature and quenched rapidly in water or oil. The length of the samples is kept at least five times the diameter to avoid end effects. After quenching the samples are cut in the middle and hardness measurements are made at various depths along a diameter on the cross-section (also called hardness traverse) or etched to reveal the depth of hardening. The hardness is plotted against the depth from the surface from either end of the diameter selected so that perfectly symmetrical curve, as shown in Figure 13 is obtained. This figure shows that the bars having smaller diameters are through hardened. If steel contains 0.8% or more of carbon, a

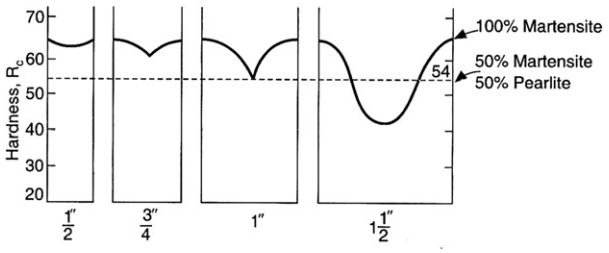

Figure 13 Rods of different diameters hardened to various depths on quenching in a given medium.[1]

hardness of 65 HRC is attained throughout the section. As the diameter increases, under the identical quenching conditions, the cooling rate at the center of steel decreases and resulting in soft core containing pearlite. As a consequence hardness decreases in the core. In 1.5″ diameter bar, the central region contains less than 50% martensite and therefore is called unhardened core. The largest diameter (1.5″) bar shown in **Figure 13** has pearlite at the center. It is notable in this sample that the hardness falls most rapidly at a value of 54 HRC which is the hardness for 50% martensite and 50% pearlite. This point where hardness fall is steepest and is called point of inflection. This inflection point is taken as the transition region between hardened and unhardened portions of the section of the steel bar. The bar sample of 1″ diameter displays 50% martensite and 50% pearlite at its center. This diameter is called 'Critical diameter, D_c.' Critical diameter, D_c, of a steel under a given quenching condition is defined as 'the diameter of the cylindrical bar which hardens up to center, i.e., contains 50% martensite at its center.' The critical diameter can also be determined as the diameter of cylindrical bar at the center of which nature of fracture changes from brittle to ductile under given quenching conditions. Any bar having diameter greater than D_c will not harden throughout, that is, up to the center. It has been observed that with increasing diameter of the bar, surface hardness also decreases (**Figure 6**). The value of critical diameter varies with composition of steel and the severity of quench. Addition of alloying elements increases critical diameter of steel. Similarly, increasing the severity of quench increases the critical diameter of steel. For instance, it has been observed that when the steel 3140 (a nickel–chromium steel with 0.41C–1.2Ni–0.67Cr) when quenched in water and oil, the critical diameter observed for water quench sample is greater (1.83″) than that (1.25″) of the sample of same diameter quenched in oil as illustrated in **Figure 14**. Thus, when hardenability is expressed in term of critical diameter, it is necessary to specify the severity of quench. Ideally, the hardenability of steel should be expressed in terms of ideal quench so as to eliminate the effect of quenching medium.

2.2.4.2 Severity of Quench

The effectiveness of a given cooling medium is expressed by a parameter called 'severity of quench'; this is designated by the symbol '*H*' which is also called coefficient of surface heat transfer between steel and quenchant. '*H*,' in general, is defined as the rate of heat removal by the quenching medium

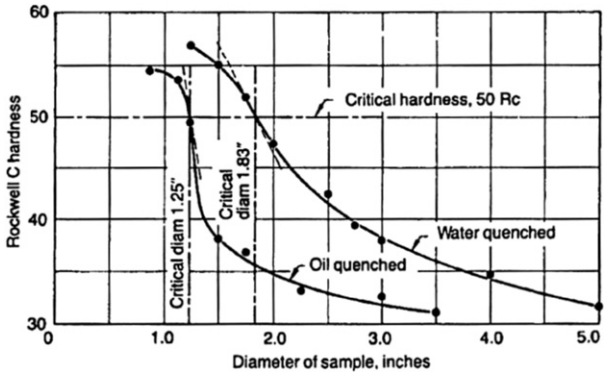

Figure 14 Hardness at the centers of water and oil quenched round bars of 3140 steel of various sizes.[11]

from an object. The cooling rate of austenitized steel when it is subjected to quenching depends on:

1. Thermal diffusivity (α) which is the ratio of thermal conductivity to volume specific heat. Here, thermal conductivity means the ability of the heat to diffuse from the interior of the steel to its surface. Thermal diffusivity increases as does thermal conductivity of the steels with the decrease of temperature.
2. Ability of the quenching medium to remove heat from the surface of the steel.

According to Newton's law of cooling, the rate of heat transfer is proportional to the difference in temperature between the surface of steel (T_s) and the temperature of the coolant (T_c), and thus,

$$Q = P(T_c - T_s) \quad [1]$$

where Q is the rate of heat transfer per unit surface area, P is the proportionality constant and denotes heat transfer coefficient across the metal–coolant interface. Severity of quench, '*H*,' is expressed in terms of rate of heat transfer coefficient (P) and thermal conductivity, K according to the relation:

$$H = \frac{P}{K} \quad [2]$$

where H has units of $(\text{length})^{-1}$, and the thermal conductivity, K has the units J m^{-1} s^{-1} $^{\circ}C^{-1}$ or W m^{-1} $^{\circ}C^{-1}$.

2.2.4.2.1 Experimental evaluation of 'H' of a coolant

Experimentally H is determined by heating a series of round bars of hardenable steel (such as steel 3140) of varying diameters to austenitizing temperature and subsequently quenching in two different media, namely, water and oil. The bars are cross-sectioned and etched to delineate the soft core and hard outer rim or case. The results are schematically represented in **Figure 15**. The cross-hatched areas represent the unhardened (or soft) core produced in various rounds. The unhardened region is assumed to have less than 50% martensite. The notable point here is that the larger the diameter, D of the bar, the greater the unhardened diameter (D_u) as is apparent from the hatched areas. Moreover, as the diameter of

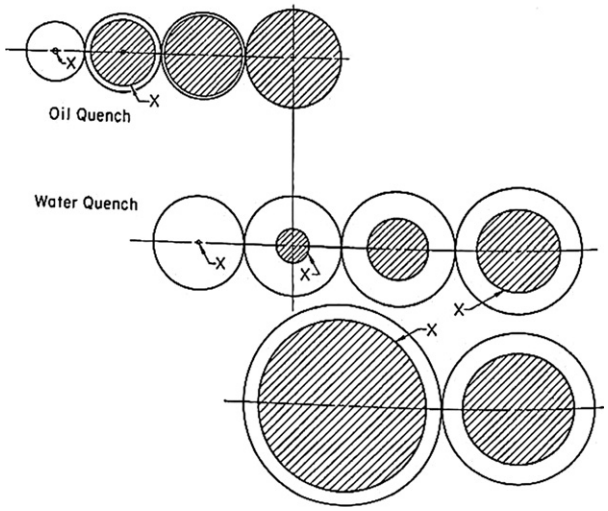

Figure 15 Etched cross-sections of SAE 3140 steel quenched in water and oil.[5]

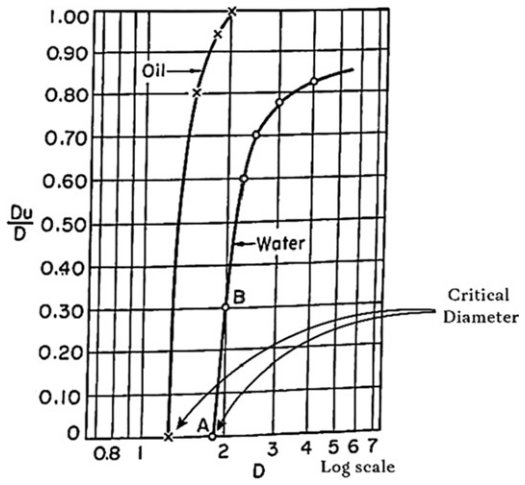

Figure 16 Plot of experimental D_u/D against D. Left curve, oil quench and right curve, water quench.[11]

bar increased beyond the critical, the proportion of unhardened core increased more rapidly in oil quench and much less rapidly in water quench. In other words, as the diameter of the bar is increased, the hardened case soon disappears in oil quench (e.g., when $D_u = D$) whereas it still exists in water quench though it is thinned down. The experimental results shown in **Figure 15**, that is, all the proportions of unhardened diameters, are plotted against the bar diameters as D_u/D versus log D for both the water- and oil-quenched series as shown in **Figure 16**. It can be noted from **Figure 10**, that the curve corresponding to oil-quench is quite steep whereas that for water-quenching bends markedly to the right. The steepness of oil-quench curve suggests the reduced power of quenching of oil so that hardening is not produced in larger sections. **Figure 16** is the basis of estimating severity of quench. A comparison of both these curves also suggests that when a bar of steel of large diameter is quenched in a milder quenching medium, hard case may not form at the surface. This is the situation when D_u equals D (**Figure 15**) for oil quenched sample. It also proves that for a steel of given hardenability greater is the severity of quench greater will be the critical diameter or for a given severity of quench, the greater the hardenability of steel the larger the critical diameter exhibited by the steel.

In order to determine H, each of the curves shown in **Figure 16** is matched with one of the large number of calculated curves available for a wide range of quench severities. The matching is generally performed by plotting D_u/D versus log D (**Figure 16**) on a tracing paper and finding the best correspondence to a theoretical D_u/D versus log HD curves shown in **Figure 17**. The matching gives HD value on x-axis.

When this HD value is divided by corresponding D value, H value can be computed. This is explained by taking an example. Considering point A (**Figure 16**) which corresponds to the critical diameter 1.83 for water quenched 3140 steel and following the above procedure to give HD value of 2.6″ H value is found to be $H = (HD)/D = 2.6/1.83 = 1.4$ for water quenched sample.

The 'H' values of commonly used cooling media in different state of agitation are listed in **Table 2**. A quenching medium that is able to extract heat from the surface of a hot steel

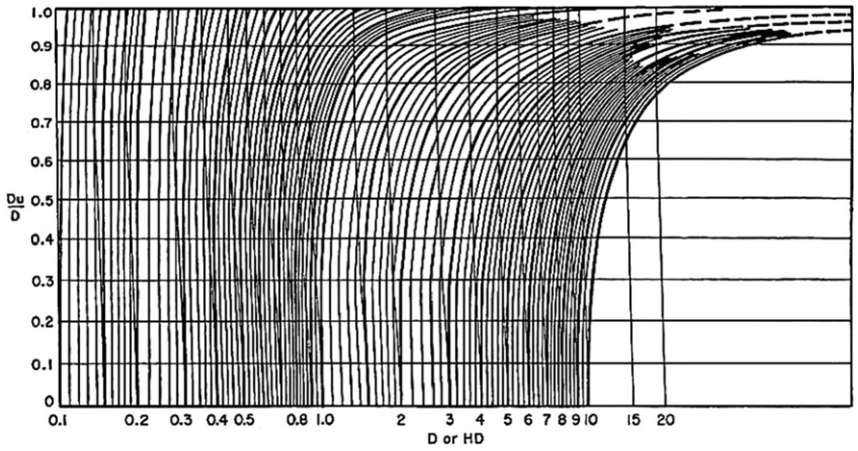

Figure 17 Curves for estimating cooling power (severity of quench) of quenching baths.[11]

Table 2 Severity of quench 'H' for some commonly used quenching media

Quenching condition	H-*values*			
	Air	*Oil*	*Water*	*Brine*
No circulation of fluid/agitation of specimen	0.02	0.25–0.30	0.9–1.0	2.0
Mild circulation/agitation		0.30–0.35	1.0–1.1	2.0–2.2
Moderate circulation/agitation		0.35–0.40	1.2–1.3	
Good circulation/agitation		0.40–0.50	1.4–1.5	
Strong circulation/agitation		0.50–0.80	1.6–2.0	
Violent circulation/agitation	0.05	0.80–1.10	4.0	5.0

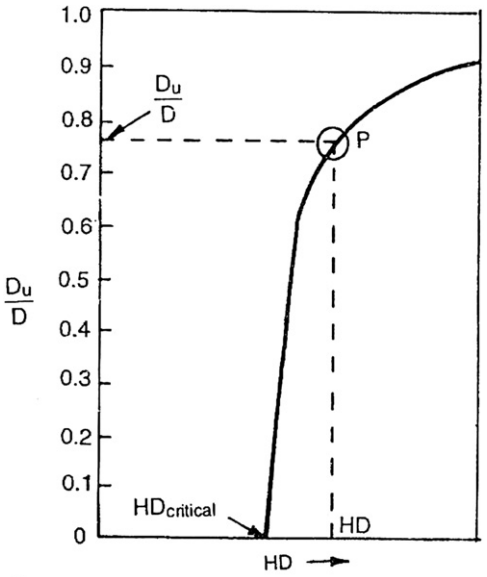

Figure 18 Calculation of D_c in a quenching medium of known '*H*' value.[4]

object extremely fast and enables the object to attain the temperature of the medium instantaneously is called 'ideal quenching medium.' Thus the ideal quenching medium is able to remove the heat from the surface of hot steel as fast as the heat is transferred from interior to the surface and brings down the surface temperature equal to its own temperature. In fact, such a quenching medium can only be imagined. It does not exist in practice. Still an ideal quenching medium is considered for comparison of its severity of quench with other quenching media used in practice. Accordingly, when H tends to infinity the cooling rate is said to very rapid corresponding to that of an ideal quench. 'H' values in practice are much lower than that of ideal quenching medium.

2.2.4.2.2 Evaluation of critical diameter

Having known the severity of quench 'H,' D_u (from experiment) for a particular diameter D of the given steel, one can calculate D_u/D and the product HD. Projections from these values on the diagram shown in **Figure 17** intersect one of the curves at point P as shown in **Figure 18**. It is known previously that at critical diameter, the unhardened region is zero, that is,

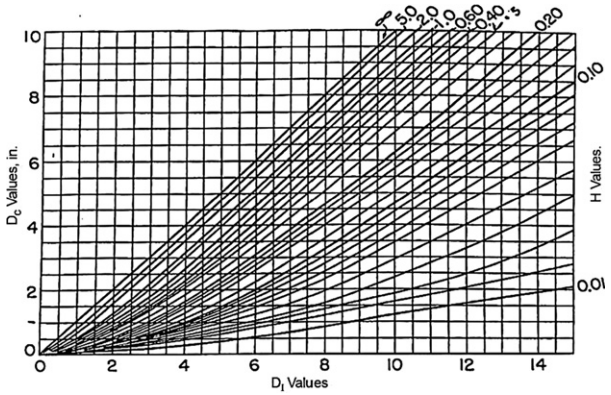

Figure 19 Relationship among experimental critical diameter, D_c, the ideal critical diameter, D_I, and severity of quench, H.[11]

$D_u/D=0$. Corresponding to this, one can obtain the value of the product HD along the curve shown in **Figure 18**. This gives $HD_{critical}$, HD_c. Critical diameter of the steel can be computed by dividing this value by severity of quench 'H.' That is, $D_c=HD_c/H$ is the critical diameter.

2.2.4.3 Ideal Critical Diameter

As illustrated in **Figure 16**, the critical diameter D_c is directly related to severity of quench (H). The higher the quench severity, larger is the critical diameter of steel bar for a given composition. Therefore, just on the basis of critical diameter one cannot compare the hardenabilities of two steels quenched in different quenching media. In order to make critical diameter independent of H, Grossmann proposed a concept based on 'ideal critical diameter.' The ideal critical diameter, D_I, is defined as "the diameter for which the unhardened core just disappears if the bar is subjected to an ideal quench." This means that when a bar of steel is subjected to an ideal quench it would have 50% martensite at its center. The diameter of this bar is then said to be ideal critical diameter. In an 'ideal quench,' 'H' is infinitely large. D_I gives value of inherent hardenability of the steel.

Grossmann has developed a relationship between the critical diameter, D_c, ideal critical diameter D_I, and severity of quench, H in the form of a master graph based on thermodynamic considerations (that is by heat flow analysis). The graph is represented in **Figure 19**. The graph shows a number of curves for various cooling rates. Knowing the value of severity of quench, 'H,' and the value of D_c, the corresponding D_I and hence the hardenability can be found out from the graph. For instance, for D_c assumed to be equal to 1″, and $H=5$ (for agitated brine quench), the ideal critical diameter (i.e., the hardenability) works out to 1.2″ (**Figure 20**). **Figure 19** shows that for D_c (10″)$=D_I$ (10″), $H=\infty$. Accordingly, the ideal quench would produce the maximum possible depth of hardening and the corresponding critical diameter would be the largest attainable which is equal to D_I. **Figure 19** also shows that for a given value of D_c, D_I is always larger than D_c, that is, always $D_c < D_I$, and that H is less than infinity. In practice, ideal quench can never be attained. However, the highest quench attainable in agitated brine quench ($H=5$) falls in close proximity to ideal quench (**Figure 19**).

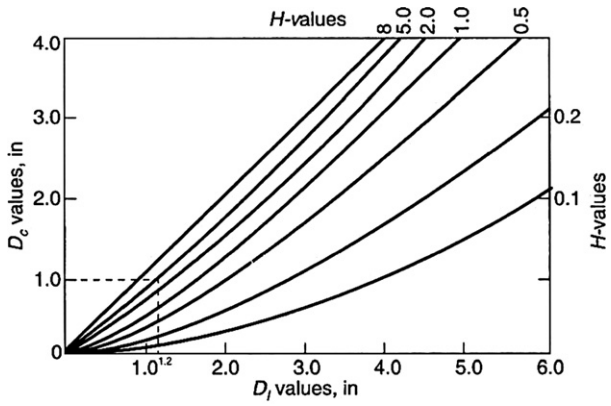

Figure 20 Relationship between D_I, D_c for fully hardened steel bar quenched in a medium with cooling power H.[12]

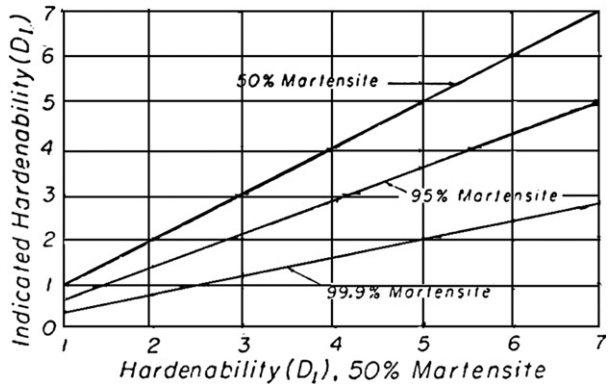

Figure 21 Average relationship between D_I and D_I with 95 and 99.9% martensite.[4]

Sometimes the criterion for hardenability is set by 90% martensite or more. In such case, first D_c can be determined experimentally for 90% or higher percentage of martensite as per requirement, and if H is known, then D_I corresponding to higher percentage of martensite can be obtained by referring Figure 19. Figure 21 gives the average relationship between D_I corresponding to 50% martensite and D_I for higher % of martensite for medium carbon low alloy steels. If D_I for 50% martensite is known, then one can obtain the value of D_I (or hardenability) corresponding to higher percent of martensite using the plot shown in Figure 21.

2.2.5 Jominy End-Quench Test

Though the Grossmann method of quantitative measurement of hardenability in terms of ideal critical diameter, is highly useful in explaining the concept of hardenability and is reproducible too, the method is highly time consuming, complicated, and expensive because it requires a series of round bars of steel to be quenched, sectioned, and tested.

End-quench test (Jominy) is a simple, generally accepted, and most widely used method of evaluating hardenability of carbon and alloy steels. This test provides much useful information to fabricators and designers. In contrast to Grossmann

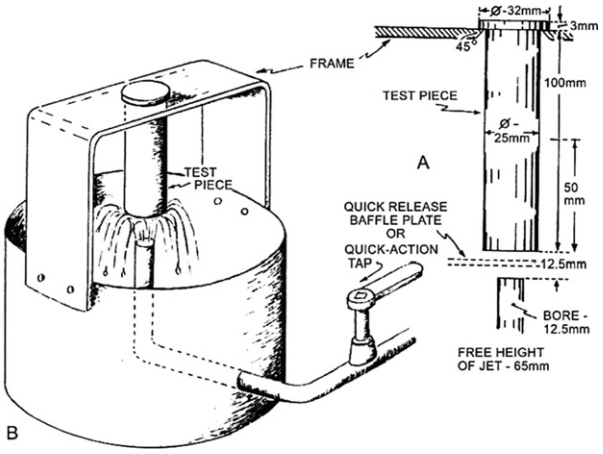

Figure 22 Experimental set-up for Jominy end-quench test.[13]

method where a series of specimens are used to perform test, Jominy end-quench test uses a single specimen to evaluate hardenability. In this method, a standard steel specimen of 1″ (25 mm) diameter and 4″ (100 mm) long with a 1.25″ (32 mm) diameter collar at one of its ends (to facilitate its holding in the quenching jig) is used for testing. The physical set-up of this test is illustrated in Figure 22. In this set up the diameter of nozzle is 0.5″ (12.5 mm). When the specimen is held in the jig, the bottom end of the specimen is kept 0.5″ away from the nozzle. Using a valve, the water flow is so controlled that when no specimen is placed in the jig, the height of unimpinged jet is 2.5″, that is, the free flight of water column is maintained as 2.5″ and that the volume of water striking the end of the specimen must remain constant.

The steel specimen is heated to about 50 °C above the lowest temperature at which full austenitic structure is obtained. The specimen is then immediately transferred to the quenching device and placed in the jig within 5 s and almost simultaneously the water jet is directed against the bottom end of the specimen at constant velocity such that water impinges on the end of the specimen only, then drains away. The cooling rate at the quench end is very rapid but it decreases progressively with distance from the quenched end. The cooling rate is very slow at the opposite end. This results in a wide range of hardness along the length of the specimen. After quenching for 10 min on the fixture, the specimen is removed. Two mutually parallel flat surfaces are ground longitudinally to a depth of 0.015 in. (0.380 mm). These surfaces are etched with 5% nital solution to remove tempered layer due to grinding. Rockwell hardness test on C scale is then performed on ground flat surface along the length at 1/16″ (about 1.6 mm) interval from the quenched end of the bar. Near the quench end, this interval may be reduced to 1/32″ to obtain higher accuracy. The results are expressed as a curve of hardness values versus distance from the quenched end of the Jominy specimen as illustrated in Figure 23. Figure 23 shows that as the distance from the quench end increases hardness decreases; this is due to the decrease of cooling rate which in turn can be correlated to the formation of equilibrium products. The curve shown in Figure 23 is called 'Jominy hardenability curve.' The distance from the quenched end is commonly known as Jominy distance – J such that one Jominy

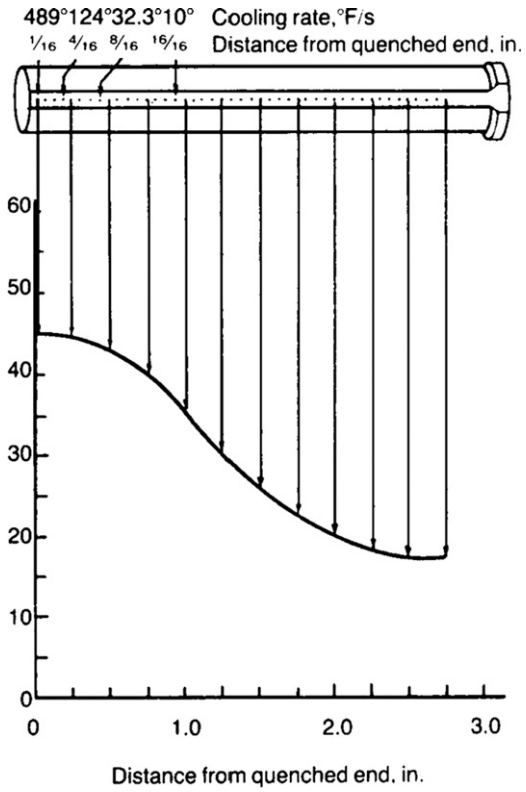

Figure 23 Variation of hardness with distance from the quench-end of Jominy specimen.[6]

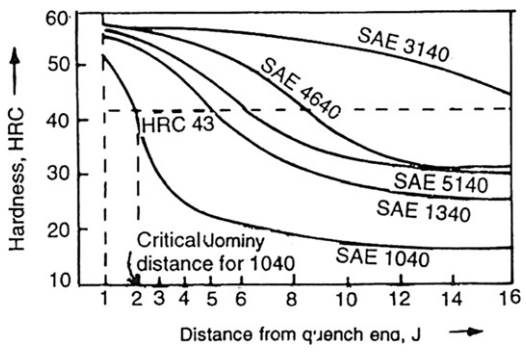

Figure 24 Jominy hardenability curves for some low alloy steels with 0.4% C.[4]

distance is equal to 1/16″ and is designated as J_1. Figure 24 illustrates Jominy hardenability curves for some grades of steels. By comparing these curves the relative hardenability of different grades of steels can be established. At a given distance from the quenched end of the specimen, the harder a steel is, higher is its hardenability than steel having lower hardness at the same distance. Thus a flatter Jominy curve implies higher hardenability. The inflection point on the hardness versus distance curve for SAE 1040 steel shown in Figure 24 generally correlates with 50% martensite and is used to measure the hardenability of steels. This distance is the critical Jominy distance. The hardness corresponding to this point is 43 HRC. This means that for the steel under consideration, 50% martensite in the

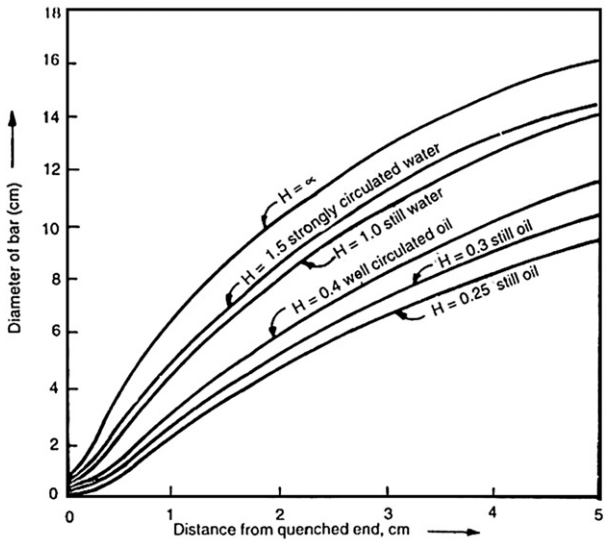

Figure 25 Correlation between Jominy distance and bar diameter, where cooling rate for the center of the bar is same as that for the point in Jominy bar.[4]

structure is represented by a hardness of 43 HRC. Now intersection of a horizontal line drawn at this hardness (Figure 24), with the hardenability curves of different grades of steels gives the critical Jominy distances or the hardenability of these steels.

2.2.5.1 Correlation between Jominy Test Distance and Grossmann Method, D_I

Both Jominy distance (as obtained from the Jominy end-quench test) and ideal critical diameter, D_I as determined from Grossmann's method are measure of hardenability of steel. A correlation between Jominy test distance, J and D_I can be established. This correlation is based on the fundamental relationship between hardness and the rate of cooling. For instance, consider a steel tested for hardenability by end-quench test and Grossmann test. Now consider a point on Jominy test specimen at a distance J from the quench end and a point at the center of the quenched round bar of diameter D_c such that both points have the same hardness. Since both these points display same hardness so cooling rate is also same at both these locations in the samples.

Thus, the critical diameter, D_c can be determined from the Jominy end-quench hardenability. After having D_c determined from Jominy test one can obtain the ideal critical diameter, D_I with the help of Figure 13. Grossmann computed the cooling rate (in terms of half-time) at the center of an ideally quenched round bar of diameter, D_I and at any point on the Jominy test bar at a distance J from the quenched-end. He developed a relationship between D_I (Grossmann) and Jominy distance, J as shown in Figure 25 for a range of cooling baths, i.e., Jominy test can be used to get D_I or D_c from Figure 25.

2.2.5.2 Hardenability Bands

It is well known that a steel producer cannot produce a steel of exact composition specified by a customer. The composition always varies to some extent from heat-to-heat. He can

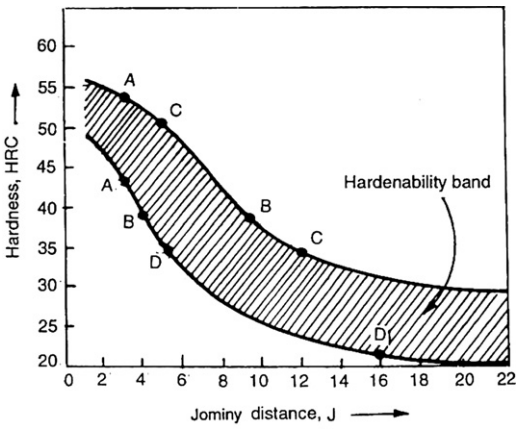

Figure 26 Hardenability band and different method of specifying hardenability.[4]

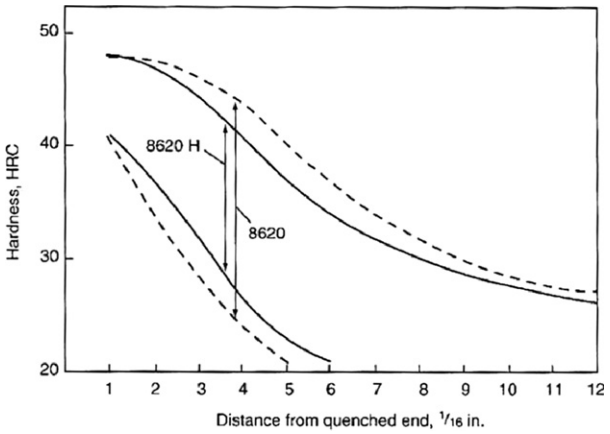

Figure 27 Comparison of Jominy hardenability curves for 8620H and 8620 steels. Chemistry at maximum and minimum of the chemistry range.[6]

produce a steel of composition that falls within the range specified by the customer. This composition range for the given steel results in two Jominy hardenability curves, one on top of the other. The upper curve represents the hardness obtained with the upper limit of elements in composition for the steel while the lower curve is that for composition at the lower limit. The area bounded by these two curves is referred to as a hardenability, or Jominy band as illustrated in Figure 26. The upper and lower curves not only show the possible variation in hardness at the quenched end caused by the allowable carbon range but also the difference in hardenability produced by the alloying elements that fall in the upper and lower side of the prescribed limits. The hardenability bands which include plain carbon steels (such as AISI 1036) and many grades of the frequently used low alloy steels are very useful in selecting alloys for particular application. Therefore, there has been trend that customer orders for steels the hardenability of which falls within the specified limits. Society of Automotive Engineers (SAE) in association with the American Iron and Steel Institute (AISI) devised hardenability bands for many steels, in particular, the low alloy steels. These steels are named H-steels. H-steels are those which are produced and sold with guaranteed hardenability bands. These steels are designated in the same way as standard grades except that numerical parts are followed by the letter H such as in 4140H steel. Thus H-steels are the modifications of the normal standard grade steels with respect to chemical composition. These compositions allow manufacturer to adjust the chemical composition of the steels that have hardenability within the prescribed limits. However, the modifications are so made as not to influence the general characteristics of the original compositions of the steels. Steels are sold either on the basis of 'chemistry only' as per standard grade such as AISI 8620 steel or based on the hardenability requirement as 8620H. A comparison of these steels as shown in Figure 27, clearly shows that the hardenability band for H-steel is narrower than that for the 'chemistry only' steel (i.e., AISI 8620).

For any H-steel, there can be various methods of specifications as illustrated in Figure 26 and listed below:

1. The maximum and minimum hardness at any desired distance on the Jominy end-quenched specimen can be specified, as for instance by points A–A, corresponding to the section size of interest to the user. The point A–A are correspond to HRC54 to HRC43 at $J=3/16''$.
2. The maximum and minimum Jominy distances at which desired hardness is to be attained as at points B–B, can be specified. The corresponding distances are $J=4/16$ to $9/16''$ at HRC39.
3. Two maximum hardness values at two desired Jominy distances can be specified, as at points C–C (HRC50, $J=5/16''$ and HRC34, $J=12/16''$).
4. Two minimum hardness values at two Jominy distances can be specified as illustrated at points D–D (HRC35, $J=5/16''$ and HRC21, $J=16/16''$).

For each steel part to be heat treated, it is essential to determine the minimum hardenability required for proper functioning of the part in specific application. Generally it is not recommended to specify higher than the minimum, as it increases the cost as well as increases the danger of quench cracking. For example,

1. 80% martensite at the center of largest section is normally needed for highly stressed parts, whereas for less highly stressed parts, 50% martensite is sufficient.
2. 80% martensite at the 3/4 radius position is needed for automotive parts where torsional loading predominates.

Hardenability can be increased either by increasing the alloy content of steel or for a specific alloy steel by increasing the carbon content. Increasing alloy content implies increase of cost of steel. Alloy steel can be hardened to a greater depth with minimum distortion or quenching cracks if quenched in oil. But then cost of oil will also be involved. Increasing carbon content deteriorates ductility and toughness of steel. Severity of quench also increases the depth from the surface to which the desired microstructure and hence hardness is achieved.

2.2.6 Factors Affecting Hardenability

Hardenability is a property of steel and this inherent property is influenced by the external factors as discussed in preceding

paragraphs. Apart from the external factors like cooling medium, section sensitivity, hardenability criterion used, there are some materials parameters which make hardenability of one steel different from others; in the design of steels these factors affecting hardenability of steels are of important considerations. All those factors which reduce the critical cooling rate (i.e., increase stability of austenite) increase hardenability. The following factors may be considered to affect the hardenability of steel.

1. Grain size,
2. Austenitizing temperature and time,
3. Carbon content of the steel,
4. Alloying element in steel.

2.2.6.1 Effect of Grain Size

Since hardenability is sometimes defined as the measure of depth below the surface of steel (bar, for instance) up to which 100% (full) martensite is formed, it tantamounts to the ability of steels to avoid pearlite transformation. The diffusional transformation products of austenite are detrimental to hardenability and this transformation takes place heterogeneously at the grain boundaries. As both pearlite and proeutectoid ferrite nucleate along grain boundaries of austenite greater availability of high energy surfaces from grain boundary accentuates diffusional transformation of austenite and hence lower the hardenability. A fine grain steel with ASTM number 7 exhibits four times grain boundary area than a coarse grain steel having ASTM grain size number 3. Higher the grain boundary area higher will be the sites for nucleation of diffusion dependent transformation. A large grain size means reduced grain boundary area per unit volume, and therefore fewer nucleation sites for diffusion dependent phase transformations (i.e., ferrite, and pearlite). Figure 28 illustrates the effect of austenite grain size on time of transformation to pearlite. Nucleation occurs at austenite grain boundary. If it is assumed that the rate of nucleation and growth are constant then it will take more time to complete the transformation to pearlite in large austenite grain than in small grain. This results in lower rate of transformation of the entire structure. The consequent effect is not only shifting the transformation start curves on the IT diagrams to longer times (increase incubation period) but also the nose of the IT diagram (Figure 29) and hence delaying the critical cooling rate. Austenite is stable below the lower critical temperature and thus transformation to martensite occurs at lower temperature accompanied with lower thermal shock. Thus, martensite is able to form even at lower cooling rate prevailing at greater depth from the surface of steel. In other words, martensite is likely to form to a greater depth along the diameter of steel section for a coarse grained austenite. Thus a higher temperature of austenitization, where a coarse grain structure is obtained, may be used in order to achieve complete hardening. The hardenability of carbon steel may increase as much as 50% with an increase of grain size from ASTM 8 (6–10) to ASTM 3 (1–4) and the effect is further intensified if the carbon content is increased. For simple shapes where the probability of quench cracks is less, it appears to be more practical to use coarse-grain steel rather than a fine-grain steel to achieve hardenability. However, from the point of view of improving hardenability, the criterion of coarsening austenite grain size is not recommended. This is because the other properties such as ductility and notch toughness get deteriorated. The martensite formed from coarse austenite grain structure prone to quenching cracks or cracking may result due to thermal shocks.

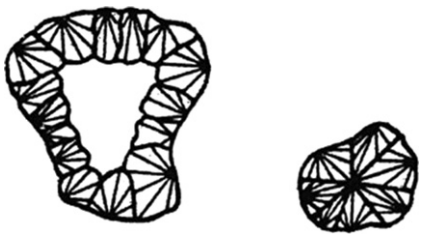

Figure 28 Effect of grain size on time of transformation to pearlite with rate of growth constant.[14]

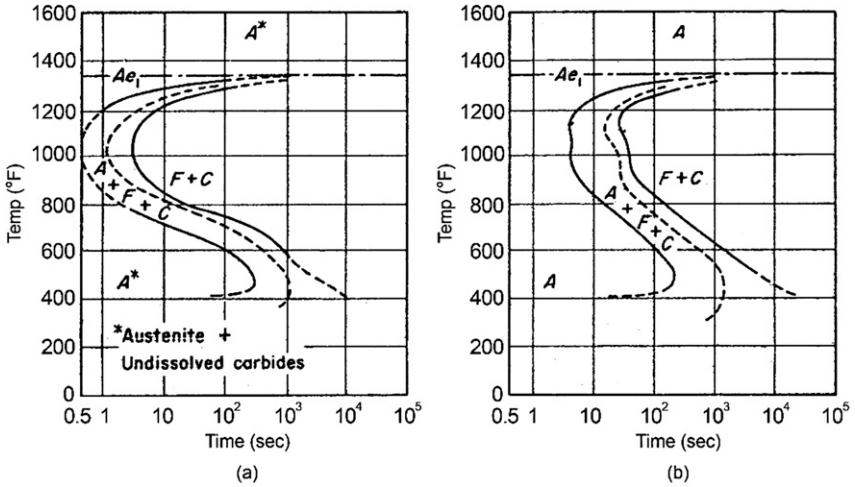

Figure 29 Isothermal transformation diagram. (a) 0.87%C, 0.30%Mn, 0.27%V steel at 815 °C; ASTM grain size 11. (b) Same steel at 1052 °C; grain size 2–3.[14]

2.2.6.2 Austenitizing Temperature and Time

Austenitizing temperature and time at temperature have significant effect on hardenability of steel. The purpose of austenitizing is to dissolve almost all the second phases such as carbides and obtain a homogeneous structure of austenite with uniformly distributed carbon and alloying elements. This is because the hardenability of steel is greatly dependant on chemical composition and grain size of austenite at the onset of quenching. If the carbides remain undissolved in the austenite then neither the carbon nor the alloy content can contribute to hardenability as both are not in the solution. Undissolved carbides, of course resist grain growth at austenitizing temperature. During quenching from austenitizing temperature, the undissolved carbides tend to promote the transformation to diffusional product and thus reduce hardenability. This is especially important in high carbon (0.5–1.1%) and alloy carburizing grade steels which may contain excess carbides at austenitizing temperature. In order to dissolve these carbides completely in austenite a higher temperature of austenitization is required. Even sometimes, the temperature of austenitization is raised to accelerate the formation of homogeneous austenite. A higher temperature may increase the austenite grain size which in turn produces deeper hardening, particularly in plain carbon steels. Iron carbides dissolve much more rapidly in austenite than more complex alloy carbides formed by chromium, molybdenum, etc. Therefore, to obtain complete solution of these complex carbides in austenite, a longer time at temperature or a higher temperature than the normal austenitizing temperature of steels of identical carbon content is necessary. The time required to obtain homogeneous austenite is longer for alloy steels than for plain carbon steels. This is because the alloying elements, in particular carbide forming ones, dissolve much slowly in austenite than simply iron carbides. Carbides of most alloying elements are stable and therefore their dissolution in austenite needs higher temperatures and longer times. Sometimes coarsening of fine-grained steel by heating to a high temperature may not improve hardenability. This may be due to the presence of nonmetallic inclusions which promote the nucleation of equilibrium soft product and thus reduce hardenability. Both higher temperature of austenitization or longer time of austenitization at lower temperature may result in decarburization and oxidation and also tend to promote cracking and distortion. So it is important to keep the temperature as low as possible to reduce the tendency toward cracking and distortion, minimizing oxidation, decarburization, and grain growth and is economic as well. To minimize the time for austenitization, the temperature is generally kept about 50–60 °C above the minimum temperature for formation of 100% austenite. The time is approximately 1 h per 25 mm thickness of steel.

2.2.6.3 Effect of Carbon Content on Hardenability

Carbon in steels serves dual functions: (1) it controls the maximum attainable hardness and (2) contributes to enhancement of hardenability. Higher content of carbon in steel tends to stabilize austenite and act in a way to delay the transformation of austenite into pearlite. The stability of austenite can be judged from the consideration of IT curves for steels with increasing carbon content. This is illustrated in Figure 30 or three plain carbon steels 1021, 1061, and 1080 (AISI designation).

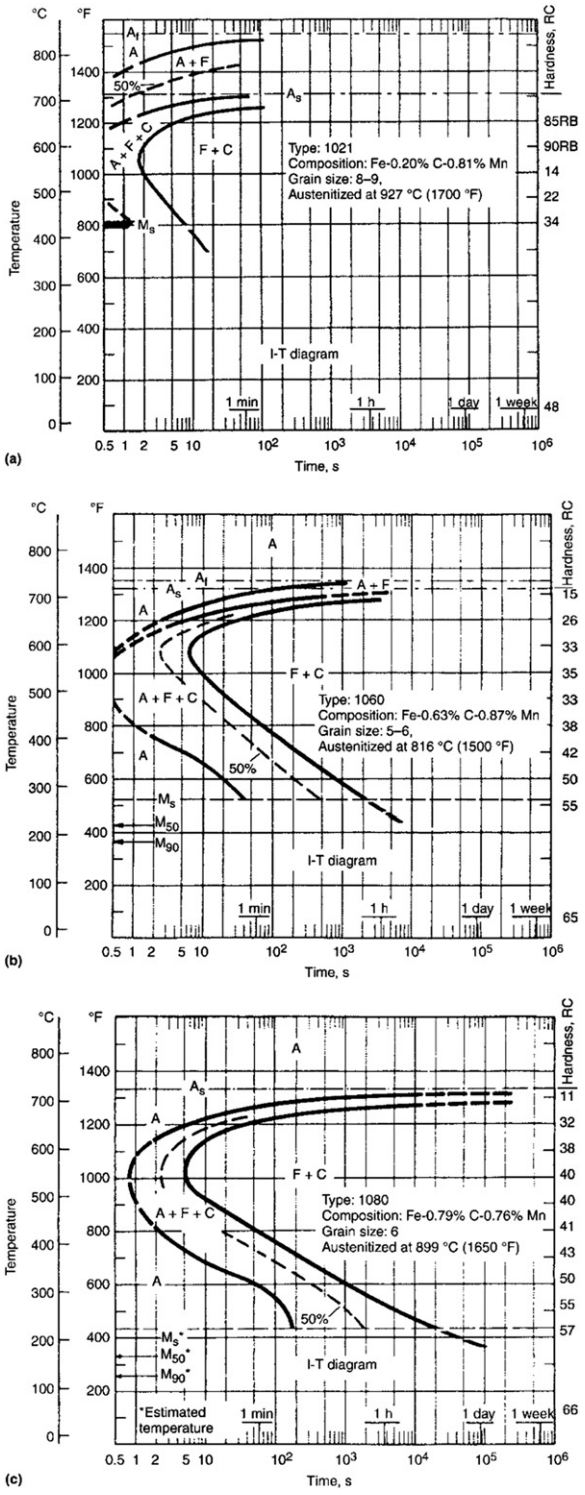

Figure 30 Isothermal transformation diagrams for plain carbon steels AISI 1021, 1060, and 1080 showing the effects of increasing carbon content.[3]

It can be noted from the IT curves of these steels that as percentage of carbon increases, the curves shift to the right, that is, for longer times. The location of the nose is shifted to longer times from below 0.5 s for 1021 and 1060 lower carbon steels to 0.8 s for 1080 eutectoid steel. The shifting of start curves to longer times also makes it difficult for the product pearlite to form from austenite. This shifting of transformation start curves toward longer times with increasing carbon concentration clearly suggests that the hardenability of steels increases with increasing carbon content. Thus it appears that increasing the carbon content of steel is the least expensive approach to improve hardenability. However, the effect of carbon on hardenability is comparatively less. It is true to some extent, but several limitations are there for use of large concentration of carbon in steel:

1. Increasing the carbon content of steel lowers the toughness at room as well as at subzero temperatures. This is because the higher carbon martensite is harder and more brittle than low carbon martensite.
2. The microstructure in the annealed state imparts hardness and wear resistance which makes cold shearing, sawing, machining, and other cold forming processes difficult.
3. Increased amount of carbon makes steel susceptible to hot shortness during hot working.
4. Increasing carbon content also makes steel more susceptible to distortion and cracking after quench hardening.
5. Increasing carbon in steel lowers M_s temperature (**Figure 30**). Steel is less plastic at lower M_s temperature and has less ability to accommodate the large volume change accompanying martensitic transformation.

Because of the above disadvantages, more than 0.6% carbon is rarely used in steels for machine parts where deep hardening is required with exception to springs and bearings. Moreover, the hardenability achieved in steels with up to about 0.8% carbon is not appreciable. Hypereutectoid steels, in practice, are generally hardened by austenitizing at above lower critical temperature where proeutectoid cementite exists. On quenching, proeutectoid cementite particles act as nucleation sites for pearlite formation resulting in lower hardenability.

Effect of carbon content on hardenability of dual phase steel has been studied by Valeria and his coworkers.[15] They observed that hardenability of dual phase steels also increases with increase of carbon content from nominal of about 0.1% to about 0.35%. As the carbon content increased, for the same intercritical temperature of 740 °C, the proportion of martensite has also been found to increase from 23% for 0.1%C to 74% for 0.38% carbon through 50% for 0.2% carbon. Also the hardness of the high carbon content steel was observed to be high. The best combination of mechanical properties was reached for steels with carbon in the range 0.1–0.15% with 50% martensite.

2.2.6.4 Effect of Alloying Elements on Hardenability

When alloying elements are present in steel, these are also nearly uniformly distributed in austenite when steel is heated to austenitic region. Upon cooling, this austenite tends to decompose into a mixture of ferrite and carbide. The carbide forming element prefers to go into cementite (carbide) while non carbide forming element prefers to go into ferrite phase. That is the alloying elements and carbon redistribute between ferrite and cementite. This process of redistribution of alloying elements involves diffusion. Diffusivity of alloying elements is much lower than that of carbon in iron. Therefore, the presence of alloying elements makes austenite difficult to transform to pearlite and shifts the transformation start curves on IT diagrams to longer times. In other words the critical cooling rate is reduced by alloying elements in steel provided these elements are completely dissolved in austenite. Thus the alloying elements which shift the IT curves toward right improve hardenability. **Figure 31** illustrates the shift of transformation start curve toward longer time on IT diagram produced by chromium and nickel. Among the common alloying elements (Mn, Cr, Ni, Si, Mo, Co, etc.) added in steels, cobalt seems to be the only element which decreases hardenability of steel. The presence of cobalt in steel increases both rate of nucleation and rate of growth of pearlite. So steels containing cobalt transform to pearlite in preference to martensite. As previously stated, the alloying elements will be effective in imparting deep hardenability only if they form complete homogeneous solution with austenite. **Figure 32** illustrates the effect of dissolved chromium on hardenability of steel.

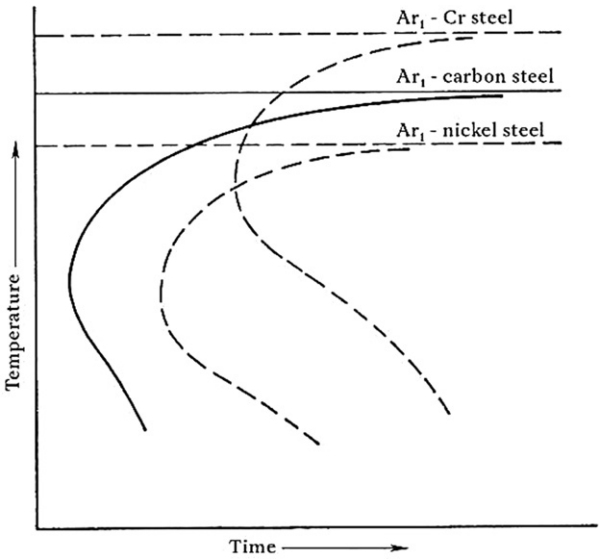

Figure 31 Effect of nickel and chromium on IT diagram.[14]

This figure also shows that hardenability increases with increasing amount of alloying elements. Different alloying elements have different effect on degree of hardenability. The effect of individual alloying elements on hardenability of steel is independent of each other as well as of carbon content. The influence of individual alloying elements is also independent of grain size of austenite.

Hardenability is appreciably enhanced by manganese, chromium, molybdenum, and very small additions of boron (0.001–0.003%). On the contrary, nickel and silicon have mild influence on increase of hardenability of steels. Effect of nickel content on hardenability of dual phase steel has been studied by Demir and Erdogan.[16] This study has shown that nickel content in dual phase steel decreases the critical cooling rate. At any cooling rate from as low as 0.1 °C s^{-1} to as high as

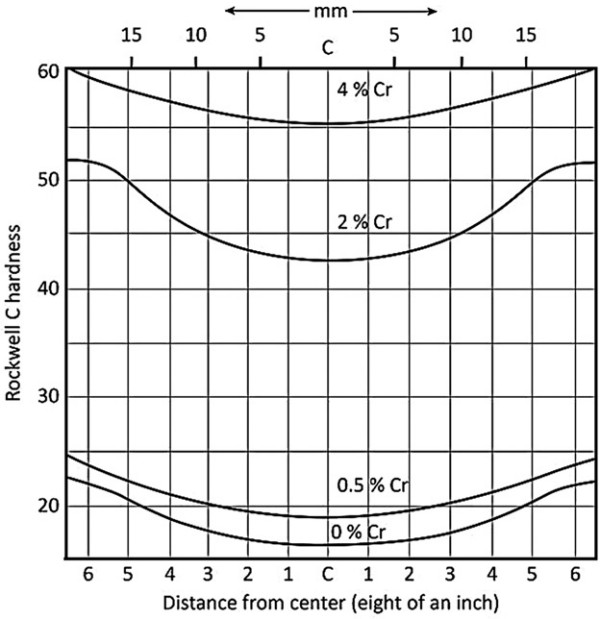

Figure 32 Variation of hardness from end to end of oil quenched 40 mm 0.35% carbon steel bar with different chromium content.[12]

1400 °C s^{-1}, the microstructure of the treated dual phase steel did not show any sign of ferrite cementite aggregate formation. These authors also observed that originally fine grain dual phase steel produced more martensite than coarse grain steel after annealing at low temperature and particularly at low cooling rates. The reason stated is that fine grain structure is more enriched with carbon content than coarse grain structure. The higher proportion of martensite in dual phase steels is correlated to high hardenability.[15,16]

It has been reported that when small amounts of several alloying elements are added, the hardenability of steel is improved significantly. Though a very small amount of boron enhances hardenability of steels to a great extent but its amount is so small that it is not regarded as alloying element in steel from the point of improving hardenability. Therefore, the effect of boron on hardenability of steels is discussed in separate section. Again combined additions of two elements like boron and molybdenum shows synergism while increasing hardenability.

2.2.7 Estimation of Hardenability from Chemical Composition and Austenite Grain Size

Though Grossmann has devised the experimental measurement of hardenability in terms of ideal critical diameter, he also proposed a method of estimating hardenability of steel based on the knowledge of chemical composition and austenite grain size. This method is further based on some facts. The hardening in steel principally arises due to carbon content. As stated earlier hardening effect increases with increasing carbon content (**Figure 3**); also martensitic hardness is not affected by the presence of alloying elements in steel as illustrated in **Figure 4** which demonstrates identical surface hardness of plain carbon steel and alloy steel. However, presence of

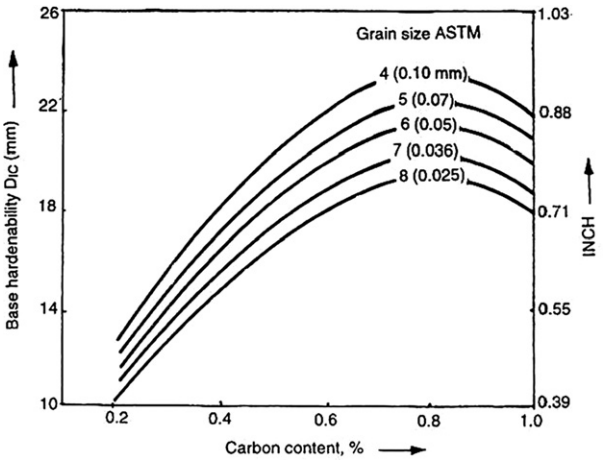

Figure 33 Effect of carbon content and austenite grain size of steel on base hardenability, D_{IC}.[4]

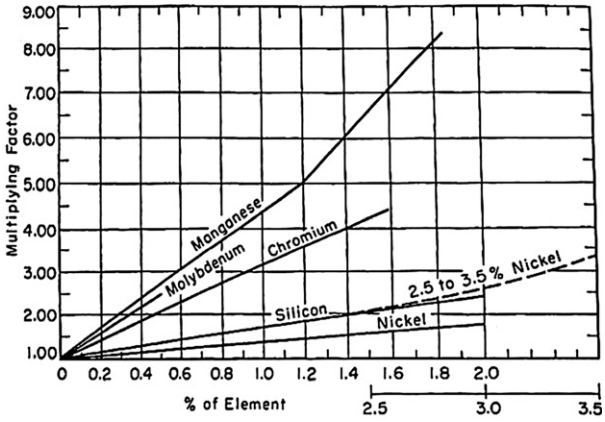

Figure 34 Multiplying factors for ordinary proportions of the common alloying elements.[11]

alloying elements affects the rate of reaction when austenite transforms to product phase during quenching. Thus, every steel has a base hardenability which is governed by its carbon content and austenite grain size before quenching. The effects of individual alloying elements on hardenability of steel are independent of each other as well as of carbon content. The influence of individual alloying elements is also independent of grain size of austenite.

Grossmann expressed the hardenability D_I (the ideal critical diameter) in terms of D_{IC} (the ideal critical diameter corresponding to a particular carbon content),the base hardenability based on carbon content and austenite grain size of steel, and the multiplying factors F_j, for the common alloying elements (other than carbon) present in steel, that is,

$$D_I = D_{IC} \times F_j \qquad [3]$$

The base hardenability, D_{IC} can be obtained from the relationship between base hardenability D_{IC} and percent carbon content as shown in **Figure 33** depending on the austenite grain size (ASTM) and the multiplying factor, F_j can be obtained from **Figure 34**. **Figure 33** is useful for steels

containing carbon content in the range 0.2 to 1.0% and the grain size in the range ASTM 4 to 8. The Grossmann hardenability multiplying factors corresponding to grain size and specific content of alloying elements including carbon are given in **Table 3**. The multiplying factor is considered unity for an element having no effect on hardenability. For instance, sulfur and phosphorous are considered as impurity in steels and therefore these elements have multiplying factors to be unity.

To illustrate the calculation (or estimation) of hardenability D_I of a steel one can consider a composition[14]: 0.395%C, 0.83%Mn, 0.31%Si, 0.20%Ni, 0.99%Cr, 0.17% Mo,0.018%P, and 0.029%S and ASTM grain size No. 7. The value of the base hardenability, D_{IC} corresponding to 0.395% C and ASTM grain size No.7, obtained from **Figure 33** for the given steel is 0.214″. The multiplying factors for the other elements present in steel are obtained with reference to **Figure 34** and these values are given in **Table 4**.

Using Grossmann eqn [3], hardenability D_I can be estimated as:

$$D_I = 0.214 \times 3.80 \times 1.20 \times 1.07 \times 3.15 \times 1.52 = 5.0''$$

Thus the hardenability of the given steel is 5″ which means that the steel with diameter of 5″ is fully hardenable.

Table 4 Multiplying factors of alloying elements present in the given steel

Percent alloying element	*Multiplying factor, F_j*
0.83 Mn	3.80
0.31 Si	1.20
0.20 Ni	1.07
0.99 Cr	3.15
0.17 Mo	1.52

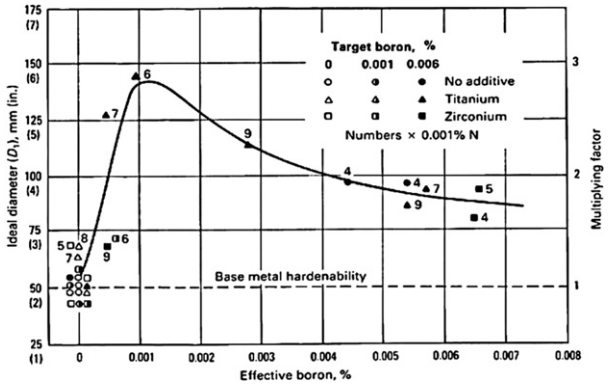
2.2.8 Effect of Boron on Hardenability

Boron forms interstitial solid solution with iron. The solid solubility of boron in iron is very limited due to its size (atomic diameter 0.188 nm) which is largest among the interstitial solid solution forming elements. Its solid solubility in γ-Fe is about 0.001% at 910 °C which increases with temperature to as high as about 0.005% at eutectic temperature. The solubility of boron in α-Fe is essentially zero. Because of its low solid solubility boron is preferentially located in the grain boundaries of austenite.

Boron plays a vital role in enhancing the hardenability of steels, in particular, those of fully deoxidized low carbon steels. In fact boron is mostly added to steels only to enhance their hardenability. Since the cost of boron is very low so it is considered as potent and economical alloying element in steels from the point of view of enhancing hardenability. The unusual features of boron hardenability can be considered in the following respects:

- A very small amount of boron has a substantial effect on hardenability.
- Hardenability effect of boron increases with decreasing the grain size of austenite.
- High temperature treatment reduces the hardenability effect of boron.
- The effect of boron on hardenability is much more in low carbon steels than in high carbon steels.

As little as about 0.001% boron in steels has substantial and optimum effect on hardenability (**Figure 35**) in fully



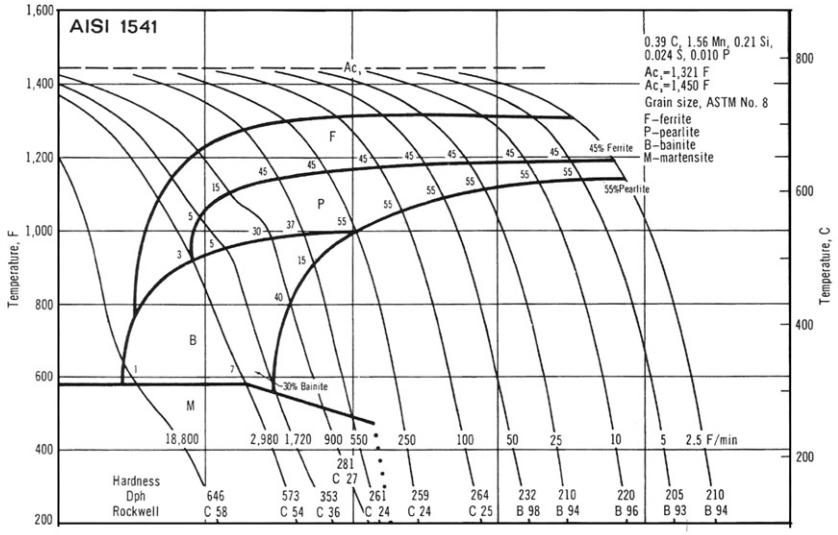


Figure 35 Influence of effective boron (B_{eff}) content on hardenability of AISI 8620 steel. $B_{eff} = B–[(N - 0.002)–Ti/5–Zr/15]$.[2]

deoxidized steels. Boron content greater than about 0.003% reduces the hardenability of steels. Any excess boron tends to form borocarbides $M_{23}(C,B)_6$ at austenite grain boundaries.[4,17] When exceed a critical size these borocarbides act as nucleation sites for proeutectoid ferrite and pearlite. Boron treated commercial steels contain 0.0005–0.005% of boron. Boron distribution, whether it is present as solute atoms or as $M_{23}(C,B)_6$ along the austenite grain boundaries has been found to be affected by cooling rate also as observed by Dong *et al.*[17] for steel containing 0.0021%B, 0.51%Si, 2.0%Mn as the principal elements. This steel when cooled from 900 °C in the cooling rate range of 10–20 °C s^{-1} significant amount of boron segregation along austenite grain boundaries has been observed. This boron in turn has been observed to retard the formation of ferrite during cooling from austenitizing temperature in the cooling rate (CR) range of $10 \leq CR \leq 20$ °C s^{-1}

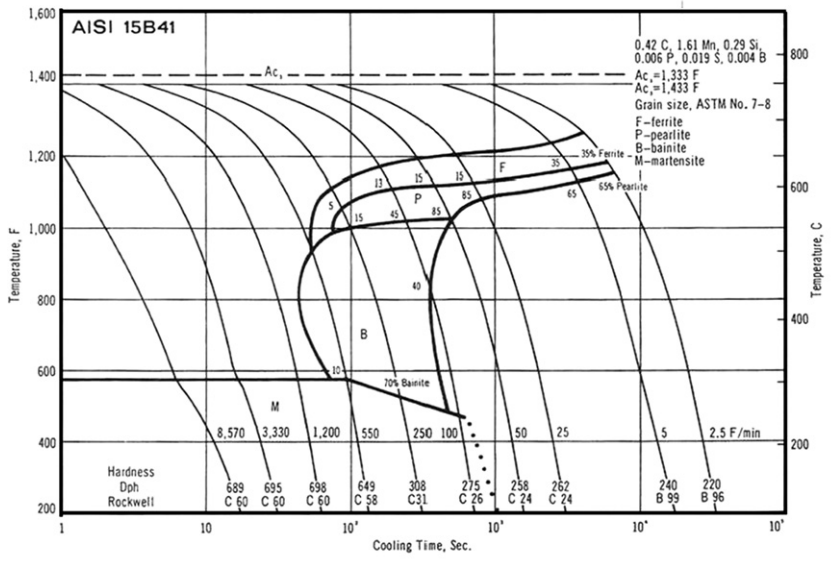

Figure 36 Comparison of CCT diagram of (a) AISI 1541 and (b) AISI 15B41, showing the boron hardenability effect.[18]

and thus improved hardenability of steel. The dramatic effect of addition of boron to a C–Mn steel (in plain carbon steels nominal content of Mn range from 0.60 to 0.90%) can be noted from the comparison of CCT diagrams of AISI 1541 and AISI 15B41 steels (**Figure 36**).

Here 0.004% boron promoted a structure which was entirely martensitic when formed at cooling rates greater than about 9 °C s^{-1} (540 °C min^{-1}). The difference in the rapidity with which transformations occur is quite evident from this figure.

Like other alloying elements, boron is effective in imparting hardenability only when it is in solution of austenite. Any boron which does not enter in austenite solution is ineffective in imparting hardenability to steel. Boron has strong tendency to combine with oxygen and nitrogen and form B_2O_3 and BN, respectively, in their presence during steel making. Once formed, these compounds cannot dissolve in austenite at the highest austenitizing temperatures used. Therefore, hardenability of boron treated steels varied with the state of deoxidation and with nitrogen content. Thus, proper steel melting practice must be used to protect boron from oxidation or nitride formation. This is done by (1) by proper deoxidation practice with the addition of Al, Si, or other deoxidizers, (2) by addition of strong nitride formers, such as Ti or Zr prior to addition of boron, or adding more boron to take care of existing nitrogen. Generally it is desirable to add boron slightly in excess over that required for optimum hardenability effect. Boron is added in steel in the form of ferro-boron alloy containing Al, Mn, Si, Ti, Zr, etc.

Boron in steel is believed to segregate to grain boundaries of austenite and retards the nucleation of proeutectoid ferrite, and thus promoting greater hardenability effect with fine austenite grain size. This means that a fine austenite grain size with large grain boundary area will promote suppression or retardation of nucleation of ferrite during austenite transformation upon quenching. This is in contrast to the effect of grain size on hardenability, i.e., boron diminishing the hardenability effect of grain size. In other words, boron has larger hardenability effect in fine grained steels. This suggests that if the boron level is too small, it is ineffective in imparting high hardenability in fine grain steels or at lower austenitization temperature but is effective to produce marked increase in hardenability in coarse grain steel. Grain size of austenite depends on austenitization temperature. Higher the temperature of austenitization coarser will be the grain structure.

Effect of hot deformation on hardenability of boron bearing low carbon high strength steel has been examined by Dong *et al.*[17] They observed that hot deformation increased the stability of solute boron that segregated to austenite grain boundaries during cooling from austenitizing temperature. This increase occurred because of the increase in boundary area by grain refinement. Hence the hardenability was improved in this steel.

Boron hardenability has been found to be affected by austenitizing temperature. An austenitizing temperature in the range 845 to 985 °C gives maximum boron hardenability but the most commonly used temperature is around 900 °C. However, as the temperature of austenitization increased beyond the above range, boron hardenability decreases with increasing the temperature. This is attributed to greater content

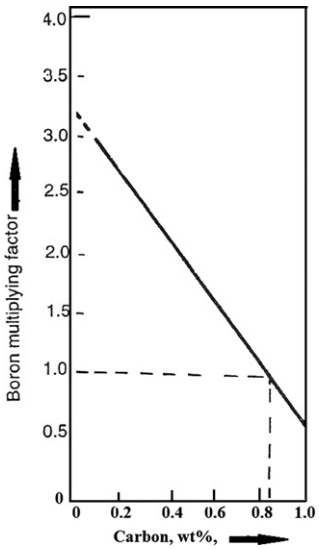

Figure 37 Effect of carbon on boron multiplying factor in 0.8%Mn steel.[4]

of boron dissolved in austenite. This promotes precipitation of borocarbides in advance of austenite transformation and is responsible for lowering the hardenability effect of boron.[17,19] For this reason, case-hardenability of boron treated steels is better if quenched from 925 °C. If the austenitizing temperature is very high, for instance, around 1100 °C, then a phenomenon called boron 'fade' occurs, in particular, in nitride bearing steels. The resultant effect is partial or total loss of boron hardenability and is permanent. The prolonged high temperatures of austenitization break the nitrogen protection provided by the elements Al, V, or Nb faster than if protected by Ti or Zr. The boron in solution is permanently lost to nitrogen resulting in decrease of hardenability.

Effect of boron on hardenability of carbon steels has been found to be more intensive in low to medium carbon steels than in high carbon steels. Even in hypoeutectoid steels, the highest effect of boron on hardenability occurs at low carbon concentration ≈0.10%. With carbon concentration greater than this the boron multiplying factor decreases continuously to unity at ≈0.80%C (**Figure 37**).

An element having multiplying factor of unity has no effect on hardenability. With further increase of carbon in the hypereutectoid range, multiplying factor of boron becomes less than unity. Combined additions two elements like boron and molybdenum shows synergism while increasing hardenability.[20]

2.3.1 Introduction

The service condition of many machine parts of steel such as gears, shafts, cams, pinions, and piston pins demands very hard and wear-resistant surface but with tough and shock-resistant core. Such a combination of properties is not usually possible from the commercial steels. A low carbon steel containing carbon 0.10–0.30% is sufficiently tough while a high carbon steel containing carbon up to 1.00% possesses adequate hardness. By suitable heat treatment the high carbon steel can be made very hard while low carbon steel will develop sufficient toughness. A machine part requiring hard surface but tough core will require a combination of high carbon surface and low carbon core which is developed by heat treatment only.

Carburizing is the most satisfactory and widely used method of surface hardening of low carbon steel. It is a process by which the carbon content of the surface of steel is increased. Since the objective of surface hardening is to obtain a hard, wear-resistant surface called case with a tough interior called core, the first consideration is the selection of low carbon (usually $\leq$0.20%) steel. It is then subjected to carburization to an extent of eutectoid–hypereutectoid composition and by subsequent heat treatment to the desired hardness.

Carburizing is the addition of carbon to the surface of low carbon steels at a temperature between 850 and 950 °C. At this temperature stable austenite structure has higher solubility of carbon which is diffused from the surrounding carburizing environment. Hardening is accomplished when the high carbon surface layer is quenched to form martensite. This produces a high carbon martensite case with good wear and fatigue resisting properties while the low carbon martensite core gives high toughness and shock resisting properties. A Schematic representation of carburizing process is shown in Figure 1.

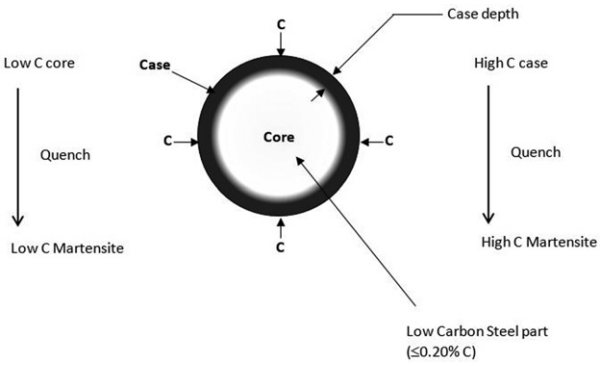

Figure 1 Schematic representation of carburizing process.

2.3.2 Methods of Carburization

There are three general methods of carburization depending on the carburizing medium.

1. Solid or pack carburization – solid medium.
2. Liquid carburization – liquid medium.
3. Gas carburization – gas medium.

Two other specialized methods are plasma carburization and vacuum carburization.

2.3.2.1 Solid or Pack Carburization

2.3.2.1.1 Carburizing process

In solid or pack carburization process parts to be carburized are charged in a heat resisting metallic box with a carburizing mixture (Figure 2). The solid carburizing mixture is of the following proportions:

Hard wood charcoal	53–55 parts
Sized coke	30–32 parts
Barium carbonate	10–12 parts
Calcium carbonate	3–5 parts
Sodium carbonate	2–3 parts

In the preparation of the above carburizing mixture, molasses is commonly used as binder. The carbonates are used as energizers. They are added to the charcoal to accelerate the carburizing process.

Workpieces, which are to be pack carburized, are first cleaned of dirt, scale, and rust. They are then placed in a box. Welded heat resisting steel boxes are generally employed. The

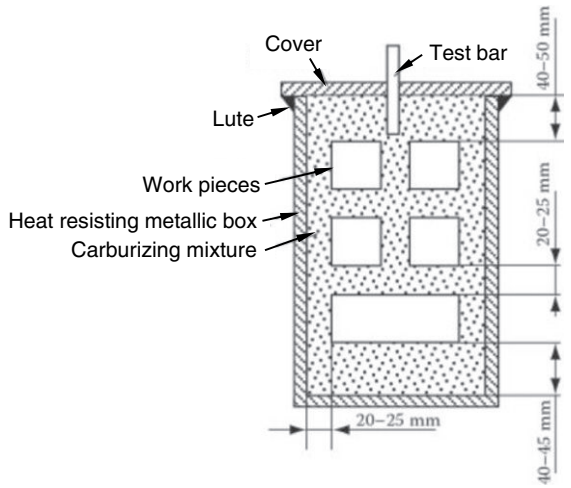

Figure 2 Packing of workpieces (low carbon steel parts) in a box for carburizing.[1]

boxes are usually in rectangular or cylindrical form. It is advisable to employ cylindrical boxes or pots. Packing the work is accomplished by first covering the bottom of the box with a 40–45 mm layer of carburizer (Figure 2). The workpieces to be carburized are placed on this layer with spaces of 20–25 mm between them and the box walls. Then they are covered with a dense layer of carburizer, 20–25 mm thick, which is rammed before laying the next row of workpieces. The upper row is covered with a layer of carburizer 40–50 mm thick. The box is closed with a cover whose edges are luted with fireclay or with mixture of clay and talc with water glass. Packed box is placed in the furnace.

The carburizing compound is in form of coarse particles or lumps, so that when the cover is sealed on the box, sufficient air will be trapped to form carbon monoxide. The box is then heated to the proper temperature (about 900–925 °C) for a required period of time (usually 3–5 h) and cool slowly in the furnace. The box is then withdrawn from the furnace and workpieces are taken out from the box.

The holding time at the carburizing temperature depends on the specified depth of carburized case. The deeper the case required, the longer the holding time should be at the carburizing temperature. The required holding times for various depths of carburized case are given in Table 1.[1]

At carburizing temperature the steel consists of austenite. Carburizing is concerned with the solid solution of carbon in austenite. The limits of carbon content of this phase depend on the temperature and composition of the steel. The maximum amount of carbon that can be dissolved in austenite at the carburizing temperature is indicated on the iron–iron carbide equilibrium diagram at the A_{cm} line (Figure 3). Therefore very quickly a surface layer of high carbon (about 1.2%) is built up. Since the core is of low carbon content, the carbon atoms trying to reach equilibrium will begin to diffuse inward. The rate of diffusion of carbon in austenite at a given temperature is dependent upon the diffusion coefficient and carbon concentration gradient. After the diffusion has taken place for the required amount of time dependent upon the case depth desired, the part is cooled in the furnace and examined microscopically. The carbon gradient will be visible in the gradual change of the structure. At the surface is hypereutectoid zone consisting of pearlite with a white cementite network, followed by the eutectoid zone of only pearlite and finally hypoeutectoid zone of ferrite and pearlite, with amount of ferrite increasing until the core is reached. This is illustrated in the Figure 4. Figure 5 shows carbon concentration gradient in the carburized steel with 0.08 in. total case.

Table 1 Relationship between case depth and holding time (carburizing temperature 930 °C)

Case depth (mm)	*Holding time (hour)*
0.4–0.7	4.5–5.5
0.6–0.9	5.5–6.5
0.8–1.2	6.2–10.0
1.0–1.4	8.0–11.5
1.4–1.8	11.5–16
1.5–1.9	13–18
1.6–2.0	14–19
1.8–2.2	16–22

2.3.2.1.2 Chemical reactions

There is always air present in the carburizing box, even when it is filled with carburizer. At the carburizing temperature, the oxygen in the air reacts with the carbon in the carburizer to produce carbon dioxide gas. This carbon dioxide further reacts with carbon in the carburizer to produce carbon monoxide.

$$C + O_2 \rightarrow CO_2 \quad [I]$$

$$CO_2 + C \rightarrow CO \quad [II]$$

This carbon monoxide is the carrier of carbon and when comes in contact with austenitic iron, iron carbide is formed, which is dissolved in austenite.

$$Fe + CO \rightarrow [C]Fe\ (C\ \text{dissolves in austenite}) + CO_2 \quad [III]$$

Energizers (like $BaCO_3$, $CaCO_3$, and $NaCO_3$) in the carburizing mixture decompose at the carburizing temperature to produce oxides and CO_2 as follows:

$$BaCO_3 \rightarrow BaO + CO_2$$

$$CaCO_3 \rightarrow CaO + CO_2$$

$$Na_2CO_3 \rightarrow NaO + CO_2$$

This ensures enough supply of CO_2 for the reaction [II] to continue, and hence enough supply of CO for the reaction [III]. The reactions cycle will be repeated.

At the initial stage of carburization, the maximum saturation limit of carbon (about 1.2%C) at the surface of the steel is reached. Then carbon begins to diffuse to the interior as shown in Figure 6. The diffusion of carbon depends on the diffusion coefficient $D = D_0\, e^{-Q/RT}$, where Q is the activation energy, R is gas constant, and T temperature in degree kelvin. As D increases, depth of penetration of carbon or case depth increases.

The relation of carburizing time and temperature to case depth is shown in Figure 7. The higher the temperature and longer the period of carburization, the greater is the case depth.

2.3.2.1.3 Decarburization

The carburization equation given previously,

$$Fe + CO \rightarrow [C]Fe\ (C\ \text{dissolves in austenite}) + CO_2$$

is reversible and may proceed to the left, removing carbon from the surface layer if the steel is heated in an atmosphere containing carbon dioxide (CO_2). This is called decarburization.

Other possible decarburization reactions are:

$$Fe_3C + H_2O \rightarrow Fe + CO + H_2$$

$$Fe_3C + O_2 \rightarrow Fe + CO_2$$

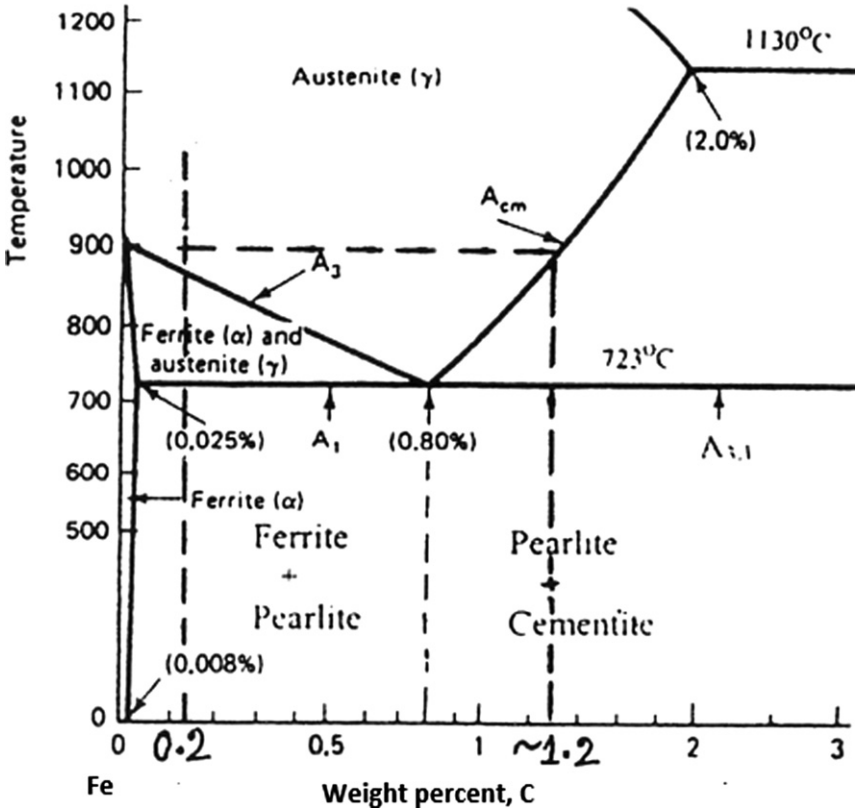

Figure 3 Portion of Iron–Iron Carbide equilibrium diagram.

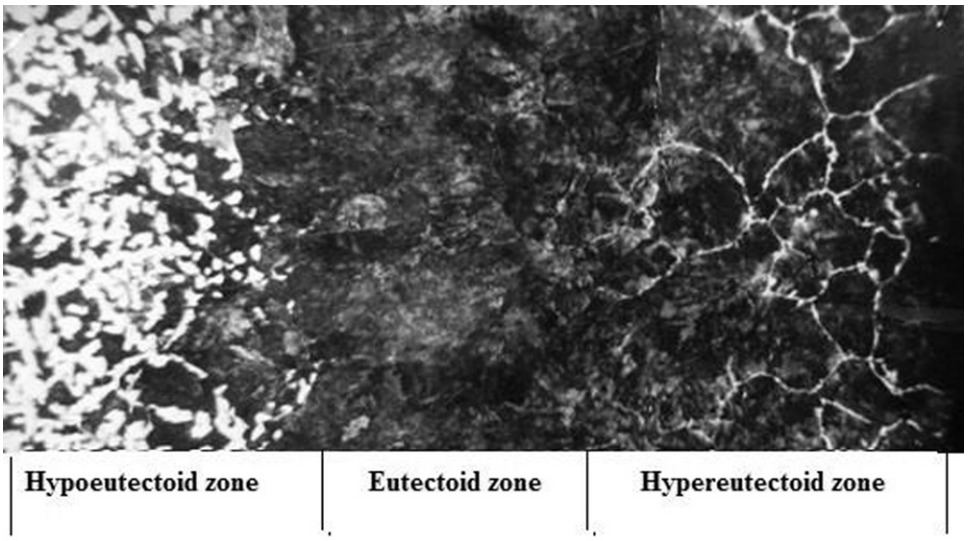

Figure 4 Microstructure of pack carburized and furnace cooled low carbon steel showing different zones from case (right) to core (left), × 400.

Decarburization is a problem primarily with high carbon steel and tool steel.

2.3.2.1.4 Advantages

- Pack carburization is economical and advantageous for small machine parts.
- Special furnaces are not required to heat the carburizing boxes.
- The soft case produced by slow cooling from the carburizing temperature permit additional machining prior to hardening.
- It does not require a controlled atmosphere furnace.

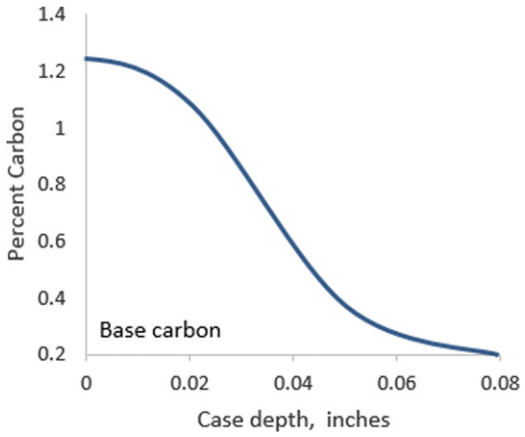

Figure 5 Carbon concentration gradient in a carburized steel with 0.08 in. total case.

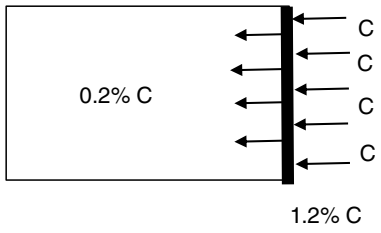

Figure 6 Flow of carbon from high carbon surface to the interior.

- Carburizing compounds give good support to parts, helping to prevent sagging at high temperatures.

2.3.2.1.5 Disadvantages

- Larger and complicated machine parts cannot be carburized effectively.
- There are some limitations in handling larger and complicated machine parts.
- Packed carburized machine parts cannot be hardened directly from the carburizing temperature.
- The box containing the charge when heated gets oxidized and warrants frequent replacement.
- Uniform case depth cannot be obtained in pack carburization.
- The preparation of judicious mixture is a skilled job and is time consuming.

2.3.2.2 Liquid Carburization

2.3.2.2.1 Carburizing Process

The liquid carburization is used for parts requiring thin carburized case. The liquid carburization is suitably practiced for complex machine parts and is carried out by heating them in a liquid bath.

In liquid carburizing, workpieces to be carburized are immersed in molten salt baths maintained at carburizing temperatures as shown in Figure 8. These baths contain sodium cyanide as a carburizing agent. Liquid carburizing

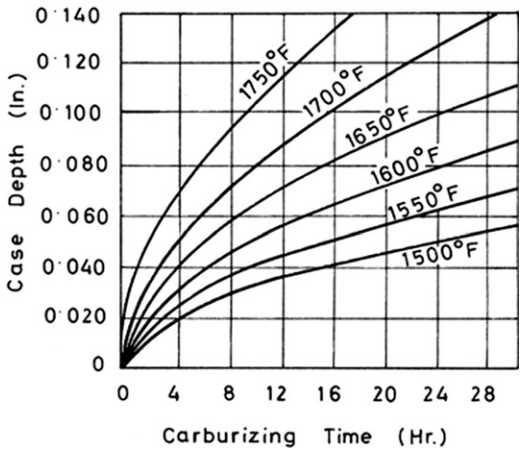

Figure 7 The relation of time and temperature to case depth.[2]

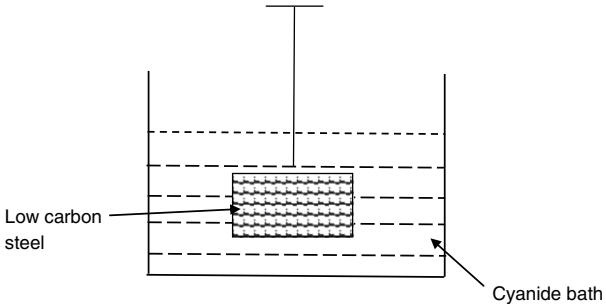

Figure 8 Liquid carburization in cyanide bath.

baths can be divided into two categories: (1) low temperature baths and (2) high temperature baths.

They not only differ with respect to temperatures of carburizing, but the compositions of these baths and the mechanisms (chemistry) of carburizing are also different. Table 2 gives compositions of these baths. Recently some noncyaniding liquid baths have also been developed.

2.3.2.2.1.1 Low temperature baths

These are normally operated at 850–900 °C and are best suited for producing shallow case depths (~0.075–0.75 mm). Typical composition of low temperature carburizing baths is given in Table 2.

Chemistry of carburizing in low temperature baths is rather complex. The main reactions involved are as follow:

$$2NaCN \rightarrow Na_2CN_2 + C \text{ (Cynamide shift)} \quad [IV]$$

and either

$$NaCN + O_2 \rightarrow 2NaNCO \text{ (Cyanate formation)}$$

or

$$NaCN + CO_2 \rightarrow NaNCO + CO \text{ (Cyanate formation)} \quad [V]$$

The cyanate (NaNCO) thus produced, further reacts to give:

$$NaNCO + C \rightarrow NaCN + CO \quad [VI]$$

Table 2 Compositions of liquid carburizing baths (in wt%)

Constituent	*Low temperature baths*	*High temperature baths*
Sodium cyanide	10–23	6–16
Barium chloride	–	30–55
Salts of alkaline earths	0–10	0–10
Potassium chlorides	0–25	0–20
Sodium chlorides	20–40	0–20
Sodium carbonate	40 max.	30 max.
Other accelerators	0–5	0–2
Sodium cyanate	1.0 max.	0.5 max.
Density	1760 kg m^{-3} (at 1173 K)	2000 kg m^{-3} (at 1198 K)

$$4NaNCO + 2O_2 \rightarrow 2Na_2CO_3 + 2CO + 4N \quad [VII]$$

and

$$4NaNCO + 4CO_2 \rightarrow 2Na_2CO_3 + 6CO + 4N \quad [VIII]$$

CO and C produced by above reactions react with Fe at the steel surface to enrich it with carbon as,

$$2CO + Fe \rightarrow C(Fe) + CO_2 \quad [IX]$$

and

$$C + (Fe) \rightarrow C(Fe) \quad [X]$$

Reactions [VII] and [VIII] deplete the activity of the bath and lead to an eventual loss of carburization potential, unless suitable replenishment is done.

2.3.2.2.1.2 High temperature baths

These are normally operated at 900–950 °C. Typical composition of high temperature baths is given in **Table 2**. High temperature baths are used for producing deeper case depths, in the range of 0.5–3.0 mm. Apart from cyanide, these baths contain a major amount of barium chloride.

In liquid carburization the carburizing reaction depends primarily on the sodium cyanide, activated by the presence of alkaline earth salt-usually barium (or calcium) chlorides. The salts (chloride) react with the cyanide to form a cyanide of alkaline earth metal, which then reacts with iron to form Fe_3C.

Although reaction given above for low temperature baths occur here also to some degree, the principle reactions in high temperature baths are:

$$2NaCN + BaCl_2 \leftrightarrow 2NaCl + Ba(CN)_2 (\text{barium cyanide}) \quad [XI]$$

$$2NaCN + CaCl_2 \leftrightarrow 2NaCl + Ca(CN)_2 (\text{calcium cyanide}) \quad [XII]$$

$$Ba(CN)_2 + Fe \rightarrow [C]Fe + BaCN_2 (\text{barium cyanamide}) \quad [XIII]$$

$$Ca(CN)_2 + Fe \rightarrow [C]Fe + CaCN_2 (\text{calcium cyanamide}) \quad [XIV]$$

Carbon content of the case can be controlled by the cyanide content of the bath. Low temperature bath operates at higher cyanide content than high temperature bath. Both high as well as low temperature baths can be operated with varying cyanide content, through which the carbon activity of the bath can be controlled to some extent. **Table 3** gives preferred operating cyanide content at different temperatures. Lower end of the cyanide content range, at a given temperature, would normally produce a hypoeutectoid case, whereas, a hypereutectoid case is obtained with the cyanide content near the upper limit.

Table 3 Sodium cyanide content in liquid carburizing bath at different operating temperature

Temperature (°C)	*Sodium Cyanide (%)*		
	Maximum	*Preferred*	*Minimum*
815	23	18	14
840	20	16	12
870	18	14	11
900	16	12	10
925	14	10	8
955	12	8	6

Reactions [VII] and [VIII] show that, there is also nascent nitrogen present in the carburizing baths to some extent. This nitrogen is also absorbed at the surface of steel and diffuses inwards. However, at cyanide concentrations of carburizing baths, nitrogen activity is relatively low and hence only very little nitrogen diffuses into the steel. Activity of nitrogen is higher at higher end of the cyanide content range at a given temperature.

2.3.2.2.2 Advantages

- Complicated machine parts can be carburized.
- Uniform case depth can be obtained.
- Less distortion and cracking in hardening.
- High output even from a relatively small furnace due to rapid rate of heat transfer.
- Labor costs are reduced, since the operation of the process is simple.
- Surface decarburization is eliminated.
- Time of carburization is reduced compared to pack carburization.

2.3.2.2.3 Disadvantages

- Materials cyanide solution and fumes coming up from the both are poisonous.
- Great care required in disposal of cyanide bearing salts.
- Necessary of removing the salt from the work by special means, such as hot water spray washing, acid dip, etc.
- There is a danger of explosion if moisture is introduced into the salt.
- Separate storage required for keeping the salts under lock and key.
- Exhaust system is required.
- High cost of the carburizing salt.

2.3.2.2.4 Safety precautions

Sodium cyanide is a very poisonous substance and requires great care in its handling and storage. At all stages of the use of sodium cyanide, care must be taken to prevent any body contact so that no cyanide can enter the blood stream

(e.g., via cuts). Adequate protective clothing must be worn. Well-designed eye shields or goggles and well-fitting helmets are essentials in order to protect eyes and head.

2.3.2.3 Gas Carburization

2.3.2.3.1 Carburizing process

In gas carburization, the carbon of the furnace atmosphere is in the form of gaseous hydrocarbon compounds such as methane, ethane, propane, and butane or carbon monoxide. The principal source of carbon in gas carburizing is methane, which is present in manufactured and in natural gas. Gas carburizing is carried out at 900–950 °C and a case depth of up to about 0.4 mm may be obtained after 1 h heating at 900 °C. A case depth of up to 1 mm is commonly produced.

The low carbon ($\leq$0.2%C) steel parts are placed in the carburizing chamber. The air inside the carburizing chamber is then driven out by introducing hydrocarbon gas or carbon monoxide gas. The carburizing chamber is then heated to the temperature (900–925 °C) in the furnace and a continuous gas flow is maintained. A typical gas carburizing process is shown in Figure 9.

At this temperature and environment the low carbon steel part is heated for 2–3 h. At the end of the holding period the temperature of the furnace is reduced to 840–870 °C in order to decrease the grain size. The carburized part is then withdrawn from the chamber and quenched directly in water or oil. As a result the high carbon surface layer transforms into a hard wear-resistant case.

Quenching produces martensite microstructure with high residual stress inside the machine parts. This residual stress is undesirable because it causes cracking and distortion. In order to remove the residual stress, the machine part is tempered at a temperature of 150–180 °C immediately after quenching.

2.3.2.3.2 Carburizing reactions

The reaction involving the actual transfer of carbon occurs at the steel surface (interface) and the reactants, which are carbon compounds (gas), may be considered independently. The interface reactions[3,4] for common carbon compounds may be written:

$$CH_4(g) + 3Fe(steel) \leftrightarrow [C]Fe(in\ austenite) + 2H_2(g) \quad [XV]$$

$$C_2H_6(g) + 9Fe(steel) \leftrightarrow [C]Fe(in\ austenite) + 4H_2(g) \quad [XVI]$$

$$C_3H_8(g) + 9Fe(steel) \leftrightarrow [C]Fe(in\ austenite) + 4H_2(g) \quad [XVII]$$

$$2CO(g) + 3Fe(steel) \leftrightarrow [C]Fe(in\ austenite) + CO_2(g) \quad [XVIII]$$

Reactions that occur for the same compounds, away from the interface (i.e., the reactions for the deposition of carbon)[3,4] are as follows:

$$CH_4(g) \leftrightarrow 2H_2(g) + C(solid\ carbon) \quad [XIX]$$

$$C_2H_6(g) \leftrightarrow 3H_2(g) + C(solid\ carbon) \quad [XX]$$

$$C_3H_8(g) \leftrightarrow 3H_2(g) + C(solid\ carbon) \quad [XXI]$$

$$2CO(g) \leftrightarrow 2H_2(g) + C(solid\ carbon) \quad [XXII]$$

After the required period of carburization the parts are either cooled in the furnace or quenched directly from the furnace.

If water vapor is present in the gas it will act as a decarburizing agent, removing carbon from steel by the reaction[3]:

$$Fe_3C + H_2O \rightarrow Fe + CO(g) + H_2(g) \quad [XXIII]$$

2.3.2.3.3 Atmospheric conditions for gas carburization

Usually the volume of the chamber of gas carburizing furnace is small and it is sealed, which ensure small volume of gas requirement for each shift. For a pit furnace having a working chamber 64 cm in diameter and 90–120 cm deep, the commonly used gas flow rate is 63–118 $cm^3\ s^{-1}$.[5] The rate at which the furnace atmosphere responds to changes in inlet gas composition depends on the mean residence time of the

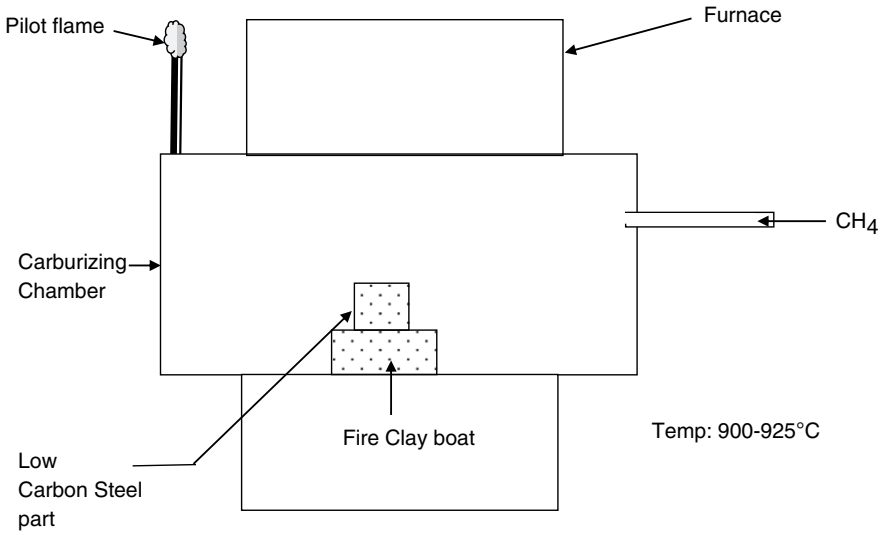

Figure 9 Gas carburizing process.

atmospheric gases in the furnace. The mean residence time (t_{res}) of the gas in the furnace is,[6]

$$t_{res} = V \cdot T_a / F \cdot T_f \quad [1]$$

where V is the chamber volume, T_f is the absolute temperature, and F is the flow rate of gas measured at ambient temperature T_a. Residence time may be from 2 to 15 min.[6] For times of this order the reaction in the furnace chamber are fast enough so that equilibrium gas composition are approached closely for the usual carburizing temperatures.

For natural gas as carburizing medium the possible constituents of the gas carburizing atmosphere are CO, CO_2, H_2, H_2O, CH_4, and C_2H_6 gases. For uniformity of carburizing the above gases have to be well circulated within the chamber and the parts being carburized must be well spaced to get contact of the carburizing gases. A positive pressure in the furnace should be maintained for effective carburization rate and to prevent infiltration of air within the chamber. For gas carburizing a positive furnace pressure of about 12–37 Pa is satisfactory[6] and it is controlled by adjusting the gas flow rate.

2.3.2.3.4 Carrier gases

In gas carburizing, it is found that the amount of carbon available is more than what is required for absorption. This excess carbon precipitates as a heavy soot and deposits on the component surface as well as on the walls of the furnace. Hence, in gas carburizing, it is necessary that the hydrocarbon gases used are diluted with carrier gas to avoid the formation of heavy soot.

Carburizing agent (hydrocarbon gas) is diluted by a carrier gas before it enters the carburizing furnace. The carrier gas itself is normally made by controlled burning of CH_4, or some other hydrocarbon gas. Most commonly used carrier gas is endothermic base, obtained by controlled burning of CH_4 in air, with air-to-gas ratio of 2:5, to give:

$$CH_4 + O_2(\text{air}) \rightarrow 2CO + 4H_2 \quad [XXIV]$$

Endothermic carrier gas, then, contains the remaining nitrogen from air, CO, and H_2 as by-products of above reaction and small amounts of CO_2 and H_2O that may form during the production of carrier gas. Composition of the carrier gas is 39–40% N_2, 20–21% CO, 38–39% H_2 and small amount of CH_4, CO_2, and H_2O (all in vol.%). Sometimes, commercially pure nitrogen is also used as a carrier gas. Ratio of hydrocarbon gas (carburizing agent) to carrier gas in a carburizing gas mixture could vary from about 1:8 to 1:30, depending upon the desired surface carbon content, temperature of carburizing, and other considerations.

2.3.2.3.5 Carbon potential

The carbon potential in a furnace atmosphere at a specified temperature is defined as the carbon content in pure iron that is in thermodynamic equilibrium with the atmosphere. The carbon potential of the furnace atmosphere must be greater than the carbon potential of the surface of the workpiece in order for carburizing to occur. It is the difference in carbon potential that provides the driving force for carbon transfer to the parts. In most systems, the addition of a hydrocarbon gas such as methane is used for the control of carbon potential.

The gases CO and CH_4 are carburizing, whilst H_2, H_2O, and CO_2 are decarburizing agents. In order to control the carbon availability of the atmosphere, i.e., the carbon potential, a hydrocarbon gas is used to enrich the carrier gas, by reducing the H_2O (dew point) according to the reaction:

$$CH_4 + H_2O \rightarrow CO + 3H_2 \quad [XXV]$$

and by reducing the CO_2 according to the reaction:

$$CH_4 + CO_2 \rightarrow 2CO + 2H_2 \quad [XXVI]$$

as well as the following carburizing reaction takes place:

$$CH_4 \rightarrow CFe + 2H_2 \quad [XXVII]$$

in addition to reaction [XXVII], the other main carburizing reactions in a CO–CO_2–H_2–H_2O–CH_4 atmosphere are:

$$CO + H_2 \rightarrow CFe + H_2O \quad [XXVIII]$$

$$2CO \rightarrow CFe + CO_2 \quad [XXIX]$$

(in the gas reactions described CFe is the available carbon, from the atmosphere, for diffusion into the steel surface).

Reactions [XXVIII] and [XXIX] are considered the main equilibrium reactions for the basic method of carbon transfer into the steel surface. The assumption is that the carburizing is taking place as a direct result of the CO content in the atmosphere.

2.3.2.3.6 Advantages

- The complicated machine parts can easily be carburized by the gas.
- Uniform case depth can be obtained by the gas carburizing compared to that by pack carburizing.
- Time–temperature cycles can be determined accurately for close control of the case depth.
- Composition of the carburizing gas can be varied to provide a close control of the carbon content of the cases.
- It is cheaper than pack carburization.
- Hardening by direct quenching from the carburizing temperature is possible in gas carburizing.
- The rate of penetration of carbon is more in gas carburizing as compared to pack carburization.
- Less time is required to attain the carburizing temperature, since there is no need to heat the boxes as in pack carburization.

2.3.2.3.7 Disadvantages

- A gas generator is required to produce carrier gas.
- Partial carburizing cannot be performed which is possible in liquid carburizing.

2.3.2.3.8 Safety measures for gas carburization

The outlet gas from the chamber is very toxic and highly inflammable whether it is mixed or unmixed with air. For this, a safety program is essential to avoid the risks of the operation especially for the personnel under work. As a safety measure, all the gas discharged from the furnace has to be burned to

ensure that poisonous carbon monoxide has been converted into carbon dioxide. Therefore, a pilot flame has to be maintained until carburizing gas flow is continued. For safety measure, it is convenient to have a source of inert gas, such as nitrogen for purging the chamber after completion of the process.

2.3.2.4 Vacuum Carburizing

2.3.2.4.1 Carburizing process

Vacuum carburizing refers to carburizing of steel components in vacuum furnaces with the introduction of controlled amounts of carburizing gaseous mixture, usually a mixture of nitrogen and hydrocarbon gases (normally CH_4 or C_2H_8), at relatively low pressure. Heating steel components in vacuum furnaces provide excellent oxidation and decarburization resistance. A vacuum furnace may be backfilled with a carburizing gas mixture after the load has been heated to the desired carburizing temperature usually 900–1050 °C. Vacuum furnaces are specifically suited for high temperature carburizing. Carburizing gas mixture containing oxygen compounds are not generally used in vacuum carburizing, as CO and H_2O react with the traditional vacuum furnace materials, such as graphite and molybdenum. Hydrocarbons present in the backfilled carburizing gas mixtures crack at the surface of steel and provide carbon to the steel surface.

$$CH_4 \rightarrow 2H_2 + C(Fe) \qquad [XXX]$$

or

$$4C_2H_8 \rightarrow 4H_2 + 2C(Fe) \qquad [XXXI]$$

Carbons produced by these cracking reactions are highly reactive and is easily absorbed at the surface of steel. As a result of cracking of hydrocarbons, the gas mixture in the furnace consists of N_2, CH_4 (or C_2H_8), and H_2. Such atmosphere has tendency to produce soot.

2.3.2.4.2 Control of carbon supply and case depth

With no chemical equilibrium available as a control parameter, the carburizing process during vacuum carburizing is controlled by controlling the process variables, i.e., the partial pressure of hydrocarbon gas in the backfilled gas mixture, and the temperature and the time of carburizing. Shallow cases, that are formed in less than 20–30 min, can be obtained by time control only, i.e., fixed amount of hydrocarbon gas is introduced and carburization is carried out for a predetermined time. For deeper cases and to allow for more accurate surface carbon control, a two-step process consisting of a boost period and a diffusion period is used. During the boost period, sufficient hydrocarbon gas is introduced to obtain saturated carbon level without undue sooting of the furnace or components. Subsequently, the furnace is evacuated of all gases and diffusion is allowed to occur. Under vacuum heating, during the diffusion period, decarburization at surface does not occur. The existing carbon at the surface is redistributed, lowering the surface carbon and increasing the depth of carburizing. Figure 10 shows typical results obtained by a two-step process. The relative durations of boost and diffusion steps depend on the desired surface carbon content and depth of carburizing, and are empirically determined.

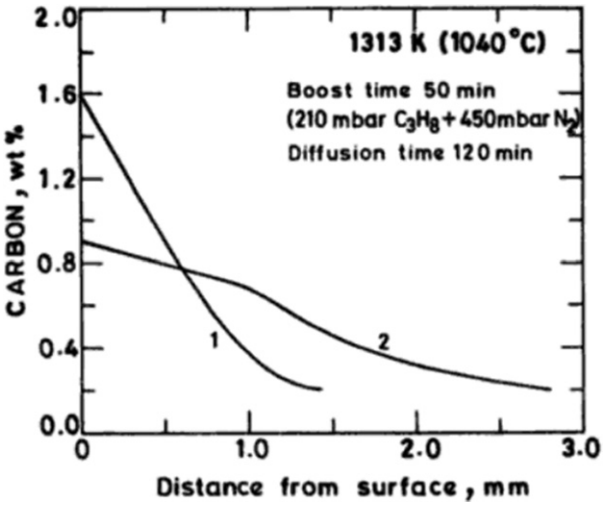

Figure 10 Carbon concentration profiles after (1) boost stage and (2) diffusion stage, in a two-step vacuum carburizing of AISI-1022 steel at 1040 °C.[7]

2.3.2.4.3 Advantages

- Fast carbon transfer.
- No surface oxidation.
- Good case depth uniformity.
- Integration into manufacturing lines.
- Small consumption of carburizing gas.
- No formation of furnace atmosphere.
- High carburizing temperatures possible.

2.3.2.4.4 Disadvantages

- Higher initial capital equipment cost than atmosphere carburizing equipment.
- Empirical process control, which requires processing loads to determine optimal settings or fine tune simulator.
- Formation of soot and tar, which occur due to the type, pressure, and quantity of hydrocarbon gas introduced.

2.3.2.5 Plasma Carburizing

2.3.2.5.1 Carburizing process

In plasma carburizing partial heating of parts and their carburization is carried out in a plasma of low-pressure ionized gases. This method is also known as 'glow discharge' carburizing. The component to be carburized works as cathode of glow discharge, with a suitable d.c voltage impressed between the cathode and anode to support a stable glow as well as to act as carburizing agent. An atmosphere of hydrocarbon gas (like CH_4) at a proper pressure is provided as a conducting atmosphere. Figure 11 schematically shows a plasma carburization chamber.

The chamber is evacuated and then backfilled with a hydrocarbon gas at reduced pressure, generally in the range of 0.1–2.7 kPa. A continuous flow of gas at reduced pressure is maintained during the carburization (boost) cycle. High

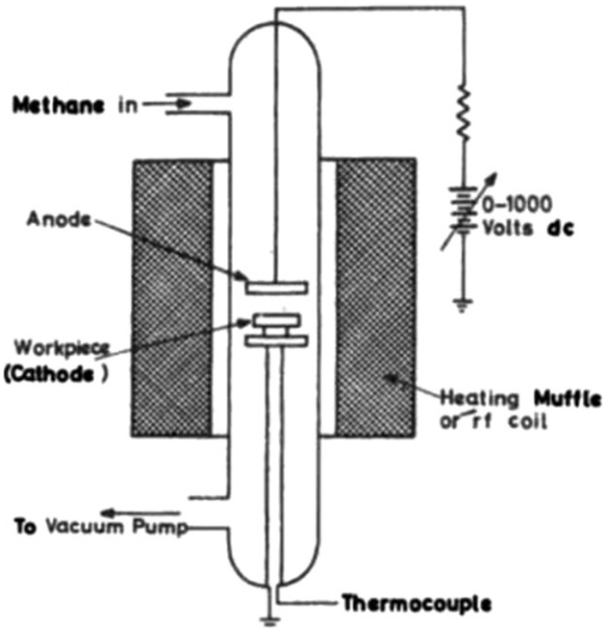

Figure 11 Schematic illustration of plasma carburizing setup.[8]

voltage (500–1000 V) is applied to strike the plasma in a methane atmosphere of ~2.7 kPa. Under these conditions, a thin plasma completely envelops the workpiece and closely follows its contours, even if the surface is quite irregular. Methane is dissociated within this thin plasma envelope and a high carbon potential is established at the workpiece surface, even though the total pressure in the furnace is relatively low.

The plasma consists of ionized gases and electrons. Positively charged ions of the type CH_i^{+n} (i=0–3) accelerate toward the cathode (workpiece) and introduce carbon at the surface, whereas electrons accelerate to the anode. In the process, both anode and cathode also get heated. However, heating the workpiece in plasma process in not sufficient to heat it up to the carburizing temperatures of 900–1050 °C. Thus to keep the workpiece at appropriate carburizing temperature an auxiliary induction or radiation heating source (Figure 11) is used.

2.3.2.5.2 Control of carbon supply and case depth

Rate of carburization in plasma carburizing is higher compared to vacuum or conventional gas carburization. Within the glow discharge gaseous molecules, some chemical reactions may occur, which would not occur under normal thermodynamic equilibrium condition. The electrons in the plasma atmosphere help to break chemical bonds and thereby dissociate methane to provide necessary carbon at the surface. Hydrogen generated by dissociation of CH_4 and ion bombardment of the surface may also dissociate surface oxides, and thus remove potential barrier to quick introduction of carbon at the surface. These factors accelerate uniform introduction of carbon and the attainment of saturation level of carbon at the surface. Like vacuum carburizing, plasma carburizing is normally carried out in two steps. In the first step, carbon is introduced at the surface by methane plasma and the second step is carried out by further heating the workpiece in vacuum to decrease surface carbon to the desired level and to

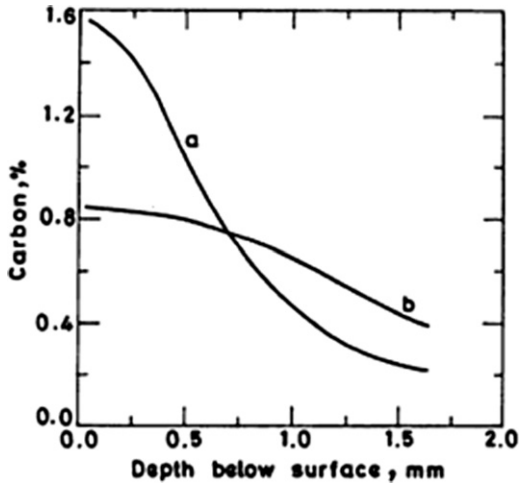

Figure 12 Carbon concentration profiles in AISI-1018 steel, plasma carburized at 1050 °C (a) after plasma carburizing for 10 min; (b) after additional diffusion period of 30 min.[8]

increase the case depth by diffusion processes. As the second step is carried out in vacuum, no decarburization at the surface occurs, only redistribution of carbon by diffusion takes place. Figure 12 shows carbon profiles obtained in AISI-1018 steel in plasma carburizing for 10 min at 1050 °C followed by a diffusion period of 30 min at the same temperature.

2.3.2.5.3 Advantages

- Consumption of gases in plasma carburizing is much less compared to conventional gas carburizing.
- No oxidation takes place at grain boundaries, and the finished surface is clean and glossy.
- Uniform carburized layer is obtained, no sooting is encountered.
- Carburizing of high concentration and the one into the hard-to-carburized materials such as stainless steel and sintered metals can easily be carburized.
- Due to fast carburizing rate and low temperature/short time treatment, no grain growth is observed and residual strain is very little.
- This is a pollution-free and energy-saving processing.

2.3.3 Theory of Carburization

The carburization of steel may be explained on the basis of two fundamental concepts. The first is diffusion, influenced by the properties of the iron, and concerned with the movement of carbon in the iron itself; the second deals with the source supplying the carbon, and with the transfer of carbon to the surface.

These two general concepts may be described briefly:

2.3.3.1 Fick's Laws of Diffusion

Fick's first law[3]: it describes diffusion under equilibrium conditions and is stated mathematically by:

$$J_1 = D_1 \frac{dc_1}{dx} \qquad [2]$$

Where D_1 is the diffusion coefficient and J_1 is the resulting flux gradient.

Fick's second law[3]: it expresses the nonequilibrium condition of diffusion where the concentration, at a point, changes with respect to time.

$$\frac{dc}{dt} = \frac{d}{dx}\left(D_1 \frac{dc_1}{dx}\right) \quad [3]$$

Carburizing is a nonequilibrium process, i.e., the gaseous constituents of the atmosphere are not fully in equilibrium with one another and the atmosphere is not in equilibrium with the steel being carburized.

The value of the diffusion coefficient is critical in any calculation dealing with carburizing or any other diffusion process. The diffusion coefficient D is defined by:

$$D = D_0 e^{-Q/RT} \quad [4]$$

where D_0 and Q are experimentally determined constants. Q is the heat of diffusion (activation energy, i.e., the energy required for one atom to jump to a new position in the lattice); R is the gas constant; and T is the absolute temperature. The greater is the value of Q, the smaller is the value of D at a given temperature and hence the slower is the rate of diffusion.

The diffusion coefficient which describes the diffusion of carbon in austenite varies somewhat with carbon content. The following expression, according to Tibbetts,[9] is a good fit to the experimental data.

$$D = 0.47 \exp(-1.6C)\exp\{-(37000-6600C)/RT\}\text{cm}^2\ \text{s}^{-1} \quad [5]$$

where, C is the carbon concentration in weight percent and T is the temperature in degrees Kelvin.

2.3.3.2 The Equilibrium State for Chemical Reaction

The equilibrium state[3] for chemical reactions may be represented by numerical constants, K_p, derived from the general expression,

$$\log K_p = \frac{A}{T} - B \quad [6]$$

where K_p is termed as the 'equilibrium constant,' which is derived from the values for the concentrations of the reactants and products of a chemical reaction. The subscript p denotes the dependency of the chemical reaction on pressure. T is the absolute temperature at which the reaction takes place. A and B are constants derived for the particular reaction.

2.3.3.3 Controlling Factors of Carburization

Instead of being developed in a formal way from the basic principles, the mechanism of carburization may be analyzed from the view point of carbon flow, by stating the controlling factors.[3] These factors may be divided for discussion into two distinct classifications:

1. Factors that control the of carbon in iron.
2. Factors that influence the transfer of carbon to the iron surface.

The mechanism may by explained as follows:

2.3.3.3.1 The flow of carbon in iron

Iron when heated in presence of carbon makes a solid solution. A solid solution may be described to be a solution of two or more components as solute and solvent sharing their atoms in their initial cells in the solid state. In other words a solution may be defined as any phase of which the composition may vary continuously within certain limits. Carburizing is concerned with the solid solution of carbon in austenite. The limits of carbon content of this phase depend on the temperature. The solid solution of carbon in gamma iron is an interstitial type of solid solution. As is evident from the iron and iron–carbide thermal equilibrium diagram (**Figure 13**), at temperature below about 910 °C (1183 K), pure iron occurs as a body-centered cubic (bcc) structure. Above 910 °C (1183 K) there is a temperature range in which iron has a face-centered cubic (fcc) structure. In fcc lattice, a relatively large unoccupied 'hole' exists in the center of the unit cell.[10] Carbon being an extremely small atom can move into this hole to produce a solid solution of iron and carbon as shown in **Figure 14**. When iron has a bcc structure at lower temperatures, the interstices between the iron atoms become much smaller and consequently the solubility of carbon in bcc iron is relatively small.

The penetration of carbon into the iron forming steel will depend upon the temperature, the time at temperature and the carburizing agent. Since the solubility of carbon in steel is the greatest above the Ac_3 temperature, carburization takes place most readily above this temperature. Furthermore, the higher the temperature, the greater the rate of carbon penetration, since the rate of diffusion is greater. It is customary to select a temperature about 50 °C above the Ac_3 point. The carburizing temperature is an important factor and is usually maintained within 900–925 °C. The depth of carbon penetration depends mostly upon the holding time.

Figure 15(a) shows the carburizing procedure in which a low carbon iron (carbon-free iron) is held for several hours at a high temperature in contact with an atmosphere, such as natural gas, capable of supplying carbon to the metal. The initial carbon content of the iron plate is zero at all distances from the surfaces. As the carbon atoms go into solution at the surface of iron, they are free to diffuse further into the plate. The maximum concentration of carbon atoms in iron at 925 °C can be used from the iron–carbon diagram, and is about 1.3%C.[11] The carburizing atmosphere can build up this carbon concentration at the surface almost immediately, so that the carbon penetration curve shortly after the beginning of carburizing is of the form shown in **Figure 15(b)**. The carbon penetration source that is produced by carburizing for a number of hours at a given temperature (925 °C in this case) is shown in **Figure 15(c)**.

The rate of flow of carbon in austenite depends on values for the diffusion coefficient and characteristics of the concentration gradient. The diffusion coefficient is in turn a function of temperature and carbon concentration. The diffusion of carbon proceeds from the higher concentration, developed from the supply source, to the lower concentration

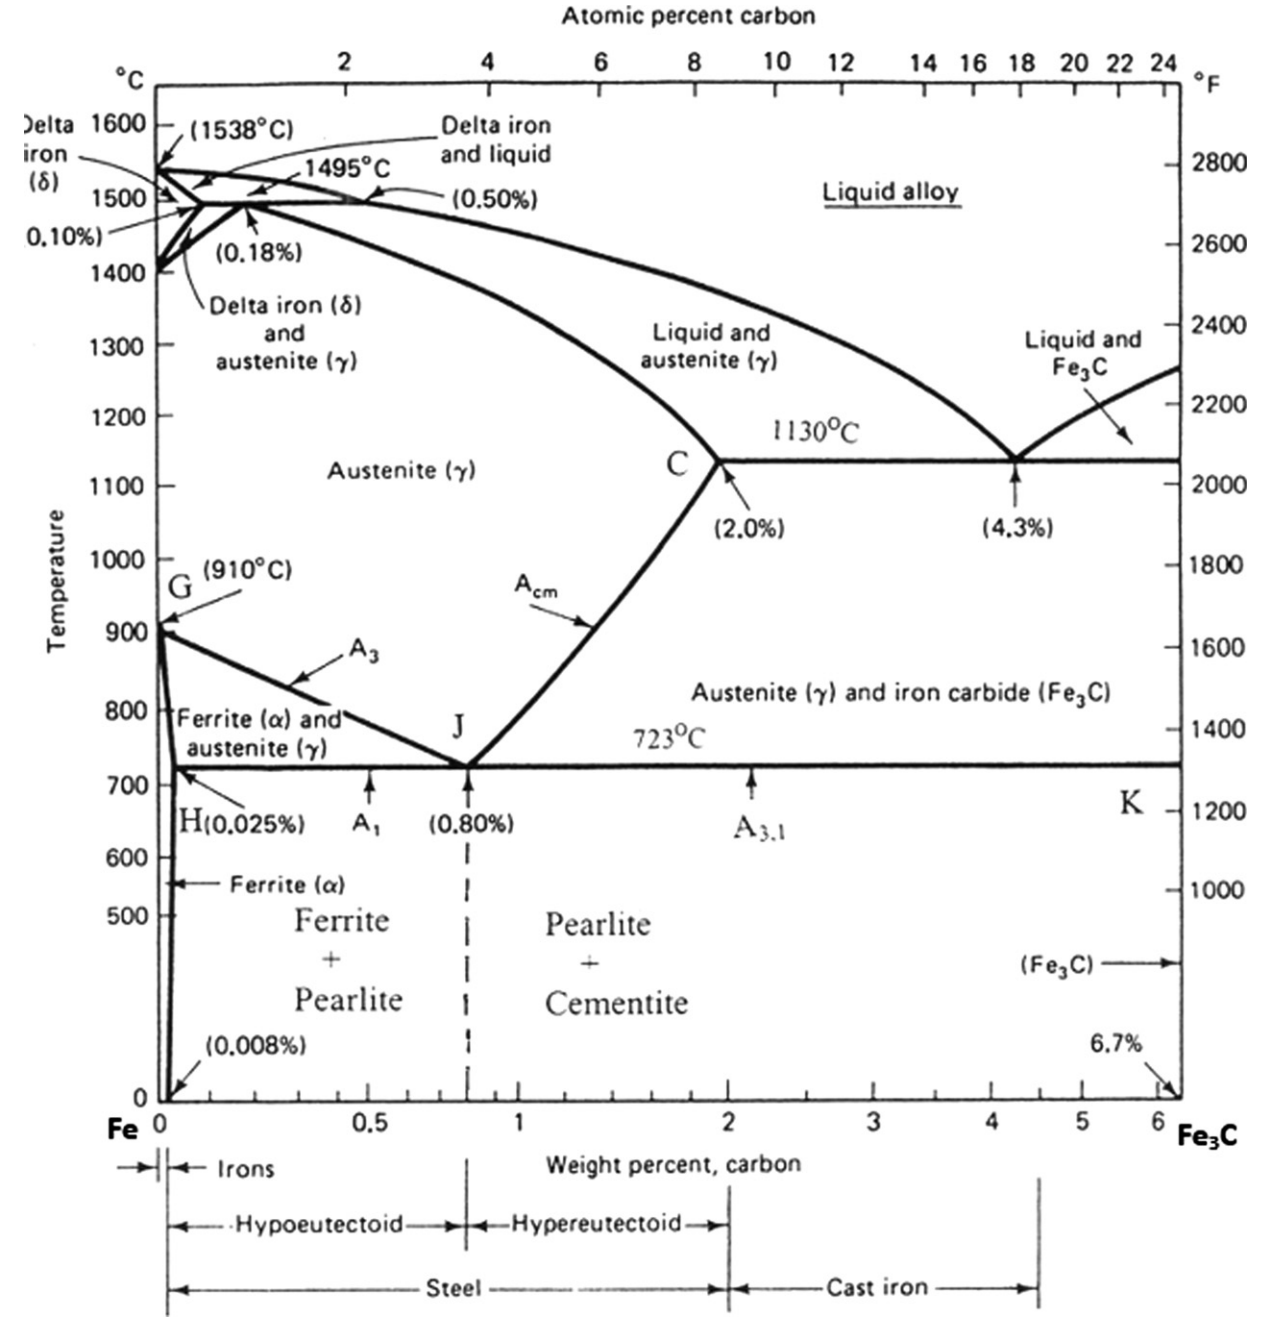

Figure 13 Iron and iron–carbide equilibrium diagram.

of the core when the concentration limits are maintained consistently, the form of the gradient may be predicted for any given and constant temperature of operation.[3]

The general form of the carbon gradient is influenced only by the range of concentration from surface to the core. For a given temperature, the rate of diffusion increases with increasing carbon concentration. For common carburizing steels and practice, the surface concentration limits are from 1.0 to 1.3%C with core concentration usually from 0.12 to 0.25%C.[3] For its attainment, the standard carbon gradient obviously requires a constant temperature of operation and a sufficient supply of carbon to the steel surfaces.

The case depth for a carburized machine parts may be considered to be the extent of carbon concentration which on heat treatment provides the desired uniform mechanical properties. The case depth for carburized steel is a function of process temperature and time. It has already been mentioned that the higher the temperature the greater will be the rate of carbon diffusion and thus deeper will be the case depth. Experiment shows that 40% more[5] will be the rate of diffusion by 50 °C rise of carburizing temperature, say from 875 to 925 °C.

For consistent results in carburizing, it is important that the temperature be uniform. Uniformity in various locations throughout the work load depends on the furnace design,

load density, gas recirculation, and heating rate. For a given density of load the difference in temperature between the outer and inner portions of the load may be high at carburizing temperatures, because the outside of the load is heated primarily by radiation and the rate of heating is rapid to reach to carburizing temperature. For better control of temperature, the thermocouple should be placed as close as possible to the work.

F. E. Harris[5] has developed a formula for the effect of time and temperature on case depth for normal carburizing:

$$\text{Case depth} = \frac{31.6\sqrt{t}}{10^{\left(\frac{6700}{T}\right)}}$$

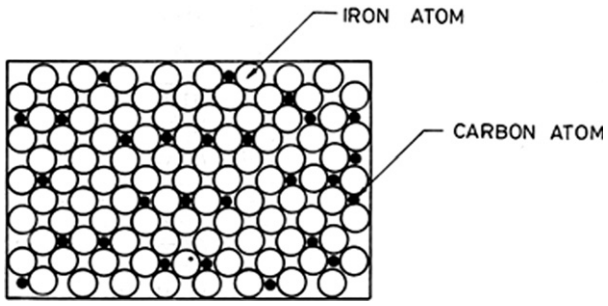

Figure 14 Interstitial solid solution (carbon in face-centered cubic iron).[10]

where case depth is in inches: t is time at temperature, in hours: and T is the absolute temperature, in degree Rankine.

For a specific carburizing temperature, the relationship becomes simply:

$$\begin{aligned}\text{Case depth} &= K\sqrt{t} \\ &= 0.025\sqrt{t} \quad \text{for} \quad 925\ ^\circ\text{C} \\ &= 0.021\sqrt{t} \quad \text{for} \quad 900\ ^\circ\text{C} \\ &= 0.018\sqrt{t} \quad \text{for} \quad 875\ ^\circ\text{C}\end{aligned}$$

When carburizing is purposely controlled to produce surface carbon concentrations somewhat less than saturated austenite, the case depth will be slightly less than the Harris equation shown above. The case depth determined by the equation is total case depth. For case depths in the range of 0.040–0.070 in the case depth corresponds to a point on the carbon gradient where the carbon concentration is about 0.07%C higher than the carbon content of the core.[5]

In addition to the time at carburizing temperature several hours may be required for bringing the work to operating temperature. For work quenched directly from the carburizer, the cycle may be further lengthened to allow time for the work to cool from carburizing temperature to a quenching temperature of perhaps 840 °C. Although some diffusion of carbon from case to core occurs during this time, diffusion is slower than it would be at the carburizing temperature. This period may be used deliberately as a moderate diffusion period to lower the carbon concentration at the surface by

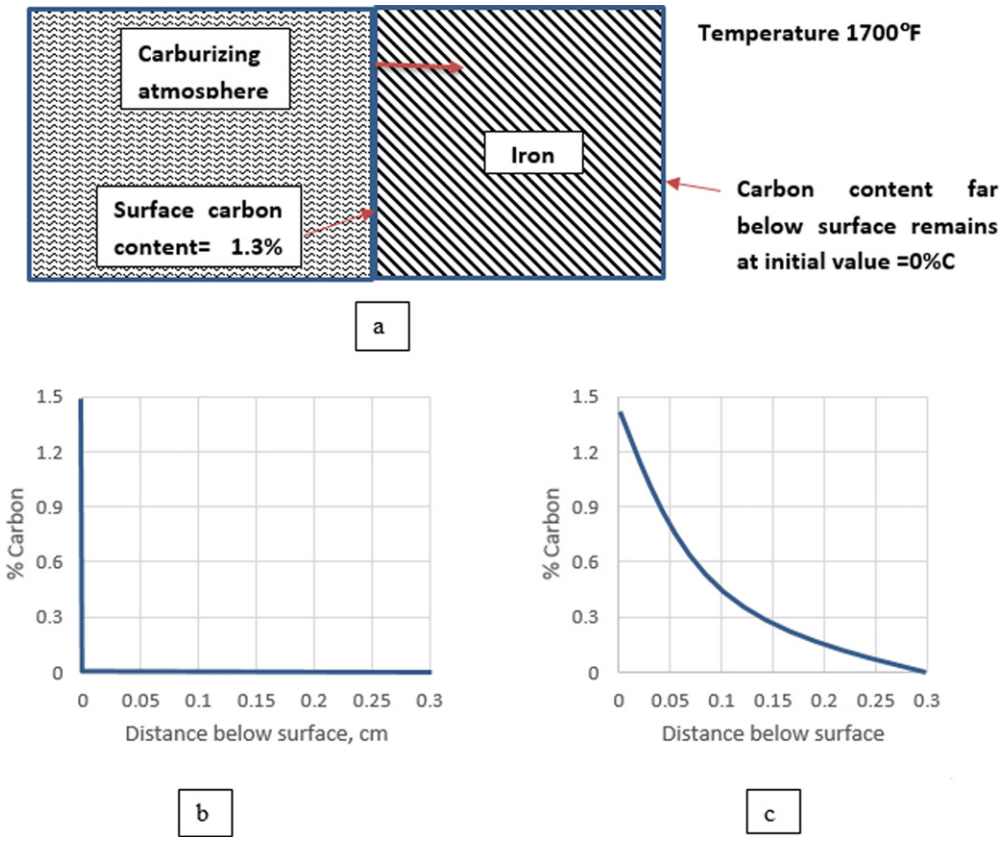

Figure 15 The diffusion of carbon in iron during carburizing. (a) Schematic representation of the procedure used in carburizing an iron plate. (b) Carbon penetration curve near the beginning of the carburizing process, and (c) after 10 h.[11]

maintaining an atmosphere of low carbon potential in contact with the work during this time.[5]

F. E. Harris[5] has also developed a method for calculating the carburizing time and diffusion time to produce a carburized case of predetermined depth and carbon concentration at the surface:

$$\text{Carburizing time} = \text{Total time}\left(\frac{C - C_i}{C_0 - C_i}\right)^2$$

and

$$\text{Diffusion time} = \text{Total time} - \text{carburizing time}$$

Where total time in hours, C is the final desired surface carbon concentration, C_0 is the surface carbon concentration at the end of carburizing cycle, and C_i is the concentration of carbon at the core. Effect of carburizing time and temperature on case depth obtained in gas carburizing is shown in **Figure 7**.

Diffusion coefficient varies with the nature of the solute atoms, with the nature of the solid structure and with changes in temperature. Higher temperatures provide higher diffusion coefficients, because the atoms have higher thermal energies and therefore, greater probabilities of being activated over the energy barrier. Carbon has a higher diffusion coefficient in iron because the carbon atom is small one. Atoms have higher diffusion coefficients in bcc iron than in fcc iron because the former has a lower atomic packing factor.[10]

The diffusion proceeds more rapidly along the grain boundaries because this is a zone of crystal imperfections.[10] At the grain boundaries between two adjacent grains there is a transition zone which is not aligned with either grains as shown in **Figure 16**. The mismatch of the orientation of adjacent grains produce a less efficient packing of the atoms along the boundary. Thus the atoms along the boundary have a higher energy than those within the grains. This higher energy of the boundary atoms is important for the nucleation of polymorphic phase changes and the lower atomic packing along the boundary favors atomic diffusion.

Other crystal imperfections namely point defects facilitate atomic diffusion more rapidly. Interstitials is the most prominent point defect which favors diffusion of carbon in iron and steel. It arises when an extra atom is ledged within a crystal structure particularly if the atomic packing factor is low. Such an imperfection produces atomic distortion as shown in **Figure 17**, unless the interstitial atom is smaller than the rest of the atoms in the crystal.

The interstitial mechanism moves atoms among the neighboring atoms of the crystal structure shown in **Figure 18**.

The interstitial atom of **Figure 18** has an equal probability of moving in the six coordinate directions. If the atoms are to change locations, the 'energy ridges' of **Figure 18** must be overcome. The energy required to overcome them is called the activation energy of diffusion. With interstitial diffusion, energy is required to force the atom into closer contact with neighboring atoms as it moves among them. The activation energy varies with a number of factors. For example, a small atom has a lower activation energy than a larger atom or a molecule. Likewise, interstitial movements require more energy than vacancy movements.[10]

2.3.3.3.2 Flow of carbon from the supply source

The primary function of carburizing mediums is to furnish an adequate supply of carbon to the steel surface. The transfer of carbon from the source of supply to the steel is involved with reactions occurring at this surface. The carburizing agent responsible for the actual transfer of carbon is a carbon compound. The extent to which various carbon compounds may supply carbon is related to the conditions that determine the equilibrium with the surface carbon of the steel. The equilibrium composition of the reactants and products is a function of temperature and also of the carbon concentration at the surface.

Low carbon steels when heated to the carburizing temperature, will be completely transformed into austenite. At the carburizing temperature austenitic iron is capable of holding

in solid solution an amount of carbon approaching the saturation limit of 1.7%. When a source of carbon, such as carbon monoxide is brought into contact with the steel in this condition, there will be a transfer of carbon from the gas to the steel. There is a difference of opinion[12] as to the exact form of the carbon.

Some feel that there is an interaction of the carbon monoxide and the iron to form iron carbides, which are then absorbed by the steel, others feel that the carbon being brought to the surface of the metal as carbon monoxide will, in the presence of austenite, break down to form atomic carbon, which will diffuse as such in the iron.

In pack carburization the carburizing compound is in reality the gas producer. In other words, the carbon monoxide is the result of the reaction between the carbonaceous compound and the oxygen from the air entrapped with the compound particles. The CO thus formed will give up its carbon to the iron according to the following equations:

$$2CO + 3Fe \rightleftharpoons 2CO_2 + [C]Fe \qquad [XXXII]$$

Without a further supply of CO this reaction between CO, CO_2, and austenite would soon reach equilibrium and carburizing would stop. Herty[12] states the CO:CO_2 ratio must be above 24 for this reaction [XXXII] to proceed and also that the rate of penetration must be about 0.01–0.02 mm h^{-1}.

Since at carburizing temperature, there is always a large amount of incandescent carbon present, the CO_2 will be constantly reduced, so that there will be a continuous supply of CO according to the reaction:

$$2CO_2 + C \rightleftharpoons 2CO \qquad [XXXIII]$$

This cycle continues to repeat itself, and the process of carburizing will continue as long as the proper temperatures are maintained and the CO:CO_2 is kept high enough. In this case the carbon will be absorbed, the concentration of carbon will be built up at the surface and will then move inward according to the simple laws of diffusion of heat or dissolved substances, i.e., from a region of high concentration to one of lower concentration as stated earlier. The carburizing phase of case hardening is, thus, one of absorption at the surface plus inward migration.

Since the usual carburizing compounds have incorporated in them one or more of the carbonates of alkaline or alkaline earth metals, it is generally considered that they may react according to the following equation:

$$MxCO_3 + \text{heat} \rightarrow MxO + CO_2 \qquad [XXXIV]$$

The M is any metal of the alkaline or alkaline earth group. The CO_2 formed will react with hot carbonaceous packing, as in reaction [XXXIII], and will increase the concentration of available CO.

It is also believed that the carbonate reacts with the hot carbon as:

$$MxCO_3 + C \rightarrow MxO + 2CO \qquad [XXXV]$$

and that the oxide thus formed will act as a catalyst between the reaction of the CO and the iron.

In gas carburizing, the carbon of the furnace atmosphere is in the form of gaseous hydrocarbon compounds such as methane, ethane, propane, and butane or carbon monoxide. The principal source of carbon in gas carburizing is methane which is present in manufactured and in natural gas.

The reactions involving the actual transfer of carbon occur at the steel surface (interface) and the reactants, which are carbon compounds, may be considered independently. The interface reactions[3,4] for common carbon compounds may be written as:

$$CH_4(g) + 3Fe(\text{steel}) \rightleftharpoons [C]Fe(\text{in austenite}) + 2H_2(g) \qquad [XXXVI]$$

$$C_2H_6(g) + 9Fe(\text{steel}) \rightleftharpoons 3[C]Fe(\text{in austenite}) + 4H_2(g) \qquad [XXXVII]$$

$$C_3H_8(g) + 9Fe(\text{steel}) \rightleftharpoons 3[C]Fe(\text{in austenite}) + 4H_2(g) \qquad [XXXVIII]$$

$$2CO(g) + 3Fe(\text{steel}) \rightleftharpoons [C]Fe(\text{in austenite}) + CO_2(g) \qquad [XXXIX]$$

Considering the reactions that occur for the same compounds, away from the interface, the reactions for deposition of carbon[3,4] are expressed as:

$$CH_4(g) \rightarrow 2H_2(g) + C(\text{Solid carbon}) \qquad [XXXX]$$

$$C_2H_6(g) \rightarrow 3H_2(g) + 2C(\text{Solid carbon}) \qquad [XXXXI]$$

$$C_3H_8(g) \rightarrow 4H_2(g) + 3C(\text{Solid carbon}) \qquad [XXXXII]$$

$$2CO(g) \rightarrow CO_2(g) + C(\text{Solid carbon}) \qquad [XXXXIII]$$

The reactions [XXXVI] and [XXXIX] are definitely reversible reactions at carburizing temperature. Pure CO_2 would decarburize steel to form CO by reversing reaction [XXXIX] and pure H_2 would decarburize steel by forming CH_4, the reverse of reaction [XXXVI]. If water vapor is present in the gas it will act as a decarburizing agent, removing carbon from steel by the reaction,[3,4]

$$H_2O(g) + Fe_3C(\text{in austenite}) \rightleftharpoons 3Fe(\text{steel}) + H_2(g) + CO(g) \qquad [XXXXIV]$$

2.3.4 Heat Treatment after Carburizing and Properties of Carburized Parts

The purpose of carburization is to develop hard, wear-resistant surface, and a tough core in some moving machine parts. Carburization mainly provides the concentration of carbon on the surface to a case depth of about 1.25–1.50 mm. The case of carburized parts is eutectoid or hypereutectoid steel and the core is a hypoeutectoid steel of initial composition containing from 0.1 to 0.2% carbon. The mechanical properties of the machine part will be obviously different for the case and the core due to differential concentration of carbon and may not be sufficient enough to respond to the desired properties wanted from the carburized machine part. **Figure 19** represents the equilibrium microstructure of a carburized machine part which is furnace cooled after carburizing.

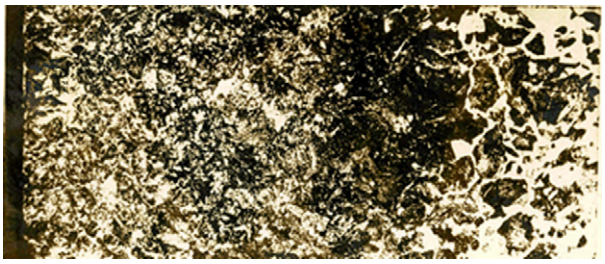

Figure 19 Microstructure of carburized and furnace cooled machine parts (× 100). High carbon case at the left, low carbon core at the right.[2]

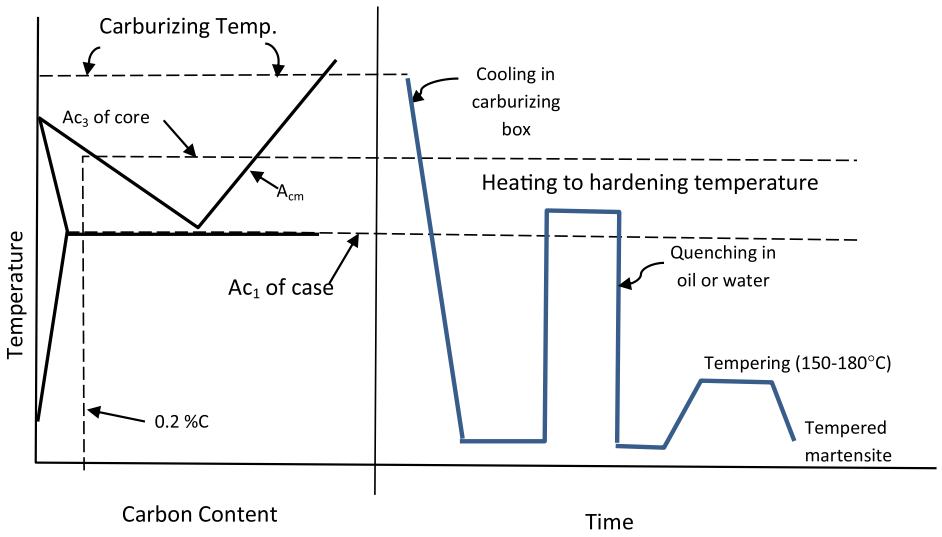

Figure 20 Heat treatment cycle without core refinement of carburized steel.

Hence the carburized machine parts are heat-treated to get higher mechanical properties namely hardness at the surface and toughness at the core.

2.3.4.1 Single Hardening without Core Refinement

Parts which are pack carburized, are first allowed to cool in the box, and then heated to a temperature necessary for hardening. After heating them just above Ac_1 temperature (750–780 °C), they are quenched in water, oil, or salt bath. In quenching from such a temperature, the outer zone will be hardened and the core will be partially refined. This avoids overheating of surface layer and results in reduced distortion. Therefore, this method is more suitable for treatment of complex shaped parts.

This method can also be adopted for parts that are carburized in salt bath, whose case depth exceeds 0.5 mm with 0.8–1.0% carbon potential. If the parts are quenched directly from the carburizing bath, it may lead to lower surface hardness due to presence of retained austenite resulting from higher surface carbon. Quenching from a low temperature results a higher hardness. The amount of retained austenite may be reduced further by subzero treatment. After quenching, the part is tempered at a low temperature of 150–180 °C to relieve stress. The heat treatment cycle is shown in Figure 20.

2.3.4.2 Single Hardening with Core Refinement

In this method, after carburizing the components are cooled slowly to room temperature. They are then reheated to a higher temperature (880–900 °C) for core refinement. Parts quenched from this temperature possess a higher impact and tensile strength. This method is widely used for automobile gears, and the resulting product has a case which secures more support from the hardened core, specially required for heavy duty services. A further advantage is the minimized distortion, since only one quenching treatment is used. The treatment is best adopted for fine-grained steels. If used on steels possessing marked hardening tendencies, the high quenching temperature favors the retention of austenite due to the presence of a relatively high proportion of alloying elements. This may result in some reduction in case hardness. Retention of austenite is undesirable, and it can be reduced by suitable subzero treatment. After quenching, the part is tempered at a low temperature of 150–180 °C to relieve stress. The heat treatment cycle is shown in Figure 21.

Single hardening with core refinement is being increasingly preferred over other methods. It is true that the grain of the surface layer is somewhat coarse, but this is quite often accepted in view of the fact that the mechanical properties of the core are equal to those produced by a double-hardening operation.

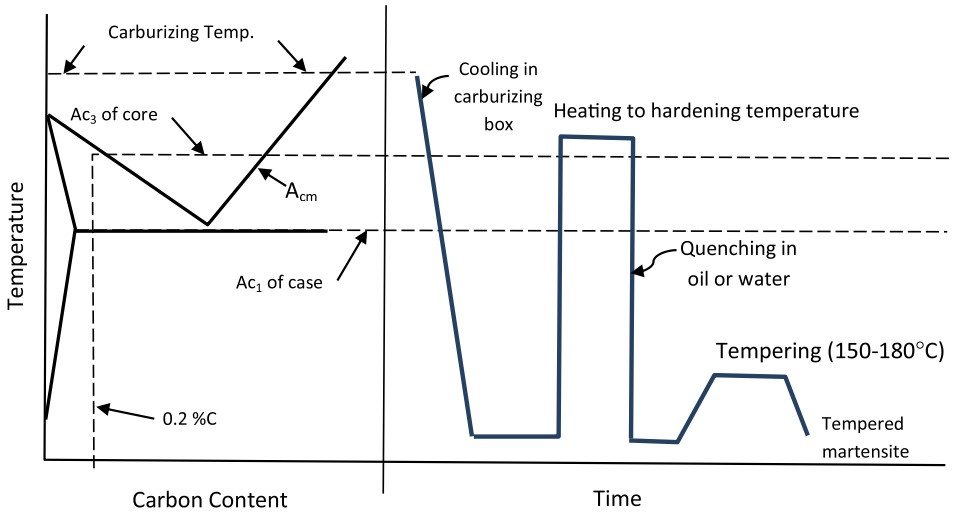

Figure 21 Heat treatment cycle with core refinement of carburized steel.

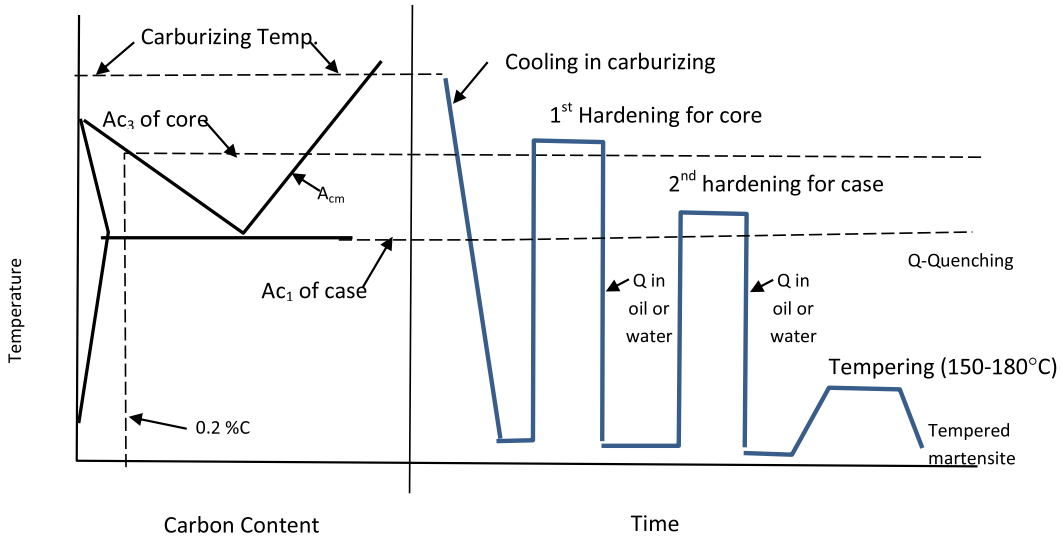

Figure 22 Heat treatment cycle for double-hardening (double heat treatment) process of a carburized steel part.

2.3.4.3 Double Hardening

Parts of carbon steel requiring high mechanical properties, are usually subject to double hardening, followed by tempering, after the carburizing process. The following considerations made double hardening a necessary procedure in these cases.

After carburizing, the work may be considered to consist of two layers: an outer layer, which is a eutectoid or hypereutectoid steels and requires a hardening temperature of 750–780 °C (above point Ac_1), and a core which is a hypoeutectoid steel of initial composition containing from 0.1 to 0.25%C and requiring grain refinement by heating above point Ac_3 (for the core), i.e., 880–900 °C. Thus to improve structure of the core and to impart optimum properties to the surface layers, a single heating to one temperature will evidently be insufficient. Therefore, the first hardening is conducted at temperature of 880–900 °C to improve the core structure of the work which has been overheated in carburization. This heating will also dissolve the cementite network which will not reappearing in quenching. The second hardening operation is conducted at 750–780 °C to eliminate the effects of overheating and to impart a high hardness to the carburized case. A schematic representation of the double heat treatment procedure is shown in Figure 22. Heat treatment is completed by tempering at 150–180 °C. The variation of hardness and toughness properties in relation to carbon contents from surface to the core of the double heat-treated carburized steel are shown in Figure 23.

The chief disadvantages of this heat treatment are the complexity of the procedure, excessive warping of the work, and the possibility of oxidation and decarburization. For these reasons, single hardening at 820–850 °C is extensively used at present for inherently fine-grained carbon steels and alloy

steels. Such procedure will refine the grain in both core and case and, at the same time, warping and decarburization will be considerably reduced.

2.3.4.4 Direct Quench Technique

In direct quenching method, the components are hardened by quenching directly from the carburizing temperature. This method can be employed when the components are carburized by using molten liquid or a gaseous medium. Quenching can be done in water, oil, or in a martempering bath, depending on the type of steel used. For minimum distortion, quenching in a martempering bath may be adopted, followed by air cooling. After water, oil, or martempering bath quenching, the components are tempered at a low temperature of 150–180 °C to relieve stress and hence to minimize cracking and distortion. For this reason direct hardening generally results in the smallest dimensional changes of the components. Figure 24 shows the direct quenching method.

Quenching directly from the carburizing temperature results in the hardening of both case and core. However, quenching directly from the carburizing temperature may leave retained austenite; when high alloy content steels are treated to minimize the retained austenite this technique is not suitable. In steels of high alloy content, it is the usual practice to control the carbon of the case to a somewhat lower level than in low alloy and plain carbon steels.

Such procedure will refine the grain in both core and case and, at the same time, warping and decarburization will be considerably reduced. But for coarse-grained structure at the case and the core, and high proportion of retained austenite is found at the case. Therefore, direct quenching for the furnace is only used when the work is made of an inherently fine-grained steel and where best properties are not required.

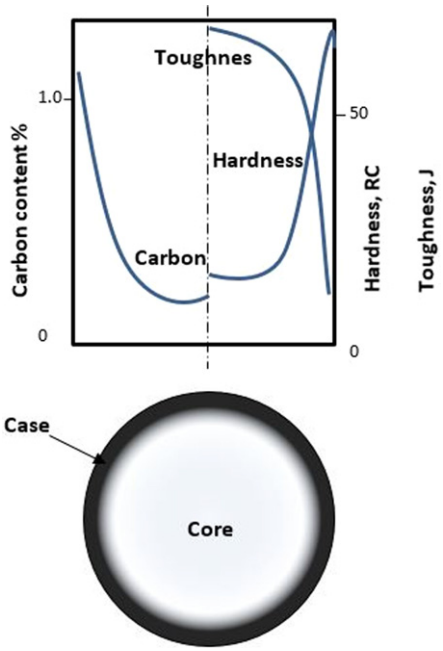

Figure 23 Variation of hardness and toughness from surface to the core of the double heat-treated carburized steel.

2.3.4.5 Quenchants for Carburized Steels

The carburized parts are hardened by quenching into a certain medium known as quenchant. The cooling rate for hardening is controlled by selection of proper quenching medium. There are numerous quenchants such as brine, tap water, salts, soluble oil and water solutions, oil and air, etc. If the part is to be used as heat-treated condition without any finishing operation to control dimensional accuracy marquenching can be used. In marquenching the part is quenched into molten salts or hot oil keeping the quenchants temperature above the M_s temperature of the case, but below the M_s temperature of the core. Consequently, the core transforms while parts are in the quenchant, to a mixed microstructure of martensite, bainite, and ferrite. The case

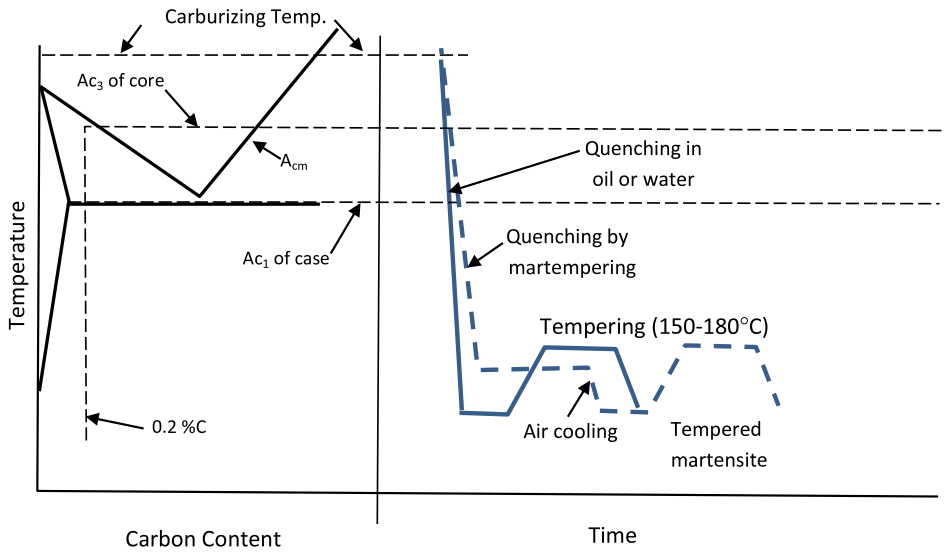

Figure 24 Heat treatment cycle for direct quenching of carburized steel.

transforms to martensite while the parts are cooling in air after leaving the quenchant.

2.3.4.6 Heat Treatment of Gas-Carburized Steels

Direct quenching is applied to gas-carburized parts at the end of carburization. The steel is precooled to 840–860 °C in the carburizing chamber (Figure 25) with the carburizing medium and then quenched in water or oil.

The surface layer, after heat treatment, will have a martensite structure with excess carbides. In cases of quenching direct from the carburizing furnace, the heating temperature of the core will be in the vicinity of Ac_3. In low carbon steels, austenite cannot be supercooled to the martensite point in quenching from this temperature and the core will have a ferrite and bainite structure. After heating austenite in alloy steels to a temperature close to point A_{cm}, it can easily be supercooled, without decomposition, to the martensite point. This core will acquire a low carbon martensite structure possessing high strength and ample toughness. After quenching, subzero treatment is done in liquid nitrogen to transform the retained austenite into martensite. Finally the part is tempered at a low temperature of 150–180 °C to relieve stress.

The microstructure of the carburized case of a low carbon steel after hardening is shown in Figure 26. The normal hardness at the surface of carburized case is usually within the range of RC 59–64.

2.3.4.7 Subzero Treatment

When alloy steels are subjected to single hardening treatment, a large amount of retained austenite will be found in the carburized case. This sharply reduces its hardness. Retained austenite may be eliminated by a subzero treatment which transforms mostly into martensite, thereby substantially increasing the hardness.

2.3.5 Microstructures of Carburized Steels

2.3.5.1 Martensite

The microstructures of hardened carburized steels consist of high carbon martensite at the surface and low carbon martensite in the core. High carbon martensite is gradually replaced by martensite of lower carbon content with increasing distance from the surface. Lightly tempered martensite is the dominant microstructural constituent of properly carburized steel. However, the martensite changes in morphology, amount, and properties as a function of distance from the surface. Other case microstructural constituents may also be present and may significantly affect the performance of carburized parts. These other microstructural features include retained austenite, carbides of various origins, sizes and morphologies; inclusions; prior austenite grain boundaries embrittled by phosphorus segregation; microcracks; and processing-induced surface oxides. Superimposed on the case microstructures are compressive residual stresses produced during quenching. Core microstructures, depending on hardenability, may consist of tempered martensite, bainite, or ferrite and pearlite.

2.3.5.1.1 How martensite forms

Under slow or moderate cooling rate the carbon atoms are able to diffuse out of the austenite structure. The iron atoms then move slightly to become bcc structure. This austenite to ferrite transformation is a diffusion-controlled process. This transformation takes place by a process of nucleation and growth and is time dependent. With still further increase in cooling rate, insufficient time is allowed for carbon to diffuse out of solution and although some movement of iron atoms take place, structure cannot become bcc while the carbon atom is trapped in solution. The resultant microstructure is called martensite. It is formed from austenite by a diffusion-less shear transformation and quenching has the important function of providing cooling rates rapid enough to suppress competitive diffusion-controlled transformations of austenite. Martensite

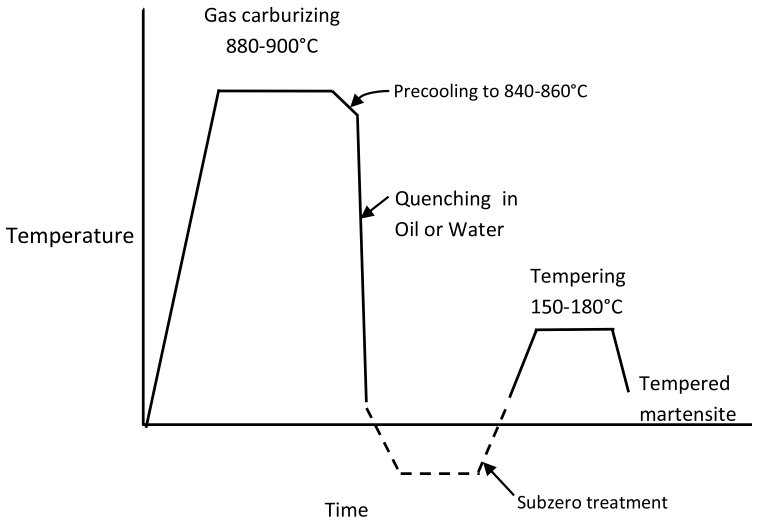

Figure 25 Carburizing cycle of gas carburized steel.

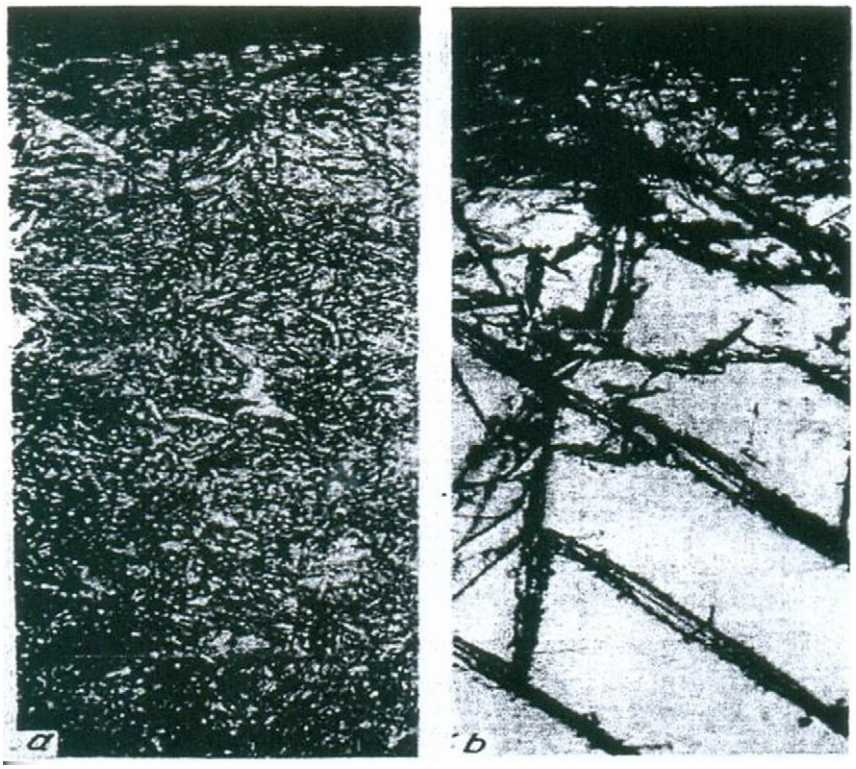

Figure 26 Structure of carburized case of low carbon steel after hardening. (a) normal martensitic microstructure, × 250 and (b) with an increased amount of retained austenite, × 500.[1]

is a supersaturated solid solution of carbon trapped in body center tetragonal (bct) structure. Two dimensions of the unit cell are equal, but the third is slightly expanded due to trapped carbon.

During carburization carbon is introduced into austenite typically at a temperature of around 925 °C. After carburization, martensite is produced by quenching. This martensite is reheated or tempered at low temperature (150–180 °C) to produce low temperature tempered (LTT) martensite. This LTT martensite is the primary component of carburized microstructure that gives the desired properties to carburized steel.

Carburizing is applied to low carbon steels containing typically 0.2 wt%C. The process introduces carbon to the surface of the steel, and the carbon diffuses into the low carbon interior. Depending on atmosphere control and carburizing temperature and time, surface carbon contents of 0.8% or more and carbon gradients over a range of distances, or case depths, into the steel are produced. The carbon gradients have a profound influence on martensitic transformation, morphology and properties. The temperature at which martensite begins to form during the quench is designated as the martensite start temperature, M_s. As carbon content increases, M_s decreases.

2.3.5.1.2 Martensite morphologies

The martensite crystals that form at low M_s temperature have a three-dimensional plate geometry, and hence are called plate martensite. Figure 27 is a micrograph of martensite in the high carbon case of a carburized low carbon Ni steel. Adjacent plates of martensite are nonparallel, and the appearance of the microstructure under the light microscope is that of a zigzag array of needles or acicular shapes. The needlelike shapes are in fact cross sections of martensite plates. The plates etch dark after tempering and are surrounded by white-appearing retained austenite. The amount of martensite that forms is determined only by the amount of cooling below M_s; therefore, the lower the M_s, the smaller the amount of martensite and the larger the amount of retained austenite after cooling to room temperature.

In contrast to high carbon regions, the martensite that forms in austenite of medium or low carbon content assumes a completely different morphology. The martensite crystals appear to have a lath or board-shaped geometry – the crystals are relatively thin and flat with one long dimension and adjacent crystals form parallel to each other in stacks or packets. Figure 28 is a micrograph of martensite in the low carbon core of a carburized steel.

The high M_s temperature of low carbon austenite provides a much wider temperature range over which martensite can form during quenching, and therefore there is little or no retained austenite in low carbon lath martensites cooled to room temperature. With increasing carbon content, the amount of retained austenite in lath martensitic microstructures increases, but the austenite is retained as thin films between the laths and is not resolvable in the light microscope.

The carbon gradients introduced into austenite by carburizing result, after quenching, in a gradient of martensitic microstructure, ranging from plate martensite morphologies with large amounts of retained austenite to lath martensitic microstructures with essentially no retained austenite (Figure 29).

Figure 27 Plate martensite microstructure in the case of a gas-carburized low carbon Ni steel. The 'needles' are cross sections of plates. Retained austenite appears white. Light photomicrograph, nital, × 500.

These gradients in microstructure are related directly to the hardness and strength gradients produced by carburizing. Although features resolvable in the light microscope influence hardness (especially retained austenite, which coexists with plate martensite in the case region), it is the carbon-dependent fine structure of LTT martensite crystals that primarily determines the strength gradients in carburized steels.

2.3.5.1.3 Effect of tempering

When the as-quenched martensite is tempered at low temperatures, very fine carbides precipitate to relieve the carbon supersaturation. Low tempering temperatures of 150–180 °C ensure that the precipitated carbides remain fine. In addition, the retained austenite remains stable at these low temperatures. Consequently, the only microstructural changes produced by tempering occur on a very fine scale within the martensite plates.

The carbides are not cementite, which forms on tempering at higher temperatures, but are transition carbides. These transition carbides have been designated either epsilon carbides or eta carbides, depending on small differences in their crystal structures and diffraction patterns. High densities of dislocations, produced by the deformations that accompany martensitic and subsequent tempering transformations, are also associated with the transition carbides.

2.3.5.1.4 Role of transition carbides

The higher the carbon content of the martensite, the higher the density of the clusters of transition carbides after tempering. These carbide arrays, and the associated dislocation substructures, make deformation by slip or dislocation motion difficult. As a result, the hardness and strength of LTT martensite increases with increasing carbon content. This is illustrated in Figure 30. The figure shows the hardness of as-quenched martensitic microstructures, and LTT martensitic microstructures tempered between 150 and 180 °C. The hardness increase is almost linear up to 0.8%C. At higher carbon contents, the rate of hardness increase falls because of larger amounts of retained austenite. Low temperature tempering lowers the hardness of as-quenched martensite because of the relief of carbon supersaturation and stress relief, but increases toughness.

Figure 28 Lath martensite microstructure in the core of a gas-carburized low carbon steel. Light photomicrograph, nital, × 300.

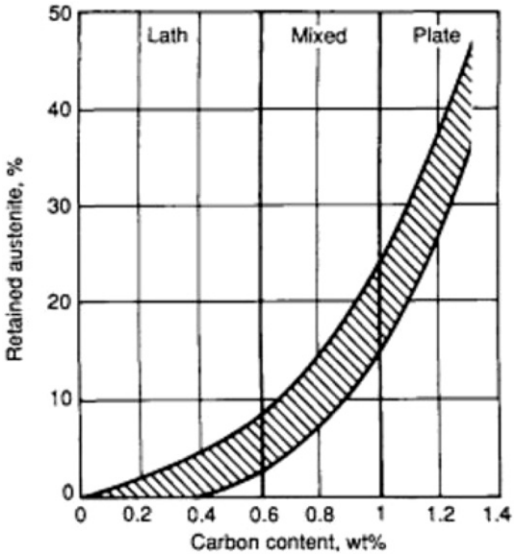

Figure 29 Percent retained austenite as function of carbon content. Vertical lines show carbon ranges in which lath and plate martensites are found in Fe–C alloys.[13]

2.3.5.2 Austenite

Although LTT martensite dominates strengthening in the case regions of carburized steels, case microstructures are actually composites of LTT martensite and retained austenite. Depending on the amount of retained austenite and the loading conditions in service, the austenite may either degrade or enhance performance of the part.

2.3.5.2.1 Characteristic features of austenite

Austenite is essential to the manufacture of carburized steels. It has a high solubility for the carbon introduced into steel by high temperature exposure to carburizing atmospheres. On quenching, the high carbon austenite transforms into high

carbon martensite. This high carbon martensite on tempering, produces high-strength tempered martensite. This high-strength tempered martensite is the backbone of carburized steels.

The parent austenite phase influences the microstructure of carburized steels in several ways. Most important, the chemical composition of the austenite, directly determines M_s temperature and the amount of austenite retained after quenching to room temperature.

Also, the grain structure of the parent austenite affects the martensitic microstructure after quenching, because austenite grain size limits the size of martensite crystals. Thus, fine-grained austenite results in fine distributions of martensite plates and improved mechanical properties.

For this reason, most carburizing grade are aluminum-killed, fine-grain steels. Small amounts of aluminum are added during melting and dissolve in austenite during subsequent high temperature bar rolling or forging. At lower temperatures (about 900 °C), where carburizing is typically performed, the solubility of aluminum in austenite is low, and the aluminum combines with nitrogen to form aluminum nitrides. These fine aluminum nitride particles restrict grain growth during carburizing. At higher carburizing temperature the aluminum nitride particles are coarser and because of higher solubility, are present in lower densities, resulting in coarser austenite grain sizes.

2.3.5.2.2 Effect of austenite composition

Martensite transformation start temperature M_s is a function of chemical composition of austenite. The relation between M_s and chemical composition is given by the following empirical equation[15]:

$$M_s(^\circ C) = 539 - 423C - 30.4Mn - 12.1Cr - 17.7Ni - 7.5Mo \quad [7]$$

where the element amounts are in weight percent. The above equation shows very strong dependence of M_s on carbon content and lesser dependence of M_s on the alloying elements manganese, chromium, nickel, and molybdenum, which are often added to improve hardenability. When the M_s temperature is calculated from the composition of a steel of uniform carbon content, or at a point in a carburized case, the amount of martensite that forms on cooling to a given quench temperature, T_q, can be estimated from[16]:

$$f_m = 1 - \exp^{-(0.011\ \Delta T)} \quad [8]$$

where f_m is the volume fraction of martensite, and ΔT is the undercooling below $M_s(\Delta T = M_s - T_q)$.

Figure 31 shows martensite and retained austenite in the case of a carburized microalloyed steel containing small amounts of niobium. The martensite plates appear dark and the retained austenite appears white between the martensite crystals.

2.3.5.2.3 Excessive retained austenite

2.3.5.2.3.1 Effect on properties

Too much retained austenite, ~40 vol.% or more, may be detrimental to the performance of carburized steels in several ways. Most important, because austenite is of much lower strength than tempered martensite, the hardness, wear resistance, and fatigue resistance of a carburized part may be reduced. Also, high retained austenite content may reduce surface compressive residual stresses and accordingly, contribute to a decrease in fatigue resistance.

2.3.5.2.3.2 Major cause

A very high carbon content is the major cause for excessive retained austenite. Equations [7] and [8] show that M_s and the

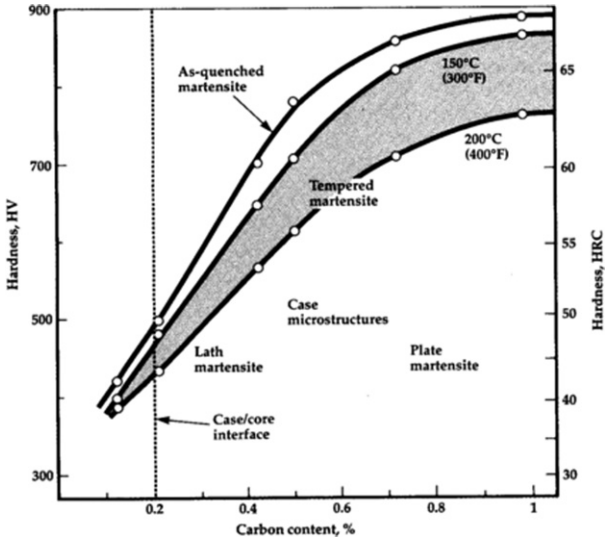

Figure 30 Hardness as a function of carbon content for as-quenched martensite and LTT martensite tempered between 150 and 180 °C. Case martensitic microstructures have similar hardness gradients, with maximum and minimum values determined by surface and core carbon contents, respectively.[14]

Figure 31 Tempered martensite (black) and retained austenite (white) in the case of a carburized Nb-microalloyed steel. Light photomicrograph, nital, × 300.

amounts of martensite formed on cooling are very sensitive to carbon content. If carburizing temperatures are high and if the austenite is allowed to become saturated with carbon, then large amounts of retained austenite can be expected.

However, excessive austenite may be retained even in boost-diffuse carburizing in regions of a part where surfaces meet at included angles of 90° or less. At such corners, carbon diffuses in from the carburizing atmosphere from two surface, but the high carbon content that results has only a limited area through which to diffuse into the interior of the part. The result is that carbon concentration at the corner remains high throughout the diffusion step. Excessive retained austenite at the corner of a gas-carburized low carbon steel specimen is shown in Figure 32(a). Figure 32(b) shows that surface hardness at the corner is considerably lower than that of the plane surface with its more moderate amount of retained austenite. Massive carbides may also be present at corners because of the high carbon concentration.

2.3.5.2.4 Reducing retained austenite

In steels directly quenched after carburizing, excessive retained austenite may be reduced by several methods, such as tempering, refrigeration, or subzero treatment. Process selection depends on the desired performance level of the carburized part.

2.3.6 Carburization of Alloy Steels

2.3.6.1 Carburization of Low Alloy Steels

Low carbon steel is usually used for carburization because of its excellent toughness. For high duty applications alloy steels are also carburized for additional properties of both the case and the core. In alloy steels, the alloying elements remain in the form of various carbide and nitride precipitates. To take precipitates into the solution higher temperature is required. For this reason, comparatively a higher carburization temperature is usually selected for alloy steels. Low carbon steels containing nickel, chromium, manganese, vanadium, molybdenum, etc. singly or in combination usually have sufficient hardenability. From these steels maximum case hardness can be attained by oil quenching and desired core properties up to a tensile strength of 1380 MPa is obtainable with suitable toughness by proper selection of the steel composition.

2.3.6.1.1 Carburization of chromium–nickel steel

Chromium increases the case depth of the carburized steels while nickel decreases it (Figure 33(a)). Chromium (as Cr_3C) and nickel refine the austenite grain size of the carburized case but nickel is more effective than chromium in inhibiting the austenite grain growth (Figure 33(b)). Both chromium and nickel promote the formation of retained austenite but chromium is more effective than nickel in promoting the formation of retained austenite in the case of carburized and hardened steels.[17]

Microhardness measurements have shown that chromium in solution and as Cr_3C increase and nickel in solution decreases the hardness of the case while both of them increase the core hardness although chromium is more effective than nickel as far as core hardness is concerned (Figure 34).

The hardenability increases with the increase of austenite grain size and with the extent of carbon penetration in the case of carburized steels. Nickel and chromium reduce the toughness of the core of low carbon steels in the carburized and hardened condition. Chromium is more detrimental to toughness than nickel.[18]

2.3.6.1.2 Carburization of molybdenum–nickel steel

Both molybdenum and nickel in steel increase the carburized case depth. Nickel is more effective than molybdenum in increasing the case depth. The combined effect of molybdenum and nickel is much greater than that of either molybdenum or nickel alone in increasing case depth (Figure 35(a)).

The undissolved particles of Mo_2C refine the austenite grain size of the carburized case. Nickel in solution does not have any effect in restricting grain growth of austenite. But the presence of nickel enhances the austenite grain size refining effect of molybdenum steel in the carburized case (Figure 35(b)).

Under identical conditions, molybdenum and nickel enhance the formation of retained austenite in the case of carburized and hardened steels but nickel is more effective than molybdenum in enhancing the formation of retained austenite. In the presence of molybdenum this enhancing

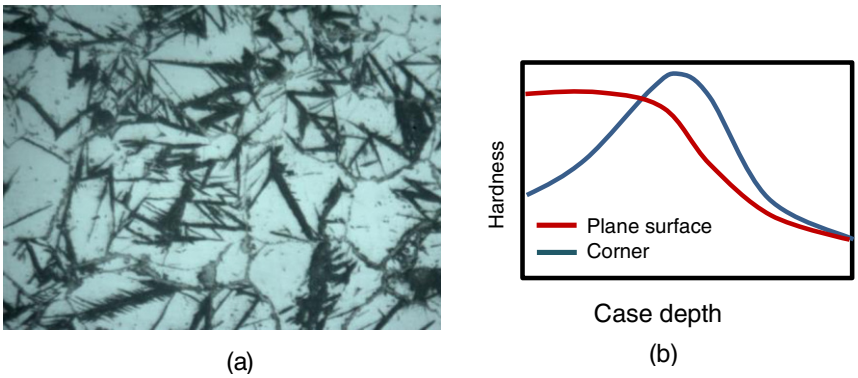

Figure 32 (a) Excessive retained austenite at the corner of a speicmen of low carbon steel. Light photomicrograph, nital, × 500. (b) Schematic representation of variation of hardness as a function of distance from a specimen corner or a specimen surface in the same steel.

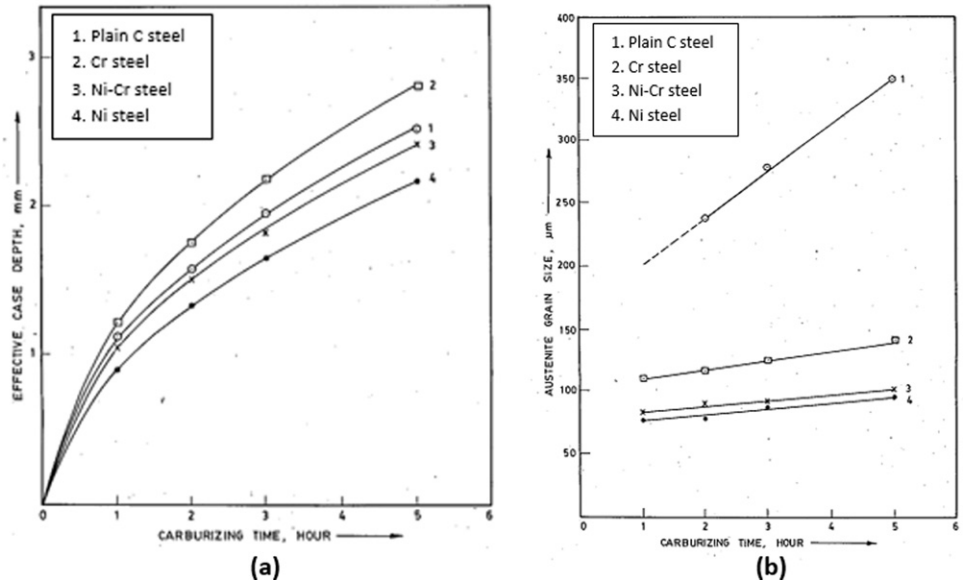

Figure 33 (a) Variation of effective case depth with carburizing time at 950 °C in steels 1–4 and (b) variation of prior austenite grain size with carburizing time at 950 °C in the case of steels 1–4.[17]

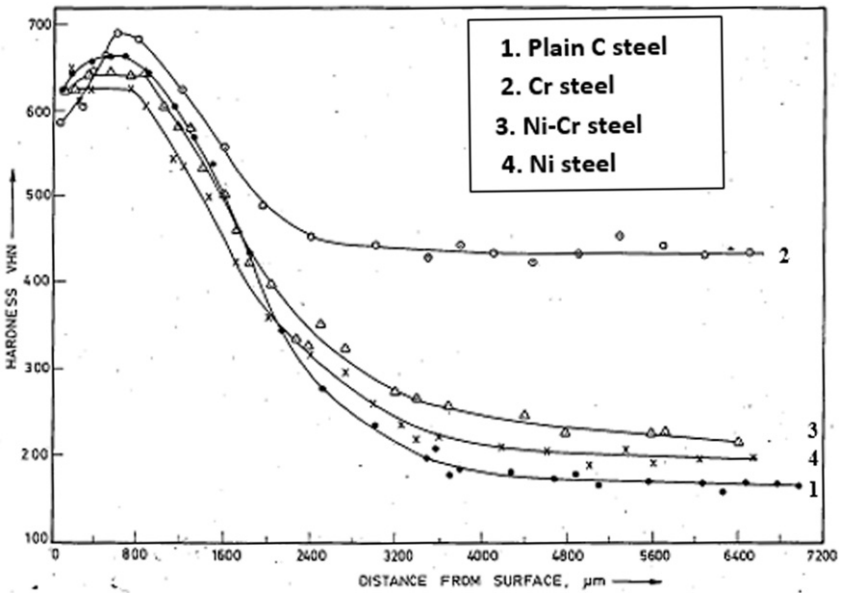

Figure 34 Microhardness profiles of steels 1–4 carburized at 950 °C for 1 h, quenched in 10% brine and tempered at 160 °C.[18]

effect of nickel is increased as shown in Figure 36. Subzero treatment substantially reduces the retained austenite content in the hardened cases of all the steels. Molybdenum and nickel both sluggish the retained austenite transformation to martensite during subzero treatment. Molybdenum is more effective than nickel in sluggishing the transformation of retained austenite to martensite. In the presence of nickel this sluggishing effect of molybdenum reduces.[20]

Molybdenum improves and nickel reduces the maximum case hardness and wear resistance of low carbon steels in the carburized and hardened condition. The presence of nickel decreases the effect of molybdenum in the increment of maximum case hardness. Molybdenum and nickel both increase the core hardness but molybdenum is more effective than nickel. Molybdenum with nickel is more effective in increasing the core hardness than molybdenum without nickel (Figure 37(a)).

Subzero treatment increases the surface hardness and maximum hardness of the carburized low carbon steels in the hardened and tempered condition (Figure 37(b)). The maximum surface hardness values of the carburized, hardened,

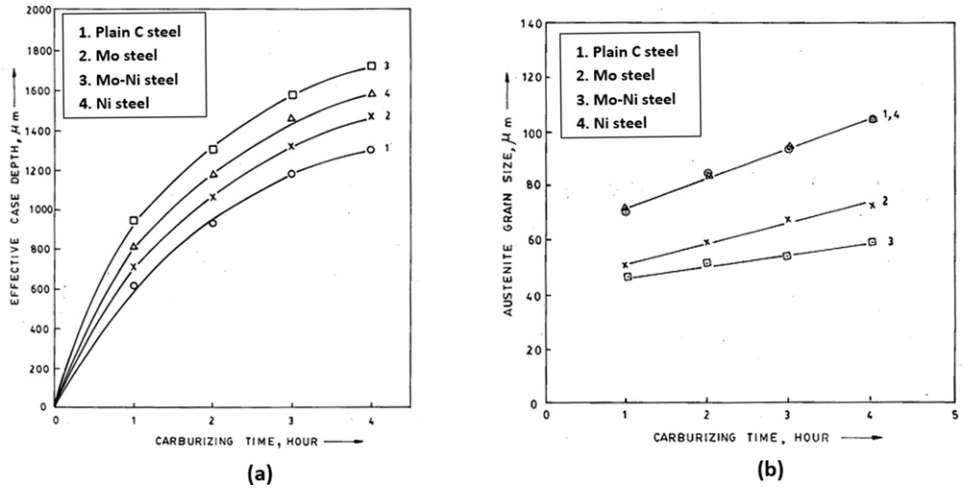

Figure 35 (a) Variation of effective case depth with carburizing time of steels 1–4 carburized at 950 °C and (b) variation of prior austenite grain size with carburizing time of the case of steels 1–4 carburized at 950 °C.[19]

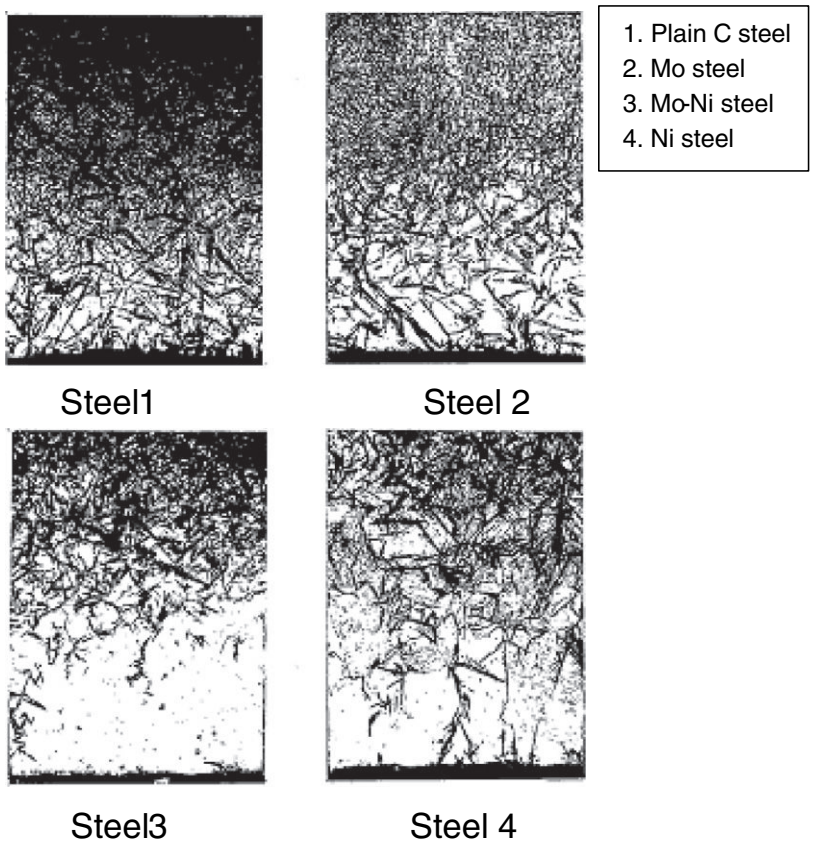

Figure 36 Optical micrographs showing the microstructures in the case of steels 1–4 carburized at 950 °C for 4 h, quenched in 10% brine and tempered at 160 °C, × 300.[20]

and tempered plain carbon, molybdenum and nickel steels are always lower than those of subzero treatment ones (Figure 37). Molybdenum improves and nickel reduces the wear resistance of the carburized case of low carbon steel. Subzero treatment improves the wear resistance of the carburized, hardened, and tempered cases of low carbon steels containing molybdenum and nickel alone and in combination. Molybdenum and nickel both reduce the toughness of the core in the carburized and hardened condition. Nickel is more detrimental to toughness than molybdenum. The combined effect of molybdenum and nickel is greater than that of either molybdenum or nickel alone in reducing toughness.[20]

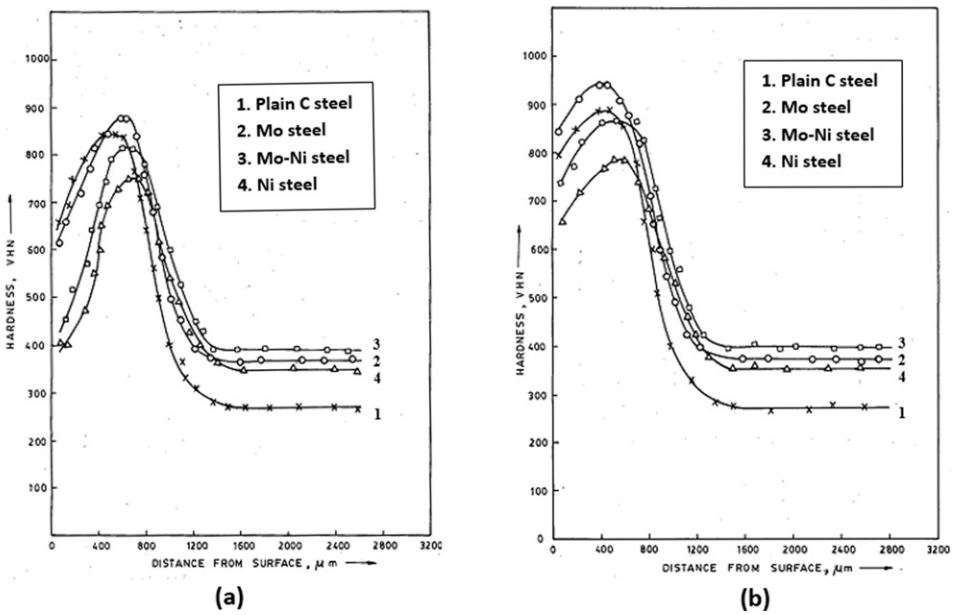

Figure 37 (a) Microhardness profiles of steels 1–4 carburized at 950 °C for 1 h, quenched in 10% brine and tempered at 160 °C and (b) microhardness profiles of steels 1–4 carburized at 950 °C for 1 h,quenched in 10% brine, subzero treated in liquid nitrogen and tempered at 160 °C.[20]

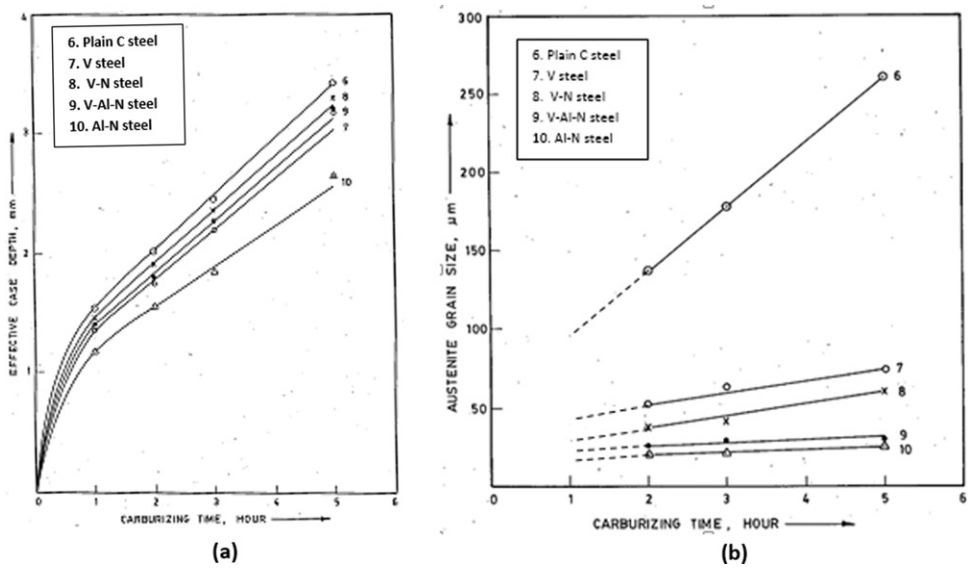

Figure 38 (a) Variation of effective case depth with carburizing time at 950 °C in steels 6–10, and (b) variation of prior austenite grain size with carburizing time at 950 °C in case of steels 6–10.[21]

2.3.6.2 Carburization of Microalloyed Steels

2.3.6.2.1 Carburization of vanadium-microalloyed steel

Microalloying elements such as vanadium with or without nitrogen and aluminum with nitrogen reduce the case depth of the carburized steels. Vanadium without nitrogen is more effective than vanadium with nitrogen in reducing the case depth while aluminum with nitrogen is the most effective of all in reducing the case depth (**Figure 38(a)**).

The undissolved particles of vanadium carbide (VC), vanadium carbonitride, (V(C,N)) and aluminum nitride (AIN) all refine the austenite grain size of the carburized case, but V(C,N) is much more effective than VC; AIN is the most effective in inhibiting the grain growth of austenite in the case of carburized steels (**Figure 38(b)**). Vanadium without nitrogen does not have any effect in the formation of retained austenite while vanadium with nitrogen promotes the formation of retained austenite in the carburized case. Aluminum is the most effective in promoting the formation of retained austenite in the case of carburized steels (**Figure 39**).

The undissolved particles of VC and V(C,N) increase the case and core hardness while AIN reduces the case and core

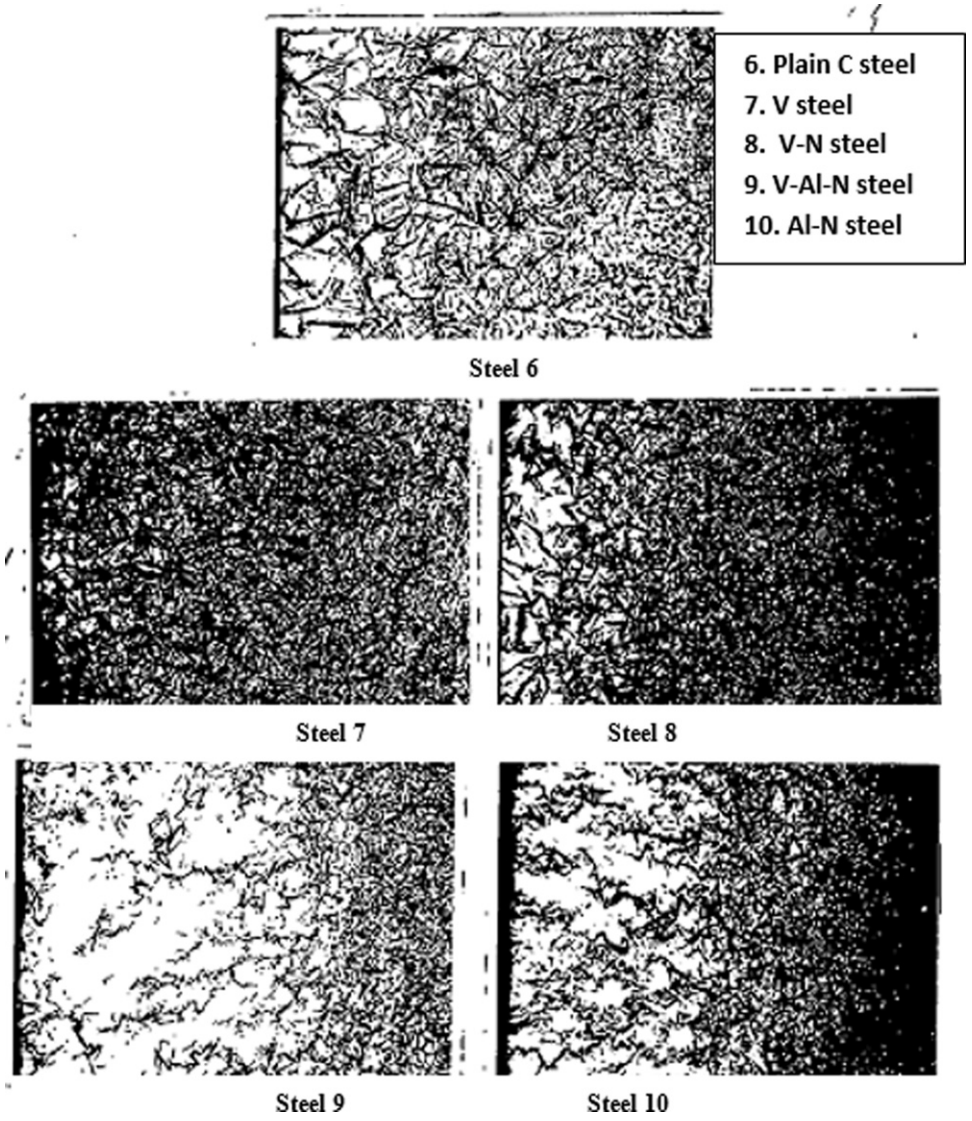

Figure 39 Optical micrographs showing the microstructures of steels 6–10 carburized at 950 °C for 4 h quenched in 10% brine and tempered at 160 °C, × 280.[22]

hardness. V(C,N) is more effective than VC in raising the hardness of the case and core. Vanadium alone and combination with nitrogen increase the case and core hardness (Figure 40) while vanadium alone reduces the toughness, and vanadium with nitrogen improves toughness.[22]

2.3.6.2.2 Carburization of niobium-microalloyed steel

Niobium with or without nitrogen decreases the case depth of the carburized steels. Niobium with nitrogen is more effective than niobium without nitrogen in reducing the case depth (Figure 41(a)). Both the undissolved particles of niobium carbide (NbC) and niobium carbonitride (Nb(C,N)) refine the austenite grain size of the carburized case, but Nb(C,N) is much more effective than NbC in restricting the austenite grain growth Figure 41(b).

Under identical conditions, niobium alone and in combination with nitrogen decrease the formation of retained austenite in the carburized and hardened steels. Niobium with nitrogen is more effective than niobium in reducing the austenite retention (Figure 42). Subzero treatment substantially reduces the retained austenite content in the hardened cases of all the steels.[24]

Niobium improves the surface hardness and maximum hardness of the case and core hardness of low carbon steels in the carburized and hardened conditions (Figure 43(a)). It also improves wear resistance of the carburized and hardened low carbon steel. Niobium in combination with nitrogen causes further improvement in hardness and wear resistance. Subzero treatment again causes further improvement in the case and core hardness of these carburized steels (Figure 43(b)).

Both the NbC and Nb(C,N) particles are detrimental to the toughness of the core of low carbon steels in the carburized and hardened condition, but Nb(C,N) precipitates are less harmful than NbC precipitates.[24]

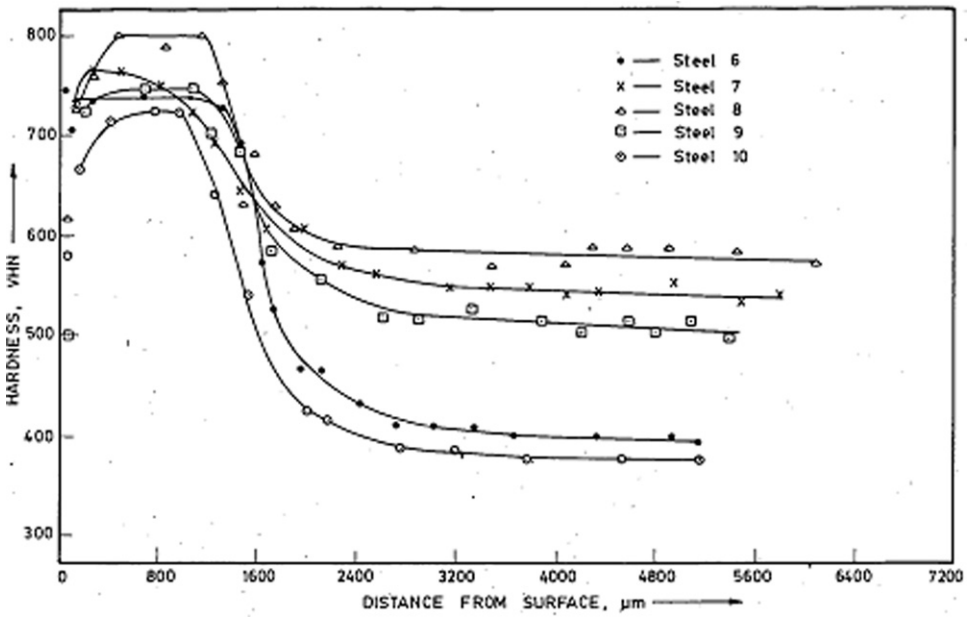

Figure 40 Microhardness profiles of steels 6–10 carburized at 950 °C for 1 h, quenched in 10% brine and tempered at 160 °C.[22]

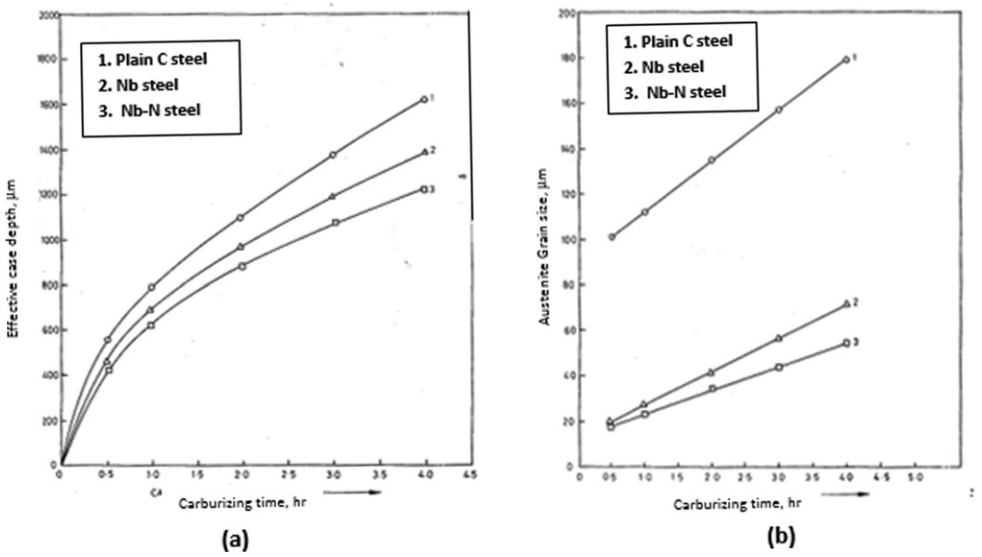

Figure 41 (a) Variation of effective case depth with carburizing time of steels 1–3 carburized at 950 °C and (b) variation of prior austenite grain size with carburizing time of the case of steels 1–3 carburized at 950 °C.[23]

2.3.6.3 Low Temperature Carburization of Austenitic Stainless Steel

2.3.6.3.1 Introduction

Low temperature carburization is a gaseous carburization process performed at atmospheric pressure, at temperatures where the kinetics of substitutional diffusion are very slow. Low temperature (350–550 °C) carburization hardens the surface of austenitic stainless steels through the diffusion of interstitial carbon, without the formation of carbides. The surface must be activated, by modification and removal of the naturally occurring chromia (chromium oxide) layer, for the diffusion process to work. The process results in a hardened diffusional case on the surface, typically 20–35 μm thick, with carbon content at the surface in excess of 10 at% and near-surface hardness of about HV 1200 (over 70 HRC). The case remains austenitic and retains its ductility.

2.3.6.3.2 Activation

Stainless steels and other chromium-containing alloys obtain their 'stainless' characteristic from the chromium-rich oxide that forms on the exposed surface. This oxide layer forms when a fresh surface is exposed to an oxygen containing medium, such as air, and will form after very short time exposures. The chromia layer on the surface of stainless steel constitutes a

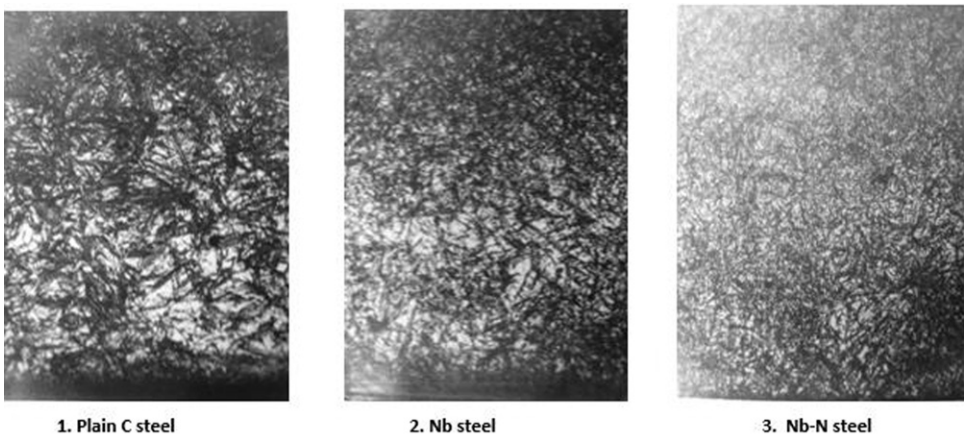

Figure 42 Optical micrographs showing the microstructures in the case of steels 1–3 carburized at 950 °C for 4 h, quenched in 10% brine and tempered at 160 °C, × 300.[24]

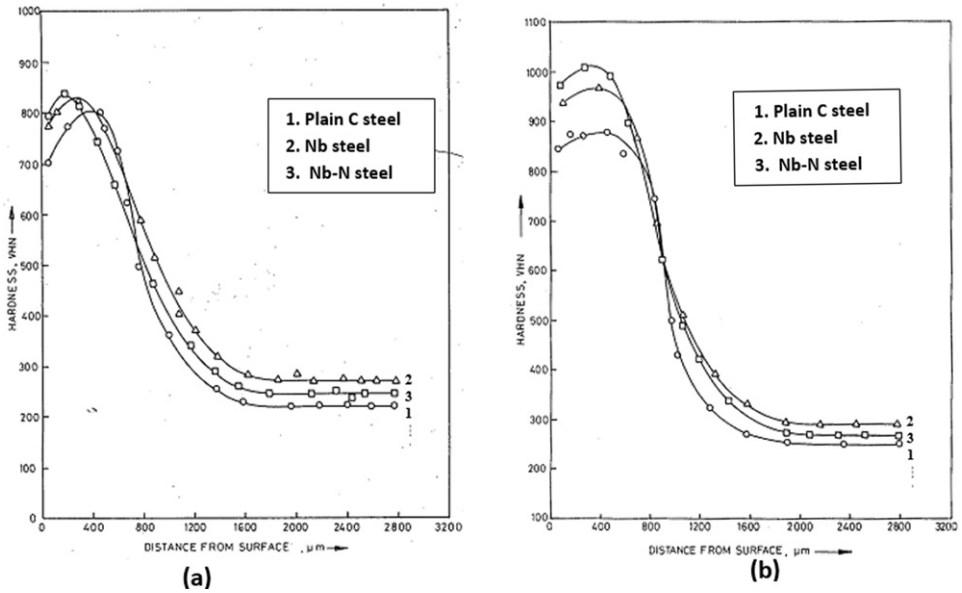

Figure 43 (a) Microhardness profiles of steels 1–3 carburized at 950 °C for 1 h, quenched in 10% brine and tempered at 160 °C. (b) Microhardness profiles of steels 1–3 carburized at 950 °C for 1 h, quenched in 10% brine, subzero treated in liquid nitrogen and tempered at 160 °C.[24]

major barrier to low temperature carburization because it prevents the inward diffusion of carbon. In order to diffuse the carbon atoms into the stainless steel from the surface, the chromium oxide layer must be removed, or at least modified to become carbon-transparent. This step generally is known as surface activation or depassivation.

Several methods have been developed[25–29] that eliminate the inhibiting effects of the oxide and activate the surface for efficient transport of carbon from a conventional carburizing atmosphere into the stainless steel matrix. Some processes, such as plasma or liquid sodium treatments, readily activate a passive stainless steel surface by removing the oxide by sputtering. In commercial production processing, activation can be achieved by exposing the furnace load to a halide-containing gas mixture such as nitrogen trifluoride or hydrogen chloride and nitrogen at atmospheric pressure. Hydrochloric acid is effective as an activating gas for a wide range of chromium-containing corrosion-resistant austenitic alloys, including stainless steels.

2.3.6.3.3 Processing temperature ranges

Low temperature carburization has a limited temperature processing range, usually 350–550 °C. At the lower processing temperature, the process becomes very slow and less economically feasible. Lower temperatures mean longer times for the same case thickness. At the upper end, it becomes increasingly difficult to avoid the formation of carbides, which depend in part on the thermally assisted mobility of substitutional alloying elements, such as chromium, in the iron matrix. Traditionally, carburization is carried out at high temperature to maximize the solubility and the rate of interstitial solute diffusion. On cooling to room temperature, however, a major part of the solute atoms will precipitate as carbide phases. Figure 44 shows the appropriate

time–temperature–transformation (TTT) diagram for the heat treatment of an austenitic stainless steel with conventional carbon contents.[30] After high temperature carburization (T > 950 °C), precipitation of carbides can be avoided only by extremely high cooling rates (path A). Furthermore, it is easy to exceed the solubility limit at these temperatures and form carbides during the carburization process itself. At the cooling rates typical of industrial processes, however, the path will cross the carbide 'nose' and precipitation will occur (path B). Carburization at low temperatures proved capable of hardening the surface of austenitic stainless steel without forming phases that would deplete the matrix of chromium, and thereby degrade corrosion resistance. In this process, the formation of carbides is kinetically suppressed (path C). This results in an extremely high carbon supersaturation, in fact far higher than can be achieved by high temperature carburization.

At moderate temperatures, substitutional solutes such as chromium and nickel diffuse much more slowly in austenitic steels than do interstitial solutes such as carbon. At 450–500 °C, the diffusivity of chromium is on the order of 10^{-21} m^2 s^{-1},[31] whereas the carbon diffusivity at this temperature is in the range 10^{-16}–10^{-17} m^2 s^{-1}.[32–34] This factor of 10^4–10^5 differences in diffusion coefficients enables homogeneous carburization in austenitic stainless steels (and other fcc alloys) under conditions where the formation of chromium-rich carbides is suppressed by insufficient diffusion kinetics for substitutional solutes. In other words, carburization is possible below the nose of the carbide curve on the TTT diagram shown in Figure 44.

2.3.6.3.4 Carburizing atmosphere

Several carburizing gas species will impart carbon to the active surface, with varying levels of efficiency at the processing temperatures required for low temperature carburization. These include acetylene and carbon monoxide, among others. A side effect of the high carbon potential needed for processing can be the generation of soot, which then has to be removed after processing using standard aqueous cleaning methods.

2.3.6.3.5 Microstructure of the low temperature carburized layer

The low temperature carburized layer is a diffusion gradient of carbon in solid solution in the austenite matrix. The structure of the case has been shown to be expanded austenite. The lattice parameter of the austenite expands from 0.360 to 0.372 nm after treatment.[35] However, there is no phase transformation and the layer does not represent a new phase. Expanded austenite is formed when large amounts of either nitrogen or carbon (or both) are dissolved in the surface of an austenitic stainless steel, forming a supersaturated solid solution without the precipitation of chromium-containing nitrides or carbides.

2.3.6.4 Carburization of Tool Steels

Carburization may be employed to retard abrasive and adhesive wear in tool steels with satisfactory case depth and improving hardenability and toughness. Different types of tool steels require relevant carburization technique.

2.3.6.4.1 Carburization of hot working tool steel

Hot working tool steels generally require a combination of high temperature strength (i.e., hot hardness and temper resistance), wear resistance, and toughness. In addition, heat check resistance is also required for applications involving thermal cycling.[36] To obtain desired properties gas carburizing can be employed to extensively increase case hardness by diffusion of carbon into the surface of a component. It is conducted at a temperature generally over 900 °C, followed by quenching and tempering operations. A typical gas carburizing cycle is depicted in Figure 45.

After normal stress relieving annealing treatment, carburization is carried out at around 930 °C followed by quenching in oil bath from 830 to 180 °C. Tempering is conducted at 200 °C for 2 h immediately after quenching. After carburizing, the surface layer is saturated with carbon to a eutectoid or moderately hypereutectoid content. The microstructure of hot working tool steels after quenching consists of high carbon martensite and some amount of carbides (i.e., Fe_3C, M_7C_3, and $M_{23}C_6$).

The determining factors for gas-carburized tool steels include microstructure, grain size, morphology and quantity of carbides, chemical compositions, hardness, and internal oxidation including retained austenite. The effect of retained austenite (softer phase) content has two different schools of thought. The transformation of retained austenite to martensite act to increase the yield stress under compression but reduce viscosity, which is favorable for friction coefficient.[37] The presence of retained austenite, under the effect of the compressive stresses, resulting from abrasion contact, can harden under the effect of

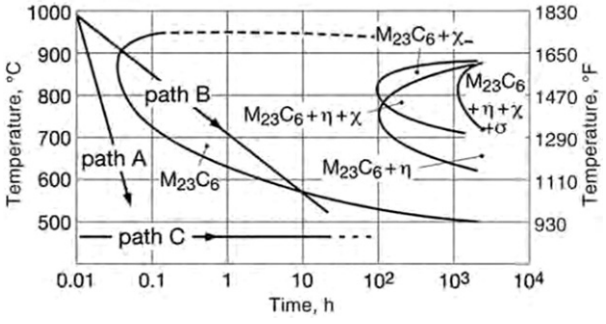

Figure 44 Time–temperature–transformation (TTT) diagram of carbide formation in austenitic stainless steels.[30]

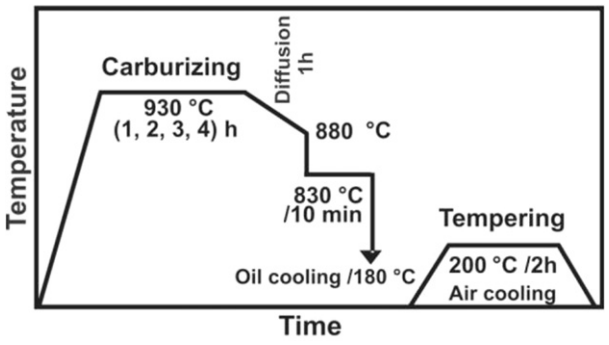

Figure 45 Gas carburizing cycle for hot working tool steels.[36]

induced work hardening, i.e., strain accommodation resulting an improvement in terms of friction.[38,39] In addition, during abrasive test the strain accommodation induces ability of retained austenite to evolve into martensite.[40]

2.3.6.4.2 Carburization of cold working tool steel

Cold work tool steels are designed for operation under the conditions of dry friction. Carburization is carried out on cold work tool steels to modify the surface layer for substantially increasing its abrasive wear resistance thereby increasing the quality of manufactured tools.[41]

Cold work tool steel introduces substantial changes to the surface layer as a result of changes of the carbide phase and the matrix. The carbide phase is responsible for the properties of surface layer. The initial microstructure of cold work tool steel consists of different degree of refinement of ledeburite carbides and dissolved dispersion and spheroidization of dispersion carbides.

After carburizing, the main carbides present in the structure are of M_3C and M_7C types with Fe, Cr, V, and Mo in their composition. Tempering causes carbides of M_3C, M_7C_3, and $M_{23}C_6$ types to precipitate from the oversaturated martensite solution with the carbides of types $M_{23}C_6$ occurring only at a temperature above 550 °C (823 K). The microstructure of matrix phase consists of a complex of austenite, martensite, and tempered martensite.

2.3.6.4.3 Carburization of shock resisting tool steel

To address repetitive impact stresses shock-resistant tool steels are employed. The specific properties to consider are good fracture toughness performance but with low-to-medium wear resistance.[42,43] To improve the surface hardness of shock resisting tool steel the vacuum carburizing surface hardening method can be adopted to obtain high surface carbon content and hardness.[44] The tool steels are generally preheated at 650–700 °C for 30 min carburized at 950 °C for 30 min under a low-pressure acetylene atmosphere followed by a rapid quench in nitrogen gas. The carburized and quenched specimens are tempered at around 300–600 °C.

As carburizing is carried out at high austenitizing temperature, alloying elements are easily dissolved in the solid solution resulting drop in M_s temperature. The microstructure corresponds to twin martensitic structure and retained austenite within the matrix. After tempering, the microstructure consists of needle-shaped tempered martensite inside cementite network.

During tempering, alloying elements, especially Cr, Mo, and V, combined with the high carbon content supplied by the carburizing to form a number of carbides of different sizes and compositions, which strongly influenced the toughness and strength of the steel. Carbide precipitation results in high surface hardness when tool steels are tempered. A typical highest fracture toughness of 80 MPa $m^{-1/2}$ can be obtained for tools steels tempered at 600 °C.

2.3.6.5 Carburization of Mold Steel

The molds made from low carbon steels (P2, P3, P4, P5, P6) in which cavities are formed by hubbing are always carburized before hardening and tempering, and molds made from P20 steel, with its higher carbon content, are frequently carburized when used for plastic molding. It is extremely important that the surfaces of parts to be carburized be as clean as possible, because foreign matter on surfaces may lead to nonuniform carburizing, which in turn leads to polishing difficulties.

Carburizing is a well-established heat-treating technology and can be accomplished by gas carburizing, pack carburizing in solid carbon-containing compounds, liquid carburizing in salt baths, vacuum carburizing, and plasma or ion carburizing. Carburizing temperatures may range from 870 to 995 °C, with carburizing times ranging between 2 and 24 h depending on the desired case depth.

All the low carbon hubbing grades and P20 are typically cooled in air or in the pack after carburizing and are therefore reheated for hardening. Reheating for hardening at temperatures below A_{cm} produces a dispersion of small carbide particles and a fine austenite grain size. This structure then transforms on quenching to a fine martensitic microstructure of high hardness and low susceptibility to intergranular cracking.[45] The carbide particles retained on austenitizing are incorporated into the martensitic structure, and the retained austenite content of reheated and hardened case microstructures is low.

Mold steels with higher hardenability, such as P4, can be hardened by air cooling directly after carburizing, but the retained austenite content may be high and the hardened microstructure will be susceptible to intergranular cracking.[45,46] The retained austenite content can be reduced by refrigeration at subzero temperatures, but reheating, as noted above, may more effectively lower retained austenite and increase hardness.

Austenitizing, quenching, and solution treating of type P21 mold steel are usually done by the tool steel manufacturer. Therefore, the only heat treatment required after machining is relatively low temperature aging between 510 and 540 °C for 20–24 h. No surface protection is necessary during the aging treatment. Type P21 can be simultaneously nitrided and aged in one operation. Once P21 steel is nitrided, it is very difficult to resoften or remove the nitrided case.

Tempering of mold steels requires no special precautions. For plastics molding, a surface hardness near 60 HRC is advantageous for polish ability and wear resistance, while molds for die casting of low-melting alloys are operated satisfactorily at a hardness of about 50 HRC or lower. To ensure structural stability and hardness retention during operation, a tempering temperature close to maximum operating temperature of the mold is desirable, though not always mandatory.

2.3.7 Problems during Carburization and their Remedy

There are a number of problems usually encountered in the carburizing process. The most commonly encountered problems are:

1. Nonuniform carburizing
2. Uneven case depth
3. Insufficient case depth

4. Low hardness
5. Sooting
6. Distortion
7. Soft spots
8. Cracking and exfoliation
9. Grinding cracks.

The above problems are discussed as follows:

2.3.7.1 Nonuniform Carburizing

This is due to improper cleaning of components before carburizing. If the components are dirty, with a greasy work surface or an oxidized surface, it will lead to nonuniform carburizing.

2.3.7.1.1 Prevention

The components are thoroughly cleaned before carburizing, either by degreasing, or sand blasting, or acid cleaning.

2.3.7.2 Uneven Case Depth

In pack carburizing, the uneven case depth may be due to an improper packing or an uneven heating of the container. In gas carburizing, if the free flow of gas all around the surface is prevented, some parts of the components will not be in contact with the gas long enough to be carburized.

2.3.7.2.1 Prevention

1. Thorough mixing of the carburizer.
2. Use of a solution of carbonate and molasses as a binder in the manufacture of the carburizer.
3. Uniform heat soaking of the container.
4. In gas carburizing, a powerful circulating fan together with a suitable baffle system should be used to have a uniform distribution of the gas around the charge.

2.3.7.3 Insufficient Case Depth

Insufficient case depth may be due to the low temperature employed during carburizing. Insufficient case depth may also be due to a weak solid carburizer or an insufficient gas feed in gas carburizing.

2.3.7.3.1 Prevention

1. Carburizing should be repeated with the usual carburizer at a normal temperature between 900 and 930 °C.
2. In gas carburizing, required case depth can be obtained by using a strong carburizer and sufficient feeding of gas.

2.3.7.4 Low Hardness

The common causes of low hardness are mainly due to a higher case depth, presence of retained austenites and decarburization.

2.3.7.4.1 Higher case depth

Higher case depth is produced when the surface of the steel is enriched by higher carbon content (~1.2–1.4% carbon) on carburization. Higher carbon content lowers the M_S and M_f temperatures during quenching. Lower M_s and M_f temperatures enhance the formation of retained austenite which is responsible for low hardness of the carburized case.

2.3.7.4.2 Prevention

This problem may be overcome by subjecting the components to a single quench treatment. That is after cooling from carburizing temperature, the components are heated above the critical temperature (800–830 °C), followed by quenching.

2.3.7.4.3 Retained austenite

Retained austenite occurs mostly in high alloy steels. The presence of carbon and alloying elements in steels prevent the transformation of austenite to martensite during quenching. This untransformed austenite is called the retained austenite. The retained austenite is soft, and hence contributes toward lowering the overall hardness of the components.

2.3.7.4.4 Prevention

This situation generally is avoided in gas carburizing by adopting a two-step process: the first step introduces a high surface carbon content (>1 wt%), while the second is performed at a lower carbon potential, which lowers the surface carbon content by permitting carbon introduced in the first stage to diffuse deeper into the steel. This process is often referred to as boost-diffuse carburizing and if properly controlled, results in reasonable levels of retained austenite.

2.3.7.4.5 Decarburization

In pack carburizing, the decarburization may occur due to slow cooling rate. As a result carbon content of the surface deceases. During quenching, low carbon martensite is formed in the lower carbon surface. This low carbon martensite will cause low hardness in the carburized layer. Decarburization may also occur due to the moisture present in the carburizing mixture.

2.3.7.4.6 Prevention

Carburizing should be repeated at a normal temperature for a short time, followed by cooling of the container in air at a faster rate. The carburizing mixture should be dried in order to make it free from moisture.

2.3.7.5 Sooting

Sooting in gas carburizing spoils the appearance of the work and also interferes with carburizing. Sooting is due to an excessive amount of gas being fed into the furnace, resulting in a free-carbon deposit on the components and in the furnace.

2.3.7.5.1 Prevention

This may be minimized, or prevented, by controlling the carburizing atmosphere, so that the rate of carbon supply to the steel surface does not exceed the rate at which it can be absorbed. Various methods can be adopted, but the use of either a diluted hydrocarbon mixture under controlled flow conditions, or a mixture of gases which will mutually react to give an atmosphere in equilibrium, is generally satisfactory.

2.3.7.6 Distortion

A certain amount of dimensional alteration usually takes place due to the change in microstructure when a part is quenched. The distortion may occur during hardening due to the following reasons:

2.3.7.6.1 Release of internal stresses

Stresses can be caused in steel by carrying out rolling, forging or machining operations before hardening. It is these stresses that will be released during heating to the hardening temperature and cause heavy distortion after hardening.

2.3.7.6.2 Prevention

It is best to release stresses due to rolling or forging by annealing or normalizing before machining.

2.3.7.6.3 Drastic quenching

Distortion may take place due to drastic quenching; the extent depends on the shape of components. Long, slender parts or parts with abrupt and considerable changes of section will always warp to a certain extent after the steel is quenched from the hardening bath.

2.3.7.6.4 Prevention

Distortion will be more if the components are water-quenched, and may be reduced by quenching in oil (60 °C). Further, it may be reduced by quenching in a warm bath maintained at 180–200 °C, and subsequently cooling in air.

2.3.7.6.5 High temperature hardening

When case-hardened mild steel parts of fair size, with only a superficial case, are water-quenched from approximately 900 °C, there is a decided tendency for warpage and expansion.

2.3.7.6.6 Prevention

Distortion may be reduced by hardening from a low (780 °C) or a medium hardening temperature (800–830 °C).

2.3.7.6.7 Rehardening

Sometimes repeated hardening will lead to abnormal dimensional changes in the component, leading to rejection of the component itself.

2.3.7.6.8 Prevention

It is necessary to counter-check the furnace temperature before hardening.

2.3.7.6.9 Uneven heating

Uneven heating is a cause of distortion. It is more common in the 'box' carburizing process, where the portion of the component nearest to the wall of the box gets heated well before the central parts get heated. Also, long shafts which have to be laid horizontally, undergo distortion as the carburizing compound underneath them gets consolidated, resulting in unevenness. Such parts can be hung vertically by using a proper fixture.

2.3.7.6.10 Prevention

The carburizing treatment of such components should be done either by liquid carburizing or gas carburizing to reduce distortion to a minimum.

2.3.7.7 Soft Spots

The causes of soft spots are as follows:

1. The presence of dirt patches or scale on the surface will hinder, or entirely prevent, the penetration of carbon. This may result in soft spots.
2. Unevenness of carburizing may be another cause for soft sports. This is more common in pack carburizing, if the compounds are not properly mixed before packing.
3. Soft sports may also result because of the insufficient time allowed for the center of the pack to attain and remain at the required temperature for a sufficiently long time during carburizing. Even though carburization may have taken place, it may be very thin in some places, and a subsequent grinding may expose the soft core.
4. Another cause for softness may be the development of an excessively high temperature under the grinding wheel.
5. Use of an insufficient quenching media, too warm a condition of quenching media, or improper agitation of the quenchant may also cause soft spots in the case of a heavy charge.

2.3.7.7.1 Prevention

1. Cleaning the components thoroughly before carburizing.
2. Proper mixing and packing of compounds.
3. Avoiding repeated use of used compounds.
4. Using proper coolant during grinding.
5. Control of temperature of quenching media.

2.3.7.8 Cracking and Exfoliation

Cracking and exfoliation occur on the carburized component due to the supersaturation of the case with carbon, leading to the formation of a carbide network. This phenomenon takes place because of too slow heating to the carburizing temperature (mainly in pack carburizing) with a high carbon potential.

In pack carburizing, if the concentration of the carburizing compound is higher, the austenite is supersaturated with carbon, leading to precipitation at the austenite grain boundaries, when the components are subjected to slow cooling from the carburizing temperature. This structure causes brittleness and is responsible for the development of cracking and exfoliation.

2.3.7.8.1 Prevention

1. Maintain appropriate carbon potential in the carrier gas during heating.
2. In pack carburizing, a low activator may be preferred.
3. A faster rate of cooling may be adopted after carburizing.
4. Single or double hardening with case refinement may be adopted during heat treatment.

2.3.7.9 Grinding Cracks

The supersaturated case has a greater tendency to crack during grinding than a eutectoid case. Even a perfect case can crack if an unsuitable wheel, without proper dressing, is used. The process of grinding heavy cuts or insufficient coolant may also cause cracks.

2.3.7.9.1 Prevention

1. Use of proper grinding wheel.
2. Proper dressing.
3. Sufficient coolant, especially with high velocity jets.

2.3.8 Recommended Processing Sequence for Carburized Components

Depending on the type of the component to be manufactured, the following processing sequences may be adopted[47]:

A. Small and medium size components:
   1. forge
   2. normalize
   3. anneal
   4. pre-machine
   5. carburize and harden
   6. temper
   7. finish machine.

B. Small and medium size components with machine operations, such as drilling, broaching, tapping, etc., after hardening:
   1. forge
   2. normalize
   3. anneal
   4. pre-machining
   5. carburize and anneal
   6. machine
   7. harden and temper
   8. finish machine.

C. Big and complicated shape components with machining operations such drilling tapping, etc., after hardening:
   1. forge
   2. normalize
   3. anneal
   4. rough machine
   5. stress relieve
   6. pre-machine
   7. carburize and anneal
   8. machine
   9. harden
   10. temper
   11. finish machine.

2.4.1 Introduction

Gas nitriding is one of the most common surface modification treatments with extensive industrial applications especially in manufacturing of machine components and tools. It is classified as a diffusion-based surface treatment, distinguished from overlay coating deposition techniques, in which the substrate is exposed to a controlled nitriding atmosphere. Gas nitriding is an industrially established finishing treatment to enhance fatigue, wear, and corrosion resistance of ferrous alloys and with the increasing trend of replacing steels with lightweight alloys, for example, titanium and aluminum alloys; it has also been adopted for wear improvements in non-ferrous alloys. Titanium and aluminum alloys are attractive candidate materials in many industrial applications due to their high strength to weight ratio, corrosion resistance, fatigue resistance, etc., and a variety of surface engineering technologies including gas nitriding have been utilized to improve their wear and corrosion resistance.[1]

Nitriding of steels is usually conducted within the temperature range of 495–565 °C in ammonia or ammonia–hydrogen atmosphere.[2] The nitriding conditions (gas composition, temperature, duration, etc.) and the microstructure and composition of the substrate determine the structure and properties of the nitrided workpieces. The nitrided microstructure is mainly composed of a compound layer predominantly consisting of ε-Fe_2N_{1-z} and γ'-Fe_4N_{1-x} (i.e., white layer) on top of a nitrogen diffusion zone (i.e., case).[3] The compound layer improves the corrosion and wear resistance. However, the compound layer is also susceptible to spallation due to its brittle nature and may cause accelerated wear and seizure, thus in many cases it is removed before service.[4] The diffusion zone consists of interstitial solid solution of nitrogen with a gradient gradually decreasing toward the bulk and iron nitride precipitates (in iron and carbon steels) and/or alloying element nitride precipitates (in steels that contain nitride forming alloying elements such as Al, Cr, V). The development of precipitation hardening and compressive residual stresses in the diffusion zone is responsible for enhancement of high-cycle fatigue strength and wear resistance.[3] Due to the relatively low temperatures practiced in the gas nitriding of steels, this treatment does not promote any adverse effects on the ductility of tempered substrates and the resulting volumetric changes and distortions are relatively small.[4]

Nitriding of non-ferrous alloys (i.e., titanium and aluminum alloys) forms a compound layer composed of TiN and Ti_2N nitrides on titanium surfaces and aluminum nitride (AlN) on aluminum surfaces.[5] In titanium alloys, due to the high solubility of nitrogen in α-Ti (~22 at% at 1050 °C[6]) a diffusion zone strengthened by nitrogen interstitial atoms develops underneath the compound layer. The compound layer increases the surface hardness and wear resistance of titanium surfaces while the diffusion zone increases the load bearing capacity of nitrided Ti surfaces by providing mechanical support for the compound layer.[1,7] Nitriding of aluminum alloys, however, tends to be more challenging due to the insolubility of nitrogen in aluminum, high-thermal expansion mismatch between aluminum and aluminum nitride, and the naturally occurring oxide layer on the surface of aluminum alloys. Furthermore, typical gas nitriding temperature lies within the solution treatment temperature range of titanium alloys (0.55–0.65 T_s) and annealing temperature range of aluminum alloys (0.75–0.85 T_s) and causes detrimental effects on the substrates microstructure and properties.[5b,8] Specifically, nitriding of titanium alloys is associated with adverse

side effects on their fatigue properties and loss of ductility due to substrate over aging and grain growth.[1,9]

Following the Introduction, a brief history of the development of gas nitriding process is given in Section 2.4.2, followed by the description of fundamentals, thermodynamics, and kinetics aspects of gas nitriding. Section 2.4.3 describes an overview of the practical aspects of gas nitriding treatment as well as commonly practiced pre- and post-treatments. Section 2.4.4 discusses the gas nitriding conditions for ferrous and non-ferrous alloys and the effect of nitriding parameters on the microstructural development of the alloys. Subsequently, the effect of gas nitriding on mechanical properties, wear and corrosion resistance of structural alloys are presented in Sections 2.4.5 and 2.4.6. Finally, the industrial applications and recent developments in the gas nitriding technology are presented in Sections 2.4.7 and 2.4.8.

2.4.2 Fundamentals of Gas Nitriding

Gas nitriding treatment was pioneered by parallel work of Machlet[10] (American Gas Company, Elizabeth, NJ) and Fry[11] (Krupp Steel Works, Essen, Germany) in early twentieth century. They discovered that nitrogen promoted hard surface layers in steels that significantly improved corrosion and wear resistance. Fry discovered that alloying elements such as molybdenum, vanadium, tungsten, aluminum, and chromium increase the surface hardness of nitrided steel and he developed the family of 'Nitralloy' steels specifically for nitriding. At the time ammonia was used to provide nascent nitrogen for nitriding but Machlet[10] found that introducing hydrogen as a dilutant gas enhanced the nitrogen activity and controlled the decomposition rate of ammonia and nitrided microstructure.[12] However, the development of gas nitriding in the United States initiated after Fry's work was presented in the 'Society of Manufacturing Engineers' conference in 1927.

Based on the findings of Machlet and Fry, McQuaid and Ketcham[13] (Timken-Detroit Axle Company, Detroit, MI) investigated the effect of process parameters such as time, temperature, cooling rate, and gas composition on the nitriding microstructure. Their findings indicated that nitriding at high temperatures (more than 650 °C) reduced the core hardness of alloy steels and increased the surface susceptibility to early formation and exfoliation due to the formation of nitride networks. Perhaps more importantly, they reported that the formation of compound layer should be avoided due to its brittle nature. They also noted that the possible decarburization of surface layers has a detrimental effect on nitriding as it increases the chances of exfoliation and premature failure of the nitride layer.

The role of alloying elements on the nitriding and carburizing chemistry of steels were reviewed and studied by Sergeson[13] (Central Alloy Steel Corporation, Canton, OH). In agreement with McQuaid and Ketcham,[13] he noted that controlling the nitriding treatment was easier than carburizing. He also investigated the effect of reheating, temperature, gas flow, and decarburization on nitriding chemistry. According to his findings while gas flow rate had little effect on the case hardness and depth, increasing the nitriding temperature resulted in the development of a deeper case and a lower surface hardness. A two-stage nitriding process composed of a first low-temperature step at 510 °C, followed by a high-temperature step at 620–650 °C was also recommended to minimize the surface brittleness.

It should be noted that the nitriding equipment used in the experiments were at their primitive stage of development. The first steps toward advanced nitriding process technology were contributed by Floe[13] (Massachusetts Institute of Technology). His research was focused on the characterization of microstructure and properties of nitrided layers and he developed a nitriding treatment to reduce the compound layer thickness, i.e., the Floe Process (to be discussed in Section 2.4.3). Soon with the advent of process technology such as sensors, computer control systems, flow control devices, and automatic monitoring of dissociation rate, and based on experimentation and theoretical calculations, gas nitriding was conducted under accurately controlled conditions.[14] The nitriding process has been the subject of many studies ever since[15] and modifications have made it applicable for other structural alloys such as stainless steels and titanium alloys[16] and new fabrication technologies such as powder metallurgy.

2.4.2.1 Thermodynamics of Nitriding

2.4.2.1.1 Iron–nitrogen system

Iron–nitrogen (Fe–N) system has been the subject of many studies over the past decades and is one of the most extensively used due to its practical significance.[17] **Figure 1** presents the equilibrium binary Fe–N phase diagram. Due to the lack of experimental data for temperatures above 1200 K, the phase diagram has been constructed by thermodynamic mathematical calculations at high temperatures.[18] Crystal structure, space group, and chemical composition of the most common solid phases in the Fe–N phases are listed in **Table 1**.

Fe–N system consists of two solid solution phases (e.g., α, γ), several nitride compounds (e.g., ε, γ', ζ), and several non-equilibrium phases (e.g., α', α''). The low temperature solid solution, i.e., ferrite (α-Fe), is stable below 912 °C has a limited nitrogen solubility. Austenite (γ-Fe) is stable above 600 °C and over a wide range of compositions. The austenite phase may undergo a martensitic transformation to α' martensite but can be fully retained at room temperature by quenching upon dissolution of 8.6 at% nitrogen.[17d] The main nitride phases in Fe–N system, from the practical point of view, are hexagonal ε-nitride and cubic close packed γ'-nitride. The cubic γ'-nitride has a narrow range of composition but ε-nitride has a wide range of compositions and shows a high ordering of the nitrogen interstitial atoms in the octahedral sites. This phase has a higher probability of formation in steels with high carbon contents. The ε-nitride with nitrogen contents below 27 at% is metastable at room temperature and dissociates into a nitrogen-rich ε phase and γ' (or α'') phase.[19]

In order to predict the nitriding behavior and obtain the desired nitrided microstructure in ferrous alloys, the phase

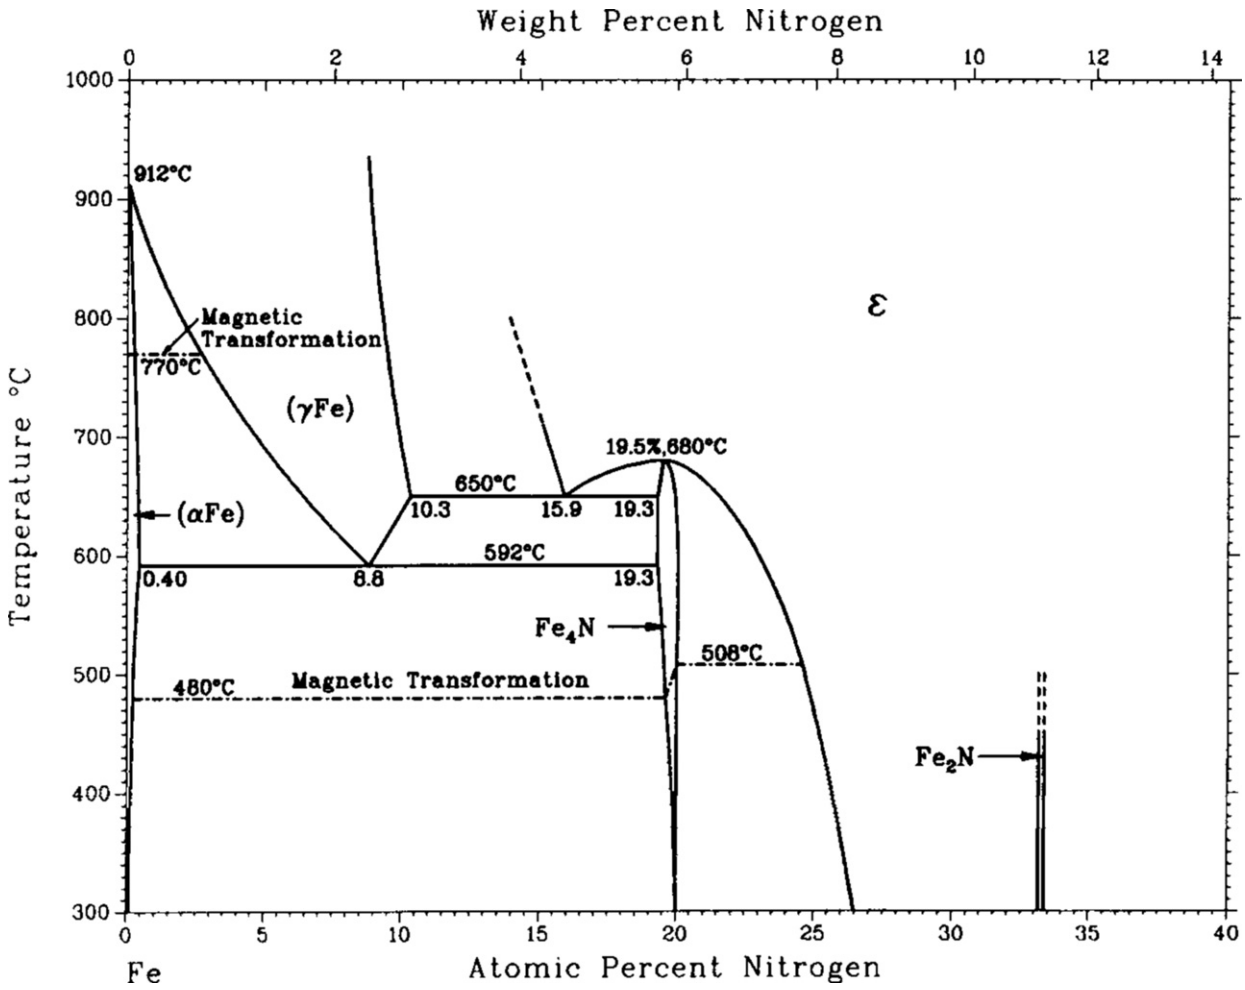

Figure 1 Equilibrium iron–nitrogen binary phase diagram.[17d]

Table 1 Crystal structure, space group, and chemical composition for phases in the iron–nitrogen system

stabilities of Fe–N system were studied in relation to temperature and nitriding medium. The investigations resulted in the development of Lehrer diagrams for describing the gas nitriding behavior of iron and steels as will be discussed in the following section.

2.4.2.1.2 Lehrer diagrams

The nitriding reaction in NH_3–H_2 atmosphere (Reaction I) can be considered as the sum of two hypothetical reactions: (1) dissociation of ammonia at the surface (Reaction II) and (2) liberation of nascent nitrogen dissolving in the metal surface (Reaction III), as schematically illustrated in **Figure 2**.

$$NH_3 \leftrightarrow [N] + 3/2H_2 \quad [I]$$

$$NH_3 \leftrightarrow 1/2N_2 + 3/2H_2 \quad [II]$$

$$1/2N_2 \leftrightarrow [N] \quad [III]$$

where [N] is the dissolved nitrogen in the substrate structure. Accordingly, the equilibrium constant of Reaction (I), K_I can be written in terms of nitrogen activity (a_N), partial pressure of nitrogen (p_{NH_2}), partial pressure of ammonia (p_{NH_3}), and pressure of gases in the reference state (p^0) according to eqn [1]. The equilibrium constants of Reactions [II] and [III] are K_{II} and K_{III} as presented by eqns [2] and [3], respectively, assuming ideal gas behavior or constant fugacity coefficients of gaseous components. Due to the local equilibrium on the surface, the chemical potential of nitrogen in the nitriding atmosphere is equal to the chemical potential of nitrogen on the nitrided surface and thus in eqn [3], $a_N = \frac{\sqrt{p_{N_2}}}{\sqrt{p^0}}$.

$$K_I = \frac{a_N \cdot p_{H_2}^{3/2}}{\sqrt{p^0} \cdot p_{NH_3}} \quad [1]$$

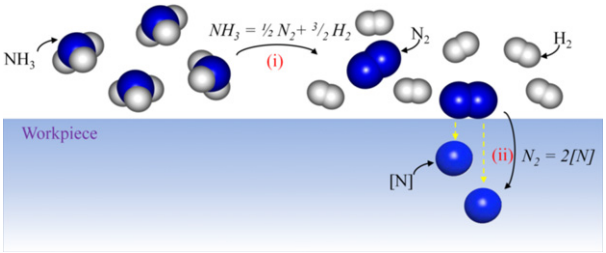

Figure 2 A schematic drawing showing hypothetical surface reactions during gas nitriding in ammonia–hydrogen nitriding atmosphere: (1) ammonia dissociation and (2) liberation of nascent nitrogen in the work surface. ([N] is the solid solution of nitrogen in the substrate structure.) Hosmani, S. S.; Schacherl, R. E.; Mittemeijer, E. J. Compound Layer Formation on Iron-Based Alloys Upon Nitriding; Phase Composition and Pore Formation. *J. Heat Treat. Mater. (HTM Härtereitechnische Mitteilungen)* **2008**, *63* (3), 139–146.

$$K_{II} = \frac{p_{N_2}^{1/2} \cdot p_{H_2}^{3/2}}{p^0 \cdot p_{NH_3}} \quad [2]$$

$$K_{III} = \frac{\sqrt{p_{N_2}}}{\sqrt{p^0} \cdot a_N} \quad [3]$$

It follows that nitrogen activity is proportional to $\frac{p_{NH_3}}{p_{H_2}^{3/2}}$, where p_{NH_3} is the partial pressure of ammonia and p_{H_2} is the partial pressure of hydrogen (eqn [4]). The nitriding potential, r_N (or K_N in German literature), was thus defined based on the partial pressure of ammonia p_{NH_3}, and hydrogen p_{NH_2} to represent the activity of nitrogen (eqn [5]).[24]

$$a_N = \frac{K_{III} \cdot p_{NH_3} \cdot \sqrt{p^0}}{p_{H_2}^{3/2}} = \frac{K_I \cdot p_{NH_3} \cdot \sqrt{p^0}}{p_{H_2}^{3/2}} \quad [4]$$

$$r_N = p_{NH_3} / p_{H_2}^{3/2} \quad [5]$$

A plot of the nitriding potential against temperature provides graphic illustration of possible thermodynamically stable phases in Fe–N system during nitriding (**Figure 3**). This plot is named after 'Lehrer' who constructed it for the first time for pure Fe. As such, a 'Lehrer diagram' can be used to predict the desired nitriding outcome by controlling NH_3–H_2 gas mixture composition and pressure, and thus the chemical potential of nitrogen in the nitriding atmosphere.[3,17a,19b,25]

When the nitriding potential is sufficiently high that the activity of nitrogen dissolved in iron is equal to its equilibrium value in iron nitrides γ' and ε, nitrides precipitate on the surface. However, the thermodynamic equilibrium is established

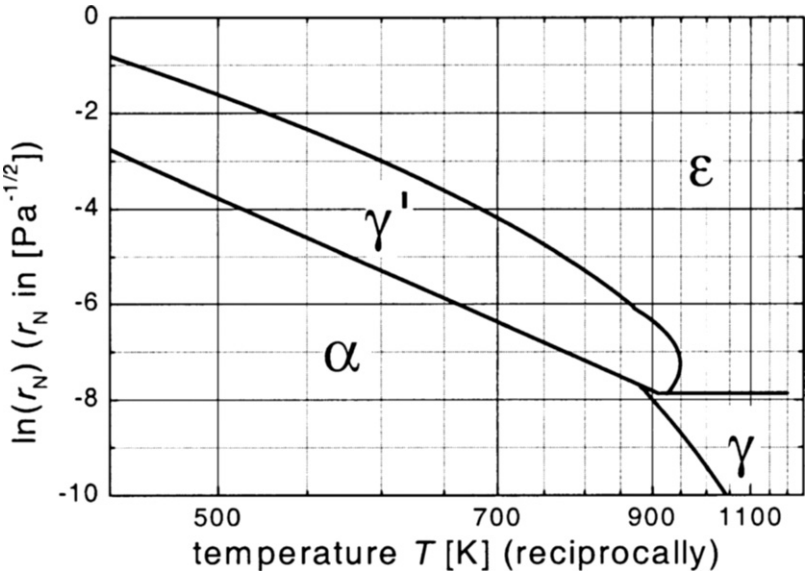

Figure 3 A schematic representation of Lehrer diagram for pure Fe; α and γ are the solid solutions of nitrogen in BCC and FCC iron, γ' and ε are Fe_4N_{1-x} and Fe_2N_{1-z} nitride compounds, respectively.[79]

only at the surface which is in direct contact with the nitriding atmosphere. Thus as the iron nitrides grow and develop a compound layer, the nitride phases that are no longer in contact with the nitriding medium will be thermodynamically unstable. As a result, γ' and ε phases have a strong tendency to dissociate into iron and nitrogen with time. The nitrogen atoms liberated from the decomposition reaction combine to form N_2 molecules at a faster rate than nitrogen escape through the compound layer, and thus N_2-filled pores form in the compound layer.[26] The pores preferentially develop within the ε-Fe_2N_{1-z} phase (mostly at grain boundaries) where the decomposition driving force is higher because it is the oldest part of the nitrided structure and has higher nitrogen concentration. The pores coalesce into channels toward the free surface or blister inside the material.[27]

Although the kinetics of decomposition is slow at low temperatures ($T < 400\ ^\circ C$), at higher temperatures it is inevitable. The decomposition rate nitrides is also faster in austenite compared to ferrite due to the higher solubility limit of nitrogen (10.3 at%) in the former compared with the latter (0.4 at%) and higher temperatures required for austenitization by nitriding. Moreover, the formation of porosity is dependent on nitrogen activity in the nitriding media, a_N, and it is proposed that low nitrogen activities reduce the probability of porous compound layers.[25b]

2.4.2.1.3 Titanium–nitrogen system

Titanium experiences an allotropic phase transformation from HCP crystal structure stable at lower temperatures (α phase) to BCC crystal structure (β phase) at 882 °C (e.g., β-transus temperature). Alloying elements such as Al, O, N, and C increase the β-transus temperature and are α stabilizers, while alloying elements such as V, Mo, Nb, Cr, Fe, and Ni stabilize the β phase through eutectoid formation or decreasing the β-transus temperature. Thus depending on their alloying element content, titanium alloys can be classified as α, $\alpha+\beta$, and β alloys.[28]

Gas nitriding is thoroughly investigated on pure titanium and α-Ti alloys, $\alpha+\beta$ Ti alloys, and β-Ti alloys.[8] The nitriding microstructure evolves according to Ti–N phase diagram (Figure 4). Nitrogen dissolves interstitially in both α- and β-Ti, with high solubility in the former and lower solubility in the latter. Ti–N system also consists of several nitride compounds. TiN_{1-x} (δ phase) has a rock salt crystal structure and is

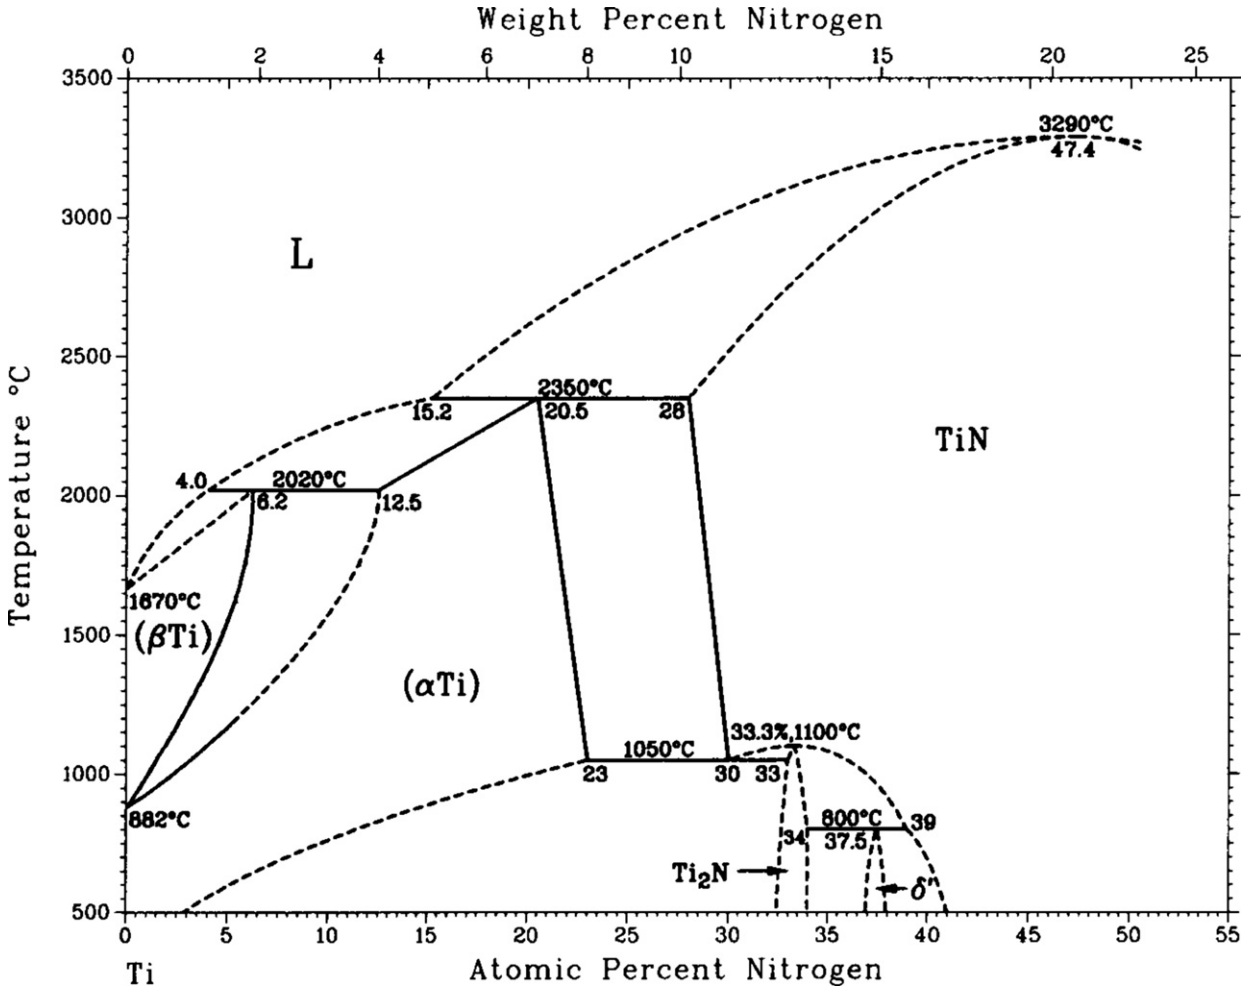

Figure 4 Equilibrium titanium–nitrogen binary phase diagram.[30]

stable over a wide range of compositions. Peritectoid Ti_2N (ε phase) has an anti-rutile tetragonal structure and is stable over a narrow composition with ~33.3 at% N.[6,29] Crystal structure, space group, and chemical composition of the main phases in titanium–nitrogen (Ti–N) system are summarized in Table 2.

2.4.2.1.4 Aluminum–nitrogen system

AlN is known as a refractory compound with high hardness (~1400 HV) and good thermal shock resistance, low coefficient of thermal expansion, high-electrical resistivity, and good corrosion and wear resistance. It has found numerous applications in electronic and semiconductor devices, handling of corrosive and molten metals, etc.[35] Nonetheless, gas nitriding of aluminum alloys is quite challenging. To begin with, aluminum alloys are typically nitrided within the temperature range of 0.8–0.9T_s (T_s is the solidus temperature), which lies above their annealing temperature. This causes severe adverse effects on the microstructure and properties of aluminum substrates. Furthermore, nitrogen does not dissolve in aluminum (Figure 5) and thus the aluminum nitrides formed on the surface do not get any mechanical support from their substrates.[8]

2.4.2.2 Nitriding Kinetics

The thermodynamic studies explained in the previous section predict the formation of nitrided microstructure at the state

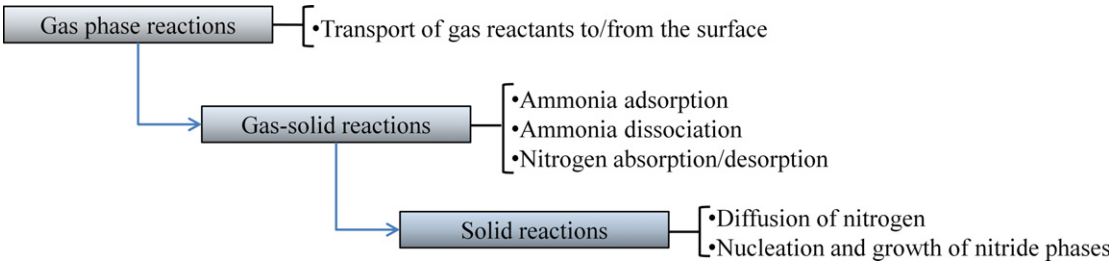

Figure 6 A schematic diagram presenting the main steps involved in the process of gas nitriding including gas-phase reactions (such as nitriding gas transport phenomena), gas–solid reactions (such as adsorption of ammonia on the work surface) and solid-phase reactions (such as nucleation of nitrides on the work surface). The overall gas nitriding rate is controlled by the rate of the slowest step. Mridha, S. Gas Nitriding of En40B Steel with Highest Growth Rate of the Case and Reduced White Layer Formation. *Int. J. Microstruct. Mater. Prop.* **2007**, *2* (1), 54–63.

of equilibrium; however, the actual composition and thickness of the nitrided layers are explained through the nitriding kinetics. The development of nitrided microstructure is the result of several steps including, gas-phase phenomena (e.g., transfer of the nitrogen-containing gas to the surface), gas–solid reactions (e.g., absorption, desorption), chemical reaction (e.g., nitride phase formation), and solid-phase phenomena (e.g., diffusion). The rate of the gas nitriding is controlled by the rate of the slowest step.[36]

Since the majority of literature on the fundamentals of gas nitriding is focused on the nitriding of iron and steels.[24,37] This section covers the concepts of nitriding kinetics for ferrous alloys, non-ferrous alloys will be discussed where applicable. **Figure 6** summarizes some of the main steps during gas nitriding that should be considered in determining the nitriding kinetics, as described below;

i. A minimum gas flow rate is essential in order to transport N-containing medium to the surface (and nitriding products away from the surface) and maintain a controlled, homogeneous nitriding atmosphere.[26]
ii. Ammonia dissociation is a catalytic reaction activated by the work surface and the interior furnace walls. Grabke *et al.*[38] proposed that this step is the result of several subreactions including physical adsorption of ammonia, dissociation of adsorbed ammonia into adsorbed NH_2, NH radicals and N atoms, and the formation of N_2 and H_2 molecules from adsorbed N and H atoms. Many factors contribute to the kinetics of this step such as surface roughness, chemical and phase composition of the surface, crystallographic orientation, etc. According to Slycke and Ericsson,[39] the overall rate is controlled by the rate of formation of nitrogen molecules from adsorbed N atoms.
iii. Inward diffusion of nitrogen atoms and the formation of surface nitrides. As the rate of nitrogen adsorption exceeds that of its inward diffusion, the nitrogen concentration at the surface increases to reach equilibrium with the nitriding atmosphere. At this point, surface nitrides begin to form on the surface possibly through a nucleation and growth mechanism.[40]

Lightfoot[20] introduced a critical flux of nitrogen (controlled by the alloy composition and nitriding potential) for the formation of nitride phases on the surface. He explained that the equilibrium state at the gas/ε-Fe_2N_{1-z}, ε-Fe_2N_{1-z}/Fe_4N, and Fe_4N/ferrite interfaces dictates a nitrogen concentration gradient within the ε-Fe_2N_{1-z} and Fe_4N layers. He stated that the formation of Fe_4N had an incubation time and under conditions of high-nitriding potential, ε-Fe_2N_{1-z} could form on the surface and grow rapidly without leaving time for Fe_4N to nucleate.

Mittemeijer *et al.*[27a,41] proposed that γ'-Fe_4N_{1-x} nitrides nucleate on the gas–solid interface at locations where the concentration of dissolved nitrogen exceeds a critical value, i.e., active centers, after a certain incubation time. The kinetics of nitride layer formation is largely dependent on the number of active centers. Several surface activation pre-treatments have been developed to increase the number of active centers via increasing the defectiveness and roughness, and removal of inherent oxides from the work surface such as cathode sputtering. Both nitrogen and argon have been used as the sputtering gas and significant improvements in the nitriding rate were reported.[42]

Having nucleated on the surface, γ' nitrides consume the dissolved nitrogen in the surrounding matrix to grow (since nitrogen dissolves faster in ferrite than γ'-Fe_4N_{1-x} nitride). At this time ε-Fe_2N_{1-z} may also nucleate on top of γ'-Fe_4N_{1-x}, if the nitriding potential is favorable. A the growth proceeds, a continuous layer of iron nitrides (compound layer) develops on the surface and further growth is then controlled by the diffusion rate of nitrogen through this layer. As discussed in Section 2.4.2.1, the iron nitrides are not at thermodynamic equilibrium as they are no longer in direct contact with the nitriding medium. They tend to decompose into iron and nitrogen, resulting in the evolution of porosity preferentially within/at the grain boundaries of ε-Fe_2N_{1-z} phase. A schematic illustration of this mechanism is presented in **Figure 7**.

Underneath the compound layer, nitrogen dissolves interstitially in the diffusion zone with limited solubility in ferrite and high solubility in austenite (**Table 1**). The inward diffusion rate of nitrogen determines the nitrogen gradient in the diffusion zone. As the nitrogen content at the surface of the ε layer is dependent on the nitriding potential of the nitriding atmosphere, assuming that the composition of surface nitrides are known and change linearly with depth at each layer, the diffusivity of nitrogen in ε phase and γ' phase can be calculated by analytical or numerical methods and verified with

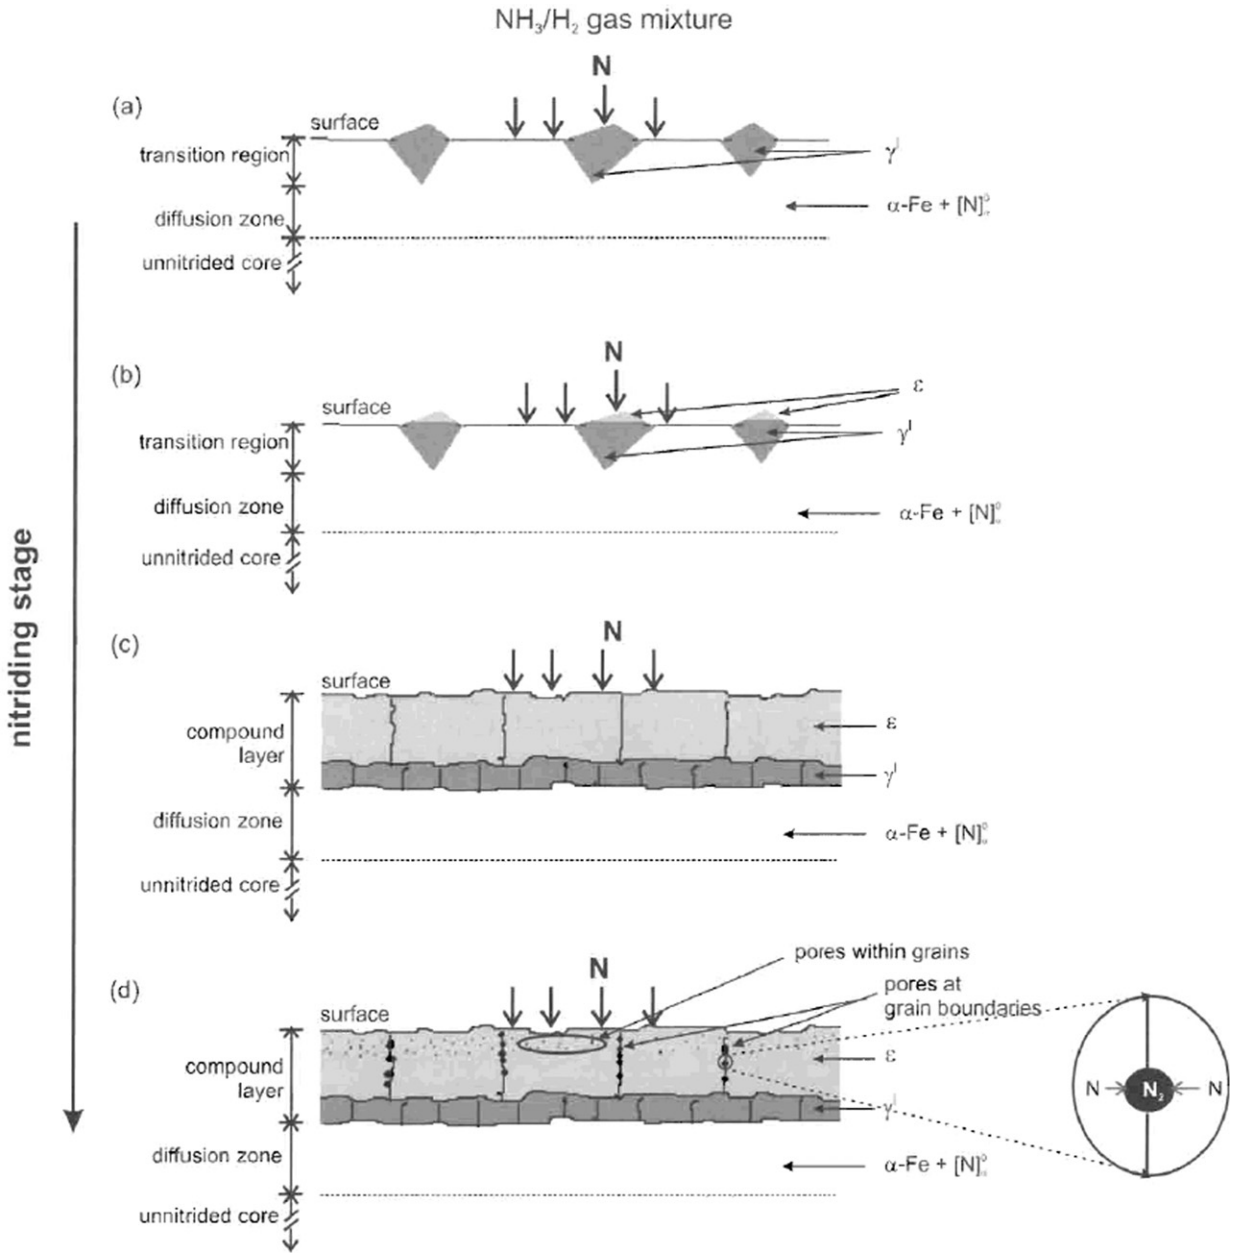

Figure 7 Schematic illustration of the nucleation and growth mechanism of the compound layer during nitriding of (ferritic) iron in NH_3/H_2 mixture. (a) Nucleation of γ' nitrides on the surface and their growth via consuming dissolved nitrogen in the surrounding matrix, (b) nucleation of ε on top of γ' phase (if the nitriding potential is favorable), (c) growth of the nitrided phases and formation of a continuous compound layer covering the entire surface; further growth requires diffusion of nitrogen atoms through this layer, (d) evolution of porosity within the ε phase, more likely at grain boundaries, due to the nitride phase decomposition and generation of N_2 molecules.[41]

experimental results (**Figure 8**).[24] Several researchers have developed mathematical models for nitriding to predict nitride layer growth rate and nitrogen concentration profile. Torchane *et al.*[43] investigated the mechanisms of phase formation and mass transfer at the gas–solid interface and validated their calculations with thermogravimetric experiments and metallurgical observations. Du *et al.*[44] used analytical models and numerical calculations to solve diffusion coefficients for modeling of compound layer growth behavior.

When substitutional alloying elements with high chemical affinity to nitrogen, for example, Ti, V, Al, Mo, Cr, W, are present in the steel composition, coherent submicroscopic nitride precipitates form in the diffusion zone during nitriding. As such, the nitriding kinetics will be affected by the alloying elements content, kinetics and thermodynamics of alloy element nitride precipitation and prior heat treatment of the steel substrate. Lightfoot and Jack[20] explained that the nitriding microstructure depends on the heat of formation (ΔH_f) and

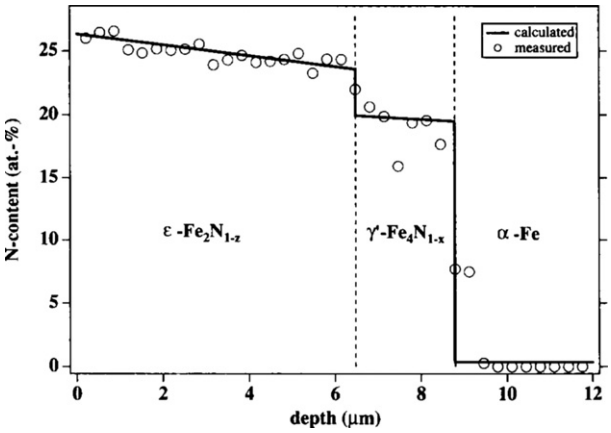

Figure 8 Nitrogen content vs. depth profile of the compound layer ($\varepsilon+\gamma'$) formed by nitriding at 570 °C for 2 h and NH_3–H_2 (56:44) gas mixture. The experimental results were in agreement with the assumption of linear nitrogen content-depth profile in each nitride layer.[41]

ease of nucleation of the alloying element nitrides. They stated that alloying elements of weaker nitride-forming tendency or slower nucleation rate such as molybdenum ($\Delta H_f^{Mo_2N} = -81.6\ kJ\ mol^{-1}$, where $\Delta H_f^{Mo_2N}$ is the heat of formation for molybdenum nitride (Mo_2N)) require large supersaturations for nitride precipitation. The nitriding response is thus controlled by the precipitation rate of nitrides and inward diffusion of nitrogen interstitials. The delayed nitride formation and competition between iron nitrides and alloying element nitrides provides sufficient time for nitrogen atoms to diffuse deeply in the structure (**Figures 9(a)** and **9(b)**). This behavior was also observed in Fe–Al, Fe-1.2 wt% Cr and Fe-5 wt% Mo.[20]

Conversely, fast precipitation rates were predicted for strong nitride-forming elements with easy nucleation such as titanium ($\Delta H_f^{TiN} = -335\ kJ\ mol^{-1}$, where ΔH_f^{TiN} is the heat of formation for titanium nitride (TiN)). A uniform surface layer with high hardness forms on the surface of titanium-containing steels during nitriding over a wide range of temperatures and nitriding potentials (**Figures 9(b)** and **9(c)**). The thickness of the nitrided layer, ξ, can be approximated by eqn [6];

$$\xi^2 = \frac{2}{r}\frac{[N]}{[Ti]}Dt \qquad (6)$$

where r is the ratio of nitrogen to titanium, [N] is the concentration of nitrogen on the surface, [Ti] is the original concentration of titanium in the steel composition, D is the diffusion coefficient of nitrogen, and t is the nitriding duration. The rate-controlling step of the nitriding process in this case is the diffusion of nitrogen from the surface to the non-nitrided interface. Fe–5Cr showed similar nitriding behavior at 500 °C and 18% NH_3 atmosphere.

In case of chromium-containing ($\Delta H_f^{CrN} = -125.5\ kJ\ mol^{-1}$, where ΔH_f^{CrN} is the heat of formation for chromium nitride (CrN)) steels, a hard surface zone forms at the beginning of nitriding with a diffuse interface between the case and the

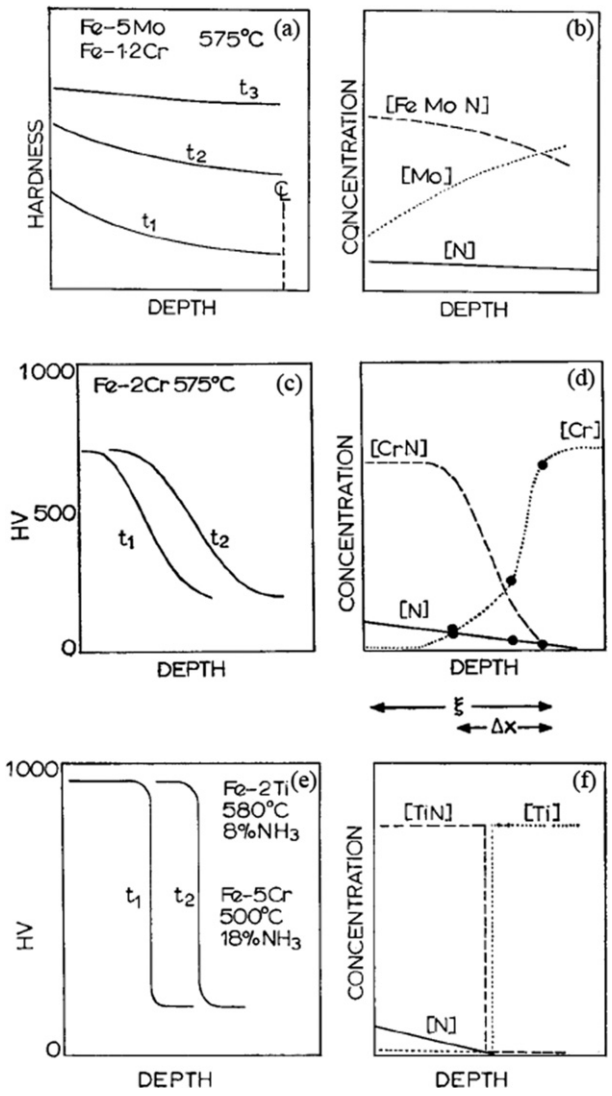

Figure 9 Schematic illustration of hardness and chemical composition profiles against distance from the nitrided surface showing the nitriding behavior of steels containing (a, b) alloying elements with weak interaction with nitrogen or difficult nucleation, (c, d) alloying elements that have strong interaction with nitrogen and easy nitride nucleation behavior, and (e, f) alloying elements that form a diffusion interface between the case and the substrate (core).[20]

substrate (core). The interface morphology depends on the nitriding potential and temperature; a sharper interface is expected for high nitriding potentials and high-chromium contents in the steel substrate (**Figures 9(c)** and **9(d)**). The depth of the nitrided zone, ξ, can be predicted by eqn [7];

$$\xi^2 \propto \frac{[N]}{[Cr]}D_N^{\alpha-Fe}t \qquad [7]$$

where [N] is the concentration of nitrogen on the surface, [Cr] is the initial concentration of chromium in the steel substrate, $D_N^{\alpha-Fe}$ is the diffusion coefficient of nitrogen in ferrite, and t is the duration of nitriding.

In addition to the concentration of substitutional chromium, the nitriding response of chromium-containing steels depends on the carbides in the substrate microstructure. Since the nitride-forming tendency of chromium is higher than that of carbon, fine CrN particles precipitate in the nitrided zone at the expense of chromium-containing cementite $(Fe, Cr)_7C_3$ in the steel substrate. Therefore, the kinetics of hardening is controlled by the decomposition rate of $(Fe, Cr)_7C_3$ carbides. High nitriding temperatures, for example, close to the tempering temperature of the substrate, lead to coarsening of $(Fe, Cr)_7C_3$ carbides which will (1) slow down their decomposition rate and (2) drain substitutional Cr atoms in the matrix that could contribute to precipitation hardening. Thus increasing the nitriding temperature does not necessarily promote higher hardness in the nitrided case of chromium-containing steels.[20]

According to Hosmani *et al.*[41,45] due to the strong interaction of alloying elements such as Ti, Cr, V with nitrogen, precipitation of alloying element nitrides at the surface precedes the formation of iron nitrides. Furthermore, the alloying element nitrides may also be incorporated in the compound layer composition. They stated that the compound layer exhibits a nonuniform thickness; at some locations penetrating deeper into the diffusion zone along the substrate grain boundaries. According to their proposed nitriding mechanism (**Figure 10**), with the progression of nitriding the coherent alloying element precipitates at the surface coarsen and grow to form a lamellar microstructure in the surface vicinity. This is accompanied by the reduction of nitrogen solubility in the surrounding ferrite matrix and liberation of the excess nitrogen in the form of grain boundary nitrides or porosity. The porosity can evolve into cracks that open to the free surface and act as preferential nucleation sites for the formation of iron nitrides. As such iron nitrides develop on the surface and along the grain boundaries and grow to cover the entire grain.

The kinetics and mechanisms of nitrogen interaction with titanium and the nitriding behavior of titanium alloys is well established in the literature.[46] Malinov *et al.*[47] stated that the evolution of nitrided microstructure during gas nitriding of titanium alloys is a diffusion-controlled process when the nitriding temperature is lower than the β-transus temperature. Their model (as schematically shown in **Figure 11**) suggests that after absorption of nitrogen from the nitriding atmosphere, nitrogen atoms diffuse interstitially in the titanium structure forming a nitrogen-rich solid solution (diffusion zone). With the progress of nitriding, the nitrogen concentration on the surface exceeds the solubility limit of α phase leading to the formation of ε-Ti_2N, and subsequently δ-TiN nitrides on the surface.

The kinetics of formation and growth of nitrided layers under different nitriding conditions exhibits a typical diffusion-controlled parabolic time dependency. If the diffusion coefficient of nitrogen in the nitrided layers is known, the inward flux of nitrogen and the rate of layer growth in the surface vicinity can be determined from Fick's equations such as eqn [8]. Both analytical and mathematical models have been utilized to solve the equations.[49] Where, $C_N(x,t)$ is the concentration of nitrogen, C_0 and C_s are the initial concentration of nitrogen and on the surface, x is the distance from the surface, D is the diffusion coefficient, and t is the nitriding duration. The diffusion coefficient has an Arrhenius-type dependence with temperature and its typical values for Ti–N and Fe–N system are given in **Table 3**.

$$C_N(x,t) = C_0 + (C_s - C_0) \cdot erf\left(x/\sqrt{4Dt}\right) \qquad [8]$$

2.4.3 Gas Nitriding Process

2.4.3.1 Pre-Treatment Step

Finishing processes such as cutting, buffing, finish grinding, lapping, and burnishing leave contaminants on the surface that retard nitriding kinetics or lead to surface defects and nonuniform nitriding. Moreover, a very thin layer (1–10 nm) of inherent metal oxide scales or water and hydrophobic agents may also exist on the surface that interferes with the nitrogen transfer during the posterior nitriding treatment. Surfaces may be cleaned by vapor degreasing, industrial cleaning agents, or grit blasting with alumina, garnet, SiC, etc. Ferrous surfaces may also undergo an oxidizing pretreatment, typically performed at 300 °C for 30–45 min, to evaporate hydrocarbons and cleaning agents. The oxidation pretreatment as well as other nucleation pre-treatments also promote the nitriding kinetics by activating the surface for enhanced nucleation and growth of the nitride phase, as explained in Section 2.4.2.[55]

More recently pre-treatments such as surface nanocrystallization have proven beneficial in improving the nitriding kinetics in steels and titanium alloys, facilitating nitriding at lower temperatures for shorter durations. The higher nitriding efficiency is due to the increased density of non-equilibrium defects and grain boundaries introduced by the severe plastic deformation. The nanocrystalline surface layer can be introduced by supersonic fine particle bombarding, shot peening, surface mechanical attrition treatment (SMAT). These pretreatments enhance the nitrogen diffusivity, as evidenced by higher depth and hardness of diffusion zone, and increase surface chemical reactivity due to the high excess stored energy. As a result significant improvements in surface hardness and wear resistance have been reported compared with conventionally nitrided surfaces.[56]

In order to minimize the dimensional and microstructural changes during nitriding (hardenable) steels are quenched and tempered prior to the nitriding treatment. The tempering temperature is 20–30 °C higher than the nitriding temperature[57] (at/above 575 °C[20]) to ensure structural stability at nitriding temperatures. With the exception of steels whose case hardness is affected by the core hardness (such as 4100 and 4300 steels). They can be tempered at lower tempering temperatures to achieve their maximum core hardness.[58]

Nitride forming alloying elements such as Al, V, Cr, Ti (in the solid solution form) lead to the formation of thermally-stable and coherent nitride precipitates (AlN, VN, CrN, TiN) in the surface vicinity. A high hardness is thus achieved in the

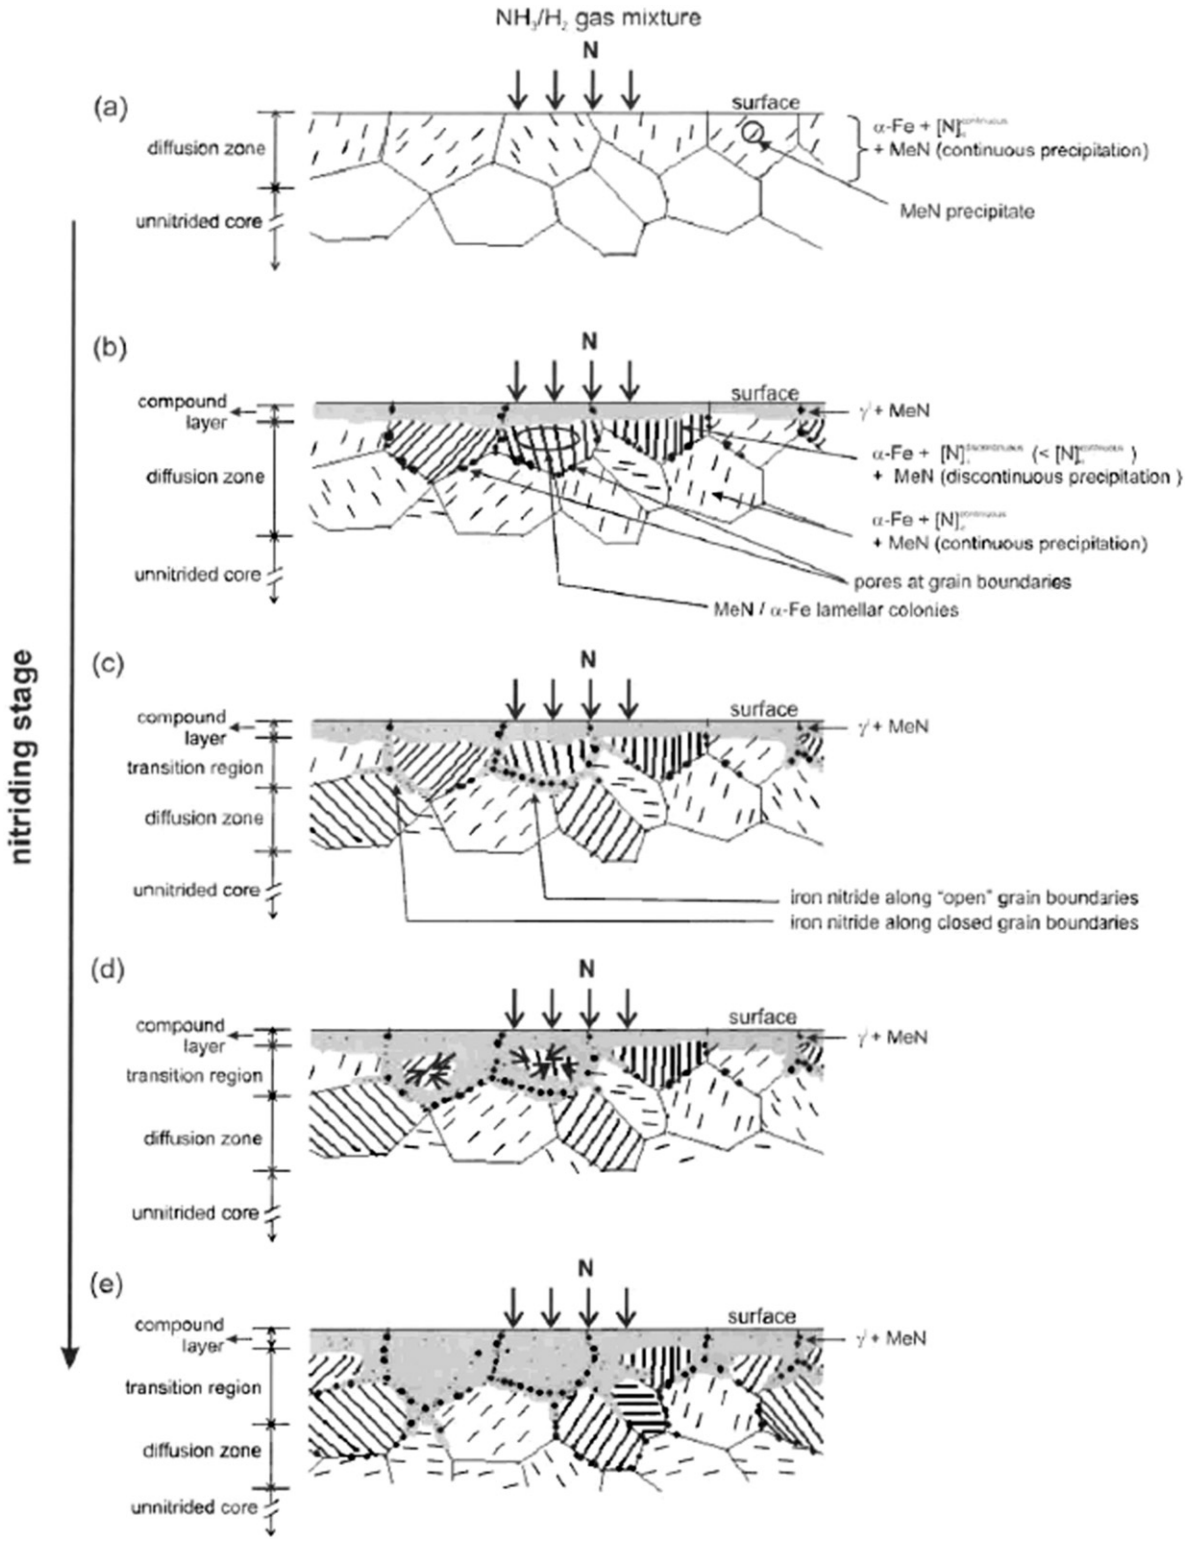

Figure 10 Schematic illustration of the evolution of compound layer on the surface of ferritic alloy steels containing nitride forming alloying elements such as Al, Cr, V in a NH_3–H_2 atmosphere. (a) Diffusion of nitrogen and precipitation of coherent alloying element nitrides in the surface vicinity. (b) Formation of compound layer on the surface and coarsening of the alloying element nitride precipitates; the coarsening of alloying element nitrides reduces solubility of nitrogen in the matrix and segregate as N_2 pores at grain boundaries. (c) Coalescence of pores and crack formation at grain boundaries. (d) Precipitation of iron nitrides along grain boundaries preferably at cracked faces and compound layer growth toward the center of the grains. (e) Full transformation of the ferrite grains to iron nitrides in the surface vicinity, precipitation, and coarsening of alloying element nitrides underneath the compound layer and void formation along the grain boundaries due to the segregation of excess nitrogen.[41]

nitrided layers while exhibiting ductility and high wear resistance. One of the common problems during nitriding of steels with carbide forming elements (Cr, V, Mo) is that carbon atoms diffuse toward the surface and form a carbide-rich region that retards further diffusion of nitrogen. Thus the recommended carbon content for the steel substrate is less than 0.15% (or a decarburization treatment prior to surface alloying).

2.4.3.2 Gas Nitriding Set-Up

Several types of furnaces are used to perform gas nitriding including vertical air-circulating furnaces, horizontal retort furnaces, bell-type movable furnaces, box-type movable furnaces, tube retorts, batch/integral quench furnaces, pusher furnaces, conveyor belt furnaces, and continuous batch-type furnaces. A typical gas nitriding furnace has a means of sealing, inlet/outlet lines for introducing/exhausting gases, heat unit and programmable controllers for temperature, time, gas flows, and a means of circulating atmosphere for uniform temperature distribution.[58,59] Advanced gas analyzers and gas distribution systems enable automatic control of the atmosphere to the desired dissociation rate or nitriding potential.[60]

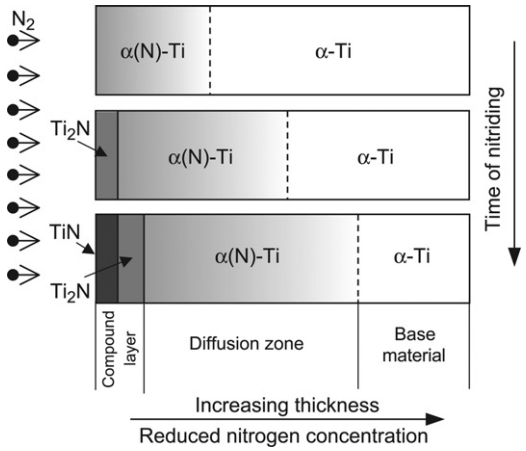

Figure 11 A schematic illustration of the gas nitriding mechanism in titanium resulting in the formation of compound layer ($TiN + Ti_2N$) and diffusion zone.[48]

The parts will be loaded and the air will be purged out using nitrogen or ammonia after sealing the furnace. The furnace will be heated to temperature (Care must be taken to avoid the ignition temperature of flammable gases. Explosion hazards are prevented by using an inert gas flow, or evacuating the chamber before purging.) and a controlled nitriding atmosphere will be sustained for the nitriding duration. In order to ensure the repeatability and reproducibility and achieve the desired metallurgical specifications and microstructures, the process parameters should be accurately selected and controlled. The furnace heating and cooling rates should be optimized for minimum temperature gradients and distortion throughout large and complex parts and maximum production economy.[59a]

2.4.3.3 Post-Treatment Step

Several post-treatment methods have been developed for further improvements in the corrosion and wear resistance of nitrided surfaces such as oxidation post-treatments. A typical oxidation post-treatment is carried out at temperature range of 350–520 °C and results in the formation of a thin (1–3 μm thick) oxide layer consisting of magnetite (Fe_3O_4) and hematite (Fe_2O_3) on top of the compound layer.[61] Investigations by Borgioli *et al.*[62] indicated that when the oxidation post-treatment of the nitrided steels was performed at lower temperatures such (e.g., 350 °C), the oxide layer was mainly composed of magnetite while hematite was detected when the oxidation post-treatments was carried out at higher temperatures (e.g., 500 °C). Their findings indicated that although the

corrosion resistance was improved in both cases after oxidation post-treatments, magnetite oxide layers were more protective against corrosion damage. This has been attributed to the partial sealing of the pores in the white layer. Doche *et al.*[63] introduced a final polymer impregnation step after the oxidation post-treatment to seal the porous structure near the surface. They reported a significant reduction in corrosion rates after the polymer impregnation step. In addition to improvements in corrosion resistance, oxidation post-treatment of nitrided steels also offered wear enhancement and reduction of coefficient of friction.[61b]

Oxidation post-treatments of the nitrided titanium surfaces were practiced at 700 °C, resulting in the formation of titanium oxide (TiO_2) with rutile structure and traces of nanocrystalline titanium oxide with anatase structure. The treated surfaces offered enhanced protection against wear-corrosion damage (wear resistance in corrosive media).[64]

2.4.3.4 Common Problems in Nitriding: Causes and Remedies

2.4.3.4.1 Formation of white layer

The formation of white layer is often not desirable during nitriding of ferrous alloys due to its brittle nature and susceptibility to spallation. The white layer is normally removed prior to service at a cost almost equal to that of the nitriding treatment. Several approaches can be taken toward control and elimination of the white layer. One of the conventional methods is grinding/lapping with abrasive papers, which is time-consuming and expensive and may not be suitable for components of complex shapes. Chemical dissolution by soaking in a hot cyanide solution is another alternative, although posing environmental hazards. Perhaps, one of the best approaches is to eliminate/minimize the formation of white layer through continuous and accurate control of the nitriding conditions (ammonia dissociation rate, temperature, etc.). Alternatively, several researchers attempted to exploit the thermodynamic instability of γ' and ε phases to design a post-treatment step for the reduction of white layer in a controlled N_2–H_2 mixture. However, this practice was accompanied by the loss of surface hardness.[65]

2.4.3.4.2 Insufficient depth or hardness of the diffusion zone

This problem may be attributed to the substrate properties and pre-treatment conditions. It is important to ensure that the composition and microstructure of the substrates are suitable for nitriding. For instance, presence of substitutional nitride-forming elements enhances the depth and hardness of nitrided case in ferrous alloys. In some steels, the case hardness is directly proportional to the core hardness and thus increasing the core hardness with prior heat treatments increases the case hardness. In addition, as mentioned in Section 2.4.3.1, surface oxides, contamination and machining residues retard the nitriding kinetics and the surfaces of workpieces are to be properly cleaned and passivated prior to nitriding. Alternatively, improper selection of process parameters is a common cause of low hardness and shallow diffusion zone. The selection of treatment parameters should be carried out accurately to avoid excessively high or low nitriding temperatures, insufficient nitriding duration and nonuniform temperature distribution inside the furnace.[58]

2.4.3.4.3 Oxidation during nitriding

This is usually a result of contamination either on the workpiece or inside the furnace. It can be avoided by ensuring appropriate pre-cleaning of surfaces and absence of leakage on the furnace seals. Any leakage inside the furnace (around pipes, thermocouple, base, etc.) results in the introduction of air, moisture, or oil into the furnace. In ferrous alloys oxidation during nitriding manifests as discoloration of surfaces.

2.4.3.4.4 Dimensional changes

Several factors are responsible for unacceptable dimensional changes in the nitrided parts including complex/unsymmetrical profiles and residual stresses from prior machining/heat treatment history. In addition, finishing treatments after nitriding upset the balance between compressive residual stresses on the surface and tensile stresses in the core and lead to dimensional changes. This can be avoided by preparing the parts close to their desired final dimensions and stress-relieving prior to nitriding.[66] Dimensional changes are generally low during nitriding of ferrous alloys – especially compared to carburizing treatments – due to their low nitriding temperatures.

The arrangement of parts inside the furnace is also an important factor that may contribute to volumetric changes and distortion. The nitriding set-up should be such that the parts see proper support and uniform heating inside the furnace.

2.4.3.4.5 Exfoliation and spallation of the compound layer

Several factors contribute to the formation of compound layers that are prone to spalling and premature failures. Improper nitriding conditions that promote thick and brittle compound layers, design and shape of the workpieces and inappropriate pre-treatment and cleaning prior to nitriding are among the main influential factors.[58] Sharp corners should be avoided in parts as the higher concentration of nitrogen at the corners leads to brittle structures that are susceptible to chipping.

In ferrous alloys, surface decarburization increases the chances of cracking and chipping by formation of nonuniform nitrided cases and brittle nitride phases, often in the form of nitride needles, inside ferritic grains near the surface.[67] This results in an 'orange peel' appearance of surfaces and can be prevented by complete removal of the decarburized layer prior to nitriding.

2.4.4 Gas Nitriding of Structural Alloys

2.4.4.1 Ferrous Alloys

2.4.4.1.1 Microstructure and phase composition

Gas nitriding of ferrous alloys may be carried out as a single-stage or a double-stage process. A single-stage process is typically performed within the temperature range of 495–525 °C and

ammonia dissociation rate of 15–35%. The high-nitriding potential promotes the formation of surface nitrides and the nitrided microstructure consists of a compound layer at the surface of a nitrogen diffusion zone. The compound layer is also referred to as the 'white layer' because it remains unetched in Nital (3% nitric acid + balance ethanol) solution.[68] In the double-stage process, also known as the Floe process,[13] the first nitriding step is followed by a second step at a higher temperature range (550–565 °C) and dissociation rate (75–80%). The main purpose of the Floe process is to reduce the thickness of the white layer, increase the depth of nitrogen diffusion and promote precipitation of fine nitrides in the diffusion zone. The higher depth and hardness of the diffusion zone promote higher fatigue strength in the nitrided alloys.[59a]

The white layer thickness can range from tens to hundreds of micrometers and mainly consists of $\gamma' - Fe_4N_{1-x}$ and $\varepsilon - Fe_2N_{1-z}$ but may also contain Fe_3C-cementite[69] and $\varepsilon - Fe_{2-3}(C,N)$, depending on the nitriding conditions and substrate composition. In irons the white layer is composed of a $\varepsilon - Fe_2N_{1-z}$ layer on top of a $\gamma' - Fe_4N$ layer (**Figure 12**). White layer offers high-corrosion resistance and enhanced lubricability. Nonetheless, due to its brittle nature and accumulation of residual stresses, the white layer is prone to spalling and premature failures and promotes severe abrasive wear in service. While the benefits of a single-phase white layer, for example, hard ε (H = 7.1 GPa) or γ' (H = 6.5 GPa) layer[70] are debatable, the formation of white layer is considered undesirable for industrial applications. In many instances the white layer is eliminated altogether by grinding or chemical treatments prior to service.[20] Moreover, as explained in Section 2.4.2.2, both γ' and ε nitrides are thermodynamically unstable under nitriding conditions and their decomposition generates porosity in the compound layer. The pores preferentially form at the grain boundaries of ε phase

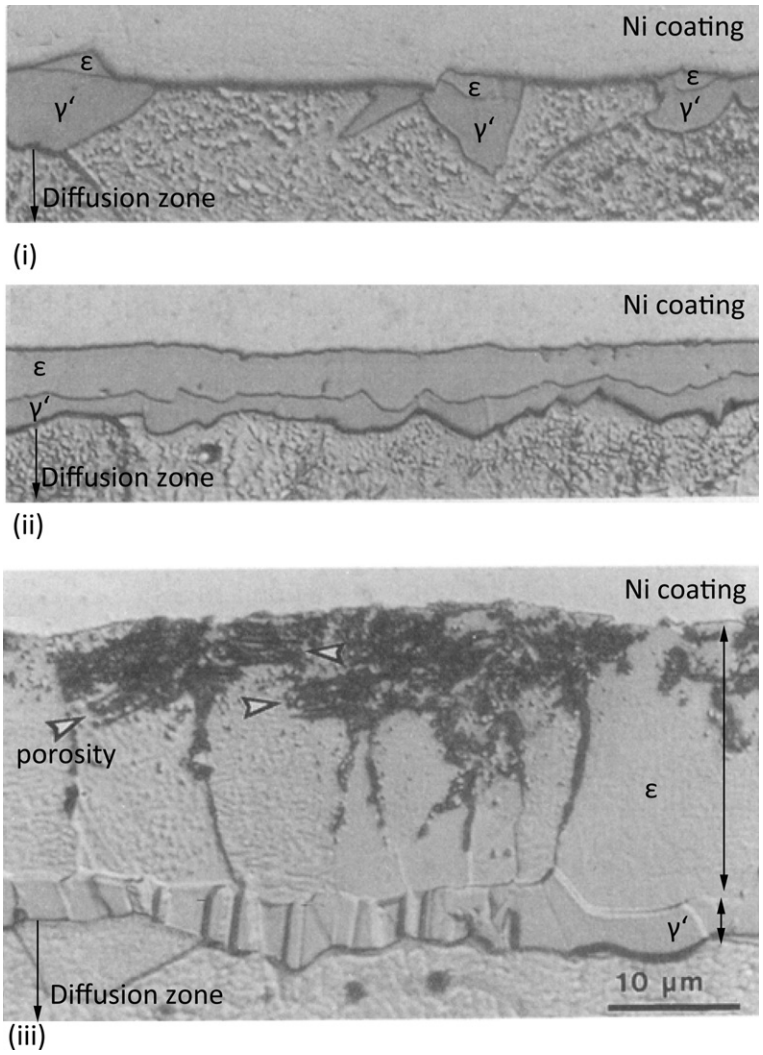

Figure 12 Typical cross-sectional micrographs showing the evolution of microstructure in iron gas nitrided at 570 °C for (i) 15 min; nucleation of ε and γ' nitrides on the surface, (ii) 35 min; growth of the compound layer ($\varepsilon + \gamma'$) into a uniform layer, and (iii) 8 h; the formation of porosity (mostly along ε grain boundaries). (Electroplated Ni coating was used in order to protect the surface against damage during metallography sample preparation.)[24]

and their coalescence channels the grain boundaries to the free surface (Figure 12). Due to the porous structure of the ε phase, the measured hardness values of the white layer are typically less than that of the diffusion zone underneath it.

Typical microstructure of the compound layer formed on the surface of (ferritic) iron is shown in Figures 12 and 13, the iron nitride nuclei grow laterally until the compound layer covers the entire surface with uniform thickness. Figures 14 and 15 show typical nitrided microstructures of steel substrates containing nitride forming alloying elements such as Al, V, Cr. Due to the strong affinity of these elements to nitrogen, precipitation of alloying element nitrides precedes the formation of iron nitrides. The coarsening of the nitrides liberates some of the dissolved nitrogen in the form of porosity or grain boundary nitrides. The voids combine together and channel toward the top surface. The compound layer has a nonuniform thickness; it evolves on the surface and along substrate grain boundaries and then grows toward the center of grains.

Diffusion zone (also known as the 'nitrided zone' or the 'Case') is a region of nitrogen solid solution in Fe structure with a concentration gradient decreasing toward the bulk that may contain iron nitride precipitates (Fe_4N or $Fe_{16}N_2$ in irons and low-alloy steels) or alloying element nitride precipitates (in steels containing Al, Cr, Mo, V, etc.).[72] The hardness and depth of diffusion zone indicate the content of nitride precipitates as well as nitrogen solid solution and depend on the nitriding parameters (temperature, time, etc.) and the material composition.[73] The alloying element nitrides are submicroscopic precipitates, finely dispersed, with coherent boundaries with the matrix. They hinder plastic deformation and slip mechanisms and induce residual compressive elastic strains that strengthen the diffusion zone and reduce the crack propagation rate.[74] In addition to alloying element nitride precipitates in the diffusion zone, several investigations found the presence of cementite precipitates along prior austenite grain boundaries parallel to the nitriding direction. Mridha and Jack[69] clarified that due to the stronger affinity of N to Cr

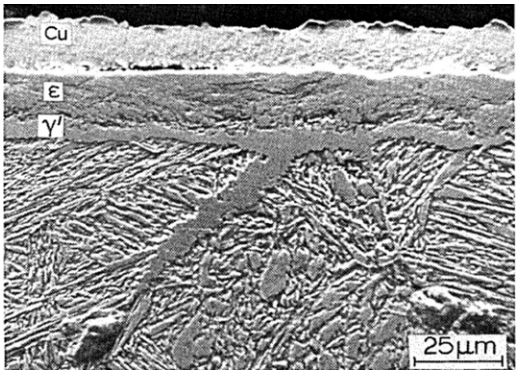

Figure 14 Typical nitrided microstructure of Fe–5Cr–0.2C after nitriding at 500 °C for 48 h in NH_3 atmosphere.[69]

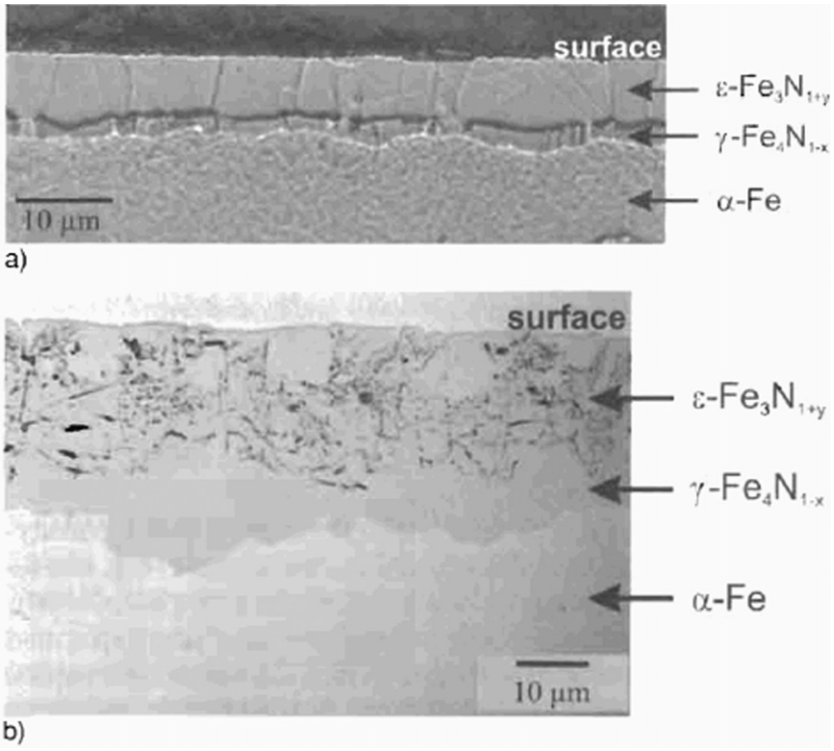

Figure 13 Optical micrographs showing the evolution of compound layer on the surface of nitrided iron. (a) After nitriding at 550 °C for 5 h, a continuous ε layer formed on top of a layer of γ'. (b) After nitriding at 560 °C for 20 h, pores were formed within the ε layer. (Nitriding potential: 2.37 $atm^{-0.5}$, etched in 1 vol.% Nital solution containing 0.1 vol.% HCl.)[41]

compared with C to Cr, chromium nitrides form in the diffusion zone at the expense of dissolution of substrate carbides or their *in-situ* replacement with CrN. The carbon atoms released from this dissolution either diffuse inwards (forming a carbide-rich zone below the diffusion zone) or precipitate along prior austenite grain boundaries in orientations with minimal compressive stress (**Figure 16**).

As such the inward migration of carbon atoms ahead of the nitriding front forms a carbon-rich region (the carbon-rich layer has limited hardening and appears black in Oberhoffer's etching solution) underlying the diffusion zone and may result in decarburization on the surface (in the absence of compound layer). From a thermodynamic point of view, this migration has a chemical (reduction of chemical potential) and a mechanical (strain balance in the tensile stress region) driving force. An uphill diffusion of carbon atoms toward the core in the presence of nitrogen was also reported by other researchers.[75]

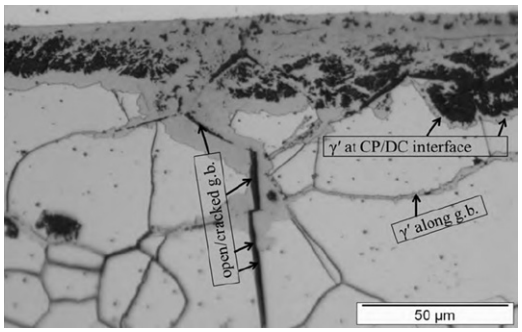

Figure 15 Optical cross-sectional micrograph of nitrided Fe–4V specimen (atomic percent) showing the formation of γ' at the surface and along the grain boundaries (Nitriding potential: 0.8 $atm^{-0.5}$, etched in 2 vol.% Nital, at 580 °C for 4 h).[71]

The limit of the nitrided zone as revealed by the etching does not correspond to any particular hardness since that depends on the nitride forming alloy content, the nitriding temperature and time and the prior tempering treatment of steel. It does mark the limit of alloy nitride formation and the transition from case containing residual compressive stresses to a core containing balancing tensile stresses.

Gas nitriding of stainless steels is relatively challenging as the surface passivity due to high-chromium content affects the nitriding kinetics and microstructure.[76] Stainless steels are nitrided at low temperatures (typically below 440 °C) to avoid precipitation of chromium nitrides and reduction of corrosion resistance. This process does not form a compound layer but promotes the formation of metastable 'expanded austenite' or 'S' phase. The expanded austenite phase is a 20–40 μm deep nitrogen-rich phase with a high hardness (~1800 HV) that does not have any adverse effects on corrosion.[42a,77] Conversely, an 'expanded martensite' region develops during low temperature nitriding of martensitic and ferritic steels. This layer may be in the form of a uniform nitrogen-rich layer or a duplex layer, with a nitrogen-rich outer layer and a carbon-rich inner layer.

The microstructure of nitrided surfaces can be controlled by the nitriding treatment operating parameters (time, temperature, atmosphere composition, and pressure, etc.) and the composition and microstructure of steel substrates (microstructural stability with temperature, ductility, carbon content, alloy element concentration, etc.) as discussed briefly below.

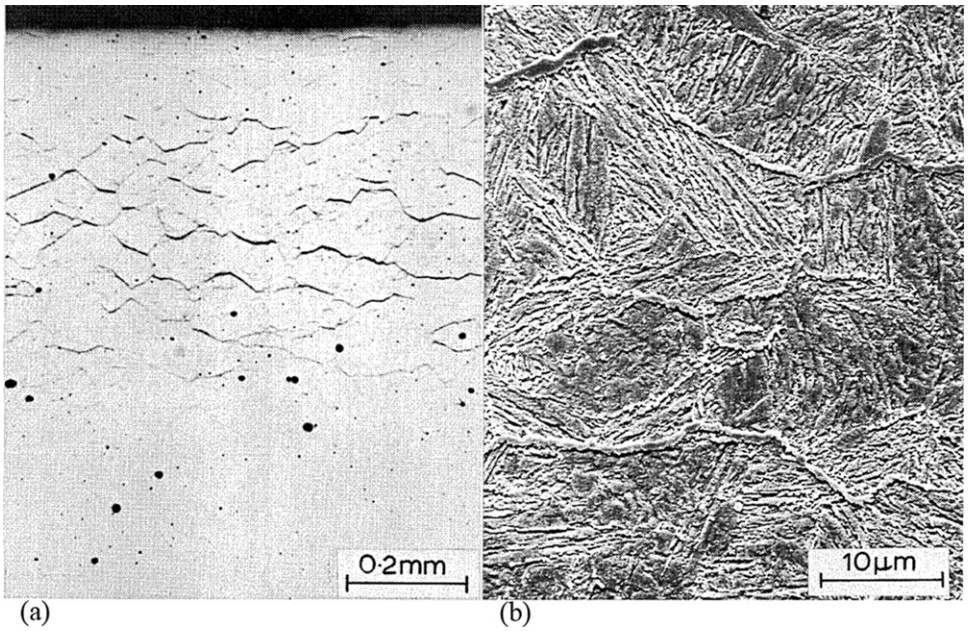

Figure 16 (a) Optical and (b) scanning electron microscopy images of the near surface microstructure (etched in boiled alkaline sodium picrate and 2% natal, respectively) of 3% Cr steel nitrided at 520° in a 30% NH_3 atmosphere for 48 h showing the precipitation of grain boundary cementite in the diffusion zone.[69]

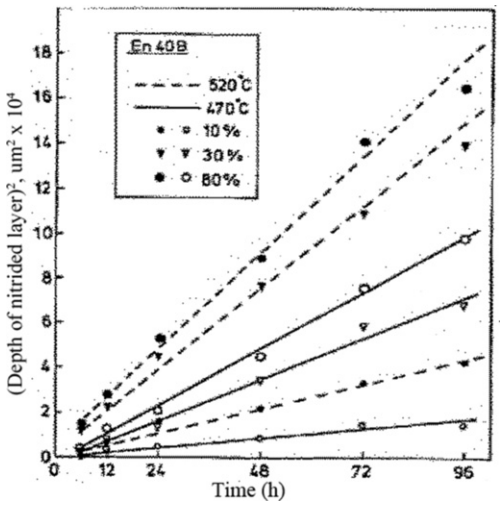

Figure 17 The parabolic relationship between depth of the nitrided layer and time.[79]

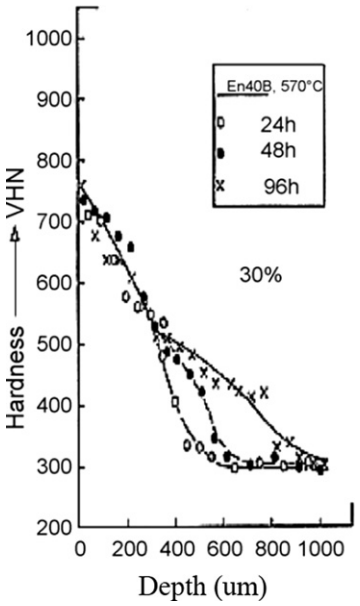

Figure 18 Hardness vs. depth profiles illustrating the evolution of hardness as a function of time in En40B steel (high-chromium nitriding steel) nitrided in 30% NH_3 atmosphere at 570 °C for 24, 48, 96 h.[78]

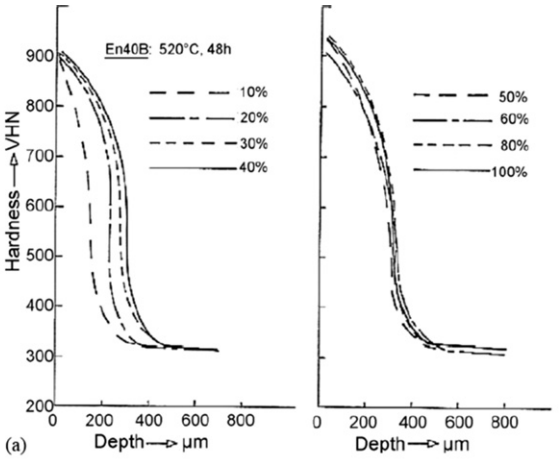
2.4.4.1.2 Nitriding time and temperature

It is established that the depth of hardening increases parabolically with nitriding time.[4] The nitriding depth also increases with temperature (**Figure 17**). However, in high-chromium carbon steels increasing the temperature may lead to a reduction in the hardness and case depth (especially at higher temperatures). This is due to the coarsening of chromium-rich carbide particles ahead of the nitriding front, leaving less chromium for precipitation of fine chromium nitrides. As such, the depth and hardness reach their maximum at the initial stage of nitriding and further increase in the nitriding duration results in the coarsening of carbide/nitride particles and reduction of hardness (**Figure 18**).[78]



2.4.4.1.3 Nitriding atmosphere

Increasing the pressure of nitriding atmosphere at a constant nitriding potential increases the nitrogen flux, facilitates the evolution of the compound layer and diffusion zone. Conversely, low-pressure nitriding offers a more homogeneous nitriding due to better distribution of nitriding gas.[80] Nitriding under a dilute medium is also similar to low-pressure nitriding, it minimizes the thickness of the compound layer and increases nitrogen diffusivity. Nitriding media normally consist of ammonia and hydrogen. Perez[81] utilized nitrous oxide and a carbon containing gas in addition to ammonia and nitrogen, in the low-pressure nitriding media for ferrous alloys. This method is known for being environmentally friendly and providing better nitriding uniformity and penetration depth. Addition of ammonium chloride to the nitriding mixture is associated with surface activation during gas nitriding of stainless steels.[82]

Mridha and Khan[78] reported that the surface hardness of the 3% Cr steel increased with the nitriding potential but the depth of nitriding was independent of the nitriding potential. Mridha[4,79] clarified that the case depth increases with the nitriding potential before the formation of white layer on the surface and then remains constant for higher nitriding potentials. At low temperatures (e.g., 470 °C) , the growth rate remained constant after the formation of a dense white layer mainly composed of γ' due to its lower diffusivity compared to α-Fe. However, at high temperatures (e.g., 570 °C) the growth of diffusion continues even after the formation of white layer due to the presence of porosity in this zone making nitrogen accessible to the substrate interface (**Figure 19**).

2.4.4.1.4 Steel composition and heat treatment history

Unalloyed carbon steels are not suitable for nitriding because of the limited hardness improvement in the diffusion zone (120–250 HV). Increasing the carbon content increases the depth of diffusion zone and results in smoother hardness gradient within the diffusion zone. Carbon increases nitrogen activity and promotes formation of iron carbonitrides at lower nitriding potentials. Transition metals (aluminum, chromium, vanadium, tungsten, and molybdenum, etc.) as alloy elements increase the nitrogen solubility of the ferrite. These substitutional alloy elements form stable submicroscopic coherent nitride particles at the nitriding temperatures, which effectively strengthen the diffusion zone. During the process of nitriding, Al alloy element diffuses toward the surface and dissolves in the γ' phase and increases the fraction of covalent bonds in the Fe lattice, resulting in higher hardness and low ductility.[83] Alloy elements such as chromium, vanadium, and molybdenum provide deeper cases with higher ductility but comparatively lower hardness.[68] The nitride precipitates tend to coarsen during high temperature nitriding treatments, resulting in a low concentration of fine nitride particles and reduction of hardness.[78] Chromium also increases the surface hardness and

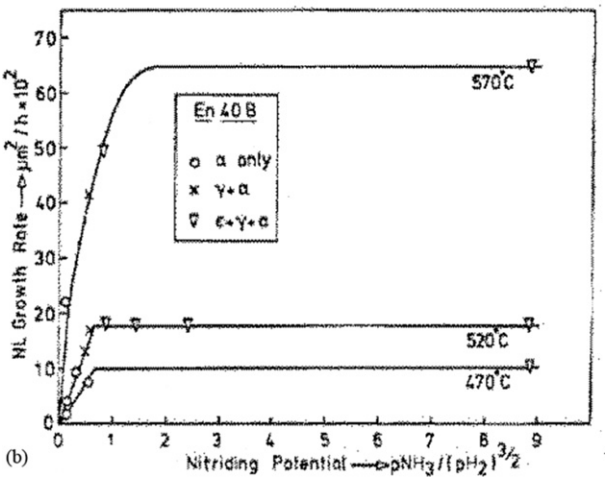


Figure 19 (a) Hardness vs. depth profiles illustrating the evolution of hardness as a function of nitriding potential (En40B steel nitrided at 520 °C for 48 h).[78] (b) The growth rate of nitrided layer against nitriding potential for EN40B commercial steel nitrided at 470, 520, and 570 °C.[79]

has a synergistic effect on Al-containing alloys by enhancing the nucleation of aluminum nitride in the ferrite matrix and the formation of (Cr, Al)N nitrides. Niobium and zirconium restrict the formation of nitride zone and grain refinement, reduce brittleness of the case and increase the hardness of the case.[83] Other alloying elements, such as nickel, copper, silicon, and manganese, do not have any significant influence on the nitriding.[84] While theoretically any type of ferrous alloys can be nitrided, certain steels are particularly suitable for nitriding such as aluminum-containing Nitralloy steels for high-surface hardness, Cr–Mo or Cr–Mo–V steels of 2.5–3.5% Cr with good hardenability, and low-alloy steels.[20]

Mridha and Khan[78] indicated that austenitizing temperature does not affect the surface hardness nor the case depth of 3% Cr steel. Tempering temperature, however, has a strong influence on the evolution of hardness in the surface vicinity. Increasing the tempering temperature results in the coarsening of chromium-rich carbide precipitates. This in turn retards the formation of chromium nitride precipitates due to the slow

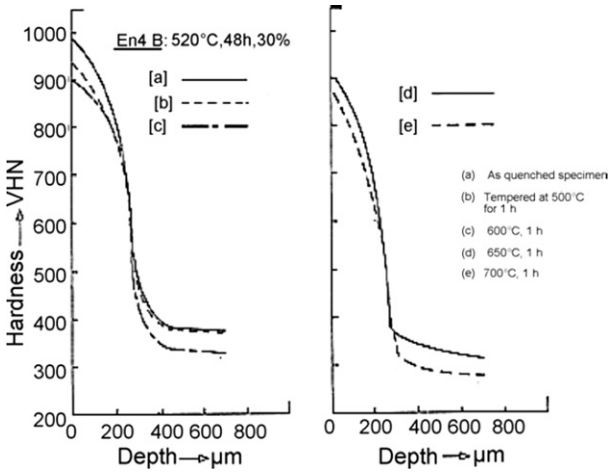

Figure 20 Hardness vs. depth profiles illustrating the evolution of hardness as a function of tempering history (En40B steel nitrided at 520 °C for 48 h).[78]

kinetics of dissolution of large carbide particles. Thus the maximum hardness and the depth of hardenability are inversely related to the tempering temperature (Figure 20).

2.4.4.2 Non-ferrous Alloys

2.4.4.2.1 Microstructure and phase composition

Gas nitriding of aluminum alloys leads to the formation of a hard AlN layer on the surface (~1500 HV). The AlN layer is susceptible to cracking and spallation due to the absence of diffusion zone to mechanically this layer since nitrogen is insoluble in aluminum.[5a] Furthermore, due to the high affinity of aluminum for oxygen and aluminum oxide films that naturally occur on aluminum surfaces hinder the reaction between nitrogen and aluminum substrate.[85] Finally, the evolution of aluminum nitride layer on the surface of aluminum alloys is restricted by the high-thermal expansion difference between AlN and aluminum substrate, which promote undesirable residual stresses in the layer. Extensive research in the field exhibited that nitriding of aluminum alloys is enhanced by surface modification techniques such as plasma-assisted nitriding technologies[86] and ion implantation.[87]

Nitriding of titanium alloys results in the formation of a compound layer composed of δ-TiN_{1-x} and ε-Ti_2N on the surface. Titanium nitrides are generally known as good high temperature materials with thermal shock resistance, high hardness, high abrasion, and wear resistance and good corrosion resistance.[35a] The compound layer may also contain $TiN_{0.3}$ titanium nitride and V_2N vanadium nitride in nitrided $\alpha+\beta$ and β type titanium alloys.[88] Due to the high affinity of titanium for oxygen, a thin layer of TiO_2 titanium oxide has also been reported on the outermost surface of titanium alloys during gas nitriding experiments.[88b,89]

A layer of nitrogen-enriched α titanium (α-Case) forms underneath the compound layer since nitrogen is an α stabilizing element (Figure 21). The α-Case has a brittle nature and usually forms at high nitriding temperatures (at or higher than

800 °C).[90] The α-Case morphology varies from a single-phase layer with preferentially oriented α grains to coarse, columnar α grains growing toward the titanium alloy core.[91] Distinguishing the α-Case is more difficult in α-titanium alloys; however, hydrogen pick up and hydride precipitation in the Ti substrate during nitriding can create contrast against the α-Case.[1] The formation α-Case is known to be detrimental to the mechanical properties of nitrided titanium alloys and is associated with a reduction of fatigue strength, ductility, and fracture toughness. Furthermore, in the presence of aluminum as an alloying element in titanium substrates, the aluminum atoms segregate below the compound layer and form an aluminum-rich region.[85] This has been attribute to the low solubility of aluminum in titanium nitride and may lead to the formation of Ti_3Al phase in this region (**Figure 22**).[92]

Typical gas nitriding temperature range for titanium alloys is $0.55–0.65T_s$ (T_s is the solidus temperature of the alloy), which is clearly higher than the temperature range for ferrous alloys. Unfortunately, the nitriding temperature of titanium alloys falls within the range of their solution treatment (β-transus temperature) and thus induces adverse effects on the microstructure and properties of the substrate.[85]

Unlike steels, nitriding of titanium alloys does not promote precipitation strengthening mechanisms and strengthening of diffusion zone occurs by the interstitial solid solution hardening of titanium with nitrogen.[93] Microstructural evolution of titanium alloys during gas nitriding is dependent on the

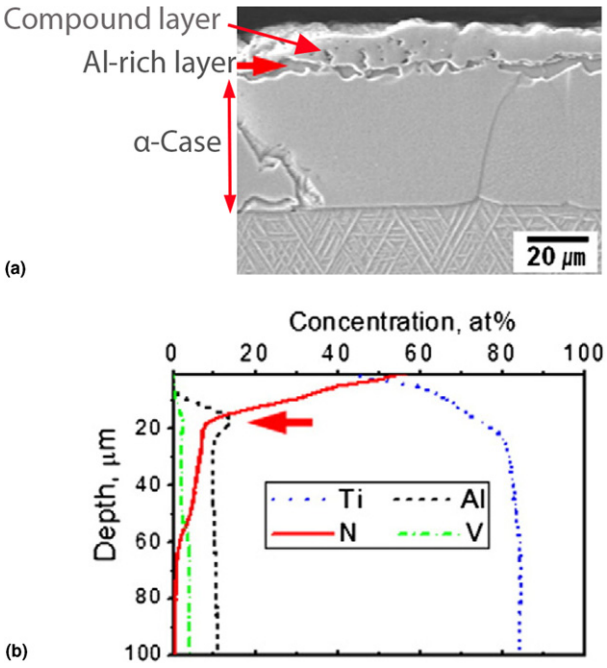

Figure 22 (a) A typical scanning electron microscopy image of the microstructure of Ti–6Al–4V alloy nitrided at 1150 °C for 10 h and (b) corresponding glow discharge spectroscopy (GDS) showing the presence of an aluminum-rich layer underneath the compound layer.[92]

alloy composition as well as nitriding conditions (e.g., time, temperature, atmosphere, etc.) as summarized below.

2.4.4.2.2 Nitriding atmosphere

Several nitriding media have been used for gas nitriding of titanium and titanium alloys including N_2, N_2–H_2, N_2–Ar, or cracked NH_3. Titanium has a high affinity for oxygen, and despite protective measures taken to avoid air/oxygen in the nitriding atmosphere, the presence of TiO_2 has been reported due to the possibility of a small amount of oxygen.[89,91b] The nitriding kinetics is complex and insignificant at low nitriding pressures (<13.3 Pa), and even at 133.3 Pa no technologically useful surface is created in N_2 or NH_3 below 800 °C. At pressures of several 100 Pa, all the absorbed nitrogen dissolves in the titanium surface without significant formation of nitrides.[29a] Treatments at higher pressures, such as 1.2 MPa, yields thicker compound layers and diffusion zones. The high pressure used in the process allows treatment of narrow, deep, blind holes, and intricate details such as fine threads. Nitriding of titanium alloys may be carried out in hot isostatic pressing equipment, where pressures of up to 100 MPa have been used. For the nitrided components in ammonia, a dehydrogenation treatment will be performed in a temperature ranging from 300 to 400 °C at a pressure of 1 Pa.[94]

2.4.4.2.3 Nitriding time and temperature

Due to the diffusion-controlled nature of gas nitriding in titanium alloys, the depth and hardness of nitrided layers increase with the time and temperature of nitriding. Moreover, the possibility of grain growth and phase transformations in the bulk microstructure is higher at higher temperatures and prolonged durations.[47]

2.4.4.2.4 Substrate composition

In titanium alloys, the α and β phases have different potential capacities for nitrogen diffusivity and dissolution. The solubility of nitrogen is higher in α-Ti (HCP structure) compared with β-Ti (BCC structure) by two orders of magnitude. However, the diffusion coefficient of nitrogen in β titanium is two to three orders of magnitude higher than that of the α phase. Therefore, even low contents of the β phase can act as diffusion paths for fast diffusion of nitrogen atoms and accelerate kinetics of the formation of the diffusion zone. As a result the surface concentration of nitrogen decreases but the thickness of the diffusion zone increases with the β phase content.[95]

Furthermore, the severity of microstructural changes during nitriding depends on the β-transus temperature of the titanium alloy. Generally, nitriding treatments performed at temperatures higher than the β-transus temperature of the alloy result in significant phase transformations in the substrate as well as the formation of α-Case, both of which impair the mechanical properties of the alloy.[47,88b,1] The family of β-Ti alloys is more susceptible to bulk microstructural changes during nitriding due to their lower β-transus temperatures compared to α and $\alpha+\beta$ alloys (**Figures 23** and **24**). Therefore, nitriding treatments are normally performed at lower temperatures in β-Ti alloys.[47,96]

2.4.5 Effect of Gas Nitriding on Mechanical Properties

2.4.5.1 Ferrous alloys

It is well established that surface hardening by gas nitriding improves the high-cycle fatigue life of iron-base alloys on account of the hardened diffusion zone and compressive residual stresses developed near the surface. The enhanced surface hardness hinders crack initiation while compressive residual stresses retard the crack propagation. At low stress amplitudes (high-cycle fatigue), the failure initiation site shifts from the surface toward internal defects such as nonmetallic inclusions in the core.[97] In case of smooth samples under rotation bending condition, the internal cracks initiate below the nitrided case, at the case/core interface. With an increase in nitriding depth, a higher bending stress is needed for initiation of subsurface fatigue cracks and thus the fatigue strength increases further. Conversely, at high stress amplitudes (low cycle fatigue) premature crack initiation from the surface due to the lower ductility of the case compared with the core and result in deterioration of low cycle fatigue strength of the alloy.[98] The presence of white layer is detrimental to the fatigue life of nitrided steels due to its brittle nature and is commonly removed by mechanical (honing, fine sand blasting) and chemical treatments (acid pickling) prior to service. Since the white layers produced in a two-stage nitriding have higher ductility compared to those of single-stage treatments, they may not have an adverse effect on fatigue properties.[68]

Even though nitriding affects a thin surface layer (<2 mm) of the total core cross section, it marginally increases the tensile strength and substantially decreases the ductility of the alloy. This has been attributed to the brittle nature of the nitrided layer and the tensile residual stress build up in the substrate.[99] Once the thin layer is broken it acts as a stress raiser. Moreover, the difference between the Poisson's ration of the case (0.3) and bulk (0.5) results in stress triaxiality at the interface as a result the core contracts more than the case and transverse stresses are generated in the radial and circumferential directions. Failure of nitrided tensile samples is normally accompanied by an array of circumferential (secondary) cracks along the gage length. Mencik[100] proposed that these cracks form when the shear stresses at the interface between the case and the core increase the tensile stresses in the case until the case strength is reached. The failure of the case creates a new crack and this phenomenon repeats itself.[100]

Limodin *et al.*[101] investigated the fatigue and tensile properties of gas nitrided AISI 4140 steel under rotation bending and axial fatigue conditions. They reported that the fatigue life of nitrided steel is a competition between surface crack propagation in the presence of compressive residual stresses and initiation and growth of internal cracks, for example, from metallurgical defects. The depth of the nitrided region and the developed compressive residual stress field, affect fatigue crack initiation from the surface; increasing the nitriding depth delayed surface failures and shifted the failure origin to an internal crack. They correlated subsurface failures,

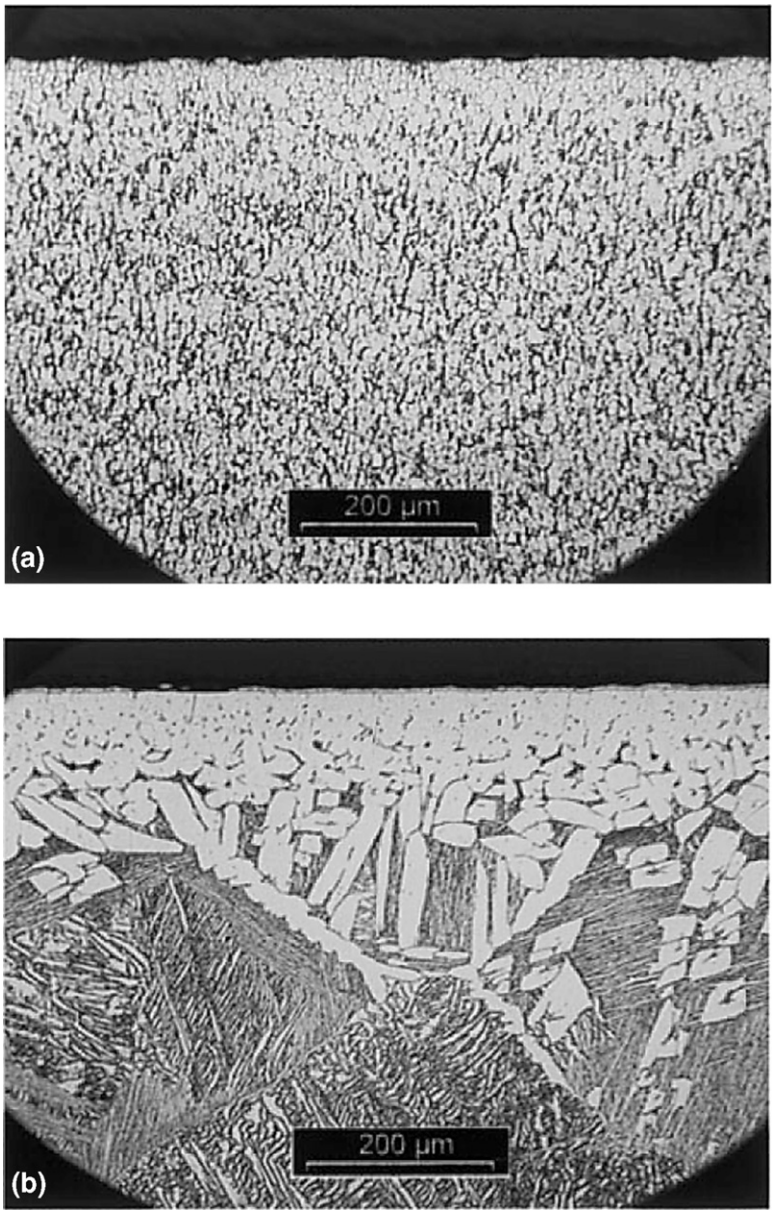

Figure 23 Typical microstructure of near-α Ti–8Al–1Mo–1V titanium alloy after gas nitriding at (a) 950 °C (below the β-transus temperature) for 5 h and (b) 1050 °C (above the β-transus temperature) for 5 h. The nitrided microstructure consisted of a thin compound layer (less than 10 μm thick) on top of a diffusion zone (~350 μm deep). Nitriding above the β-transus temperature resulted in phase transformations in the core and formation of coarse nitrogen-stabilized α-Ti grains underneath the compound layer.[91b]

also known as 'fish-eye' cracks, with the core metallurgical properties especially to the size and distribution of internal defects. Similar observations were reported by Murakami *et al.*[102] They found that the fatigue strength can be predicted by the maximum size of inclusions defined by the square root of the projected area of an inclusion.

Gas nitriding of high strength maraging steels (nitrided at 500 °C, 24 h, 20–30% NH_3 dissociation) was investigated in an early work by Tsyrlin *et al.*[103] They found that compared with the baseline alloy (treated at 500 °C, 24 h, and vacuum), the nitrided alloy had lower ultimate tensile strength, yield strength, and fracture toughness. It was proposed that nitriding reduces the critical defect size, $\left(K_{IC}/\sigma_y\right)^2$, and leads to easier crack propagation. Nonetheless, the tensile and yield strength of the nitrided alloy where similar to those of the untreated material but the fracture toughness decreased considerably after nitriding. This was attributed to the change of stress condition from plane stress to plane strain and easier crack initiation. The load-deflection curves and fractographic observations indicated ductile characteristic of the core confirming that nitriding did not have an adverse effect on the plasticity of the core material.

Hussain *et al.*[104] studied the effect of retained austenite on the properties of gas nitrided maraging steels (nitrided at

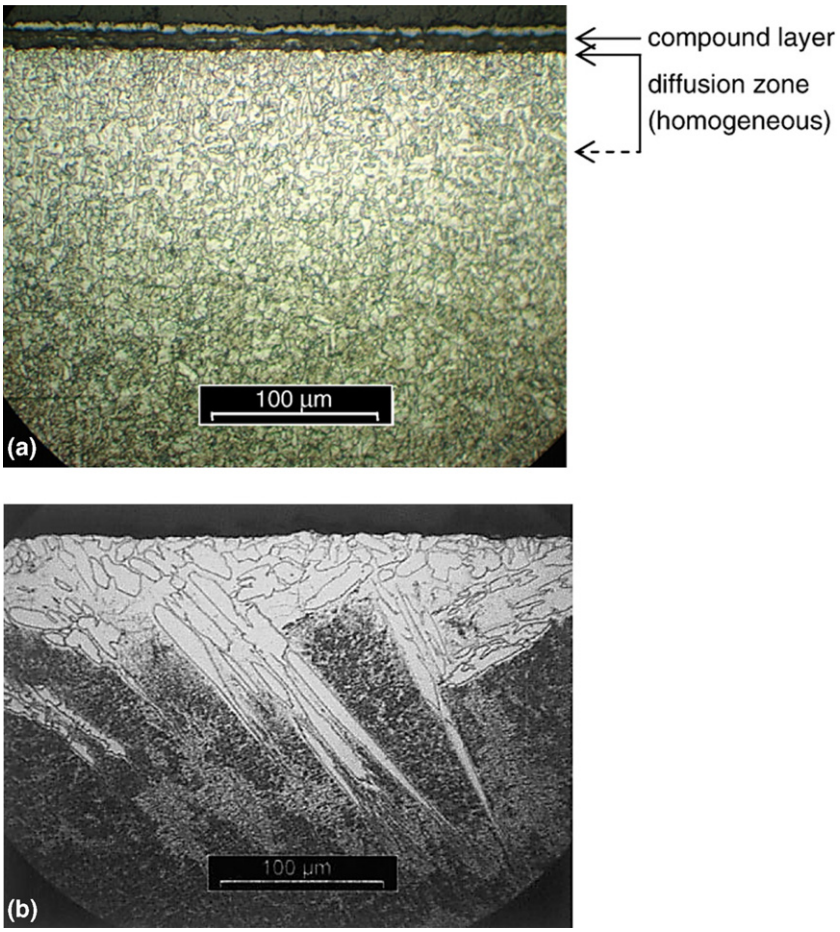

Figure 24 Typical microstructure of near-β Ti–10V–2Fe–3Al titanium alloy after gas nitriding at (a) 750 °C (below the β-transus temperature) for 5 h and (b) 950 °C (above the β-transus temperature) for 5 h. The nitrided microstructure consisted of a thin compound layer on top of a diffusion zone. Nitriding above the β-transus temperature resulted in phase transformations in the core and formation of coarse nitrogen-stabilized α-Ti grains underneath the compound layer.[88b,91b]

450 °C, 8 h in 35% dissociated NH_3 atmosphere). They reported that the surface hardness and case depth were inversely proportional to the retained austenite content of the alloy possibly due to lower diffusivity of nitrogen in austenite. Higher surface hardness and case depth were developed in the nitrided alloy with lower retained austenite content. As a result the fatigue resistance decreased because of higher elastic modulus mismatch between the core and the case.

Guagliano and Vergani[105] studied the fatigue behavior of 42CrMo4 steel nitrided at different conditions (505–530 °C, 5–55 h, 20–70% NH_3 dissociation). They reported that at low stress amplitudes fatigue cracks initiated in the subsurface region underneath the case and nitriding had a beneficial effect on the fatigue strength. However, upon increasing the stress level (low cycle fatigue), the fatigue life of nitrided alloy decreased especially after longer duration treatments. This was attributed to the stiffness mismatch between the case and the core, the case stiffness increased with the nitriding duration, resulting in stress concentration in the case and premature crack formation at the surface.

2.4.5.2 Titanium Alloys

The effect of elevated temperatures involved in the nitriding procedures on the bulk microstructure is an influential factor on the fatigue behavior of titanium alloys.[5] Fairly high nitriding temperatures (>700 °C) are necessary to produce a moderate nitrided depth in titanium alloys, due to the slow kinetics of nitrogen diffusion in titanium. Nitriding of titanium alloys is performed at the temperature range of 750–1000 °C for several hours and cause significant grain growth and over aging of the microstructure.[1]

Investigations by Morita *et al.*[106] indicated that the compound layer formation on the surface and grain growth in the substrate were both responsible for the reduction of fatigue strength after gas nitriding of titanium. Their fractographic observations revealed that the fatigue cracks initiated from the brittle fracture of compound layer. They proposed that the stiffness gradient between the compound layer (E=426 GPa) and the substrate (E=100 GPa) led to stress concentration in former. The developed stress concentration canceled the

positive effect of residual compressive stresses and resulted in brittle fracture at the surface. They also found that the fatigue strength of nitrided titanium had a Hall–Petch relationship with grain size. The effect of grain growth was more pronounced than the brittle compound layer, after a 1 h treatment at 880 °C, however, a 24 h treatment both the low fracture toughness of the compound layer and grain growth had detrimental effects on fatigue strength (Figure 25a). Consequently, they reported promising results by inhibiting grain growth through a low temperature nitriding process (Figure 25b).

Similarly, Tokaji *et al.*[9] reported loss of fatigue strength and endurance limit in Ti–6Al–4V ($\alpha+\beta$ Ti alloy) and Ti–15Mo–5Zr–3Al (β-Ti alloy) after gas nitriding at different temperatures (750–850 °C) and durations (4–60 h). They studied the effect of microstructural changes in the substrate during nitriding on fatigue properties by treating a series of titanium alloys under vacuum. The fatigue limit of nitrided alloys after a 4-h treatment was slightly higher than that of the vacuum treated condition; however, after 15 h of nitriding the fatigue strength was significantly reduced. They discussed that the formation of the compound layer and diffusion zone were both responsible for impaired fatigue properties and confirmed their findings by gradual removal of the nitrided surface layers by electropolishing. Improvements were observed in fatigue life by complete removal of the compound layer and partial removal of the diffusion zone (Figure 26).

Conversely, Steinert *et al.*[107] reported fatigue improvements after nitriding of Ti–6Al–4V alloy at 870 °C for 8 h in a N_2–NH_3 atmosphere (95:5). The nitrided alloy showed a 20% higher fatigue strength compared to a PVD TiN-coated alloy and slightly higher strength compared to the untreated electropolished alloy in the rotation bending fatigue tests. It was found that while fatigue cracks initiated from multiple locations on the surface of gas nitrided alloy, there was a single crack initiation origin on the surface of PVD coated alloy. This was attributed to the steep stiffness gradient between the TiN coating deposited by the PVD process and the titanium substrate. However, for the gas nitrided alloy, the compressive residual stress in the compound layer and diffusion zone suppressed dislocation slip and early crack initiation and resulted in a higher fatigue strength.

Rodriguez *et al.*[108] reported that the low cycle fatigue resistance of Ti–6Al–4V alloy also deteriorated after nitriding. They carried out several nitriding treatments at 850 and 900 °C for 1 and 4 h and noted that the fatigue results of the nitrided samples were similar to – or even slightly better than – those that went through the same treatment under vacuum. Therefore, the reduction of low cycle fatigue resistance was attributed to the substrate microstructural transformations. They proposed that when the imposed strains during cyclic loading were not sufficiently high for compound layer failure, the residual compressive strains on the surface of nitrided samples could slow down the crack nucleation process. However, at high cyclic strains due to the stiffness difference between Ti–6Al–4V and titanium nitrides, cracks nucleated and propagated in the brittle compound layer. Surface roughness was also found to be an influential factor since an increase in the average surface roughness during nitriding leads to stress

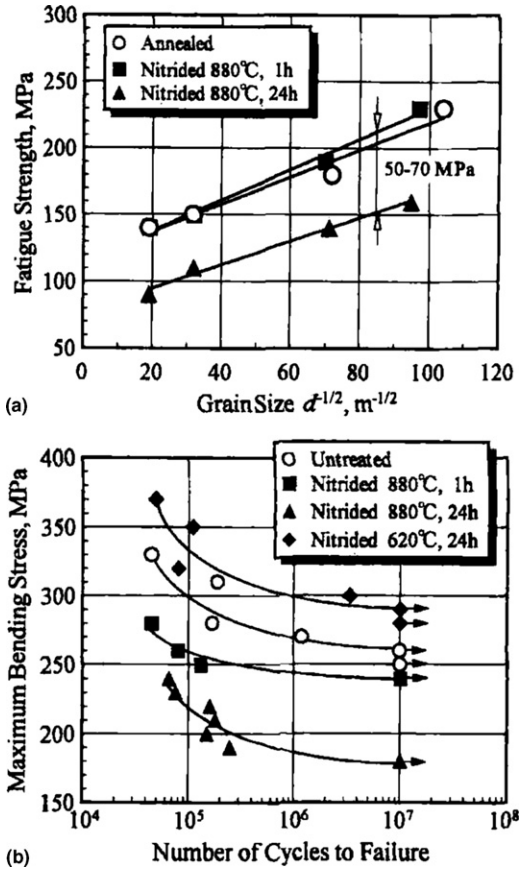

Figure 25 (a) A Hall–Petch type of relationship between the fatigue strength and the grain size in nitrided titanium and (b) typical S–N curves for nitrided titanium showing significant improvements in fatigue strength by low temperature nitriding.[106]

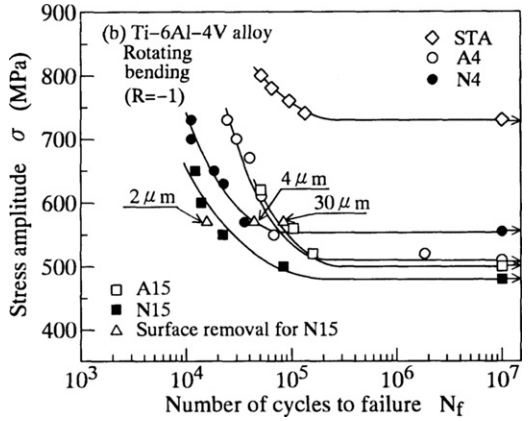

Figure 26 The S–N curve obtained by rotation bending fatigue tests on Ti–6Al–4V alloy. STA: solution treated at 950 °C for 1 h and aged at 540 °C for 4 h; A4 and N4: annealed and nitrided at 850 °C for 4 h; A15, N15: annealed and nitrided at 850 °C for 15 h.[9]

concentration at the surface and promotes early fatigue crack nucleation.[108,109]

2.4.6 Effect of Gas Nitriding on Wear and Corrosion Resistance

2.4.6.1 Ferrous Alloys

Improvements in wear and corrosion resistance after nitriding were correlated to the low coefficient of friction of the compound layer, its chemical resistivity in different media (neutral salt solutions, atmospheric corrosion, chloride irons, liquid metal, etc.), as well as high hardness and improved pitting/crevice resistance of the diffusion zone.[58]

Kato *et al.*[110] identified the responsible wear mechanisms for untreated and gas nitrided EN41B steel (chromium–aluminum–molybdenum nitriding steel) and constructed the corresponding wear maps. They carried out wear investigations over a wide range of applied loads and sliding speeds and observed three distinct wear regimes (mild wear, severe wear, and extremely severe wear) for untreated steel and two different wear regimes (mild wear, severe wear) for gas nitrided steel. For untreated steel, oxidation dominated wear in the mild wear regime characterized by low wear rates, formation of patchy oxides on the surface and generation of fine Fe_2O_3 and Fe_3O_4 debris particles. Severe wear regime was distinguished by high wear rates (one or two orders of magnitude higher than those of the mild regime), plastic deformation, and generation of large metallic wear debris. Adhesion dominated wear in the extremely severe wear regime, characterized by transfer of steel to the counterface and generation of very large metallic debris. Conversely, the nitrided surfaces showed lower wear rates at all tested conditions (between two and four orders of magnitude lower than those of the untreated steel). Gas nitriding also delayed the transition from mild (oxidative) to severe (metallic) regimes and extended the mild wear region toward higher loads and sliding speed. They observed that the compound layer was removed during the initial stages of sliding and thus the enhanced wear performance of nitrided surfaces was attributed to the hardness of the diffusion zone.

Similar results have been reported for stainless steels where gas nitriding resulted in substantial increase in the surface hardness and wear resistance.[111] However, despite improvements in wear resistance and load bearing capacity, gas nitriding can lead to precipitation of dissolved chromium as chromium nitrides and impair the corrosion resistance of stainless steels. In order to inhibit precipitation of chromium nitrides and compound layer formation nitriding of stainless steels is practiced at low temperatures (at or below 450 °C). This results in the development of shallow cases of high hardness. Alternatively, nitriding of stainless steels may be performed at temperatures above 1000 °C (i.e., solution nitriding) to create deep austenitic diffusion zones.[112] According to Spies *et al.*[113] when nitriding temperature was kept below 440 °C, resistance against general corrosion improved in both austenitic and ferritic stainless steels. The pitting corrosion resistance, however, significantly improved in austenitic stainless steels and marginally decreased in ferritic stainless steels.

2.4.6.2 Titanium Alloys

Titanium alloys possess excellent resistance against general corrosion due to the presence of a naturally occurring protective passive film on their surface, mainly composed of TiO_2 (possibly also TiO and Ti_2O_3). This oxide film is highly adherent and due to the high affinity of titanium and oxygen it forms instantaneously on fresh titanium surfaces exposed to air or water.[114] Titanium alloys exhibit corrosion resistance in atmospheric conditions, brines, sea water, and salt solutions (pH level ranging from 3 to 11) such as chlorides, bromides, iodides, sulfites, phosphates, carbonates, etc. Titanium alloys also exhibit corrosion resistance in mildly reducing to highly oxidizing acidic environments. Nonetheless their performance is dependent on the temperature, acid concentration and titanium alloy composition. The influence of gas nitriding on corrosion resistance of titanium alloys is diverse and highly affected by the corrosive environment and test temperature. In an investigation by Sha *et al.* the effects of alloy composition and corrosive media were studied on Ti–8Al–1Mo–1V and Ti–6Al–2Sn–4Zr–2Mo after nitriding at 950 °C for 5 h. Their findings indicated that both untreated and nitrided titanium alloys showed excellent corrosion resistance in NaCl solution (0.5 M concentration). When exposed to very aggressive reducing acid solution environment (HCl solution, 4.9 M concentration), the corrosion rate slightly increased for Ti–8Al–1Mo–1V after nitriding, but for Ti–6Al–2Sn–4Zr–2Mo the corrosion rate was substantially higher after nitriding. In an oxidizing acid solution (H_2SO_4, 1.8 M concentration), regardless of the testing temperature, the corrosion resistance of both alloys decreased after nitriding.[47]

Improvements in the wear resistance of titanium alloys after gas nitriding have been attributed to increased surface hardness due to the formation of titanium nitrides (TiN,Ti_2N) and mechanical support from the nitrogen-strengthened diffusion zone underneath. Wear investigations by Januszewicz and Klimek[80a] on gas nitrided commercially pure (CP) titanium and Ti–6Al–4V alloy indicated that the surfaces treated at a high temperature of 850 °C exhibited higher wear resistance as the nitrided surfaces and were able to withstand relatively high contact pressures due to a deeper hardened diffusion zone. Titanium alloys treated at lower temperatures of 650 and 750 °C experienced high wear rates and third body abrasive wear due to the compound layer failure during early stages of wear testing.

Shashkov *et al.*[115] promising wear results were achieved when nitriding was performed below 900 °C. They reported that nitriding temperatures exceeding 900 °C were accompanied by of the development of thick nitride layers and detrimental microstructural changes in the bulk (e.g., grain coarsening) that led to higher wear rates.

2.4.7 Industrial Applications

Gas nitriding of ferrous alloys has found numerous applications due to its effective role in improving wear, corrosion, and fatigue properties. Furthermore, gas nitriding is a versatile surface hardening process where the nitriding parameters can

be adjusted to achieve the desired properties. It is extensively used in manufacturing of aircraft and automotive components, textile machinery, and turbine generation systems.[58]

The nitriding conditions are adjusted toward the formation of compound layer for applications requiring wear and corrosion resistance, such as automotive and aerospace components subject to sliding, for example, crankshafts, seat screws, components of solenoid actuators, and car window sector.[59b] The components that are subject to high shock loads or very high contact stress levels and need to maintain surface hardness at elevated temperature, such as gears.[68]

For the components where the formation of a brittle compound layer is unfavorable such as cutting tools or fatigue resistance is required such as crankshafts, nitriding will be modified to obtain deep diffusion zone. Gas nitriding is also extensively applied to extrusion tools. The extrusion tools experience high friction at elevated temperatures, which deteriorates their dimensional tolerance and the surface quality of the extruded profiles. Dies and die casting molds are required to possess optimum formability, lubrication properties, and corrosion resistance to molten metal and thus need a combination of compound layer and diffusion zone.[116]

With the recent trend in replacing cast irons and steels with lightweight alloys, gas nitriding of titanium alloys has gained much industrial popularity. Titanium components such as surgical instruments, implant materials, racing engine and racing car components, golf club heads, watch cases, and precision machine parts are frequently nitride.[117] It should be noted that the negative effect of gas nitriding on fatigue life of titanium alloys has posed restrictions on their extensive application.

2.4.8 Recent Developments in Gas Nitriding

An alternative to conventional gas nitriding technologies is solar gas nitriding in which concentrated solar energy provides the energy source for nitriding in a nitrogen-containing atmosphere. Investigations of Olías *et al.*[118] and Rodriguez *et al.*[119] showed a great reduction of nitriding time and greater nitriding rate in titanium alloys using solar gas nitriding technology.

Laser gas-assisted nitriding has also been successfully applied for surface modification of steels and titanium alloys.[120,121] The optimization of laser treatment process to avoid residual tensile stresses on the surface and surface cracking has been the subject of many studies.[122] It has been reported that after process optimization, the laser nitrided surfaces exhibit increased hardness, better corrosion and wear/cavitation erosion resistance.[123]

Several investigations have also been undertaken to produce wear resistant nitrided layers by simultaneous surface melting and nitriding under in nitrogen-rich atmosphere.[124] Hioki *et al.*[124b] achieved significant improvements in the surface hardness (almost four times higher than the bulk) and depth of the hardening ($\sim$0.2 mm) in aluminum by this method. They reported that the nitrided microstructure consisted of AlN and α-Al lamellae. Microstructural investigation of nitrided titanium surfaces by tungsten inert gas torch melting were carried out by Mridha.[124c] He reported a dendritic structure with inhomogeneous distribution within the melt zone on top of a heat affected zone. A high density of fine, interconnected TiN dendrites randomly distributed in the surface vicinity increased the surface hardness to more than 2000 HV. Coarser dendrites of TiN, Ti_2N, and $TiN_{0.3}$, oriented perpendicular to the surface, were observed deeper in the melt zone. The hardening depth exceeded 3 mm from the surface of the melt zone owing to the dissolution of nitrogen atoms and formation of α' martensite phase.

Furthermore, during the past decades many duplex surface engineering techniques have been designed and implemented to exploit the hardening depth of gas nitriding processes as a mechanical support for wear resistant surface coatings such as PVD or CVD nitride coatings and DLC.[125] In one of the earliest investigations Spies *et al.*[126] deposited PVD TiN and Cr_2N coatings on nitrided 31CrMoV9 low-alloy steel and reported that the duplex treatment resulted in considerable improvements in wear and friction of nitrided surfaces without affecting the fatigue limit. They attributed their findings to the presence of compressive residual strains and a deeply strengthened diffusion zone that mitigated the hardness mismatch between TiN coating and steel substrate. Further adhesion improvements were achieved by incorporation of a Ti–TiN_x interlayer at the interface of TiN/nitrided surface[126a] or the deposition CrN PVD coating on the nitrided surface.[127] Nonetheless, the extent of improvements in the surface hardness and wear resistance by duplex treatments, according to Zeghni and Hashmi,[128] is a function of surface roughness, type of PVD coating, and gas nitriding conditions.

2.5.1 Introduction

Lasers are widely used in surface engineering because of their superior processing characteristics. Some of these characteristics include precision of operation, local treatment, fast processing, and low cost. Although laser surface treatment has several advantages, high cooling rates during the processing give rise to development of high stress levels in the treated layer. If the process is not controlled through the proper selection of laser treatment parameters, surface defects including micro-cracks and voids become unavoidable. This lowers the treated surface quality and limits the practical applications of the laser-treated surface. In general, laser beam intensity distribution is Gaussian and the peak intensity occurs at the irradiated spot center. In order to increase the melted region across the irradiated spot, laser intensity remains high at the surface. This gives rise to partial evaporation at the surface, particularly in the region of the irradiated spot center. In some situations, the presence of oxygen in the laser-treated region triggers the exothermic reactions in the treated region. The excess energy released during the exothermic reaction results in increased rate of evaporation in the irradiated region while forming a deep cavity at the surface. Although the use of inert gas, as the assisting gas, during processing prevents the exothermic reactions, high intensity beam at the irradiated center can still cause the formation of the cavity at the surface. The size of the cavity can be controlled through the melt flow from the irradiated region toward the cavity center, however, care must be taken to avoid excessive melting and overflow of the molten material at the surface. The excessive melting and molten flow at the surface increases the surface roughness and modifies the morphological characteristics. In this case, wear resistance or surface hydrophobicity is negatively affected by the overlay of the molten material at the treated surface.

In laser surface treatment process, repetitive pulses with high frequency of repetition is favorable.[1] This is because of the fact that the repetition of the laser pulses results in overlapping of the irradiated spots when the workpiece or laser beam moves at a constant speed during the processing. Therefore, closely spaced scanning tracks are formed during the laser processing. The laser scanning tracks has two-fold effects, which are: (i) regular surface texture can be possibly resulted, and (ii) self-annealing effect can be created, which reduces the thermal stress levels in the irradiated region. In this case, heat conduction from the lately formed laser scanning tracks toward the early formed tracks alters the cooling rates in the laser-treated region. Consequently, this lowers the temperature gradients and thermal strain in the surface region while suppressing high levels of stress formation in this region. On the other hand, assisting gas contributes to the cooling rates through forced convection heat transfer from the irradiated surface. However, it was demonstrated that the heat transfer coefficient at the heated surface under the assisting gas is in the order of $3 \times 10^3\ \mathrm{W\,m^{-2}\,K^{-1}}$, which is relatively low as compared to the irradiated energy.[2] Therefore, the effect of assisting gas on the cooling rates is not significant at the laser-treated surface.

In the present chapter, laser treatment of three different materials including phosphorous bronze, yttria-stabilized zirconia, and Rene 41 is presented in line with the previous studies.[3–5] The background and relevant findings are given in accordance with each material considered.

2.5.2 Experimental Studies

Although theoretical analysis provides useful information on the thermal and stress fields taking place during laser surface treatment process, the experimental studies are necessary to

explore the actual changes in the laser-treated layer. Consequently, in this chapter, the main focus covers the experimental study of the laser surface processing.

A CO_2 laser (LC-ALPHAIII) delivering a nominal output power of 2 kW was used to ablate the workpiece surface. The nominal focal length of the focusing lens was 127 mm. The laser beam diameter focused at the workpiece surface was of the order of 200 μm. Nitrogen assist gas emerging from the conical nozzle and co-axial with the laser beam was used. The laser surface ablation process was carried out with different laser parameters. Therefore, through trial and error, the optimal laser parameters resulting in surface ablation with low surface roughness were selected. The laser melting/ablation parameters are given in **Table 1**. The laser treatment experiments were repeated three times to ensure almost the same topology at the surface under high pressure (600 kPa) nitrogen assisting gas ambient.

Material characterization of the laser ablated surfaces was carried out using SEM, EDS, AFM, and XRD. A Jeol 6460 electron microscope was used for the SEM examination and a Bruker D8 Advanced with CuKα radiation was used for XRD analysis. A typical setting for the XRD system was 40 kV and 30 mA, the scanning angle (2θ) was ranged over 20°–90°. The parabolically-shaped Göbel Mirror was used in the Bruker D8 Advanced; this provided highly-parallel X-ray beams.

A microphotonics digital hardness tester (MP-100TC) was used to obtain Vickers microindentation hardness values at the ablated surface. The standard test method for Vickers indentation hardness of advanced ceramics (ASTM C1327-99) was adopted. Microhardness was measured at the workpiece surface after the laser ablation process. The measurements were repeated five times at each location for the consistency of the results.

A linear micro-scratch tester (MCTX-S/N: 01-04300) was used to determine the friction coefficient of the laser ablated and as-received surfaces. The equipment was set at the contact load of 0.03 N and end load of 5 N. The scanning speed was 5 mm min^{-1} and loading rate was 5 N min^{-1}. The total length for the scratch tests was 5 mm.

The residual stress measurement relied on the stresses in fine grained polycrystalline structure. The position of the diffraction peak exhibited a shift as the specimen was rotated by an angle ψ. The magnitude of the shift was related to the magnitude of the residual stress. The relationship between the peak shift and the residual stress (σ) could be written as:

$$\sigma = \frac{E}{(1+\upsilon)sin^2\psi}\frac{(d_n - d_o)}{d_o} \quad [1]$$

where E is Young's modulus, υ is Poisson's ratio, ψ is the tilt angle, d_n is the d spacing measured at each tilt angle, and d_o is the stress-free lattice spacing. If there are no shear strains present in the specimen, the d spacing changes linearly with $\sin^2\psi$.

The fracture toughness of the surface was measured using the indenter test data for microhardness (Vickers) and crack inhibiting. In this case, the crack length generated due to indentation at the surface was measured. The length (l) measured corresponded to the distance from the crack tip to the indent. The crack lengths were individually summed to obtain $\sum l$ as described in the previous study.[6] The crack length 'c' from the center of the indent was the sum of individual crack lengths ($\sum l$) and half the indent diagonal length '$2a$.' Therefore, $c = a + \sum l$. However, depending upon the ratio of $\frac{c}{a}$, various equations were developed to estimate the fracture toughness (K). However, the equation proposed by Anstis *et al.*[7] has limitations due to nonlinearity of the coefficients for values of $\frac{c}{a} > 2$, which is not appropriate for the silicon carbide (≈ 1.5–2.1). Therefore, the equation proposed by Evans and Charles[6] is used to determine the fracture toughness (K_c), which is applicable for ($0.6 \leq \frac{c}{a} \leq 4.5$), i.e.:

$$K_c = 0.079\left(\frac{P}{a}\right)^{1.5} \cdot \log\left(4.5P\frac{a}{c}\right) \quad [2]$$

where P is the applied load on indenter, c is the crack length, and a is the half indent diagonal length.

The wetting experiment was performed using Kyowa (model – DM 501) contact angle goniometer. A static sessile drop method was considered for the contact angle measurement. The water contact angle between the water droplet and the laser-treated surface was measured with the fluid medium as deionized water. Droplet volume was controlled with an automatic dispensing system having a volume step resolution of 0.1 μl. Still images were captured, and contact angle measurements were performed after 1 s of deposition of water droplet on the surface. The experiments were repeated three times at different locations at the laser-treated and as-received surfaces. In order to determine the surface free energy of the laser-treated surface contact angle measurements are extended to include glycerol and diiodomethane. The analysis related to the surface energy formulation is presented in the light of the previous study.[8] The surface energy of solids and liquids can be divided into components according to Van Oss *et al.*[9–12]; in which case, the surface energy can be written as:

$$\gamma = \gamma^L + \gamma^P \quad [3]$$

Where γ^L is the apolar component due to Lifshitz–van der Waals intermolecular interactions and γ^P is due to electron acceptor and electron donor intermolecular interactions. However, γ^P can be written as[9–12]:

$$\gamma^P = 2\sqrt{\gamma^+ \cdot \gamma^-} \quad [4]$$

where γ^+ and γ^- are the electron acceptor and electron donor parameters of acid–base component of the solid and liquid

Table 1 Laser ablation conditions used in the experiment

Scanning speed (m s^{-1})	*Power (W)*	*Frequency (Hz)*	*Nozzle gap (mm)*	*Nozzle diameter (mm)*	*Focus setting (mm)*	*N_2 pressure (kPa)*
0.1	97	1500	1.5	1.5	127	600

surface free energy, respectively. The interfacial free energy for a solid–liquid system can be written as[9–12]:

$$\gamma_{SL} = \gamma_S + \gamma_L - 2\sqrt{\gamma_S^L \cdot \gamma_L^L} - 2\sqrt{\gamma_S^+ \cdot \gamma_L^-} - 2\sqrt{\gamma_S^- \cdot \gamma_L^+} \quad [5]$$

where subscripts S and L represent solid and liquid phases, respectively. However, the Young's equation for the surface free energy of a solid is[13]:

$$\gamma_L cos\,\theta = \gamma_S - \gamma_{SL} - Pe_L \quad [6]$$

where γ_S is the solid surface free energy, γ_{SL} is the interfacial solid–liquid free energy, γ_L is the liquid surface tension, θ is the contact angle, and Pe_L is the pressure of the liquid film, which is negligibly small and considered to be zero.[14] Combining eqns [5] and [6] and re-arrangements yield:

$$\gamma_L(cos\,\theta + 1) = 2\sqrt{\gamma_S^L \cdot \gamma_L^L} + 2\sqrt{\gamma_S^+ \cdot \gamma_L^-} + 2\sqrt{\gamma_S^- \cdot \gamma_L^+} \quad [7]$$

Equation [7] can be used to determine the values of γ_S^L, γ_S^+, and γ_S^- while incorporating the contact angle data for γ_L^L, γ_L^+, and γ_L^-. However, the data for γ_L^L, γ_L^+, and γ_L^- can be found in the open literature for water, glycerol, and diiodomethane, which are given in **Table 2**.[10,15] Since eqns [7], [4], and [3] are applicable only for smooth surfaces, experiments are repeated at lower power intensity to ensure thin layer of melting in the irradiated region. In this case, surface evaporation is avoided and the surface texture was not formed due to ablation. The contact angle measurements are repeated several times to ensure the repeatability of the contact angle data.

2.5.3 Background

The background and the literature for the surface treatment of the selected materials for the case studies are presented under the relevant subheadings in line with the previous studies[3–5]:

2.5.3.1 Phosphorous Bronze

The relevant literature related to the laser heating of phosphorus bronze is given below in line with the previous study.[3]

Phosphorous bronze finds wide applications in industry due to its good formability, desirable resistance to corrosion in marine environments,[16] and high electrical and thermal conductivities. In general, copper alloys have antimicrobial attributes and several bacteria, known to be human pathogens, die when they come in contact with dry copper and copper alloy surfaces at room temperature. It was demonstrated the amount of live bacteria dropped by several orders of magnitude, to zero in 1–2 h when they were in contact with a copper alloy surface.[17] However, the use of phosphor bronze in antibacterial environments requires special attention to improve the surface properties of the alloy prior to its application in such environments. In this case, improvement of the surface hydrophobicity of the alloy reduces the contact area of bacterial fluid and minimizes the stains left over after the dry-out of the hazardous fluid at the surface. However, phosphor bronze surface is hydrophilic and it is hard to repel the infected fluids from the surface.[18] The surface hydrophobicity can be improved significantly via texturing of the surface while forming a nano/micro size poles and cavities. One of the methods to texture the bronze surface is the laser ablation of the alloy surface in a controlled environment. In addition, laser surface treatment improves tribological properties of the surface such as hardness, wear, and corrosion resistance.[19–21] Although laser treatment improves surface characteristics of bronze, high temperature gradient generated during the process causes thermally induced cracks and limits the practical application of the treated surface. In addition, high thermal conductivity of bronze makes the desired thermal texturing difficult to achieve.

A study on surface properties of gilt-bronze artifacts after Nd:YAG laser cleaning was carried out by Lee *et al.*[22] They demonstrated that chemical cleaning removed corrosion products of copper through dissolution, however, the removal was not uniform at the surface. Microstructure and performance of laser cladding on surface of aluminum bronze was studied by Xu *et al.*[23] They demonstrated that the microstructure of cladding was affected by solidification rate and the microstructure was cellulated crystal at the surface; however, it was dendritic crystal in the middle section of the cladding. Laser surface alloying of a marine propeller bronze using aluminum powder was investigated by Cheng *et al.*[24] They showed that the galvanic effect between the laser-treated and as-received samples was small. Laser processing of nickel–aluminum bronze for improved surface corrosion properties was examined by Cottam *et al.*[25] The findings revealed that laser processing improved the corrosion resistance of the treated surface. Investigation of laser surface melting of a manganese–nickel–aluminum bronze was carried out by Tang *et al.*[26] They indicated that erosion–corrosion synergism constituted a significant contribution to the overall cavitation erosion–corrosion in 3.5 wt% NaCl solution for the treated surface. Mechanical and electrochemical properties of laser surface modified titanium alloy for biomedical applications were examined by Khosroshahi *et al.*[27] They showed that a high value of microhardness was resulted, which could be attributed to grain refinement associated with laser melting and rapid solidification. Laser melt injection of WC particles on aluminum surface was studied by Li *et al.*[28] They demonstrated that the powder should be fed from the back side of the laser beam to achieve appropriate surface enhancement effect and the depth of the melt layer increased first, and then decreased with increasing laser power. Laser processing of TiC reinforced composite layer on Al–Si alloy surface was investigated by Chan *et al.*[29] They demonstrated that unlike bronzes exposed to oxidizing conditions, which developed protective SnO_2 layers, the H_2S (aq)-exposed surface was considerably depleted in Sn.

Table 2 Lifshitz–van der Walls components and electron donor parameters used in the simulation

	γ_L ($mJ\,m^{-2}$)	γ_L^L ($mJ\,m^{-2}$)	γ_L^+ ($mJ\,m^{-2}$)	γ_L^- ($mJ\,m^{-2}$)
Water	72.8	21.8	25.5	25.5
Glycerol	64	34	3.92	57.4
Diiodomethane	50.8	50.8	0.72	0

2.5.3.2 Yttria-Stabilized Zirconia

The background and relevant literature on laser treatment of yttria-stabilized zirconia are given below in line with the previous study.[4]

Stabilized zirconia is widely used in industry due its superior properties such as high wear and temperature resistances, low thermal conductivity, etc. Some of the applications include thermal barrier coating in jet and diesel engines to allow operation at higher temperatures,[30] sensor technologies for oxygen sensing,[31] and fuel cell membranes operating at high temperatures.[32] The surface characteristics of stabilized zirconia, including hardness and hydrophobicity, can be improved further through various surface treatment methods. Since biomimetric characteristics of surfaces received great attention in industry, various methods have been developed in this regard. Some of these methods include phase separation,[33] electrochemical deposition,[34] template method,[35] emulsion,[36] plasma method,[37] crystallization control,[38] chemical vapor deposition,[39] sol–gel processing,[40] lithography,[41] electrospinning,[42] and solution immersion.[43] However, transforming lowsurface-energy materials into textured surfaces is one of the techniques, which can be used to enhance hydrophobicity of the surfaces. Laser surface texturing through a controlled ablation offers considerable advantages over the conventional texturing methods. Some of these advantages include high speed operation, high precision, local treatment, and low cost. However, the presence of the mixed regime of melting and ablation at the surface modifies the surface texture, which alters the wetting state of the surface. In addition, high stress levels are developed in laser-treated region because of the high temperature gradients, which are formed in the irradiated region due to high heating and cooling rates. The fraction toughness of the surface also reduces due to microhardness enhancement at the surface after the treatment process. Consequently, investigation of laser treatment of zirconia surface for improved hydrophobicity and assessment of the residual stress and the fracture toughness in the treated region becomes essential.

Laser surface treatment of partially stabilized zirconia for biomedical applications was presented by Hao and Lawrence.[44] They observed that the thickness of the adsorbed layer decreased as the polar surface energy of partially stabilized zirconia increased. Laser treatment of zirconia surfaces was examined by Chwa and Ohmori.[45] They indicated that the surface roughness of zirconia prior to the laser treatment was important, since the melt depth of the polished coatings was approximately half of the rough coatings when treated at the same power density. Laser surface treatment of plasma-sprayed yttria-stabilized zirconia coatings was investigated by Pinto *et al.*[46] They showed that the microstructure of the treated layer presented a cellular structure which has grown perpendicular to the surface and the micrographs depicted small cracks and absence of porosity. Laser surface nitriding of yttria-stabilized tetragonal zirconia was studied by Kathuria.[47] The findings revealed that the transformation of the t-ZrO_2 exhibited the typical yellow-gold color of ZrN with high hardness at the surface. Laser surface modification of plasma-sprayed yttria-stabilized zirconia coatings was examined by Shankar *et al.*[48] They observed that distinct interface separating fine and coarse grains took place at all scan speeds and the microhardness of the glazed surface improved considerably. Laser treatment of zirconia surface and morphological and microstructural changes in the treated layer was investigated by Daniel *et al.*[49] They showed that the surface morphology closely followed the microperiodic heat treatment provided by the interfering laser beams and the pore size distribution within the periodic surface morphology ranged from a few nanometers to a maximum of half of the periodic line distances. Laser ablation characteristics of yttria-doped zirconia in nanosecond and femtosecond regimes were studied by Heiroth *et al.*[50] They showed that femtosecond pulses prevented the exfoliation of micron-sized fragments, but result invariably in a pronounced ejection of submicron particles. Thermal fatigue properties of laser-treated surfaces were investigated by Aqida *et al.*[51] They observed that carbides and oxide compounds were formed on the laser-treated surface after the thermal fatigue test. Thermal stability of laser-treated die material for semisolid metal forming was examined by Aqida *et al.*[52] The findings revealed that crystallization in glazed zone increased as the annealing temperature increased and the microhardness decreased due to local crystallization at the surface.

Hydrophobicity of the substrate surfaces can be improved through forming fine poles at the surface during laser texturing.[53] The surface energy of zirconia can be modified by a laser heating at the surface,[54] which may further improve surface hydrophobicity.

2.5.3.3 Rene 41

The literature related to the laser treatment of Rene 41 is provided below in line with the previous study.[5]

Rene 41 is one of the nickel-based high-performance alloy, which exhibits excellent mechanical strength and high resistance to creep at high temperatures. It finds applications in the aerospace,[55] industrial gas turbine, and marine turbine industries.[56] Surface characteristics of high-performance alloy, such hardness, can be improved through restructuring of the surface through adopting some techniques while integrating grain refinement and hard particle injections at the surface. One of the methods to achieve improved surface hardness is laser controlled melting and hard particle injection during the process, since laser melting is involved with high heating and cooling rates, which result in grain refinement in the melted region. In addition, the depth of laser melted region is limited to tens of micrometers, which allow imbedding the hard particles, such as carbide particles, during the melting process.[57] However, high heating and cooling rates as well as presence of hard particles give rise to high micro-stress levels in the laser-treated layer, which trigger the formation of defect sites such as micro-cracks and crack networks at the treated surface. This, in turn, limits the practical application of the resulting treated surface. Consequently, investigation of surface characteristics due to laser control melting and presence of hard particles of Rene 41 surface becomes essential.

Effect of heat treatment on microstructure and mechanical properties of laser-treated Rene 41 was investigated by Li *et al.*[58] They showed that extensive precipitation of γ' resulted in high hardness and ductility, and the subsequent alignment and coalescence of γ' precipitates induced low strength in the

laser-treated layer. Microstructure evolution of laser repair welded nickel-based superalloy cast was studied by Wang *et al.*[59] Their findings revealed that, due to suffering from different thermal histories during the multi-pass welding process, microstructures within the weld region formed six distinct zones. In addition, no cracks were formed in the weld fusion zone or in the heat-affected zone when appropriate welding parameters were used. Laser treatment of nickel-based superalloy was examined by Durocher and Richards.[60] They indicated that laser-treated region was free from asperities and laser treatment could be one of the good candidates for repair applications of nickel-based superalloys. Laser treatment of nickel-based superalloys, in relation to repair applications, was studied by Rush *et al.*[61] They showed that cracking was caused primarily by liquation in the laser-treated layer and it was exacerbated by post-weld heat treatment cracking during the process. Influence of heat treatment on microstructure and hot crack susceptibility of laser-treated nickel-based superalloy was studied by Osterle *et al.*[62] They demonstrated that increasing fraction of grain boundaries with densely spaced borides and lack of secondary γ'-particles in matrix channels between the coarse cuboidal γ'-precipitates increased the rate of cracking in the laser-treated layer. Hot cracking in the heat-affected zone of laser-treated nickel-based superalloy was investigated by Matijasevic-Lux *et al.*[63] They showed that laser treatment resulted in different hot crack lengths in the heat-affected zone, which depended on local microstructural configuration in the close region of the treated region.

2.5.4 Findings and Discussions

The findings of the laser surface treatment of selected materials, including phosphorous bronze, zirconia, and Rene 41 are given in line with the previous studies[3–5] under the appropriate subheadings.

2.5.4.1 Phosphorous Bronze

The characteristics of laser-treated phosphorous bronze surface are given below.[3] The phosphor bronze with elemental composition (wt%) of 6% Sn, 0.1% P, and balance of Cu was used in the experiments. The samples were prepared from phosphor bronze sheet within the size of 3 mm in thickness and 20 mm × 20 mm (length × width).

Figure 1 shows SEM micrographs of laser ablated phosphor bronze surface. Laser ablation takes place during the irradiation of repetitive laser pulses along the laser scanning direction.

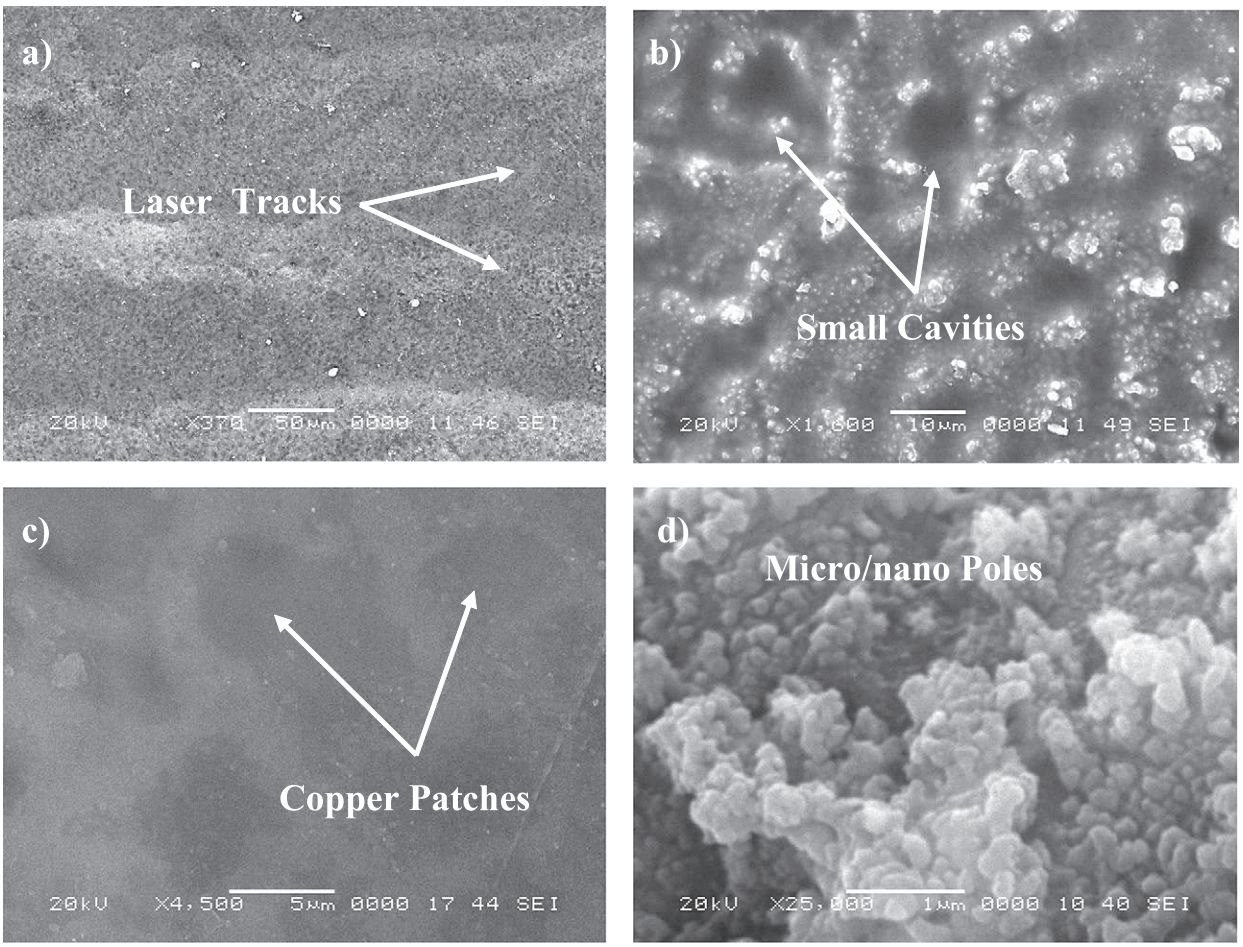

Figure 1 SEM micrographs of laser ablated phosphor bronze surface: (a) regular laser scanning tracks, (b) fine size cavities at ablated surface, (c) mahogany color and scattered Cu_3N dissolved spots, and (d) micro/nano size surface texture.[3]

The overlapping ratio is in the order of 70% at the surface. Laser intensity distribution is Gaussian and the pulse intensity remains high at the irradiated spot center. This in turn, results in surface evaporation in the region limited to the irradiated spot center and the melting takes place in the remaining region of the irradiated spot. The melt flow toward the cavity center from its neighborhood modifies the cavity shape and reduces to the cavity depth. Therefore, surface texture consisting of micro/nano poles and cavities is resulted at the treated surface. However, the close examination of the surface reveals that surface appears a mahogany and the presence of randomly scattered few red spots, which are indications of copper. The mahogany color represents the presence of Cu_3N in the surface region, which is also observed from X-ray diffractogram (Figure 2), i.e., the presence of Cu_3N (100) is associated with the high nitrogen pressure incorporated in the laser treatment process. The presence of few scattered copper spots is due to the dissolution of Cu_3N at elevated temperatures through forming NO_x gases. In this case, in the near region of the cavity, surface melts and solidifies rapidly because of the convection cooling of the nitrogen assisting gas; therefore, the dissolution of Cu_3N does not cover the whole surface. Laser-treated surface composes of submicron grains, which is attributed to the rapid solidification and formation of nitrides at the surface region. In addition, the submicron size of the packed particles indicates that each particle contains many single crystals of Cu_3N as consistent with the early work.[64] Although use of assisting gas increases cooling rates at the surface, no micro-cracks are observed in between the packed grains.

Figure 3(a) shows SEM micrographs of cross-section of the laser ablated layer. A dense structure, consisting of submicron-sized packed particles and extremely fine grains are formed in the surface region (Figure 3(b)). Formation of Cu_3N in the surface region lowers the density and causes volume shrinkage in the dense layer. In addition, the high quench rates in the cooling cycle after laser ablation is responsible for the formation of fine grains in the dense layer. A dendritic structure with elongated grains is observed at some distance below the dense layer (Figure 3(c)). The formation of a dendritic structure indicates the high rate of solidification in this region and the non-uniform cooling is responsible for the formation of the elongated grains. As the distance below the surface increases further, a cellular structure is formed (Figure 3(d)), which is associated with the relatively lower cooling rates as compared that of the surface region. EDS data for the elemental composition of the laser-treated surface are given in Table 3. Although quantification of the light elements in EDS data involves with error, presence of nitrogen is evident, which has a high concentration at the surface. The absence of Sn in some EDS spectrums indicates that Sn was evaporated in the surface region during the laser ablation process. The heat-affected zone is shallow without forming a demarcation line between the heat-affected zone and the base material, which is attributed to the high thermal conductivity of the bronze.

In the case of residual stress calculation, if shear strains are not present in the specimen, the d spacing changes linearly with $\sin^2\psi$. However, d_o is the inter-planar spacing when substrate material is free from stresses. Therefore, the calculations were performed for $Cu_3N(100)$ planes ($2\theta = 23.44^\circ$) with an inter-planar spacing of 0.3844 nm. It should be noted that Cu_3N is identified in accordance with the ICDD 00-055-0308 card. The linear dependence of $d(100)$ results in a slope of $-1.9 \times 10^{-3} \pm 9.12 \times 10^{-5}$ nm and intercept of $0.3844 \pm 4.75 \times 10^{-3}$ nm. The elastic module and Poisson's ratio of phosphor bronze are 96.5 GPa and 0.34,[26] respectively. The residual stress measured is of the order of -350 MPa, which is compressive, and the estimated error is ± 10 MPa, which is 2.4%. It should be noted that the error is estimated based on three repeats of the XRD measurements. Since ablation takes place along the laser scanning tracks, lately ablated regions creates a self-annealing effect on the previously ablated regions. This in turn modifies the cooling rates, particularly, below the surface. However, the self-annealing effect created during the cooling period does not significantly alter the stress levels in the surface vicinity because of the convective cooling of the assisting gas at the surface; therefore, the residual stress remains high in the surface region. It should be noted that the residual stress measured is limited to the surface vicinity, since the penetration depth of the X-ray radiation is of the order of few micrometers. Although the workpiece surface expands freely during the laser ablation process, the surface vicinity is not free to expand and

Table 4 Microhardness and residual in the coating produced using two different wire materials

	Hardness (HV)	*Residual stress (MPa)*
Laser ablated surface	580 (+30/−30)	−350 (+10/−10)
As-received surface	140 (+10/−10)	–

compressive stresses are formed. This behavior is responsible for the attainment of high residual stress in the surface region. The microhardness and residual stress data for the laser ablated surface are given in **Table 4**. The microhardness of the laser ablated surface is high (580 ± 30 HV), which is almost four times hardness of the base material (145 ± 10 HV). This is due to one or all of the following: (i) the dense structure formed in the surface region, and (ii) the formation of Cu_3N compounds in the surface region after the laser ablation process. The residual stress measured by the XRD technique is of the order of -350 ± 10 MPa. **Figure 4** shows the scratch test results used to determine the friction coefficient of the laser ablated and as-received surfaces. The friction coefficient of the laser ablated surface is lower than that corresponding to as-received workpiece surface. This is mainly associated with the microhardness enhancement at the laser ablated surface because of the dense layer formation in the surface region under the high cooling rates and formation of Cu_3N at the surface due to high pressure nitrogen assisting gas. It should be noted that no peeling and delamination of the surface is observed during and after the scratch tests.

Since the laser ablated surface is chemically heterogeneous because of the local nitride formations (Cu_3N) and nitride dissolutions (through NO_x gas formation) at the surface the application of Young's equation[65] is limited to assess the contact angle. Wenzel[66] and Cassie and Baxter[67] proposed a relationship between the contact angle of a liquid droplet and the surface roughness factor to overcome this limitation. **Figure 5** shows optical images of the water droplet on the laser ablated and untreated surfaces while **Table 5** provides the data on the contact angle measurements at different locations at the surfaces. The contact angle varies slightly with the location at the surface, which is attributed to the surface texture variation and the texture composition at the surface.[68] In general, laser-treated surface demonstrates superhydyrophobic behavior and the averaged contact angle of the surface is in the order of 142°. Consequently, the texture of the laser ablated surface, consisting of fine pillars and poles at micro/nano scale, results in large contact angles of the water droplet.

2.5.4.2 Yttria-Stabilized Zirconia

The findings of the laser-treated zirconia surface characteristics are provided in line with the previous study.[4] The zirconia tiles measuring 25 mm × 15 mm × 3 mm were used in the experiments.

Figure 6 shows scanning electron microscope micrographs of the top surface of the treated layer. The laser scanning forms regular ablated/melted tracks at the surface. Due to the repetition of the laser pulses during the processing, laser irradiated spots are overlapped at the surface during the scanning. The overlapping ratio of the spots is in the order of 72%, which provides continuous ablated/melted sites along the tracks. The laser-treated surface is free from large scale asperities such as large scale cracks or crack networks, pores, and cavities. In addition, no melt flow is observed across the laser scanning tracks. The treated surface composes of micron/nano-sized grooves as consistent with the previous work.[69] The surface roughness varies along the laser scanning tracks, which is associated with the ablation of the surface during the scanning. In this case, laser beam partially impinges onto previously formed cavity and partially onto the neighboring untreated

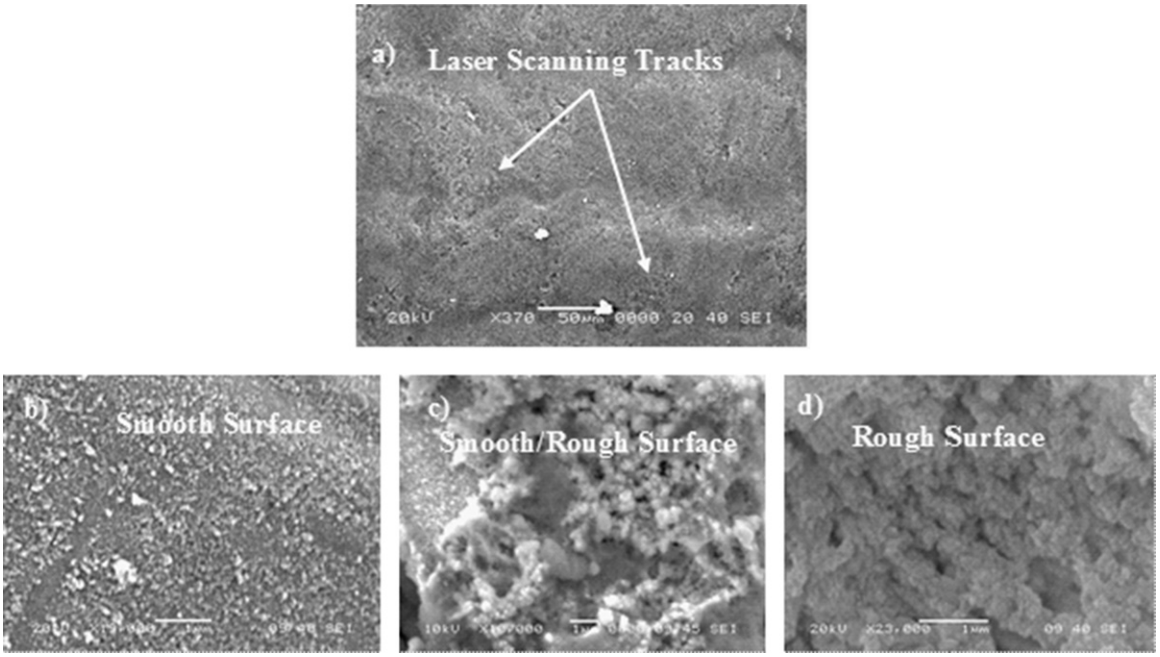

Figure 6 SEM micrographs of laser-treated zirconia surface: (a) laser-treated zirconia surface and presence of scanning tracks, (b) laser-treated zirconia smooth surface, (c) mixture of smooth and rough structures at laser-treated zirconia surface, and (d) laser-treated rough zirconia surface.[4]

surface along the scanning direction. Since the overlapping ratio is high, the area where the laser intensity incident onto the untreated neighboring surface becomes larger than that corresponding to the initially formed cavity surface. Therefore, laser intensity remains high on the untreated neighboring surface than that of the initially formed cavity surface because of the Gaussian intensity distribution of the incident laser beam. Low intensity causes partial melting of the initially formed cavity surface while modifying surface texture and altering the surface roughness along the scanning tracks. The micro-sized cavities are few and they are randomly distributed at the surface. The formation of micro-sized cavities can be explained in terms of the thermal agitation of the surface plasma at the irradiated surface. In this case, evaporated front absorbs the incident laser energy and forms small surface plasma, which is transiently hot.[70] The surface plasma acts like an additional heat source at the surface while increasing the cavity size during the ablation.

Figure 7 shows scanning electron microscope micrographs of the cross-section of the laser-treated layer. Laser treatment results in dense layer at the surface because of the high cooling rates in this region. The dense layer consists of fine grains and closely spaced fine dendrites forming a feathery-like structure in this region. The formation of dense layer is because of high cooling rates at the surface while forming the small grains. The surface layer has higher density than that of the untreated substrate below the dense layer, which causes volume shrinkage in the surface region. The dissolution of ZrN through NO_X formation and volume shrinkage in the dense layer causes some small size voids to be formed below the dense layer. However, the voids are small and few in numbers in the treated layer. As the depth below the surface increases, slightly longer and larger columnar structures are formed. This is attributed to the relatively lower cooling rates taking place in this region as compared to that in the surface region. Microcracks are not observed in the dense layer and in the large columnar region despite the occurrence of high cooling rates at the workpiece surface. This is because of the self-annealing effect of the lately formed laser scanning tracks. In this case, lately formed tracks act as heat source to initially formed tracks while generating a self-annealing effect on the previously formed tracks. The heat-affected zone is not observable at the interface of the laser-treated layer and the base material, which is associated with the low thermal conductivity of zirconia.

Figure 8 shows XRD diffractograms of the laser-treated and as-received surfaces. As-received material comprises of tetragonal ZrO_2 (t-ZrO_2). The presence of ZrN peaks are observed from the diffractogram for the laser-treated surface. The use of nitrogen at pressure is responsible for the formation of ZrN compound at the surface. However, ZrN compound is formed through a two step process. Firstly, the transformation of tetragonal structure of zirconia (t-ZrO_2) into cubic zirconia (c-ZrO_2), which takes place at high temperatures at the surface. Secondly, oxygen release through the dissociation process, which results in formation of zirconium nitride (ZrN). Therefore, the chemical process can be outlined as: $t\text{-}ZrO_2 \rightarrow c\text{-}ZrO_2$ and $2ZrO_2 + N_2 \rightarrow ZrN + O_2$, which occurs at elevated temperatures (above the melting temperature). However, the reactions that take place in the surface vicinity results in formation of vacancies in the zirconia,[71] which alters the surface energy. Elemental composition across the treated surface remains almost uniform, which can be observed from Table 6, in which the EDS data obtained from the laser-treated surface are given. Although the quantification of light elements, such as nitrogen, from the EDS data involves error, the presence of nitrogen is evident from the EDS data. This agrees with the presence of ZrN peaks in the XRD diffractogram. Table 7 gives the microhardness and fracture toughness of the

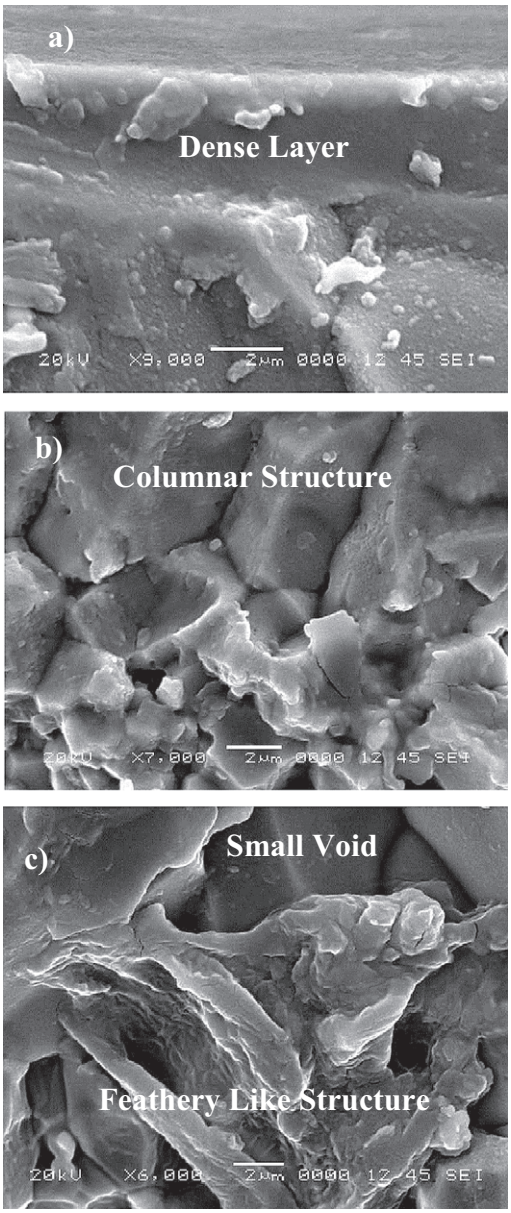

Figure 7 SEM micrographs of cross-section of laser-treated zirconia layer: (a) dense layer formed at the surface vicinity, (b) columnar structure formed below the surface, and (c) feathery-like structure in the treated layer.[4]

laser-treated and as-received surface. It is evident that the laser treatment improves the microhardness at the surface, however, fracture toughness reduces because of the microhardness enhancement at the surface. The formation of a dense layer, feathery-like structures, and presence of ZrN compound in the surface vicinity are responsible for the microhardness enhancement at the surface. The linear dependence of d(113), in nanometer unit, on $\sin^2\psi$ in the region of laser-treated surface can be used to determine the residual stress. The Zr_3O peak takes place at 63.106°, which corresponds to (113) plane with the inter-planar spacing of 0.147 2 nm. The slope of the curve indicates that the in-phase residual stress is compressive. The XRD experiment for the residual stress measurement was repeated five times at four locations at the laser-treated workpiece surface to secure the repeatability of the results. The error related to the measurements is estimated as 3%. The residual stress predicted is compressive and it is in the order of -1.6 ± 0.05 GPa.

Figure 9 shows images obtained from the contact angle measurements and **Table 8** gives the contact angles measured at different locations on the surface. The surface texture and surface energy influence the wetting properties of the surface.[68] Since the surface texture composes of micro/nano grooves, the wetting state varies across the surface. In addition, formation of ZrN at the surface alters the wetting state due to modification of the surface energy; in which case surface energy of laser-treated reduces due to formation of ZrN.[72,14] In the present study, the surface energy of laser-treated workpieces is measured as 49.33 mJ m^{-2}, which is very close to finding of the previous study (52.6 mJ m^{-2}) for ZrN.[15] In addition, the surface energy of as-received (untreated) workpiece is measured as 55.31 mJ m^{-2}, which is in agreement with the data reported in the previous study (56.1 mJ m^{-2}) for zirconia.[72] Consequently, laser treatment reduces the surface energy of the workpiece while contributing to surface hydrophobicity increase. Moreover, the combined wetting states can be explained through the Laplace pressure. In the case of nano-sized texturing, having a heterogeneous interface, confining the water at the air/water interface takes place. However, increasing Laplace pressure allows more air to be trapped in the groove, which in turn prevents the droplet meniscus touching the bottom surface of the groove while causing increased contact angle. The Laplace pressure estimated varies at the laser-treated surface because of combined micro/nano textures. The Laplace pressure estimated is in the range of $0.9 \times 10^4 - 0.1 \times 10^4$ Pa. This indicates the presence of Cassie state,[67] which can also be seen from the images of contact angle measurements. At some locations, where the micro-texturing is dominant, the Laplace pressure calculations lose its meaning and water meniscus touches the treated surface. Wenzel state[66] dominates in this region and the contact angle reduces, which can be seen from the image in **Figure 9**. The composite surface texture with the combination of micro/nano grooves results in two state of hydrophobicity at the treated surface, which can be seen from **Figure 9**. Since the droplet angle measurements repeated at nine locations at the treated surface, seven locations prevails the presence of Cassie state and two locations are in Wenzel state; therefore, Cassie state dominates over Wenzel state. It can also be observed from the photographs that in the first case (rough surface), Wenzel state takes place; therefore, the water droplet penetrates into the grooves and touches the surface without presence of the air gap.

2.5.4.3 Rene 41

The results obtained from laser-treated Rene 41 surfaces are given in line with the previous study.[5] Rene 41 sheets measuring 20 mm × 15 mm × 3 mm (length × width × thickness) are used in the experiments. The water soluble phenolic resin (thermoset viny-phenolic resin) mixed with B_4C and SiC particles are applied to the workpiece surfaces separately.

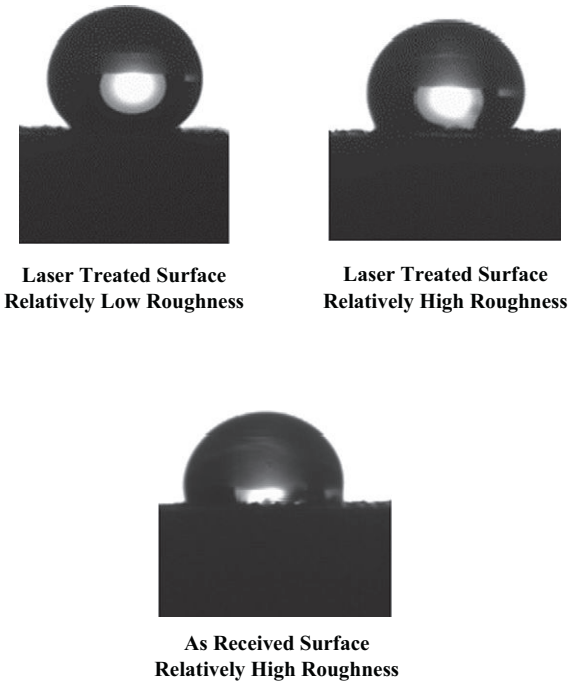

Figure 9 Photographs of water droplet shapes on the zirconia surface.[4]

The samples prepared for B_4C (only) and SiC (only) at the surface are kept at 8 bar argon pressure and 175 °C for 2 h in the furnace. The conversion of the phenolic matrix into carbon layer is ensured through monitoring the density. The average size of the B_4C and SiC particles is in the order of 2 and 4 μm, respectively, and the volume fraction of B_4C and SiC particles inserted into the carbon film is about 5%.

Figure 10 shows SEM micrographs of laser-treated surface. It can be observed that laser-treated surface composes of regular tracks, which are formed during laser scanning at the surface. Since laser pulses at high frequencies (1500 Hz) is used during scanning, overlapping of irradiated laser spots is responsible for the formation of these tracks. The overlapping ratio of laser irradiated spots is estimated as 70%, which in turn results in continuous melting of the surface along the laser scanning track. The close examination of the surface reveals that no melt

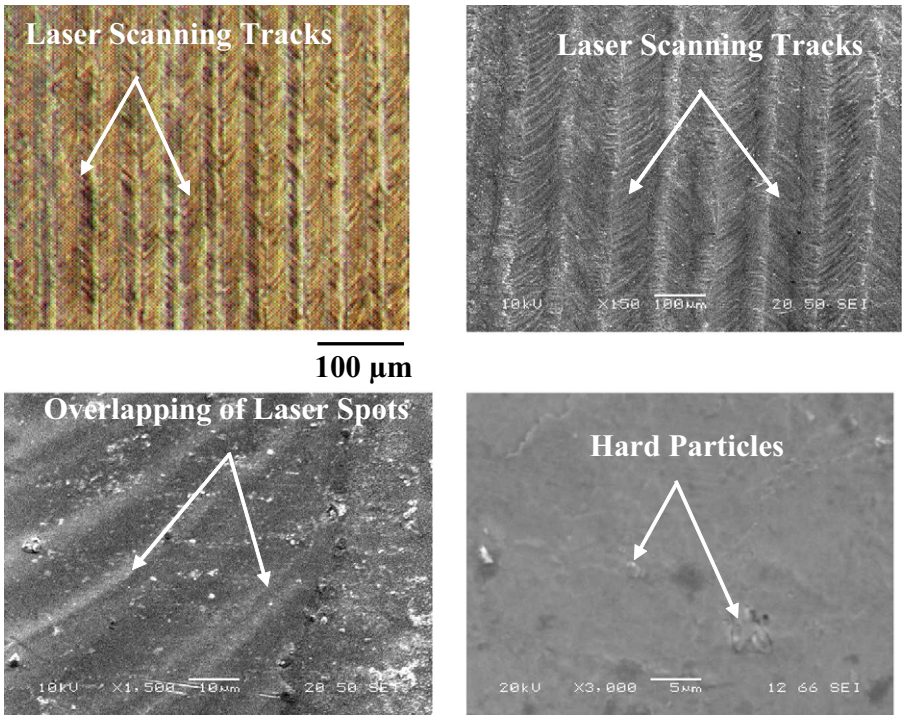

Figure 10 Optical and SEM micrographs of laser-treated Rene 41 surface with presence of B_4C particles.[5]

flow across the tracks and large size cavities are observed at the treated surface. This indicates the proper selection of laser parameters during scanning of the surface. It should be noted that slight increase in laser output power and decrease in scanning speed cause surface evaporation in the irradiated region. This, in turn, results in cavities and melt overflow at the surface while increasing the surface roughness. Surface roughness of the laser-treated workpiece is in the order of 2.3 µm, which is considerably low. Treated surface is free from asperities such as voids and cracks. This is attributed to self-annealing effect of the lately formed laser scanning tracks, which suppress stress levels in the region of the initially formed tracks. In this case, heat conduction from lately formed laser scanning tracks toward initially formed laser scanning tracks suppresses the cooling rates at the treated surface. Moreover, partially imbedded hard particles are evident from SEM micrographs. This is because of the high melting temperature of carbide particles, which remain in solid phase during the treatment process. Although thermal expansion coefficients of hard particles and the base material are different, no micro-cracks or crack networks are observed in the vicinity of the hard particles at the surface. It should be noted that expansion and contraction of hard particles differ from that of the base material; consequently, micro-stresses are formed in the near region of the hard particles after solidification of treated surface. The carbon film at the workpiece, prior to laser treatment, forms carbonic gasses during the high temperature laser processing at the surface. In addition, full wetting of the hard particles is observed at the surface, i.e., no partially wetted particle while causing a void in its near neighborhood is observed. It should be noted that because of the differences in thermal expansion coefficients between the hard particles and the base substrate, wetting state of the particles may change during the solidification process. In this case, the surface tension force, due to melted base material, generated around the hard particle surface overcomes the force created by the differences in thermal contraction between the melted metal and the solid hard particle during the solidification.

Figure 11 shows SEM micrographs of cross-section of laser-treated regions. Laser-treated layer, mainly, composes of three

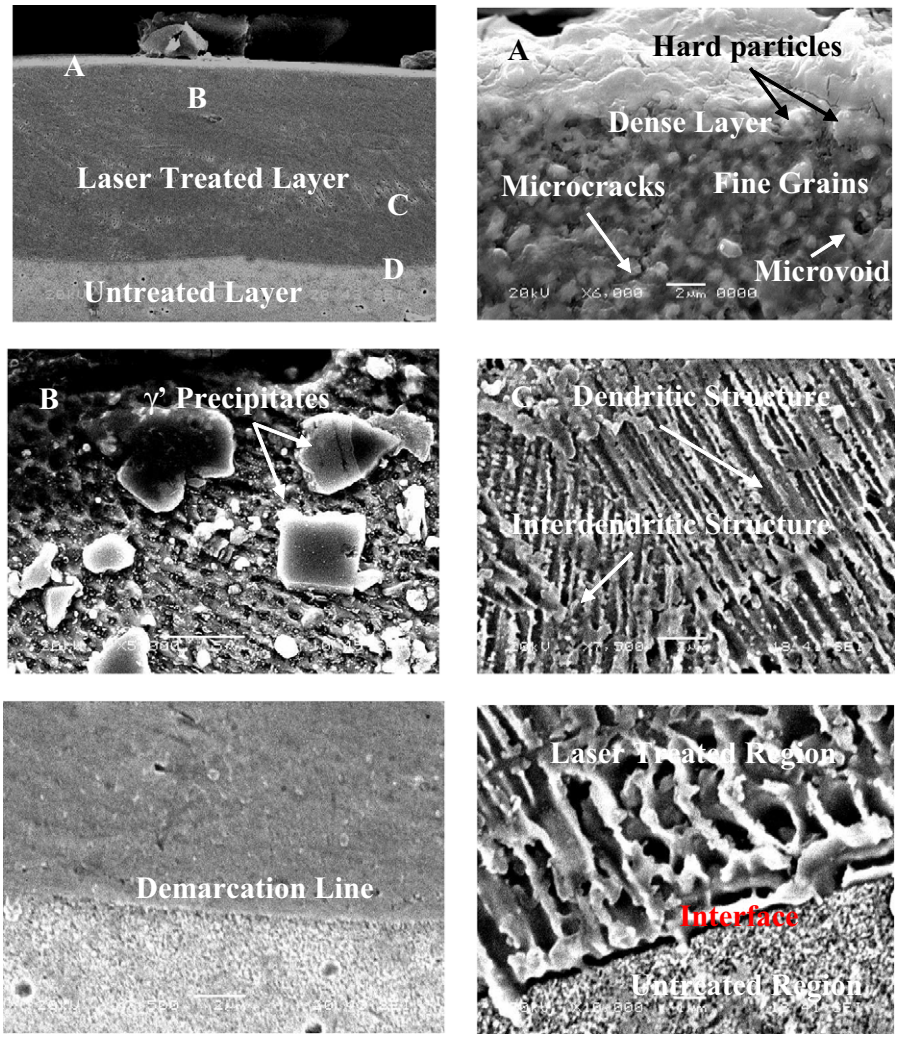

Figure 11 SEM micrographs of laser-treated layer cross-section for Rene 41: (a) Cross-section, (b) Dense layer composes of fine grains and hard B4C particles, (c) γ' phases below the treated surface, (d) dendritic structure and short interdendritic arms, (e) demarcation line at the vicinity of heat-affected zone, and (f) interface between treated layer and the untreated base material of Rene 41.[5]

regions. In the first region, a dense layer is formed, which consists of fine grains and hard particles. This is attributed to high cooling rates at the surface and high melting temperature of hard particles. Convection effect of the assisting gas contributes to cooling rate enhancement at the surface. However, dense layer increases the density of the treated layer while causing volume shrinkage in this region. Therefore, volume shrinkage due to the density mismatched in the treated layer causes increased stress level, particularly in the interface zone of the first region. Moreover, mismatch of thermal expansion coefficients between hard particles and base material contributes to the stress levels in the surface region, which is particularly true for B_4C carbide particles ($12.6 \times 10^{-6}\,K^{-1}$), which have higher thermal expansion coefficient than that of SiC particles ($5.68 \times 10^{-6}\,K^{-1}$).[73] Consequently, few microcracks are observed around B_4C particles in the region close to the surface. These cracks are locally distributed and do not conform a crack network below the surface of laser-treated layer. This is attributed to the stress relaxation after the microcrack formation in the neighborhood of hard particles. In addition, a micro-void next to the hard particle is observed, which is associated with the difference between the contraction rates of hard particles and base material as well as surface texture of hard particles. It should be noted that the wettability state of the surface is highly influenced by the surface texture.[74] Nevertheless, the size of the voids is small and they are few in number, which do not cover a large area in the treated layer. The dendritic structures are formed in the region below the dense layer and locally distributed MC carbides are formed in the interdendritic regions (where M represents Ti and Mo). This is attributed to the interdendritic zones where solidification takes place slowly and liquid phase solidifies lastly. This in turn, results in solute enrichment leading to the formation of MC carbides.[75] The secondary dendrite arms are present because of large dendrites formed below the dense layer, which are attributed to relatively slow cooling rates as compared to that of at the surface. γ' phases of cubic morphology are also observed in this region and their sizes varies. Since small solutes precipitate diffuse to form large ones, the coarsening of γ' phases takes place through minimization of

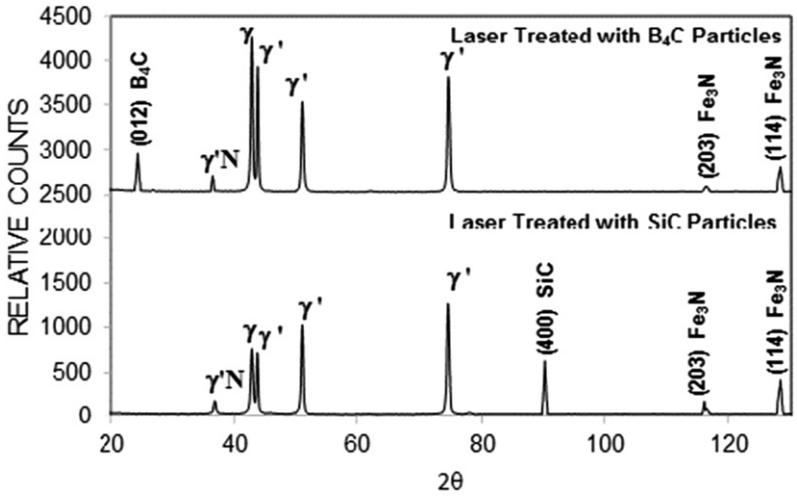

Figure 12 X-ray diffractogram for laser-treated Rene 41 surfaces.[5]

Table 9 EDS data obtained at laser-treated surface with presence of particles (wt%). Each spectrum represents a treated surface with different particles

interfacial energy.[76] The presence of heat-affected zone is evident and the demarcation zone is clearly observed between the treated layer and base material.

Figure 12 shows X-ray diffractogram of the laser-treated surface with presence of B_4C and SiC separately at the surface. $\gamma'N$ nitride peak is evident from the diffractogram at the surface, which is subjected to high pressure nitrogen assisting gas during the treatment process. Therefore, high temperature reactions at the surface results in formation of $\gamma'N$ nitride species at the surface. In addition, γ and γ' phases are visible in the diffractogram. The presence of B_4C and SiC peaks reveal the existence of solid phase particles at the surface vicinity. Fe_3N peaks are observed in the diffractogram, which is attributed to a high pressure nitrogen assisting gas impinging at the surface. Due to small volume of intermetallic phases, MC carbides are not observed in the diffractogram. The EDS data (as shown in Table 9) reveals that the elemental composition of laser-treated and untreated surfaces are almost the same. In addition, aluminum reduction does not occur at the treated surface unlike the observation presented in the previous study.[77] The quantification of nitrogen, which is one of the light elements, is involved with an error in energy dispersive spectroscopic analysis, yet its presence is evident from the EDS data.

Indentation test results for microhardness are given in Table 10 for laser-treated and untreated surfaces. The data presented in the previous study for laser induced surface nitriding are also included for the comparison reason. In general, inclusion of hard particles (TiC, SiC, and B_4C) results in higher microhardness at the surface than that corresponding to laser gas assisted nitrided surface. This is associated with the

Table 10 Microhardness data for TiC and laser-treated, laser-treated, and as-received surfaces

	Microhardness (HV)	*Residual stress (MPa)*
As-received surface	390	–
Laser nitrided surface	460	−680
TiC and laser treated	520	−850
SiC and laser treated	500	−720
B_4C and laser treated	610	−890

micro-stress levels developed in the close region of the hard particles at the surface. In addition, laser-treated surface with presence of B_4C particles results in the highest microhardness. This is attributed to thermal expansion and contraction of B_4C particles, which is higher than those of SiC and TiC.[73] Consequently, the micro-stress levels developed in the near region of B_4C particles become higher than those of due to SiC particles. As compared to base material hardness, laser treatment enhances microhardness at the surface, which is because of the formation of fine grains, nitride species, and micro-stresses developed due to presence of hard particles in the surface region.

The (114) reflection from the ε-Fe_3N (ICDD-PDF4 04-007-2962) was used for residual stress measurements. The measurements were carried out normal to the workpiece surface and the linear dependence of d(114) on $\sin^2\psi$ in the region of laser-treated surface was established. The ε-Fe_3N peak takes place at 128.445°, which corresponds to d(114) plane with the inter-planar spacing of 0.8570 Å. The linear dependence of d(114) results in the slope of -5.08×10^{-13} m and the

intercept of 0.8570×10^{-10} m for the laser-treated surface containing B_4C particles. The residual stress, therefore, determined from the XRD technique at the surface vicinity is of the order of -890 ± 30 MPa. The measurements are repeated for the other laser-treated surfaces containing SiC particles. XRD measurements are repeated three times and the error related to the measurements is of the order of 3%. Residual stresses are given in Table 10 for laser-treated with presence of hard particles and laser gas assisted nitrided surfaces. Residual stress increases with presence of hard particles, which is more pronounced for B_4C particles. This is because of high micro-stress levels developed around the hard particles at the surface, particularly in the near region of B_4C particles. In addition, the formation of dense layer in the surface region, due to high cooling rates, causes the volume shrinkage in the surface region, which contributes to residual stress enhancement at the treated surface.

2.5.5 Concluding Remarks

Laser surface treatment offers considerable advantages over the conventional methods. In order to achieve the desired texture and characteristics at the treated surface, the proper selection of the laser treatment parameters are essential. Metallic and nonmetallic material surfaces can be treated with high precision, in which case, surface asperities including micro-cracks, voids, and cavities can be avoided. In addition, the use of high pressure nitrogen assisting gas forms the nitride species at the surface, which improves the microhardness and hydrophobicity of the surface. Laser scanning along the closed spaced tracks at the workpiece surface creates self-annealing effect in the treated region while modifying the cooling rates at the surface. This in turn lowers the thermal strain and stress levels in the laser-treated layer. The conclusions of the case studies are given in line with the previous studies under the appropriate subheadings.

2.5.5.1 Phosphorous Bronze

The laser-treated phosphorous bronze surface consists of micro/nano poles and cavities, which result in superhydrophobic characteristics at the ablated surface. The average contact angle of the surface is 142°, which is well above that corresponding to as-received surface. The use of high pressure nitrogen assisting gas gives rise to the formation of Cu_3N phase at the surface, which contributes to the formation of a dense layer in the vicinity of the ablated surface via volume shrinkage. A dense layer comprises of submicron-sized packed particles and extremely fine grains, which in turn contributes significantly to microhardness enhancement at the surface. Microhardness of the laser ablated surface is four-fold higher than as-received workpiece surface, which in turn lowers the friction coefficient at the surface. The residual stress formed in the surface vicinity is compressive and it is in the order of -350 ± 10 MPa. The findings reveal that laser ablation of phosphor bronze provides superhydrophobic surface, high hardness, reasonably low residual stresses, and low friction coefficient.

2.5.5.2 Yttria-Stabilized Zirconia

The surface of laser-treated zirconia is free from large size cracks and cavities and the surface texture composes of fine grooves. The surface roughness was well-altered by the laser processing with the maximum surface roughness generated to be of the order of 0.35 μm. This in turn, modifies the wetting state of the surface, provided that Cassie state dominates over Wenzel state at the treated surface. In addition, formation of ZrN modifies the surface energy while contributing to the hydrophobicity enhancement at the surface. A dense layer consisting of fine size grains are formed at the surface. The volume shrinkage, because of the dense layer formation at the surface, causes few scattered voids in the dense layer. The treated surface is free from large scale asperities such as micro-cracks and crack networks, and large size pores and cavities. The use of high pressure nitrogen assisting gas during the processing resulted in the formation of ZrN compounds at the surface. Laser treatment increased the microhardness and lowered the fracture toughness of the surface. The measured decrease in the fracture toughness was associated with the microhardness enhancement at the surface. The residual stress measured from the X-ray diffraction data is in the order of -1.6 ± 0.05 GPa, which is compressive.

2.5.5.3 Rene 41

The laser-treated Rene 41 surface is free from large size asperities such as cavities and cracks. High cooling rates results in dense layer formation in the surface region while causing volume shrinkage and contributing to residual stress formation. Use of nitrogen at high pressure as an assisting gas results in formation of nitride species, such as $\gamma'N$ and Fe_3N at the treated surface. These new nitride phases also contribute to microhardness and residual stress enhancement at the treated surface. MC carbides are formed in the interdendritic regions below the dense layer. Due to the mismatch between the thermal expansion coefficients of hard particles and base substrate, micro-stresses are formed in the neighborhood of hard particles, which is more pronounced for B_4C particles. In this case, the wetting characteristics of hard particles vary and few micro-voids are formed adjacent to B_4C particles. In addition, because of high thermal expansion confident of B_4C, few scattered micro-cracks are observed around B_4C particles. Residual stress is the highest for laser-treated surface with presence of B_4C particles, then follows SiC and B_4C particles.[5]

2.6.1 Idea of Induction Surface Hardening

Induction hardening in general is such a form of the heat treatment in which a whole metallic workpiece or only its selected part is heated by induction, then kept for a short period of time for a temperature equalization and finally quenched. It is a modern, innovation, environment-friendly, and energy saving heat treatment technology especially frequently used for axi-symmetric and flat steel elements. It is in fact the most popular application of induction heating in industry especially in case of the surface treatment.[1]

The idea of the surface hardening is connected with the hardening of rather thin surface zone only and keeping the internal part of the treated material soft, which means in general remaining of not hardened structure in internal parts of the material. Due to features of the induction heating the surface induction hardening could be realized as stationary or continual. The first solution means induction heating and immediate cooling by spraying or by merging the body into a container with any suitable quenchant. The second solution means simultaneous heating and the consequent immediate cooling of the heated part.

In general the induction surface hardening consists of three consecutive stages:

I. Induction heating. Fast heating of the surface and a thin layer of the material to be hardened provided during a short heating time t_h up to a hardening temperature T_h being bigger than the upper critical temperature A_{c3}. The metallurgical result of the stage should be forming the uniform austenite microstructure,
II. Austenitization. It means holding a temperature of the body during short, but sufficient period of time t_e in order to obtain a structural equilibrium in the hardened zone of the body,
III. Quenching. It means the intensive cooling of the body in order to achieve the more harder, stable martensitic microstructure.

In the surface induction hardening process the austenitization time t_e is often minimized to a technological break between heating and cooling only, necessary to remove the body from the inductor into cooling treatment region.

The main factors influencing on the hardness and the depth of the hardening zone are as follows:

- chemical composition of steel,
- temperature distribution within the body,
- starting microstructure of the material,
- quenching conditions.

Induction surface hardening is realized mostly for steel with the carbon content of about 0.35–0.6%. Content of carbon influences the maximum obtained hardness.[2]

A typical time evolution of temperature within the hardened body is shown in **Figure 1**. The induction heating starts from any initial temperature which could be in general equal to the ambient temperature T_a. In order to obtain the requested uniform austenite microstructure before quenching the final temperature at the surface and in the thin surface layer of the body should be bigger than the upper critical upper temperature A_{c3}

$$T_h = T|_{t_h+t_e} \geq A_{c3} \qquad [1]$$

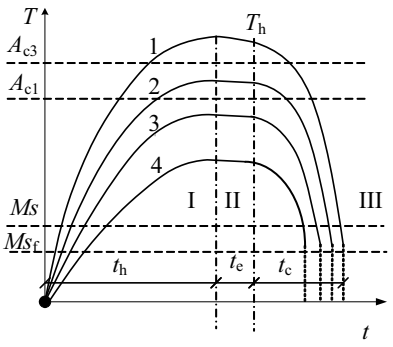

Figure 1 Time evolution of temperature in different zones of the hardened body. I – induction heating, II – austenitization, III – quenching. 1 – curve for zone with expected completely hardened material, 2 – curve for zone with expected incompletely hardened material, 3 and 4 – curves for zones of expected not hardened material, A_{c3} and A_{c1} – upper and lower critical temperature, Ms – martensite start temperature, Ms_f – martensite finish temperature, T_h – hardening temperature, t_h – heating time, t_e – austenitization time, and t_c – quenching time.

 doi:10.1016/B978-0-12-803581-8.09189-X

In order to secure the structural equilibrium of the material the hardening temperature should be sufficiently bigger than the A_{c3} temperature

$$T_h = A_{c3} + (35 \div 50)\ ^\circ C \quad [2]$$

As it is mentioned such a condition is satisfied not only at the surface but also at the thin zone near the surface of the body represented for instance by curve 1 in **Figure 1**. It represents the part of material with the uniform austenite microstructure. We could expect that a complete hardening characterized by the uniform acicular martensitic microstructure and the highest hardness will be noticed there. However, for deeper zones of the material the temperature is smaller than the upper critical temperature A_{c3}, but still higher than the lower critical temperature A_{c1}

$$A_{c3} \geq T|_{t_n+t_e} \geq A_{c1} \quad [3]$$

For such temperatures of the material the austenite begins to form, but the process is not completed. So in this zone of the body represented for instance by the curve 2 in **Figure 1** we obtain the not fully formed austenite microstructure and we may expect here the incomplete hardened material. The resultant hardness is smaller than at the surface of the body and the microstructure contains a mixture of martensite, pearlite, and ferrite. And finally for more deeper layers of the body the material does not reach even the lower critical temperature A_{c1}

$$T|_{t_n+t_e} \leq A_{c1} \quad [4]$$

The austenite microstructure do not start to form and the material remains unchanged. When the temperature before cooling is only slightly smaller than the lower critical temperature A_{c1} we could observe, depending on grade of steel, a tempering phenomenon (see curve 3 in **Figure 1**). If the temperature before cooling is distinctly smaller than the lower critical temperature A_{c1} (see curve 4 in **Figure 1**) the material remains unchanged.

For the dual frequency induction surface hardening of the process if the induction heating stage is divided into two parts (**Figure 2**):

Such a kind of induction surface hardening is applied for instance for gear wheels. It makes possible to obtain the specific contour zone.[3] The first longer period of the induction heating is characterized by a high current of the medium frequency MF and when the average temperature of the body surface reaches a prescribed value, the final part of induction heating realized by a current of lower value and higher frequency HF is provided. A time break between them t_b should be as small as possible. Resulted hardness of the material and its microstructure finally depend on cooling. The classical time temperature cooling (CCT) diagram for a typical plain carbon steel presenting cooling of the material from the hardening temperature T_h being sufficiently bigger than the upper critical temperature A_{c3} is shown in **Figure 3**. The CCT diagram shows the dependence of the resultant hardness on the time of cooling.

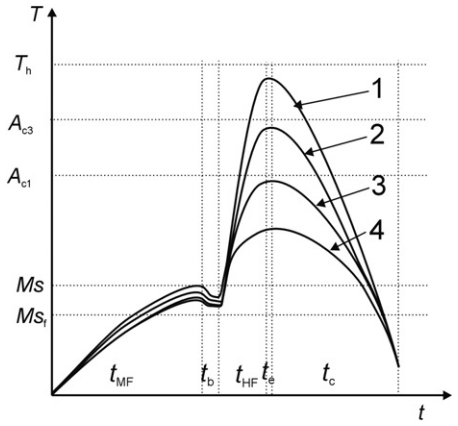

Figure 2 Time evolution of temperature in different zones of the hardened body for the dual frequency induction hardening. MF – medium frequency, HF – high frequency, t_b – time of break between MF and HF heating. Other denotations as in **Figure 1**.

For the surface zone the cooling lines start from the hardening temperature T_h. Its value at the moment when cooling starts

$$T|_{t_n+t_e} \geq A_{c3} \quad [5]$$

is still higher than the upper critical temperature.

When the hardened material reaches *Ms* temperature the transformation from austenite into martensite begins. Cooling should terminates at a temperature lower than the martensite finish temperature Ms_f defined as a temperature when 99% of the austenite transforms into the martensite

$$T|_{t_n+t_e+t_c} < Ms_f \quad [6]$$

The higher velocity of cooling means obtaining the harder microstructure. For the cooling lines from **Figure 3** only three of them pass through the martensite region (M). For them the final temperature of material after heating and cooling satisfy inequalities eqns [5] and [6], respectively, and we obtain the uniform acicular martensitic microstructure. It leads to the complete hardening process for a part of the body which is characterized by such a time evolution of temperature. Resultant hardness of 750, 735, 700 HV, respectively, as well as acicular martensitic microstructure are achieved. It is characteristic that induction surface hardening provides to slightly higher hardness that it would be achieved for the conventional hardening. The phenomenon is sometime referred as a super hardening.[4] The next curves characterized by a lower speed of cooling (located in the right part of **Figure 3**) pass through the areas of the CCT diagram containing bainite (B), pearlite (P), or ferrite (F). It leads to an incomplete hardening process which means the lower hardness and mixed microstructure containing partly martensite with the addition of bainite, pearlite, and ferrite. For the very slow cooling ($v_c = 0.02\ K\ s^{-1}$) the resultant hardness is equal to 263 HV only. The material in this part of the body remains unchanged.

Another problem is connected with a speed of heating. For the induction hardening it is characteristic a big value of the

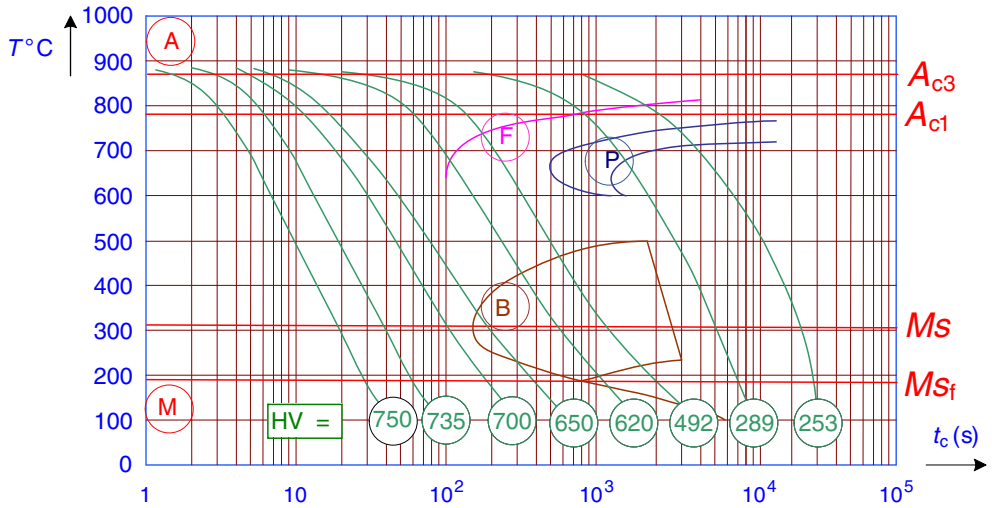

Figure 3 The classical time temperature cooling diagram for a typical plain carbon steel. M – martensite, A – austenite, B – bainite, P – pearlite, F – ferrite, and HV – hardness in Vickers degrees.

heating rate, which could reach in some cases values of about 1000 K s^{-1} or more. It causes a change of critical temperatures. So for such a rapid heating the relation [2] is not valid. In order to obtain the uniform austenite microstructure of the material it is necessary to heat the body till the distinctly bigger hardening temperature T_h. It resulted by increasing the temperature of beginning and termination of austenite transformation in comparison with the classical process and consequently increasing of the hardening temperature T_h

$$T_h = A_{c3} + \Delta T(v_c) \qquad [7]$$

Transformations taking place during austenitization with a big velocity of induction heating could be analyzed based upon the TTA diagrams (Time – Temperature – Austenitization) for the hardened material. As the example let us consider the TTA diagram for the plain steel with carbon content of 0.45%. Speed of pearlite – austenite transformation and criteria temperature increases with increasing speed of heating. In order to analyze this phenomenon some experiments are provided.[5] For classical conditions of conventional austenitization of samples made from the investigated steel the critical temperatures are as follow: $A_{c1} = 736$ °C and $A_{c3} = 801$ °C. The TTA diagram for the rapid induction heating taken from experiments is presented in **Figure 4**.[5]

The TTA diagram confirms that both criteria temperatures A_{c1}, A_{c3} strongly depend on the speed of heating. For example, if the speed of heating $v_h = 97$ K s^{-1} the lower critical temperatures increases to the value of $A_{c1m} = 781$ °C and the upper critical temperature to the value of $A_{c3m} = 879$ °C. In comparison with the determined earlier classical critical temperatures it means the increase of them of about $\Delta T = 50 \div 70$ °C.[5] Details are collected in **Table 1.**

At the highest applied speed of heating ($v_h = 1000 \div 3000$ K s^{-1}) the lower critical temperature A_{c1} increases till (804 ÷ 820) °C, however, the upper critical temperature A_{c3} also increases to (978 ÷ 1074)°C. In comparison with the determined earlier critical temperatures for the conventional hardening the distinct increasing is noticed:

$$A_{c1m} = A_{c1} + \Delta A_{c1}(v_c); \quad \Delta A_{c3} = 70 \div 80 \text{ K} \qquad [8]$$

$$A_{c3m} = A_{c3} + \Delta A_{c3}(v_c); \quad \Delta A_{c3} = 180 \div 270 \text{ K} \qquad [9]$$

For the conventional heat treatment process the hardening temperature $T_h = 840$ °C. It means that for a typical range of the induction heating speed (50 ÷ 1000 K s^{-1}) the hardening temperature T_h should be distinctly higher:

$$T_h \approx 1000 \div 1050°\text{C} \text{ and } \Delta T_h \approx 100 \div 210°\text{C} \qquad [10]$$

Dependence of the hardening temperature on speed of heating is shown in **Figure 5.**

Transformations taking place in samples made from steel with carbon content of 0.45% during fast induction surface hardening characterized by rapid both processes of heating and cooling are presented at the non-conventional TTC$_C$ (Time – Temperature – Cooling continual) diagram (**Figure 6**). It differs from the classical one (the similar classical diagram is shown in **Figure 3**). It is obtained by measurements. The samples of the hardened material are heated with the average speed of $v_h \approx 1000$ K s^{-1} to the hardening temperature $T_h = 1050$°C, then kept for austenitization at the short period of time $t_e = 2$ s and finally cooled by water spraying with an average speed of $v_c = 1 \div 333$ K s^{-1}.

The investigated steel in condition of induction hardening characterized by slightly bigger hardenability in comparison with a classical heat treatment. Martensite microstructure is obtained for samples cooled with a critical speed of $v_c \geq 100$ K s^{-1}. For samples cooled with speed of $v_c \approx 50$ K s^{-1} the microstructure contains not only martensite but also bainite. If the speed of cooling becomes more slower ($10 \text{ K s}^{-1} \leq v_c \leq 35 \text{ K s}^{-1}$) some particles of ferrite are appeared. For the smallest investigated speed of cooling ($0.01 \text{ K s}^{-1} \leq v_c \leq 7 \text{ K s}^{-1}$) the microstructure consists of mixture of martensite, bainite, ferrite, and pearlite.

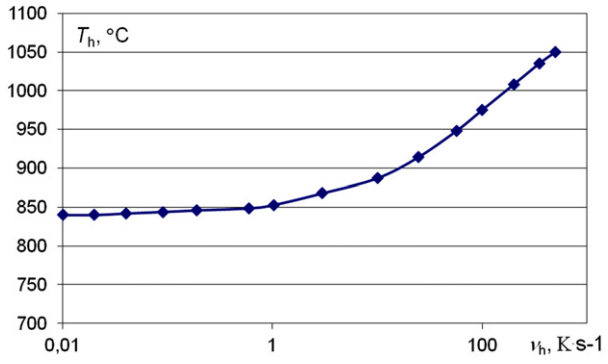

Figure 5 Dependence of the modified upper critical temperature A_{c3m} of the speed of heating.

The induction heating technology seems to be particularly suitable for the realization of this process because of:

- the possibility to locate the heat treatment process exactly within a surface layer of the body facing the inductor, whose thickness depends on many factors like: the field current frequency, the thermal material properties and heat transfer parameters of the body and the total heating time,
- developing very high volumetric power density in the hardened layer making possible to obtain thin hardened zones.

There are no general rules that allow to define the optimal values of:

- the distribution of the induced current in the hardened body,
- the induction heating time and its influence on the upper critical temperature,
- the time interval between the end of the induction heating and the beginning of the quenching,
- the speed of quenching.

All these mentioned above quantities depend on:

- material properties of the treated body,
- the shape of the workpiece and presence of any irregular parts (holes or edges),
- configuration of inductor–body system including thickness of the air-gap between the inductor and the body,
- the required thickness of the hardened layer.

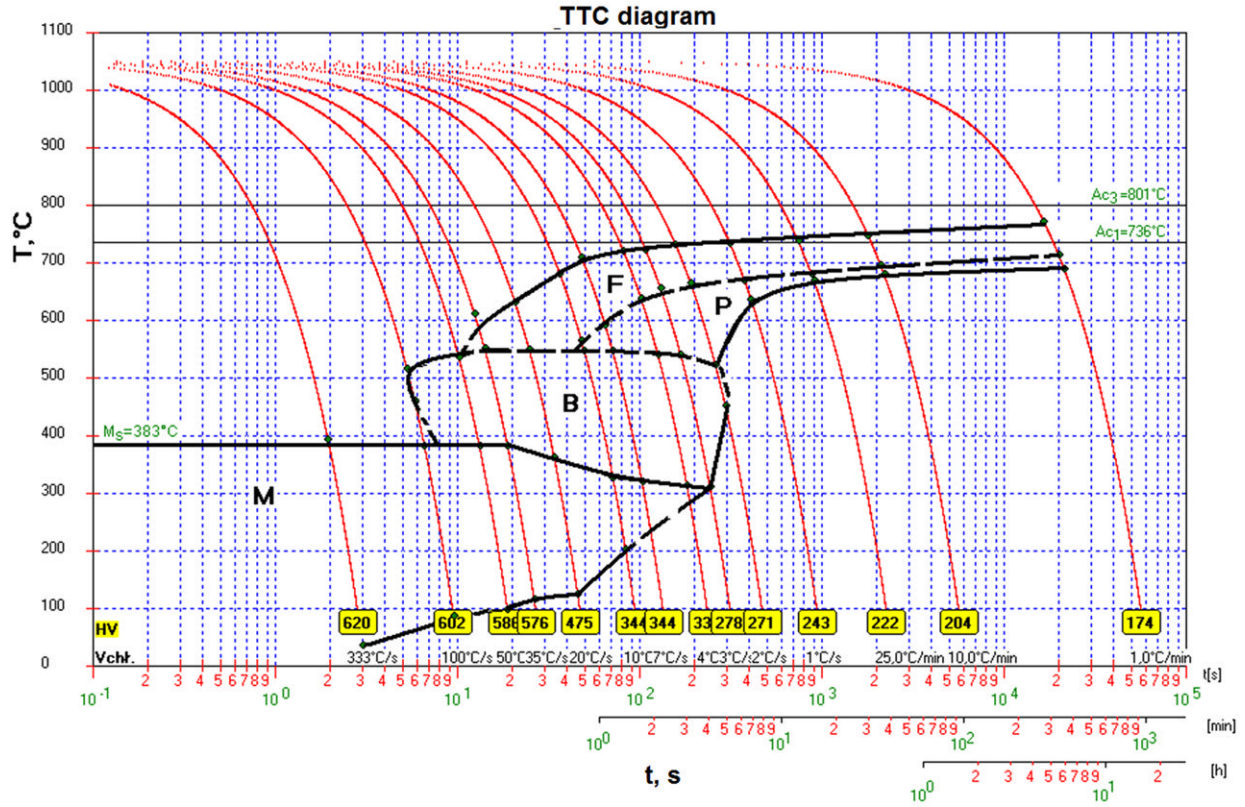

Figure 6 Modified diagram TTCc for steel with carbon of 0.48% obtained by dilatometric measurements.

The depth of hardening Δg is defined as a distance between the surface and any point inside the body where the hardness decreases to 80% of its minimal value at the surface.[4] However, hardness requirements are often more complicated. They of course depend on the particular technology. The requirements are often connected not only with the value of hardness and martensite microstructure at the surface of the body and in the thin surface zone but also with a hardness and microstructure distribution within the whole body. As a good example of such a specific demand the dual induction surface hardening of gear wheels should be shown. Let us consider the gear wheel made of the special quality steel with the carbon content of $0.43 \div 0.5\%$ (Figure 7).

The region of the tooth and its root are divided into four zones with different hardness requirements. The thin contour zone (1) is fully hardened with the acicular martensite microstructure. It is heated to the hardening temperature above A_{c3m}. For the investigated steel its hardness should reach values between $620 \div 720$ HV. For the analyzed case its thickness is $\Delta g = 0.2 \div 0.3$ mm. The transition zone (2) represents a part of incompletely hardened material with a hardness between $500 \div 660$ HV. Its value is lower than that in zone (1). The hardness of the internal zone (3) representing the core of the tooth should be below 500 HV. And finally, the hardness of the zone (4) containing the base material is required to be below 266 HV.

In order to implement the surface induction hardening into industry a numerical simulation is applied as the effective tool.

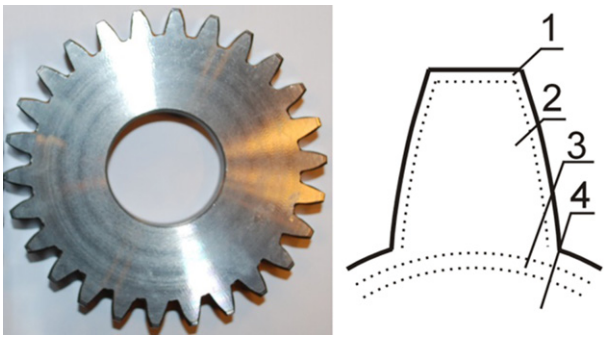

Figure 7 View of gear wheel and its zones with different hardness requirements. 1 – contour zone, 2 – transition zone, 3 – internal zone, 4 – zone of unchanged material.

However, the computations should be realized jointly with a successful experimental verification and adjustment of the inductor in order to achieve the required results.

2.6.2 Mathematical Modeling of Surface Induction Hardening Processes

Induction hardening requires description of interaction of several coupled physical fields: electromagnetic, temperature, heat stress, and metallurgical. They are described by means of

partial differential equations system for the separate fields with the exception for metallurgical field. Hardness and microstructure are mostly described based upon the experimental data. The simplified algorithm for such a computation model is shown in Figure 8.

For electromagnetic field calculations constant values for expected average temperature of the magnetic permeability μ and the electric conductivity γ are taken. Based upon the known distribution of electromagnetic field the volumetric Joule losses p_v released in the body are determined. Then temperature distribution within the body using average values of material properties: heat conduction λ, specific heat at constant pressure c_p, convection and radiation heat transfer coefficients α_{cc} and α_r, respectively, are calculated. If the average temperature of surface of the hardened body reaches prescribed value the induction heating stage terminates. The task is analyzed as the inverse problem using simplified optimization procedures in order to determine parameters of induction heating systems (field current density and its frequency, configuration and dimensions of inductor–hardening body system, heating time, or speed of movement) in order to achieve the required distribution of temperature in the hardened element. Then the distribution of heat stresses are determined. If deformations are too big it would be necessary to modify parameters of the induction heating process. Then temperature distribution at beginning of the intensive cooling is determined. Next the temperature field during intensive cooling in the quenchant is calculated with taking into account non-linear dependence of the convection heat transfer coefficient on temperature $\alpha_{ch}(T)$. Radiation is taken into consideration for the induction heating and the austenitization stages only. Such a simplification is correct for cooling by merging also for cooling by spraying, however, in the second case a radiation through semi-transparent layer may be taken

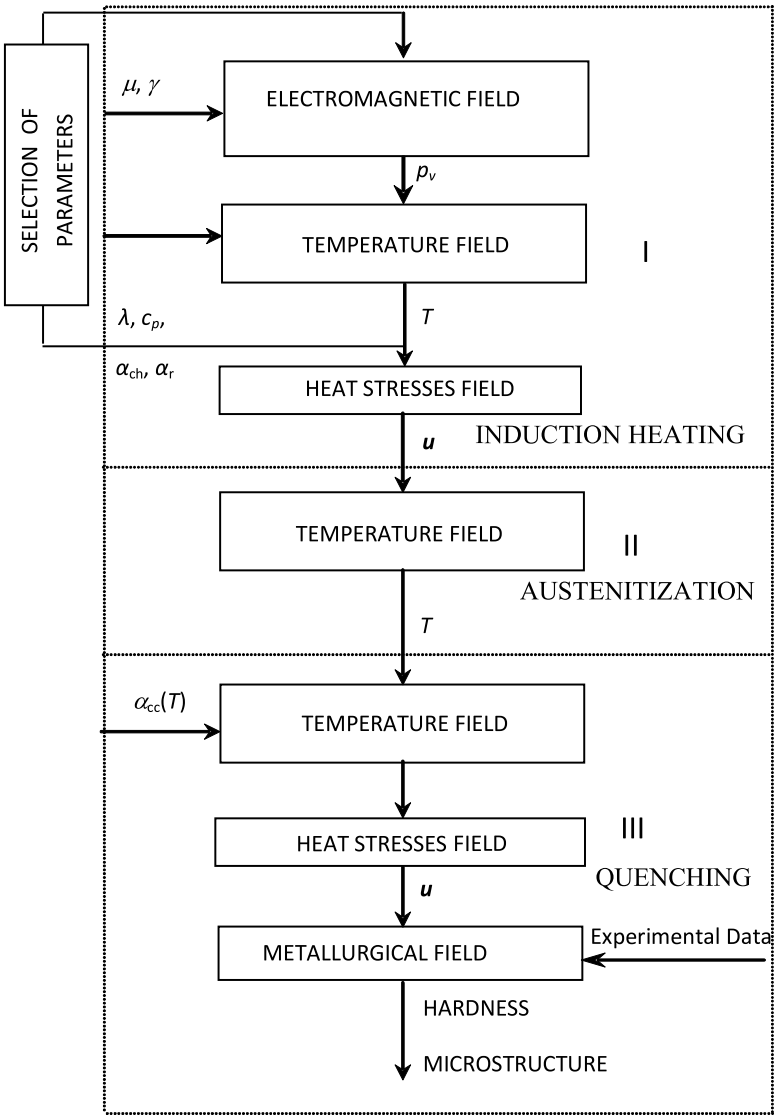

Figure 8 Simplified algorithm of two step coupled electromagnetic, thermal, heat stress, and metallurgical fields for modeling of induction surface hardening.

into consideration. The heat stresses are calculated again. If the final temperature reached the prescribed value (lower than the Ms_f temperature). Then hardness distribution and microstructure of hardened layer are determined. They are based on the experimental data. Such a simplified calculation method may cause significant errors. Its advantage is a simplicity. However, it is especially good in case of systems with complicated geometry like gear wheels. Its main advantage is mostly a relatively short time of computations.

In order to provide more precise calculations a direct coupled model is applied (Figure 9). In the stage I induction heating phenomena are analyzed. For material properties taken at an initial temperature T_i the electromagnetic field is calculated. As a result of these calculations the magnetic flux density

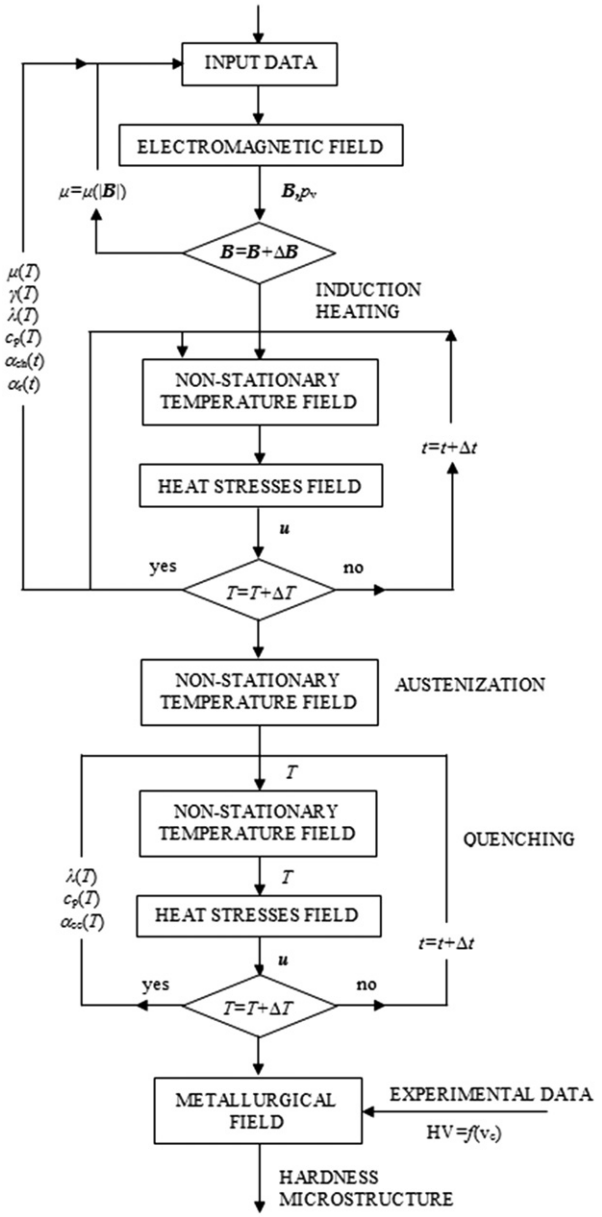

Figure 9 Algorithm of electromagnetic, thermal, heat stress, and metallurgical fields indirect coupled formulation.

$\boldsymbol{B}$ and volumetric Joule losses p_v for particular time are determined. If for any next stage the calculated value of magnetic flux density $\boldsymbol{B}$ differs from the previous one more than as assumed $\Delta\boldsymbol{B}$ the electromagnetic field calculations are repeated for the new value of magnetic permeability $\mu(B)$. Then nonstationary temperature field is calculated. If temperature increases more than of ΔT the material properties (conduction heat, specific heat, and both heat transfer coefficients) of heated body are corrected. Then electromagnetic computations are provided again for corrected values of magnetic permeability μ and electric conductivity γ. Heat stress field is determined in order to check if deformations are not too big.

Then the next cycle of the electromagnetic and temperature calculations is provided for the period of time $t+\Delta t$ until $t=t_n$ (the end of induction heating). Of course for small calculation steps Δt, $\Delta\boldsymbol{B}$, and ΔT a big accuracy could be achieved, but in opposite it causes a longer computation time. Then in the short stage of the austenitization the temperature distribution for time $t=t_n+t_e$ is calculated. The quenching begins with computations of nonstationary temperature field during intensive cooling in a fluid quenchant. Temperature decreasing of ΔT causes correction of material properties λ, c_p, α_{ch}, α_r in the next steps. At the next step the heat stress field is calculated again. Heat stresses and their distribution within the hardened body is a basis for a possible decision to repeat the computations or to continue the heat treatment by tempering. Calculations of quenching terminate at $t=t_n+t_e+t_c$ (see Figure 1) after achieving of selected criteria of the assumed time of intensive cooling or average final temperature being of order of the martensite finish temperature Ms_f. Then based upon the experimental data and registered history of cooling the hardness and microstructure distribution are determined.

Mathematical model of the process is described by a system of differential equations for electromagnetic, thermal, and heat stress fields. The electromagnetic problem is an open boundary task, but it may be considered as a classical closed boundary problem after location of the steel element inside the domain with external borders sufficiently distant to the inductor–body system. Dimensions of the domain is selected based upon some preliminary calculations. For the analyzed task the external border of the domain is selected in a sufficient distance from the inductor–workpiece system being at least seven time bigger than diameter of the hardened element.[6] Electromagnetic field is described by the classical equation for the magnetic vector potential $\boldsymbol{A}$[7]

$$\operatorname{curl}\left(\frac{1}{\mu}\operatorname{curl}\boldsymbol{A}\right)+\gamma\left(\frac{\partial\boldsymbol{A}}{\partial t}+\boldsymbol{v}\times\operatorname{curl}\boldsymbol{A}\right)=\boldsymbol{J}_z \qquad [11]$$

where μ denotes the magnetic permeability, γ is the electric conductivity, $\boldsymbol{v}$ is the velocity of movement, and $\boldsymbol{J}_z$ is the field current density.

For coreless inductor and for the case when the magnetic permeability of hardened element may be considered as constant at each cell of the system the eqn [11] may transform into the Helmholtz equation for the phasor of the magnetic vector potential $\underline{\boldsymbol{A}}$:

$$\operatorname{curl}\operatorname{curl}\underline{\boldsymbol{A}}+\mathrm{j}\omega\mu\sigma\underline{\boldsymbol{A}}-\mu\gamma(\boldsymbol{v}\times\operatorname{curl}\underline{\boldsymbol{A}})=\mu\underline{\boldsymbol{J}}_z \qquad [12]$$

where j denotes the imaginary unit and ω is the angular frequency.

The eqn [12] is simplified by neglecting the third term of the left side. It is possible when the velocity of inductor movement to the workpiece is not very big, which is normally satisfied in typical induction hardening installations. The problem is discussed with more details for instance in ref.[8]

$$\text{curl curl } \boldsymbol{A} + \mathrm{j}\omega\mu\gamma\underline{\boldsymbol{A}} = \mu\boldsymbol{J}_z \quad [13]$$

For surfaces of external borders of the domain:

$$\underline{\boldsymbol{A}} = 0 \quad [14]$$

For the symmetry plane $z=0$

$$\underline{\boldsymbol{A}} \times \boldsymbol{n} = \boldsymbol{0} \quad [15]$$

For 2D arrangement:

$$\frac{\partial \underline{\boldsymbol{A}}}{\partial \boldsymbol{n}} = 0 \quad [16]$$

Hysteressis losses are neglected. Eddy current density $\underline{\boldsymbol{J}}_{\text{ind}}$ and volumetric Joule losses p_{v} are expressed, respectively:

$$\underline{\boldsymbol{J}}_{\text{ind}} = \mathrm{j}\omega\gamma\underline{\boldsymbol{A}}, \quad p_{\text{v}} = \frac{\underline{\boldsymbol{J}} \times \underline{\boldsymbol{J}}^*}{\gamma} \quad [17]$$

Temperature calculations are provided by means of the Kirchhoff-Fourier equation supplemented by internal heat source represented by the volumetric Joule losses taken from electromagnetic calculations[9]

$$\text{div}(\lambda \text{grad} T) - \rho c_p (v \text{grad} T) - \rho c_p \frac{\partial T}{\partial t} = -p_{\text{v}} \quad [18]$$

where λ denotes heat conduction, ρ is the density, and c_p is the specific heat.

On symmetry planes:

$$\frac{\partial T}{\partial n} = 0 \quad [19]$$

At external surfaces of the body the third kind of boundary condition of convection and radiation heat transfer is satisfied[10]

$$-\lambda\frac{\partial T}{\partial n} = \alpha_{\text{ch}}(T - T_{\text{c}}) + \sigma_{\text{o}} \cdot \varepsilon_{\text{p}}\left(T^4 - T_{\text{r}}^4\right) = \alpha_{\text{ch}}(T - T_{\text{c}}) + \alpha_{\text{r}}(T - T_{\text{r}}) - p_{\text{r}} \quad [20]$$

where α_{ch} denotes convection heat transfer coefficient for induction heating, T_{c} is the temperature of convection environment, σ_{o} is the Stefan–Boltzmann constant, ε_{p} is the total emissivity, T_{r} is the temperature of radiation environment, and p_{r} is the component connected with multiple reflection phenomena.

Often we could suppose that $T_{\text{c}} \approx T_{\text{r}} = T_{\text{cr}}$. It is possible as well to neglect multiple reflection phenomena.[11,12] Then we could apply one general heat transfer coefficient α_{g} taking into account convection and radiation heat transfer between steel element and surroundings

$$-\lambda\frac{\partial T}{\partial n} = \alpha_{\text{g}}(T - T_{\text{c}}), \quad \alpha_{\text{g}} = \alpha_{\text{cc}} + \sigma_{\text{o}} \cdot \varepsilon_{\text{p}}\left(T^2 + T_{\text{cr}}^2\right) \cdot (T + T_{\text{cr}}) \quad [21]$$

For surface induction hardening the inductor is often supply by high frequency field current. Volumetric Joule losses are concentrated practically only near the surface. From the numerical point of view it is better to neglect volumetric Joule losses in eqn [18] and introduce to the condition eqn [20], additional term of the surface power density p_{s}. For cylindrical workpiece of diameter R the surface power density p_{s} could be determined based upon assumption that the heat delivered to the elementary surface with length of dz is equal to the heat released due to eddy currents

$$q = p_{\text{s}} \cdot 2\pi R \cdot \text{d}z = \int_0^R p_{\text{v}} \cdot 2\pi r \cdot \text{d}r\text{d}z \quad [22]$$

where q is the heat delivered to the body during unit of time.

So the eqn [18] and boundary condition eqn [20] transform to forms eqns [23] and [24], respectively

$$\text{div}(\lambda \text{grad} T) - \rho c(\boldsymbol{v}\,\text{grad} T) - \rho c\frac{\partial T}{\partial t} = 0 \quad [23]$$

$$-\lambda\frac{\partial T}{\partial n} = \alpha_{\text{c}}(T - T_{\text{c}}) + \alpha_{\text{r}}(T - T_{\text{r}}) - p_{\text{r}} - p_{\text{s}} \quad [24]$$

During induction heating and especially during intensive cooling could appear heat stresses connected with non-uniform temperature distribution within the hardened body. Heat stress field and associated deformations may be described by Lame equations for displacements[14]

$$(\varphi_{\text{u}} + \psi_{\text{u}})\text{grad div } \boldsymbol{u} + \psi_{\text{u}}\nabla^2 u - (3\varphi_{\text{u}} + 2\psi_{\text{u}})\alpha_{\text{T}}\text{grad } T + f_{\text{m}} = 0 \quad [25]$$

where φ_{u} and ψ_{u} coefficients defined by means of relations eqns [26] and [27], respectively, $\boldsymbol{u}$ is the vector of displacements, α_T is the temperature extension coefficient, and f_{m} and volumetric density of the Lorentz force.

$$\varphi_{\text{u}} = \frac{v \cdot E}{(1 + v) \cdot (1 - 2v)} \quad [26]$$

where v is the the kinematic tension coefficient and E is the Young's modulus.

$$\psi_{\text{u}} = \frac{E}{2(1 + v)} \quad [27]$$

$$f_{\text{m}} = \boldsymbol{J}_{\text{ind}} \times \text{curl } \boldsymbol{A} \quad [28]$$

Based upon known distribution of displacements tensors of deformations ε and stresses σ are determined.

$$\left.\begin{aligned}
&\varepsilon_{xx}=\frac{\partial u_x}{\partial x},\quad \varepsilon_{yy}=\frac{\partial u_y}{\partial y},\quad \varepsilon_{zz}=\frac{\partial u_z}{\partial z},\\
&\varepsilon_{xy}=\frac{1}{2}\left(\frac{\partial u_x}{\partial y}-\frac{\partial u_y}{\partial x}\right),\quad \varepsilon_{yz}=\frac{1}{2}\left(\frac{\partial u_y}{\partial z}-\frac{\partial u_z}{\partial y}\right),\\
&\varepsilon_{zx}=\frac{1}{2}\left(\frac{\partial u_z}{\partial x}+\frac{\partial u_x}{\partial z}\right)
\end{aligned}\right\} \quad [29]$$

$$\left.\begin{aligned}
&\sigma_{xx}=\varphi_L\left(\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}\right)+2\psi_L\varepsilon_{xx}-(3\varphi_L+2\psi_L)\alpha_T\cdot T,\\
&\sigma_{yy}=\varphi_L\left(\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}\right)+2\psi_L\varepsilon_{yy}-(3\varphi_L+2\psi_L)\,\alpha_T\cdot T,\\
&\sigma_{zz}=\varphi_L\left(\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}\right)+2\psi_L\varepsilon_{zz}-(3\varphi_L+2\psi_L)\alpha_T\cdot T,\\
&\sigma_{xy}=2\psi_L\varepsilon_{xy},\quad \sigma_{yz}=2\psi_L\varepsilon_{yz},\quad \sigma_{zx}=2\psi_L\varepsilon_{zx}
\end{aligned}\right\} \quad [30]$$

Values of displacements appeared during induction heating is rather small (about 10^{-6} m or less). Only if speed of induction heating is very big they may take into consideration.

The austenitization stage is analyzed based upon eqn [23] and boundary condition eqn [21]. And finally the next stage is intensive cooling of the steel element in quenchant. For this stage the eqn [23] could be applied. The boundary condition has a form of eqn [31]

$$-\lambda\frac{\partial T}{\partial n}=\alpha_{cc}\cdot\left(T-T_q\right) \quad [31]$$

where α_{cc} denotes temperature dependent convection heat transfer coefficient for cooling and T_q is the temperature of quenchant.

For determination of temperature field a key role plays accuracy of heat transfer coefficient α_{cc}. The best way seems to be its determination by measurements of the material sample of a shape similar to the analyzed element.[13]

The basic part of the numerical analysis of induction surface hardening is the directly coupled electromagnetic thermal problem (**Figure 10**). So in further part of the chapter where illustrative example will be present heat stress problems are neglected and the basic interest is concentrated on coupled electromagnetic thermal problem.

Selection of input data is done in a way described previously. Material properties of hardened element and its temperature dependences are measured. In case of the magnetic permeability its dependence on temperature and on module of the magnetic flux density, obtained also from measurements, is taken into consideration. Dependence of the magnetic permeability on field current frequency is neglected. Arrangement of the induction hardening system is selected based upon preliminary calculations and database systems. Electromagnetic and temperature fields are considered by the modified indirect coupled approach, which is different from this one presented in **Figure 9**.[13] Boundary condition for temperature field takes into account radiation with multiple reflection phenomena. The computation of induction heating terminates when the average temperature in the surface zone of the material reached the prescribed value being a range of the hardening temperature. This value is determined by measurements using the modified TTA diagram. Then computations of non-stationary temperature field during austenitization with

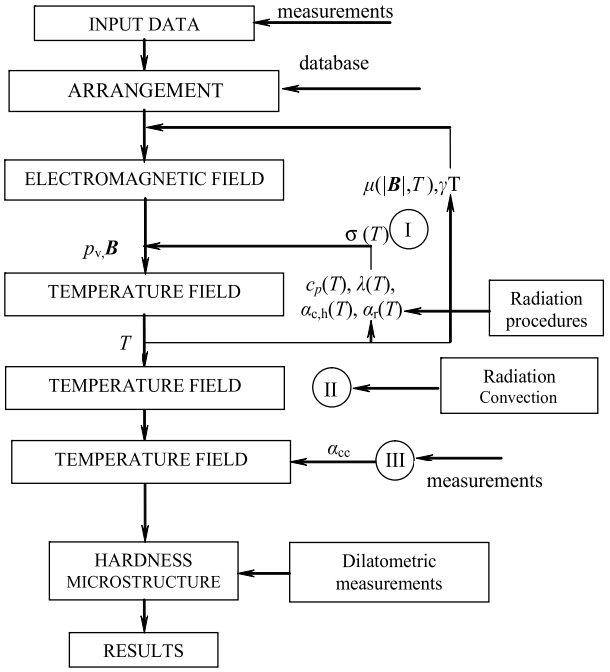

Figure 10 Calculation model of modified indirect coupled electromagnetic and temperature for simultaneous induction surface hardening. I – induction heating, II – austenitization, and III – cooling.

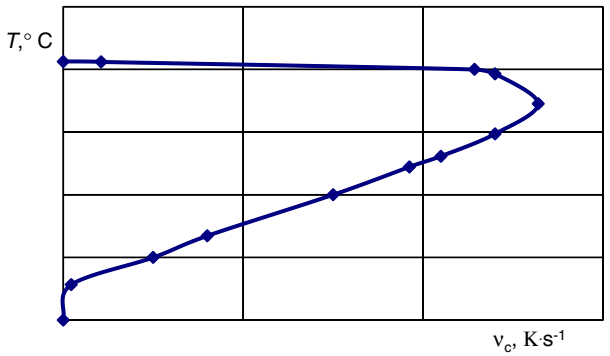

Figure 11 Dependence of temperature on cooling velocity of a cylinder made from the investigated steel in water.

taking into account both convection and radiation are provided. After that nonstationary temperature field with convection only is calculated. The convection heat transfer coefficient α_{cc} is determined by measurements provided at samples of investigated material. Dependence of temperature on cooling velocity (**Figure 11**) and time (**Figure 12**) in water of a cylinder made from the investigated steel are determined by the specialized measuring system.[13]

Based upon curves from **Figures 11** to **12** and the heat balance eqn [32] it is possible to determine the convection heat transfer coefficient and its dependence on temperature (**Figure 13**)

$$q=\rho c_p\cdot V\cdot v_c(t)=\alpha_{cc}(T)\cdot S\cdot\left(T-T_q\right) \quad [32]$$

Determination of $\alpha_{cc}(T)$ for the real hardened element having in general a different shape than the cylindrical sample is realized by means similarity criteria using Nusselt and Reynolds numbers (Holman). Calculation of nonstationary temperature field during cooling terminates when the average temperature at the body surface satisfy eqn [6]. Then based upon obtained from dilatometric measurements the CCT diagram the hardness and microstructure distribution is determined.

The computation algorithm for continual induction surface hardening is presented in **Figure 14**.

Numerical algorithm for computation of the continual induction hardening is based on the assumption that the continual movement is replaced by n small discrete shifts Δl.[15]

$$\Delta l = v \cdot \Delta t \qquad [33]$$

where v is the velocity of movement and Δt is the time step.

The number of shifts n should be sufficiently big in order to achieve the expected accuracy of the modeling. Calculations begin at the starting position of the inductor–sprayer system. The distribution of electromagnetic field in the total area and corresponding volumetric density of the Joule losses in the hardened element are determined. Then the temperature field is calculated. Material properties and heat transfer parameters for heating and cooling are corrected in iteration procedures. During induction heating the convection heat transfer α_{ch} is determined based upon Nusselt criterion Nu

$$\alpha_{ch} = \frac{Nu \cdot \lambda_f}{d} \qquad [34]$$

where λ_f denotes conduction heat of fluid in a layer near surface of the element and d is the characteristic dimension.

Determination of the convection heat transfer α_{cc} for cooling by spraying is more complicated. A way of its determination is described for instance in refs.[11,12] For that case the procedure consists of following steps:

- experimental induction hardening of the steel element made from the same material and having the same shape and based upon known parameters of spraying like flow-rate of quenchant and its pressure,
- measurement of hardness distribution,
- determination of convection heat transfer for the investigated sample based upon known unbalanced phase diagrams for the hardened material,
- usage of criteria of similarity including Nusselt and Reynolds numbers in order to recognize convection heat transfer coefficient for investigated body.

The presented procedure makes it possible to determine average value of the convection heat transfer coefficient for analyzed range of temperature.

Exemplary dependence of the convection heat transfer coefficient during cooling by spraying α_{cc} on temperature is presented in **Figure 15**.

Achieved results for water spraying are about 10 times smaller than for cooling in water by merging. The temperature distribution in the whole hardened element at all time steps is determined. Then inductor–sprayer system is removed for the next position and computations are repeated. If the final position of the inductor–sprayer system is reached, hardness and microstructure distribution is determined.

2.6.3 Calculation Example

Let us consider as the illustrative example the induction surface hardening of bending brakes. The arrangement of the hardening system is presented in Figure 16.

Surface of the element which should be fully hardened is depicted in Figure 16 (segments BC, B′C′), however, the segment CD and C′D′ should remain soft. Segment AB, A′B′ may be incompletely hardened. Induction hardening is provided as continual process. Inductor–sprayer system moves along the z axis with a velocity of several millimeter per second. Typically the frequency of the field current is equal to several kHz. It means that currents induced in the hardened body because of movement could be neglected.[10]

There are two reasons making very difficult to solve the problem as nonstationary. The first of them is connected with

a long computation time due to a disproportion between the field current frequency and the time of heating. The second reason requires more detailed explanations. The magnetic permeability of hardened body used for the electromagnetic computations is temperature dependent. However, when we start the electromagnetic distribution of temperature within the hardened body is unknown. So the distribution of the magnetic permeability is also unknown. In order to simplify the computation model and to shorten the computation time the analyzed domain of the element is divided into two parts (Figure 17).

It is assumed that in the first part – thin surface layer the temperature exceeds the temperature of the magnetic transformation and the relative magnetic permeability

$$\mu_r|_{T \geq T_{Curie}} = 1 \quad [35]$$

Dimensions of the thin surface layer are determined based upon estimations.

In all remaining points of the element the temperature does not exceed the temperature of the magnetic transformation and

$$\mu_r|_{T < T_{Curie}} = \mu_r(|H|) \quad [36]$$

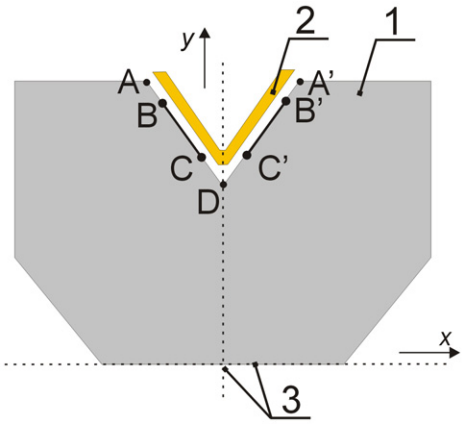

Figure 16 Cross-section of bending brake. 1 – element, 2 – inductor, and 3 – symmetry axes.

The problem is solved for the following parameters of the hardening system:

1) material: steel C50E with a carbon content of about 0.48%,
   a) its critical temperatures $Ms = 325\ ^\circ C$, $A_{c1} = 730\ ^\circ C$, $A_{c3} = 780\ ^\circ C$, $A_{c3m} = 880\ ^\circ C$,
   b) hardening temperature $T_h = 930\ ^\circ C$,
   c) dependence of hardness on velocity of cooling is determined from the CCT diagram, dependence of material properties on temperature are taken into account,
   d) hardness requirements: 600÷720 HV in thin surface zone between points BC, less than 600 HV in thin surface zone between points AB, not hardened material in other points.
2) dimensions: length $l = 0.118$ m, width $b = 0.095$ m, and height $h = 0.0125$ m
3) inductor and its supply parameters:
   a) copper conductor of the rectangular cross-section $3 \times 9 \cdot 10^{-3}$ m,
   b) field current density $J_z = 1.05 \times 10^7$ A m^{-2},
   c) its frequency $f = 10$ kHz,
   d) velocity of inductor–sprayer system movement $v = 2 \times 10^{-3}$ m s^{-1}.
4) heat transfer and cooling parameters:
   a) quenchant: water in spray of temperature $T_q = 10\ ^\circ C$,
   b) generalized heat transfer coefficient for heating $\alpha_{ch} = 20$ W m^{-2} K^{-1},
   c) convection heat transfer coefficient for cooling $\alpha_{cc} = 500$ W m^{-2} K^{-1},
   d) ambient temperature $T_a = 30\ ^\circ C$.

Numerical model for analysis of continual induction surface hardening of the bending brakes steel is presented in Figure 18. At the beginning ($t = 0$) the inductor–sprayer system is located in the initial position (depicted by lower Ω_2 in Figure 18). After some period of time because of continual movement with a small velocity $v = 10^{-3}$ m s^{-1} the system changes its position into the final one (depicted in Figure 18 by the upper Ω_2).

Calculations start with the completion of input data partly based on measurements of material properties. At the beginning the stationary induction heating of the front part of the bending brake is provided. Computation of the quasi-stationary

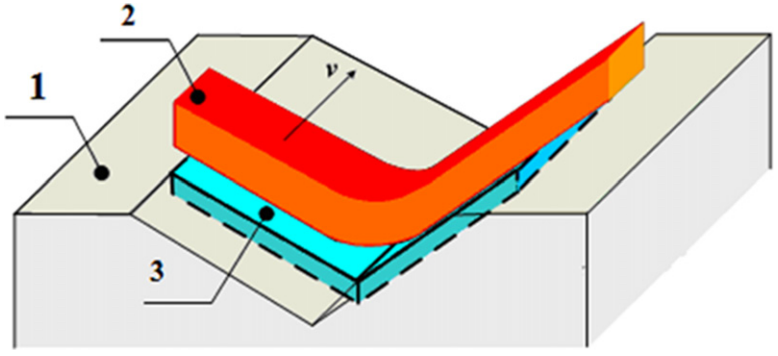

Figure 17 The view of the hardening system. 1 – bending brake, 2 – inductor, 3 – thin part of the element with temperature bigger than the temperature magnetic transformation.

electromagnetic field for the starting position of the inductor–sprayer system is provided. Based upon known value of the volumetric Joule losses the nonstationary temperature field is calculated. After a selected period of time the inductor–sprayer system starts to move. Continual movement of inductor–sprayer system is replaced by a number n of discrete shifts. It means a different configuration of the inductor–sprayer system in each position and time dependent boundary conditions of the temperature field. The time step $\Delta t = 0.5$ s corresponds to the shift $\Delta l = 10^{-3}$ m. For each cycle the dependence of material properties on temperature is taken into consideration. Results of temperature distribution is saved in order to use them for further hardness determination. Then the inductor–sprayer system is shifted to the next position and the computations are repeated. When the final position of inductor–sprayer system is reached the cooling of last part of the bending brake is calculated and then the hardness distribution is determined. The calculations are provided by the FEM based single-owned software prepared in the framework of the Polish–Czech project (Figure 19).[15,16]

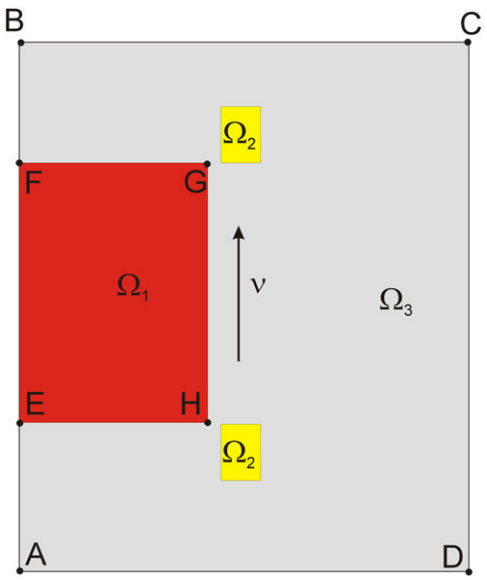

Figure 18 Numerical model for analysis of continual induction surface hardening of steel element Ω_1 – element, Ω_2 – inductor, and Ω_3 – surroundings.

The mesh for electromagnetic field has about 250 000 elements, but for the temperature field contains about 30 000 elements.

The time evolution of temperature during heating and cooling for two points on a line parallel to the axis z passing through a center of BC segment is presented in Figure 20.

The temperature in this zone reaches its maximum of 1000 °C. There are temperature differences before points along this line in a range of not more than 15 °C. However, the lowest value of the maximal temperature (not shown in Figure 20) is noticed in the front part of the body where induction heating

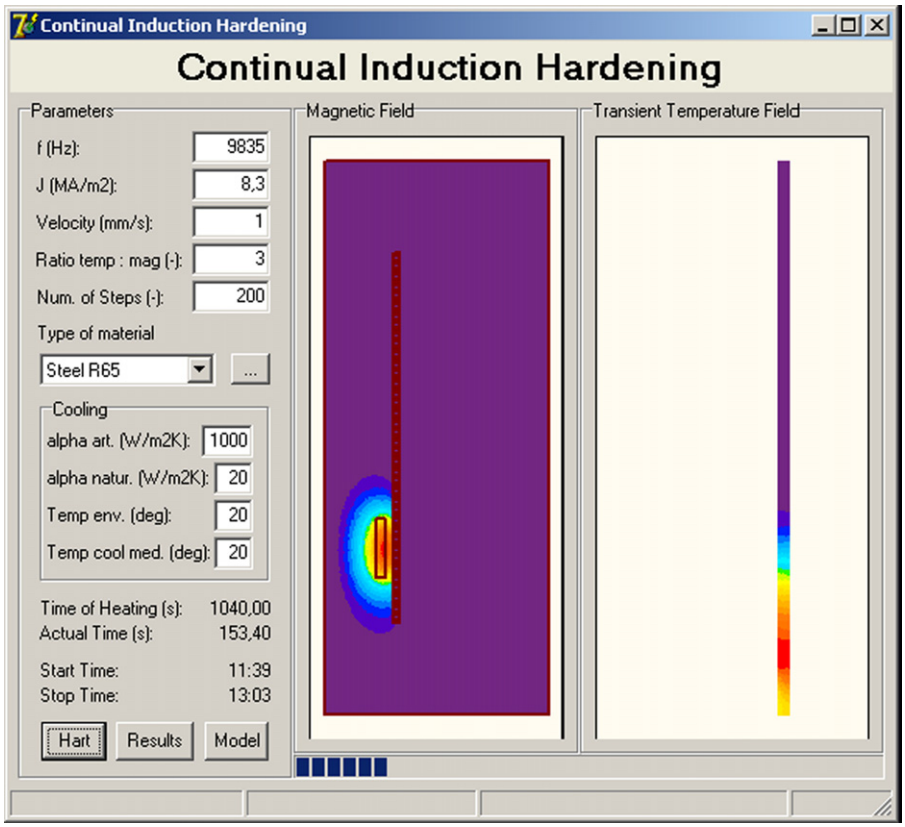

Figure 19 Cover page of the continual induction hardening software.

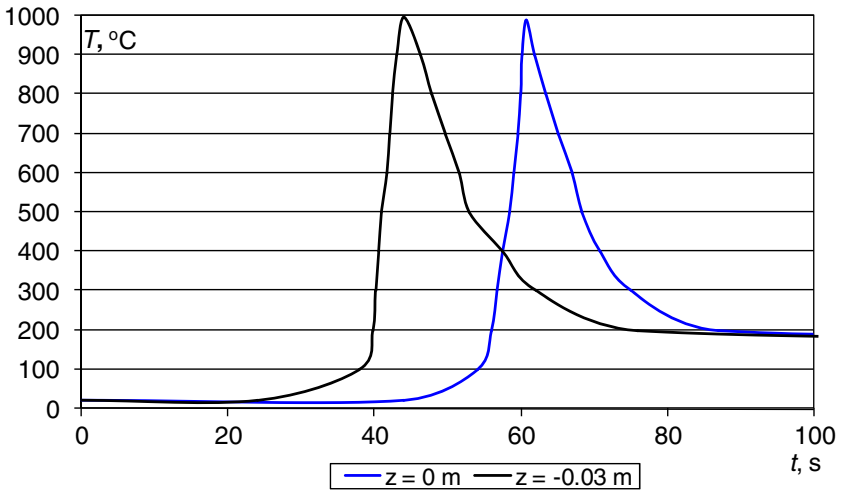

Figure 20 Time evolution of temperature on two selected points of central part of the bending brake in a line parallel to the axis z passing through a center of segment BC.

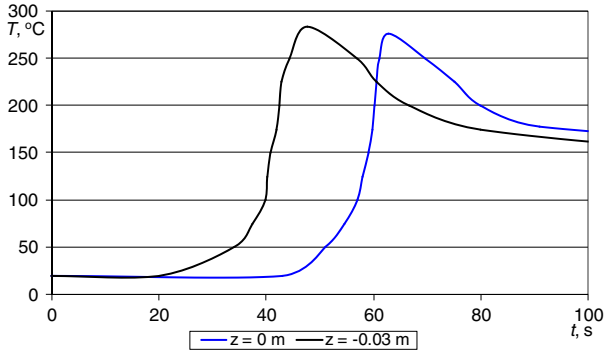

Figure 21 Time evolution of temperature of two selected points of central part of the bending brake in a line parallel to the axis z passing close to point D.

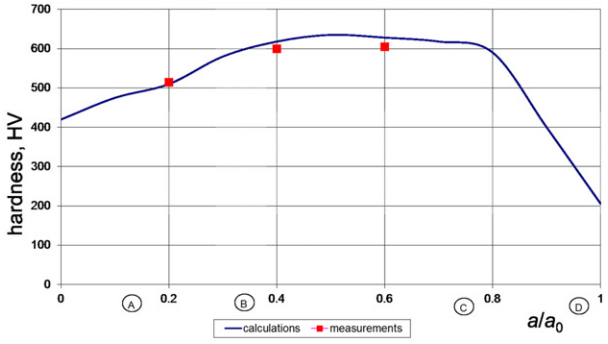

Figure 22 Hardness distribution along the line crossing the working surface of the bending brake. A, B, C, D points depicted in Figure 16.

starts (T=960 °C). Such a temperature evolution secures the complete hardening of the material in this part of the body.

The time evolution of temperature during heating and cooling for two points on a line parallel to the axis z passing through a point located near the point D is presented in Figure 21. According to requirements material in this zone of the bending brake should remain soft. Average value of temperature after induction heating does not exceed 290 °C, however, there are bigger differences between points along this line in comparison with a previous results. They are in a range of 70 °C with the maximum of 330 °C for not depicted in Figure 17 line for $z = -0.059$ m. Such a temperature evolution match the requirements and secures keeping the material soft in the part of the body.

But these calculations were provided with a simplification: without taking into radiation and multiple reflection phenomena. For comparison the similar computations by means of the Ansys package having a built-in special procedure making possible to analyze multiple reflection phenomena are provided. Taking into account both convection and radiation with multiple reflection phenomena increasing of the maximal temperature of about 60 ÷ 100 °C is noticed.

However, in order to optimize the hardening process and to get expected hardness during the whole element including boundary areas the process consists of three parts:

- stationary induction heating without movement t_i=7.5 s,
- continual hardening like described previously,
- stationary cooling of the end of the element without movement t_f=3.5 s.

Calculated and measured hardness distribution along the working surface of the bending brake for such a regime of hardening is presented in Figure 22.

There is a quite good accordance between measurements and computations with a maximal inaccuracy of 28 HV. Also distribution of hardness along the working surface match the requirements. At the upper corner of the hardened body the hardness exceeds 420 HV. It means the incompletely hardened zone. At the central part of the bending brake the hardness exceeds 600 HV. The material is fully hardened there. And finally at the lower part of the body near point D hardness is about 210 HV. It means that material remains soft. Dependence of hardness on distance from the working surface directed into the interior part of the treated material was presented in Figure 23.

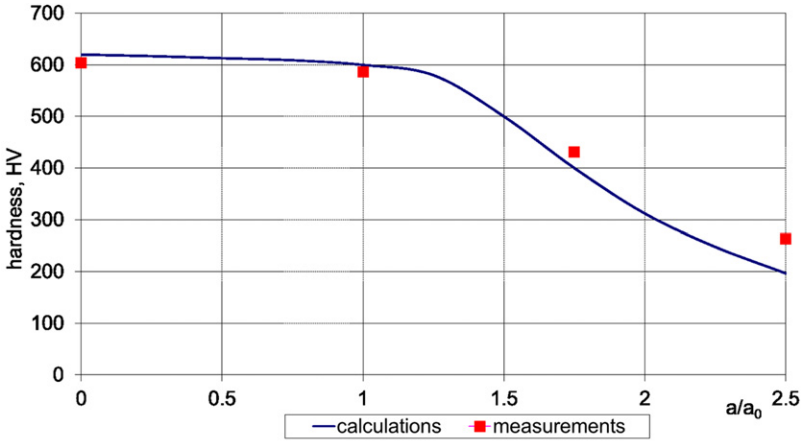

Figure 23 Hardness distribution in a function of distance from the surface.

Figure 24 Microstructure of steel C50E after induction hardening near point B (Figure 16). Acicular martensite with some retained austenite (enlargement $\times 800$).

The thickness of the hardness layer being equal to about 10^{-3} m seems to be reasonable and matching the requirements. The computations were compared with measurements provided on the laboratory stand. Quite good accordance being of order of $1 \div 3\%$ between computations and measurements is achieved. Both computations and measurements have confirmed that the length of the hardened later is acceptable and totally match the technological requirements. Another point seems to be the microstructure of the surface layer. The microstructure at the surface layer between point B and C is presented in Figure 24.

2.6.4 Some General Remarks on Induction Surface Hardening Installations

The design of inductors applied in induction surface hardening installations seem to be a complex problem.[1,4,17–23] Its solving, even with the use of advanced numerical programs, needs unfortunately expensive and time consuming experimental validation. The hardened bodies are often made from materials whose properties and their dependences on temperature are known with a big inaccuracy only. In any case in order to reduce time of experimental works it is necessary to predict the effect produced by a certain type of inductor in the different parts of the workpiece. It means estimation of the total induced power in the hardened body, its distribution within the body and on the treated surface and the inductor impedance of the inductor–body system. For frequently applied axi-symmetrical configuration of the inductor–body systems we can take into account the radial variations of the material properties produced by the temperature distribution necessary for the induction hardening. It is based upon assumption that the cylindrical workpiece can be divided into three zones (layers):

- external nonmagnetic surface layer representing zone with the average temperature exceeded the hardening temperature T_h,
- two internal zones the nonmagnetic layer with average temperature exceeded the Curie temperature and magnetic core with lower temperatures.

The design problem is more complicated for induction surface hardening of steel elements with more complicated shapes like for instance gear wheels.[1,4,5,16–18,23] A typical example of such a heat treatment seems to be the simultaneous induction surface hardening of gear wheels by means of cylindrical inductor. The purpose of the process is to obtain an uniform hardened layer along the whole working surface of the teeth including the tip, the flanks, and the roots. In this case, the choice of the optimal field current frequency has a big importance not only from the temperature distribution view point but also the electrical one. From the electrical viewpoint a good enough electrical efficiency of the inductor–hardened body system η_e defined as the ratio of the power released in the body P_i to the total power of the inductor:

$$\eta_e = \frac{P_i}{\int_V p_v \mathrm{d}V} \qquad [37]$$

has guaranteed requested energy transmission from the inductor to the hardened body. Of course it could be practically realized for gear wheels with the module satisfying inequality eqn [38]

$$m \leq 2 \div 3 \quad [38]$$

The choice of the field current frequency depends on the desired hardness thickness. This leads to the conclusion that the choice of single frequency heating system will be a kind of a compromised solution only. In fact it required the realization of the conditions mentioned above would theoretically require two different frequencies. In the case of the spin induction hardening the entire gear part is brought up to the hardening temperature by means of an inductor surrounding it and is subsequently quenched. The gears are rotated during heating to ensure an even distribution of energy. In doing this it is possible to through harden the gear part down to the tooth root (in the same way as the classical case hardening) or to harden the outer surface at either a uniform or irregular depth from the surface. Although the best pattern is usually an uniform thickness of the hardened layer along the contour, different patterns may be acceptable, or sometimes desirable depending on the application. In particular, breaks in the hardened layer may be accepted on the tips of the teeth where mechanical loading is very low, while on the flanks and roots it must be continuous in order to withstand big contact pressure and tensile stresses from loading. The main parameters playing a dominant role in obtaining the required hardness pattern are:

- geometry of the inductor–hardened body system,
- field current frequency,
- volumetric (surface) power density,
- total heating time,
- quenching conditions.

In particular, contour profile of the hardening layer can be obtained by a single frequency or dual frequency treatments. The single frequency single shot hardening process is a kind of the spin hardening in which all teeth are simultaneously contour hardened by means of a single frequency. It requires the use of high induced power density and short heating time in order to avoid the heat transmission from the surface layer to the core of the material and eliminate the possibility of through hardening of the teeth. Moreover, the process requires a convenient choice of the field current frequency in order to obtain suitable values of the induced power density at the flanks, tips, and roots of the teeth. In order to estimate the optimal value of field current frequency f_{opt} the formula eqn [39] is applied[23]:

$$f_{opt} \approx \frac{3 \cdot 10^5}{m^2} \quad [39]$$

where m denotes module of the gear in m^{-3}.

Often the single frequency induction surface hardening with preheating called also as the pulsing single frequency process has been used.[4] It consists of four consecutive stages:

- slow preheating with a reduced power to the temperature of about 500–700 °C (exact value of temperature is dependent on a grade of steel),
- fast main heating (pulse) to the hardening temperature with the high power density and in a relatively short time,
- immediate quenching,
- low temperature tempering.

Advantage of such a way of hardening seems to be:

- obtaining the correct contour zone with a convenient heated depth at the roots,
- no overheating of gear tips,
- better initial microstructure consisting of homogeneous fine grained tempered martensite,
- reduction of distortions.

Dual frequency induction surface hardening could be applied for gear wheels of rather small diameter ($d \leq 0.25$ m). This limitation is caused by a very short heating time and the corresponding high volumetric power density, which require the use of supply sources with output power of about several hundreds kW. The process is divided into four consecutive stages:

- slow preheating by applying a low power of medium frequency (MF) (3 kHz $\leq f_{MF} \leq$ 20 kHz),
- fast final heating with a big high frequency (HF) power (30 kHz $\leq f_{HF} \leq$ 500 kHz) during a very short heating time,
- immediate quenching,
- low temperature tempering.

The selection of suitable values of the field current frequency, power and time of heating depends on type of gear, its size, kind of material and required hardness pattern. The preheating temperature is usually distinctly below the lower critical temperature.

$$T|_{t = t_{MF}} = A_{c1} - (100 \div 300\ ^\circ\mathrm{C}) \quad [40]$$

The value of preheating temperature depends on type and size of the gear, tooth shape, initial microstructure, required hardness pattern, and expected level of distortions which could be accepted.[4] During the final heating the hardening temperature should be reached very quickly (0.1 s $\leq t_{HF} \leq$ 1.5 s). In order to avoid through heating of the tooth the final heating requires a very precise control of time and power and immediate transfer of the gear from the MF inductor to the HF inductor and also small enough switching speed. The alternative method of the dual frequency hardening is the simultaneous method (SDF). The common inductor is simultaneously supplied with the MF and HF power. The power ratio is given by the formula eqn [41]

$$k_p = \frac{P_{MF}}{P_{HF}} \approx 2 \quad [41]$$

The typical heating time is also given by eqn [40].

The correct choice of the quenchant has the same importance as the selection of the heating system.[1,4,11,23] The most used quenchants are: water, oil, synthetic polymers solutions, aqueous emulsions of oil, solutions of water and salt, air, baths of salt melts, and some metal melts. Numerical modeling of the temperature field during quenching makes possible to choose the requested velocity of cooling in relation to the dimensions, form and material of the hardened body.

Too fast cooling may cause irregular martensitic transformation and induce substantial internal stresses which can cause unexpected deformations. The problem is especially important in case of bodies with a complex shape (like gear wheels) or having any surface defects.[24]

2.6.5 Conclusions

Induction surface hardening belongs to modern technology making possible to apply energy efficient and environment-friendly heat treatment method to a wide sort of steel elements well known for many years. The main factors deciding about efficiency of the induction hardening methods seems to be the elaboration of good but simple computation methods making possible to design induction hardening systems. For calculation of such systems the available professional software supplemented by several singled owned procedures could be applied. The most important factors deciding about effectiveness of the applied methodology are as follows:

- well preparation input data like material properties and their temperature dependencies for the investigated steel and corrected values of the critical temperatures for induction hardening conditions. They should be first based upon well – completed databases or if possible better by especially prepared measurements. In case of the modified critical temperatures their values could be determine by dilatometric measurement done at samples of the material for initially recognized known speed of the induction heating and the intensive cooling,
- formulation of the mathematical model including coupled formulation of several physical fields including some optimization procedures and preparation of experimental-based algorithm describing dependence of hardness on time of cooling. It makes possible to finish the computations with hardness and microstructure distribution,
- experimental verification of the computations.

The induction surface hardening seems to be the innovative especially effective in many high tech applications like:

- contour induction hardening of gear wheels applied in aerospace or automobile or other branches of machinery industry,[17–20,22,23]
- laser assisted induction treatment.[24]

2.7.1 Introduction

The history of mechanical surface treatment dates back to as early as 2700 BC. Evidence suggests that during that time, gold helmets were hammered on the surface to improve their mechanical properties in the city of Ur.[1] During later periods, this technique was applied to enhance the properties of the sword. Mechanical surface treatment evolved into a manufacturing process in the early 1920s and 1930s. Today, it is a well-established process for enhancing the properties of metallic components in wide-ranging industries such as automotive, aerospace, medical, and others.

In mechanical surface treatment, a localized elastic–plastic deformation is introduced near the surface region of metallic components. The deformation leads to intense work hardening, severe breakdown of microstructure, and the formation of a compressive residual stress. The strengthened near-surface region may result in significantly higher resistance to the initiation and early growth of fatigue crack. It can also lead to improved resistance to stress corrosion, corrosion fatigue or fretting fatigue, and wear.

During the mechanical surface treatment process, deformation is usually applied as mechanical pulses by impacting the surface with hard shots. Sometimes a high-pressure water jet is used to induce deformation at the surface layer. In a modern variation of the process, shockwaves created by laser beam incident on the surface are used to achieve the same results. Mechanical surface treatment can also be performed by deep rolling. In this technique, near-surface region is plastically deformed by applying a controlled force using a spherical or cylindrical rolling element. Examples of components that are commonly treated by mechanical surface treatment to improve their properties include helical springs, rockers, welded joints, propeller, blades, transmission shafts, torsion bars, and others.[2]

This chapter is intended to provide an overview of recent research advances in the field of mechanical surface treatment. The first part of the chapter deals with different peening processes. The second part describes recent developments in the area of surface mechanical attrition treatment (SMAT) to create a nanostructured surface layer.

2.7.2 Peening

Peening is defined as the mechanical surface treatment process in which peening media with a specified shape and sufficiently high degree of hardness are accelerated onto the specimen, thereby inducing compressive stresses or relieving tensile stresses already present. Peening can also encourage strain hardening of the surface metal. It is the process of working a metal surface to improve its material properties, usually by mechanical means such as hammer blows, by blasting with shots (shot peening), or blasting high-intensity light beams (laser peening).

2.7.2.1 Shot Peening

In this process, small spherical peening media hit the surface of metal components at high-speed.[3] This process creates large compressive residual stress on the surface and changes the structure and properties of the surface layer.[4] The modified mechanical behavior of the peened components is mainly due to the residual stress field, strain hardening, and grain distortion caused by the multiple impacts of the shot.[5] Impact energy imparted to the surface of the workpiece is able to cause surface plastic deformation.

The shot peening process under normal conditions produces compressive residual stress on the surface of a material without inducing phase transformation. However, the shot peening process produces phase transformation (e.g., nanoferrite layer and metal flow layer) on the surface of carbon steel under intensified peening conditions of high peening velocity and the use of high-hardness shot media.[6] Conventional shot peening can be applied to obtain surface nanocrystallized materials.[7]

Conventional shot peening is performed with two methods. The first method involves the acceleration of shot material with compressed air. Shot material is introduced into a high-velocity air stream that accelerates the shot speed up to 250 ft s^{-1}. The second method involves accelerating the shots with a wheel. The shots get dropped onto the middle of the wheel and are accelerated to the outer edge, where they leave on a tangential path. Normally, there are three main types of shots used in the process: glass or ceramic beads, steel shots, and cut wire shots. Ceramic shots are harder and can be reused. Another issue that needs to be considered during this process is the intensity of shot peening.[8]

Shot peening is already established as being excellent at preventing stress corrosion cracking (SCC). This crack initiates at the surface of the chemical equipment due to the combined effect of tensile stress and corrosion. The mechanism of preventing this cracking is the same as that for preventing fatigue failure. Yoshie[9] explained that by applying shot peening on the chemical processing equipment, the performance and lifetime of the equipment are improved. He described that the intergranular SCC was detected at the vapor zone of a reactor. The intergranular SCC was caused by the sensitization due to the heat effect of the welding. Modification and repair of SCC is performed by welding, and then shot peening is applied to the vapor zone of the reactor. This shot peening process would change the tensile stress of welding at the surface to compressive stress.

2.7.2.1.1 Surface of morphology

Shot peening induces roughness on the surface that is linearly proportional to the velocity/intensity of the shot. As a general rule, larger shot size results in greater roughness at lower velocities,[10] as shown in Figure 1, where a comparison is made between steel shot (ss230, ss110, and s70) and glass beads (100, 50, 35 μm GB). The roughness of the surface is the side effect of the shot peening process. Microstructure observation after the peening process detected defects on the shot peening surface, as seen in Figure 2.

Figure 3 shows the surface morphology of as-received and shot-peened Al–Li alloy.[11,12] Smooth surface and material flow direction can be seen in the as-received sample. On the shot-peened sample, a certain increase in surface roughness, a degree of surface damage, local delamination, and cracked phenomenon around the crater are seen. The average crater size was approximately 100 μm. In addition, the overlap of the impact region of each shot caused the differences in the shape of the crater.

2.7.2.1.2 Residual stress and microhardness analysis

A certain depth of compressive residual stress is generated in the surface layer of the Al–Li alloy after shot peening (Figure 4). The residual stress is seen to gradually decrease

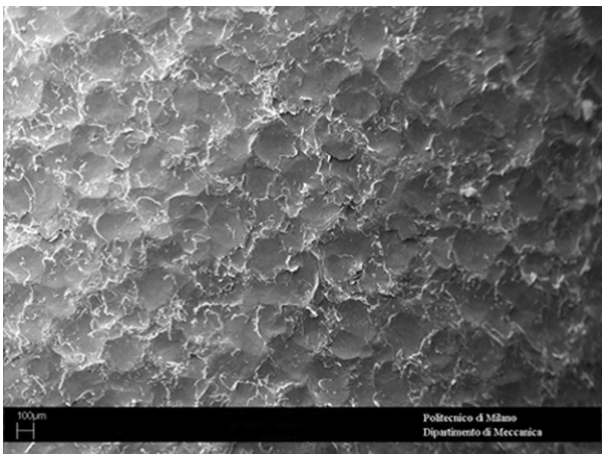

Figure 2 SEM micrograph showing the surface morphology of the SSP (severe shot sample) sample.[7]

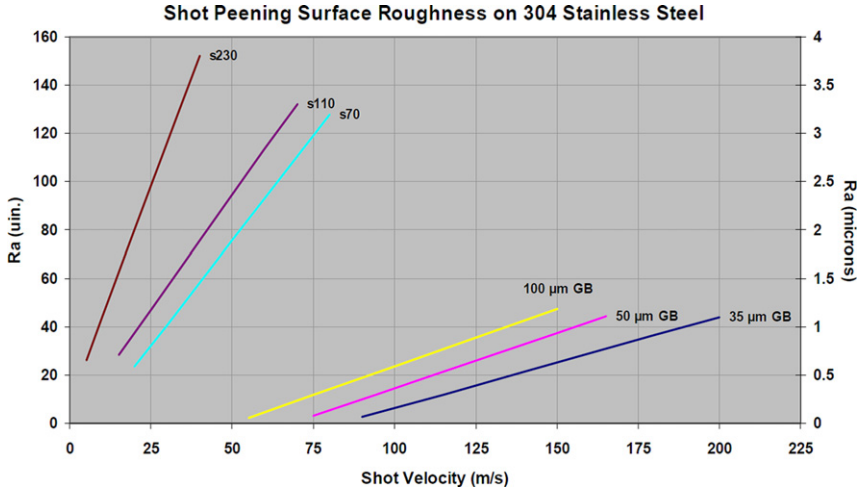

Figure 1 Surface roughness versus shot velocity.[10]

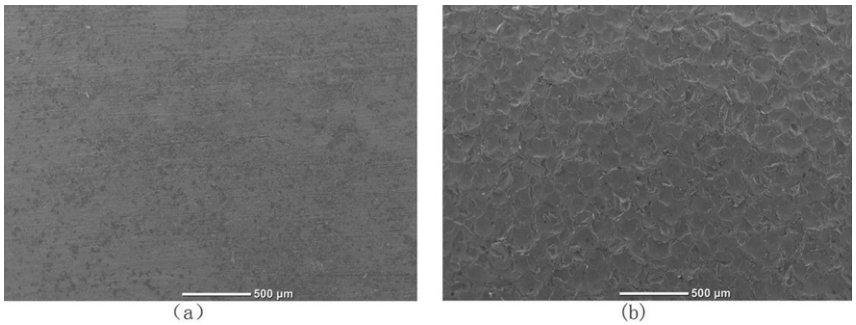

Figure 3 Surface morphology of (a) as-received and (b) shot-peened Al–Li alloy.[12]

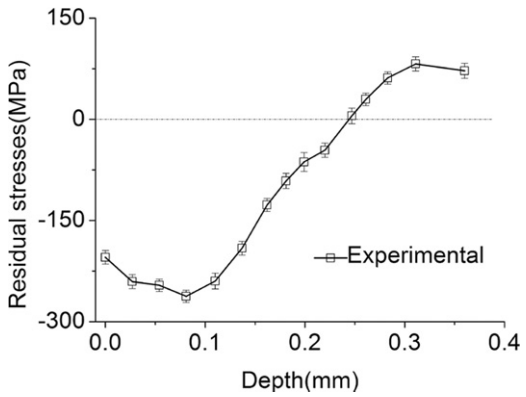

Figure 4 Residual stress distributions of Al–Li alloy.[12]

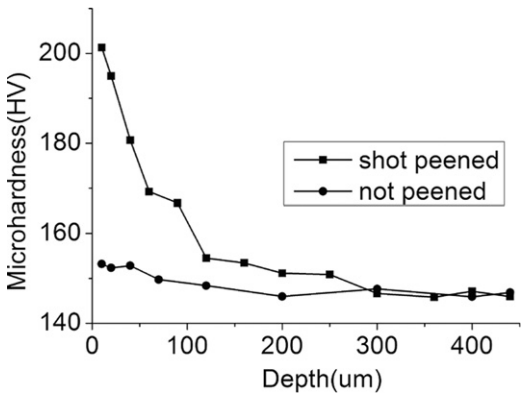

Figure 5 Microhardness profiles of as-received and shot-peened Al–Li alloy samples.[12]

within a few hundred micrometers of the surface. The residual compressive stress of the surface layer can hinder the generation of fatigue cracks, which greatly improves the fatigue resistance of the part.

The microhardness values of as-received and shot-peened specimens of the Al–Li alloy are shown in **Figure 5**. The increase in the microhardness of peening Al–Li at the surface is due to the grain refinement and work-hardening during the peening. As the surface of the workpiece is continuously impacted by the shots, it causes plastic deformation on the

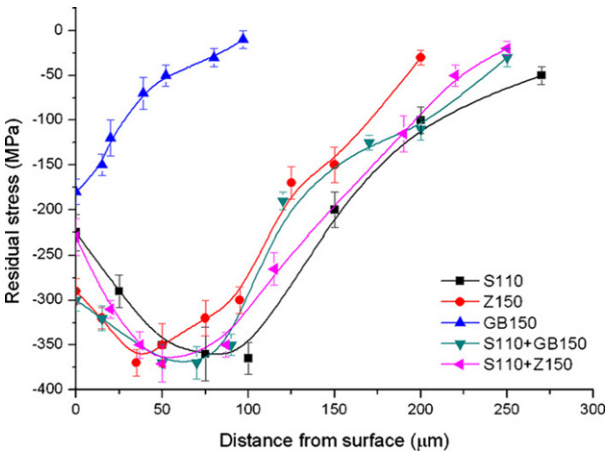

Figure 6 Compressive residual stress field caused by shot peening of 7050–T7451 aluminum alloy using different shots (S110: steel shot; Z150: ceramic bead; and GB150: glass bead).[13]

surface of the specimen. The surface hardening caused by shot peening improves surface hardness and wear resistance.

7050–T7451 aluminum alloy has been treated by the shot-peening technique to improve its fatigue performance. This alloy has been used in the fatigue-critical aircraft components due to its high strength, good stress corrosion cracking property, and high fracture toughness. Gao *et al.*[13] have discussed the effect of different shot peening on the compressive residual stress along the surface layer of 7050–T7451 aluminum alloy. **Figure 6** shows the compressive residual stress distribution along the surface layer for shot-peened samples under different shot materials. The material peened with glass beads (GB150) at an intensity of 0.10 A showed the lowest absolute value and thinnest compressive layer among all peened samples. For both ceramic beads (Z150) and steel shots (S110) with diameters of 0.15 and 0.28 mm, respectively, peening at an intensity of 0.20 A led to higher values of surface residual stress and deeper compressive residual stress fields.

Gao *et al.* also showed that by using double shot-peening, further modification of surface topography and higher surface compressive residual stress can be obtained. This double shot-peening is performed by peening the material first with high-intensity shots, and then a second shot-peening operation at a lower intensity.

2.7.2.2 Warm Peening

Warm peening is a variant of the shot-peening process whereby the workpiece is exposed to an elevated temperature during shot peening. The most common concern regarding this warm peening is that the temperature should not be too high because this would cause the decrease in hardness due to an annealing effect and therefore reduce the benefit of peening. Thus, the active temperature level should occur on the workpiece and the shot only. It was found that the dynamic and static strain aging effect during and after shot peening can stabilize the dislocation structure and therefore contribute to higher stability of the induced residual stress.[14]

2.7.2.2.1 Warm peening procedure

Warm shot peening treatment can be performed using an air blast machine. An air flow heater can be applied to the air blast machine for the warm peening system. Warm shot peening can also be performed in a heat-circulating oven. The appropriate temperature of warm shot peening is between 200 and 350 °C or below the tempering temperature. Residual stress of the specimen is normally determined using an X-ray technique. The depth of the distribution of the residual stress was determined by the iterative electrolytic removal of thin surface layers and subsequent X-ray measurement.[14] The residual stress and the microdeformation state of the material can be characterized by the half width at full maxima of a suitable X-ray diffraction peaks.

2.7.2.2.2 Residual stress in warm peening

Warm-peened samples have higher compressive residual stress compared with samples treated by the conventional peening. However, the stability of the residual stress is improved by peening at elevated temperatures due to the strain aging process.

Compressive residual stress developed in tempered AISI 4140 steel after shot peening at temperatures between 20 and 410 °C is shown in Figure 7.[14] At higher temperatures, thermally induced dislocation movement is possible, leading to rearrangement and annihilation of dislocations. This results in internal stress relaxation and decreased compressive residual stresses.

Warm peening generally increases the quasi-static as well as cyclic yield strength of the material. This is due to optimized peening temperatures resulting from dynamic and static strain aging effects. The strain aging phenomenon substantially contributes to reducing the Bauschinger effect by stabilizing the dislocation structure. The dislocations are locked through diffusion of carbon atoms to preferred edge dislocations and formation of very small carbides. Dislocation movement is restricted and the residual stresses are stabilized.

2.7.2.2.3 Relation between temperature and fatigue life

The increase of surface hardness by warm peening is the reason for the improvement of fatigue life.[15] The temperature involved below the recrystallization temperature allows some hardening to occur. Even though the fatigue life is dependent on many factors, in this process the surface roughness, strain hardening, and residual stresses are the parameters affected by the shot-peening temperature and need to be considered.

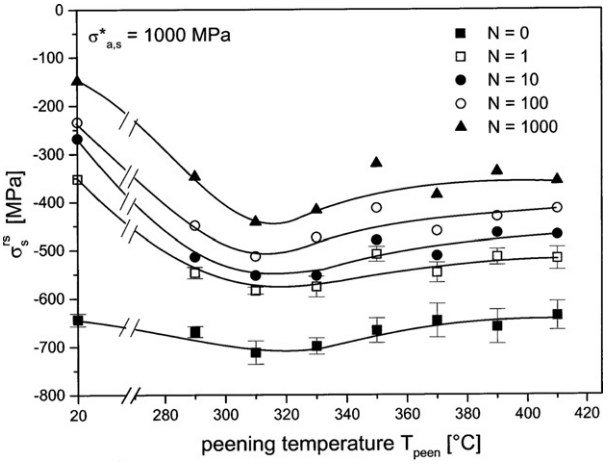

Figure 7 Residual stresses versus peening temperatures after different numbers of cycles of alternating bending load N.[14]

Ruy *et al.* investigated the effect of warm peening on the fatigue performance of spring steel (SAE 5161), in which the increase in fatigue life is due to the strain hardening effect.[16]

2.7.2.3 Laser Peening

Laser peening or laser shock peening is a technique similar to shot peening that imparts compressive residual stresses in materials for improved fatigue resistance. During a laser shock peening event, pressures well above the dynamic yield strength of the material are imparted on the target in a fraction of a microsecond. The severity of the loading causes local plastic deformation that ultimately results in the development of favorable residual stresses.[17] Laser shock treatment is a process whereby the surface of the specimen is exposed to the laser pulse for a certain duration. This method can be applied for the mechanical treatment of the near-surface regions of the workpiece, reaching surface depths of approximately millimeters. Laser shock was proven to generate plastic deformation on metallic targets.[18] This technique can result in significant improvement of metal properties such as wear resistance, resistance to stress corrosion, and fatigue strength of highly stressed metallic components used in a variety of engineering applications.[19] In this process, a thin, opaque overlay, such as a black tape, is placed on the metal surface. A transparent overlay, such as a water layer, is then applied on the black tape. The water layer directs the energy of the shock wave onto the surface. As the laser beam passes through water, it creates a shock wave that deforms the metal up to a depth of a few millimeters.

The process is dependent on the pulse energy or the intensity, as well as the duration of the pulse. In this process, the metal target is subjected to a certain pulse ($\sim$20 ns) of generated laser light (GW cm^{-2}) through a surface plasma.

2.7.3 SMAT

Most failures such as fatigue, wear, and corrosion initiate on the surface of materials. Modification of surface structure and

properties of materials enhance the life of materials by suppressing the initiation of failures. Development of a nanostructured surface is an effective surface modification process that is widely accepted in industrial applications. A nanostructured surface mainly consists of a nanocrystalline structure that improves the overall properties and behavior of the material by enhancing the surface properties without altering the chemical composition. Usually, nanocrystalline structures possess more novel properties in terms of strength and wear fracture as compared to conventional crystalline structures. Usually, nanostructured surfaces can be formed by two techniques, either by coating and deposition of nanoparticles by conventional techniques (Figure 8(a)) such as PVD, CVD, and plasma processes or by grain refinement of the surface layer by the localized plastic deformation (Figure 8(b)) process. The latter one is referred to as smart mechanical attrition (SMAT), which is a recent advancement in surface treatment methods that enables formation of a surface layer of nanostructure materials on the conventional bulk structure.

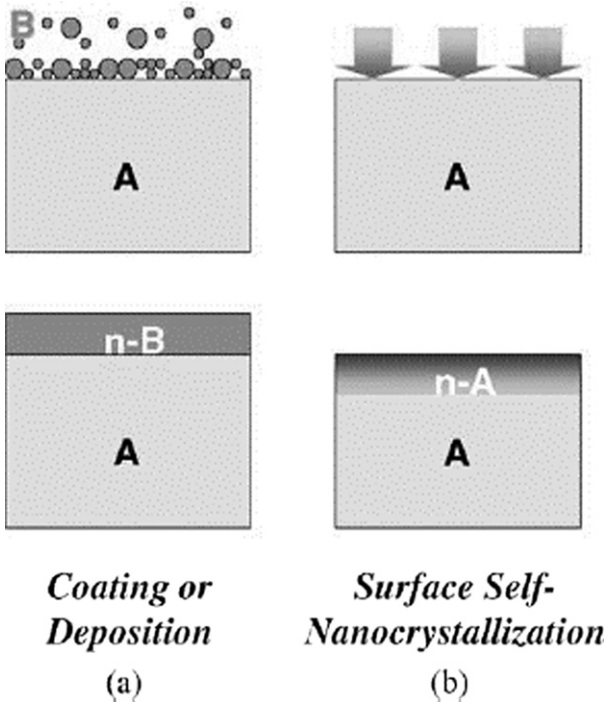

Figure 8 Schematic presentation of nanocrystallized surfaces formed by (a) surface coating or deposition and (b) surface self-nanocrystallization.[20]

The SMAT is a fairly recent surface modification technique in which a large number of metallic balls are vibrated at high frequency by a generator. The vibrating balls are impinged on the surface of the sample, which is fixed at the upper side of the chamber. The high impact of the balls on the sample surface causes severe plastic deformation. These processes will only transform a few micrometers of the surface to nanocrystalline, but the bulk material structure will remain unchanged. Due to severe plastic deformation during SMAT, grain refinement takes place and sub-grain boundaries also form at the submicron level. The parameters that control the nanostructure formation are: the size, weight, speed, and nature of the impacting balls; duration of treatment; and frequency and amplitude of the vibration. The salient features of a surface treated by the SMAT method are improved surface hardness and fatigue strength and increased corrosion resistance. The SMAT method can be successfully applied in various kinds of materials, including pure metals, steels, and alloys.[20]

2.7.3.1 SMAT Process

Usually, SMAT is performed in a chamber containing samples and spherical balls made of steel, glass, or ceramics (Figure 9). The metal balls of different diameters are placed at the bottom of the pot and are used to peen the surface of the tested metal/alloy during SMAT. The samples are fixed at the top and the balls are vibrated by a vibration generator. The distance between the sample and the balls varies. The sample pot is evacuated by a rotary pump before treatment and the low pot pressure is maintained during the treatment. Typically, ball sizes are 1–10 mm in diameter and the vibration frequency of the chamber ranges from 50 Hz to 20 kHz. The sample surface is randomly impacted by a large number of resonated balls at a velocity ranging from 1 to 20 m/s over a short period of

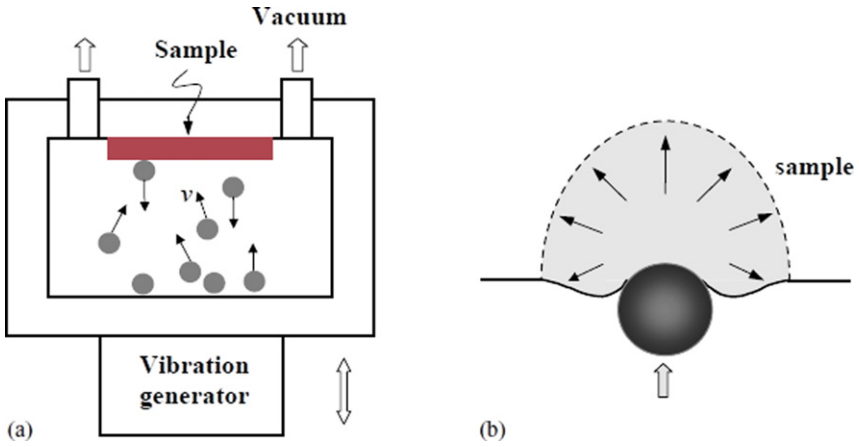

Figure 9 (a) Arrangement of sample and balls on the surface during mechanical attrition treatment and (b) impact of flying balls deforming the surface of the test sample.[25]

time. The time duration of the SMAT process is generally approximately 15 min. During the process, the sample surface encounters repeated impact from the balls, which induce severe plastic deformation and grain refinement. As a result, an increase in temperature is also noted, for example, for an iron sample, it is approximately 50–100°C,[20] depending on the intensity of the impact.

2.7.3.2 Mechanism of Surface Nanocrystallization by SMAT

The severity of deformation in terms of strain and strain rate by SMAT has a gradient from a few nanometers (on the top surface layer) to several micrometers at the subsurface of the sample. The deformation induces grain refinement during plastic deformation and forms nanostructures from the coarse-grained polycrystals through subgrain formation associated with various dislocation activities. The nanostructure formation in metals depends mainly on the lattice structure and the stacking fault energy (SFE). For materials with high SFEs, subgrains are formed by the ease of movement of dislocation walls accumulating strains, and sub-boundaries are formed to subdivide coarse grains. However, for those with low SFEs, the plastic deformation mode may change from the dislocation slip to mechanical twins (especially under high strain rate and/or low temperature).[20] Research has been conducted regarding three metals/alloys with different crystal structures and SFEs to explain the mechanisms of the nanocrystallization process by SMAT treatment. **Table 1** shows the features of the nanocrystal structure of these three metals and alloys.

Pure BCC iron, a structure with the highest SFE, showed a thin surface layer of grain refinement that occurs in three successive three stages: (1) formation of a high volume of dense dislocation walls (DDWs) and dislocation tangles (DTs) originating from plastic deformation; (2) sub-boundaries; and (3) refined subgrains are formed by the relocation of DDWs and DTs.

In copper with medium SFE with FCC structure, after the SMAT treatment, a different grain refinement mechanism occurred compared to BCC iron (Fe), with following sequence: (1) under plastic deformation, a high density of dislocations at different planes formed a cell boundary with equiaxed dislocation cells (DCs) instead of DDWs or DTs as in Fe and (2) a low level of dislocations inside the cell. With further increases in strain, in addition to DCs, mechanical twinning activates in some grains, thus dividing the original coarse grains into ultrafine (sub)grains. Finally, at maximum strains, subgrain boundaries transform into conventional grain boundaries with large misorientations.

With low SFE, AISI 304 stainless steels have different dislocation movements under plastic deformation.[21] The dislocation movements in this austenite phase usually occur at planes, forming regular dislocation grids instead of irregular DCs (as in FCC Al alloy, Cu) or DDWs (as in BCC Fe) due to the restriction of partial dislocations to cross-slip. With increasing strains, twins in different planes intersect with each other, and the formation of the strain-induced martensite phase of different ranges (nanometer to micrometer) at the intersections of the twin is reported. In the top surface layer, similar to other systems, randomly oriented nanocrystallites are formed via grain rotation or other grain boundary activities (motion or sliding) to accommodate the high strains.

2.7.3.3 Microstructure Characterization of the SMAT

In most cases, after SMAT, material phases remain the same but vary in deformation severity: nanostructures to microstructures in terms of nanograins to micrograins are observed from the surface to depths. Unlike steels, some grades of stainless steels undergo phase changes reported in the literature.[22] A scanning electron microscopy study of SMAT for a steel sample is shown in **Figure 15**.[23] A comparison between an original (**Figure 10(a)**) microstructure and the surface layer after SMAT treatment of the same sample (**Figures 10(b)** and **10(c)**) is also presented. Coarse grain structures in the range of 100–200 μm are clearly seen in the untreated surface; after SMAT of the microstructure of the treated surface layer (approximately 30 μm thick), grain structures are significantly refined. The existence of grain refinement can also be validated by studying XRD diffraction patterns of the refined crystal structure.[23]

Figure 11 shows the XRD patterns for the Fe sample before and after SMAT. Grain refinement and microstrain development in SMAT clearly broaden the Bragg reflections relative to the coarse-grain sample. Several quantitative analysis methods, such as the Scherrer–Wilson method, are utilized to estimate the grain size of the surface layer using X-ray diffraction patterns after SMAT. This is because the grain size measurement of the SMAT surface layer by a standard microscopy technique is difficult to obtain.

Investigators also compared[24] the X-ray diffraction peaks of nickel-based alloys with and without SMAT (**Figure 12**). Broadening of the Bragg diffraction peak observed in the sample after SMAT can be attributed to the small crystallite size and microstrain.

2.7.3.4 Properties of SMAT Surface Layer

It has already been mentioned that hardness, strength, fatigue, and wear of the surface layer of SMAT material improved significantly as compared to that of bulk material. Nanoindentation measurements revealed that in the SMAT Fe sample,

Table 1 Typical features of metals/alloys in nanocrystallization

Materials	*Lattice structure*	*Stacking fault energy (mJ m^{-2})*	*Mechanism involved*	*Depth of refinement*	*Grain size at surface*

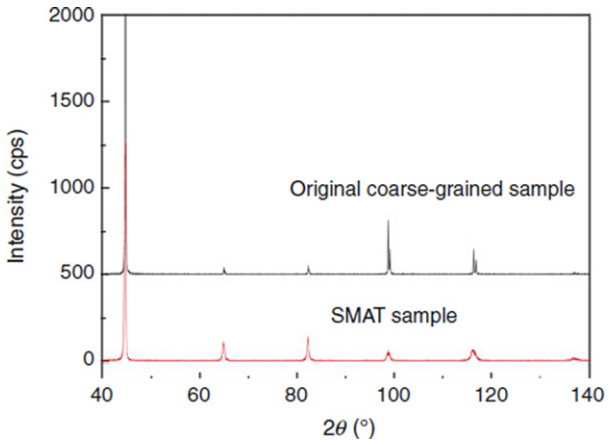

Figure 11 X-ray patterns of the original Fe sample and the SMAT Fe sample.[23]

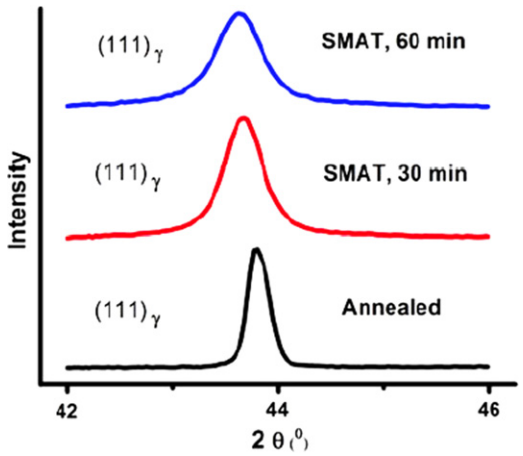

Figure 12 XRD profiles of nickel-based alloy 718 in annealed and SMAT conditions.[24]

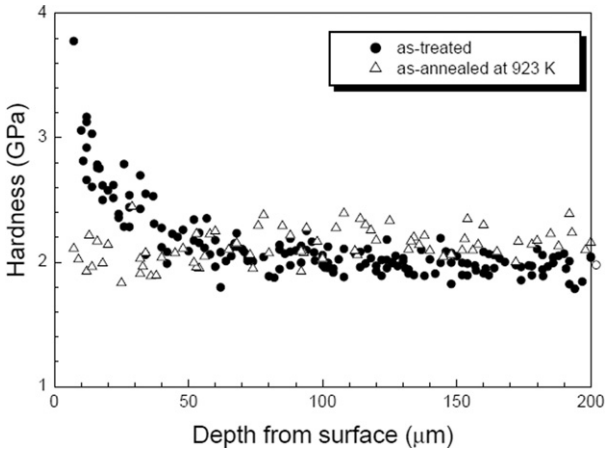

Figure 13 Measured hardness as a function of depth from the top surface for the SMAT Fe sample and for the annealed (at 593 K for 30 min) sample.[20]

treated surface possesses two- to three-times higher hardness compared with untreated coarse grain structure beneath the treated layer (Figure 13).

After SMAT, the sample was stress-relieved and annealed, and the hardness was measured again, but there was no change in hardness profile. This implies that the increment in the surface hardness resulted from refined grain structure, but not from the effect of strain hardening by SMAT. However, after recrystallization annealing for which nanostructures transform to a coarse-grain structure at the surface, the hardness in the surface layer decreases to that of the coarse-grain matrix. In addition, hardness values versus measured grain sizes from the surface to substrate validate the Hall–Petch relation in a wide range of grain sizes (from 10 nm to 50 μm). Strength tests for both low-carbon steel and stainless steel sheet with SMAT clearly showed the enhanced strength of the treated samples as compared to that of untreated samples. Such a strength enhancement can be attributed to the strong

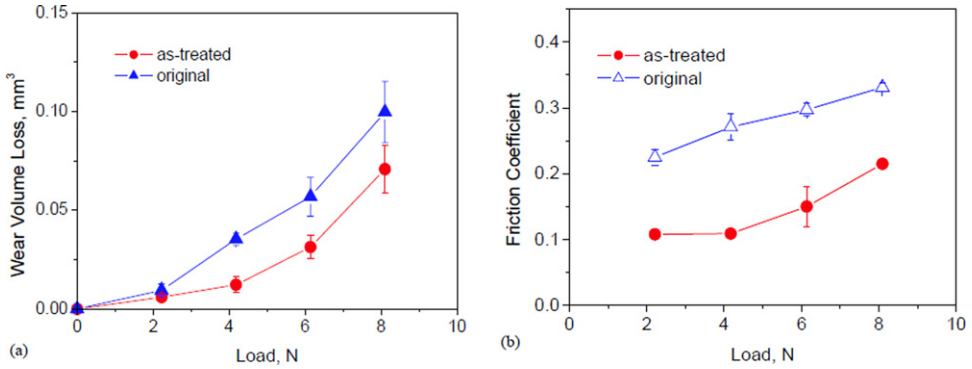

Figure 14 Variations of the wear volume loss with load (a) and variations of the coefficient of friction with load (b) for the SMAT and the original low-carbon steel samples.[20]

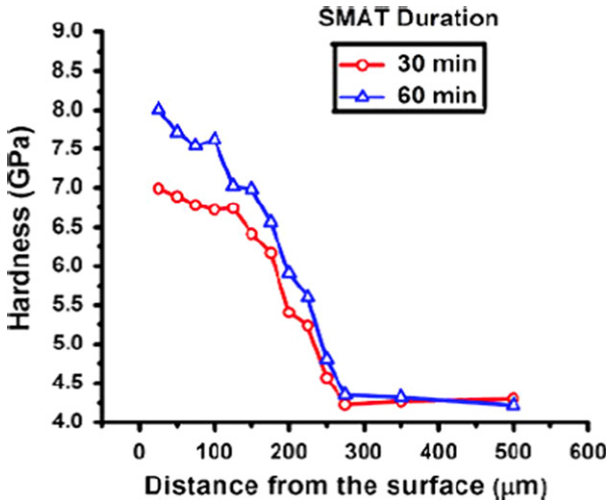

Figure 15 Variation of hardness with distance from surface of nickel-based alloy (718) subjected to SMAT.[24]

nanostructured surface layers on both sides of the sample. The increase in surface hardness and tensile strength is attributed to the grain refinement and strain hardening.

Although a study of wear mechanism was not comprehensively performed, some research results indicate the improvement of wear properties in terms of less wear volume loss and low coefficient of friction. The effects of work hardening, material transfer, and erosion during wear situations result in microstructures of wear surfaces comparable to those observed during mechanical attrition.[20] In particular, during sliding wear, large plastic strains and strain gradients are created near the surface[20] due to grain refinement of the SMAT specimen. As shown in Figure 14, the wear volume loss of the nanostructured surface layer in the SMAT sample is lower than that for the untreated original. The friction coefficient values at different applied loads for the as-treated sample are evidently smaller (approximately half) than those for the original sample. These observations indicate that the friction and wear properties of the low-carbon steel can be improved by means of formation of the nanostructured surface layer. The improved wear and fraction properties can be attributed to the strong surface layer with nanograins and a gradient variation in the microstructure and properties along the depth near the top surface.[20]

The effect of SMAT and its duration on fatigue life of nickel-based alloy 718 has been studied.[24] The SMAT process was performed in a vacuum (-0.1 MPa) with SAE 52100 steel balls with a 5-mm diameter for 30 and 60 min at a vibrating frequency of 50 Hz. SMAT resulted in surface nanocrystallization, higher surface roughness, higher surface hardness, higher compressive residual stress, higher tensile strength, reduced ductility, and superior fatigue lives. The increase in hardness of the alloy after SMAT is due to the increase in grain refinement and strain hardening (Figure 15). The enhancement in the fatigue lives of treated samples can be attributed to the positive influence of nanostructured surface layer, compressive residual stress, and work-hardened layer, which surpassed the negative effect of increased surface roughness.[25]

2.7.4 Conclusions

The development of mechanical surface treatment is one of the most important challenges facing industries such as automotive, aircraft, power plant, and petrochemical. Various surface treatment methods, including mechanical and thermo-mechanical methods, are competing with each other to increase the performance and strength of individual components. Factors required for component design as well as manufacturing conditions control the choice of the optimal surface treatment method. Usually, mechanical surface treatments allow for improving the mechanical and structural properties of metallic material. This study outlines some effective mechanical surface treatment methods, such as shot peening, warm peening, laser peening, and mechanical attrition. Based on their technological details and the associated characteristics of modified surface conditions, fatigue, wear, hardness, and several other properties of materials are explained. In addition, influence of residual stress state, work-hardening state, microstructural changes, and roughness after nanosurface treatment are also highlighted. Currently, most research activities are concentrated to achieve surface modification by generating nanostructured surface layers to improve localized mechanical properties. However, difficulties still exist in fabricating nanostructured layers because the

layers are not free from porosity, contamination, and other defects. Attention is required to develop special processes for increasing the stability of surface layers associated with defect-free structures.

2.8.1 Introduction

The steels having common engineering applications are quite often commercially important; sometimes huge requirements of certain class of steels for specific application area make them attractive to manufacturing industries. Paradigm shift of design philosophy has raised the demand for development new and high-performing steels for commercial applications at less cost. In general the commercially important steels may be grouped as structural steels, automotive steels, ultrahigh strength steels for critical applications, abrasion and shock resistance steels, and above all stainless steels; being low-, medium-, or high-alloy steels of varying carbon contents, the above mentioned commercially important steels have posed additional challenges in heat-treatment practices to insure improved mechanical and mechano-chemical properties.

Therefore in the present chapter, attempts are made to discuss the basic principles underlying heat treatment of some important commercial steels. This encompasses discussion of the whole spectrum of commercially important steels ranging from medium carbon commercial steels with low or no alloy contents to the present generation advanced high-strength steel (AHSS). Present trend in development of ultrahigh-strength steels envisages the modification of AF1410 or AerMet 1000 steels. This calls for newer strategy for heat treating these steels. Special attention is also paid in designing the heat treatment of this class of steels. Current interest in development of new generation AHSSs for safe, reliable, and cost-effective application in automotive sectors is also duly regarded while describing the heat-treatment challenges of these steels.

Evolution of microstructure during heat treatment of the steels under consideration is also followed so as to gather a

 doi:10.1016/B978-0-12-803581-8.09190-6

better understanding of their processing–structure–property relationship. Moreover the criticality of phase transformation associated with the heat treatment of maraging steels is elaborated in the current chapter. Heat-treatment processes of different varieties of stainless steels, its limitations, and protocol to develop suitable microstructure are separately discussed. There are always some constraints in industrial heat-treatment practice. Taking example of austenitic manganese steels and other steel castings in general, efforts are made to explain how a heat treater can overcome the difficulty confronting the achievement of ideal microstructures in real life industrial situation.

2.8.2 Medium-Carbon Low-Alloy Steels or Plain-Carbon Steel

2.8.2.1 Forging Quality Steel

It is known that forging quality steels are used in production of gears and tooth wheels in automobile sector. In present scenario the objective of profitable production of above automotive components are to:

1. achieve a very high strength and toughness,
2. adopt shortest possible heat-treatment cycle, and
3. improve damage tolerance.

The commercially important forging quality plain-carbon steels include AISI 1040 and 1045 steels along with other similar ones.

Medium-carbon steels are known to be quite suitable for applications where a good combination of strength, toughness, and wear resistance is required. AISI 1045 is one such medium-carbon steel which is used for manufacturing of forged parts which require sufficient strength and toughness for applications as crank-shafts and couplings. These medium-carbon steels are normally forged from 1250 to 1200 °C, finished forging temperature being 950–1000 °C. However the forging temperature depends upon the geometry and amount of deformation to be given during forging. The forged components are subjected to the following heat treatment.

2.8.2.1.1 Annealing

Full annealing of the forged steel components is accomplished at a temperature between 900 and 850 °C followed by slow cooling at 10 °C h^{-1} till 600 °C; afterward the stock may be air cooled.

2.8.2.1.2 Normalizing

Normalizing of the annealed component is carried out by heating at 870 °C, holding for sufficient time and then cooling the components in still air. A lower temperature around 850 °C is preferred for normalizing in the event, it is the final heat treatment. The normalized stock is then hardened from a temperature of 850 °C; quenching is normally carried out in oil. Depending upon the application of a component, induction hardening is carried out by quickly heating it to the desired case depth and then quenching in water. The induction hardened parts are normally tempered at a low temperature like 150–200 °C to reduce the residual stress without much affecting the hardness at the surface of the component, which is normally kept at R_c 56–58. For the volume hardened material, the tempering temperature ranges between 400 and 675 °C in accordance with the required mechanical properties. Microstructural changes accompanying heat treatment of AISI 1045 steel is shown in Figures 1(a)–1(c).

The low-alloy steel so far used for such components is 42CrMo4, whose composition is shown in Table 1.

Heat-treatment cycle of 42CrMo4 steel is as follows:

1. Normalized from 880 to 900 °C after holding for 1 h per 25 mm thickness.
2. Hardening is done after heating to 860–880 °C; holding is done for sufficient period of time, and finally quenched in oil at 80 °C.
3. Tempering is carried out at suitable temperature between 530 and 680 °C. The exact tempering temperature is determined by final property required.

In general this class of steels is used in quenched and tempered condition; by controlling the heat-treatment process, it is possible to derive the required properties of the steels.[1] The structural changes taking place due to forging of varying amount and post-forging cooling rates is shown in Figure 1(d).

However the recent trend for shortening the process route has led to emergence of ferrite-pearlite precipitation hardenable steel, 38MnVS6. The composition of 38MnVS6 and a modified version of precipitation hardenable ferrite-pearlite steels is shown in Table 1. The microstructure of precipitation hardened ferrite-pearlite steels against quenched and tempered one is shown in Figure 2.

The steel is heated to a temperature around 1150 °C to dissolve all carbides in solution so that a homogenous austenite is available.

After forging the rate of cooling is controlled because it is a very important parameter for control of microstructure in alloy steel. After forging the components are cooled in air. The cooling rate should preferably be within the range of 1–5 °C s^{-1}. This rate of cooling must be continued till the component attains a temperature of 600 °C. The microstructure shows ferrite-pearlite structure with very fine precipitates of vanadium carbide (Figure 2). The high ultimate tensile strength above 900 MPa with impact strength around 20 J is achievable in both 38MnVS6 and the modified version precipitation hardened ferrite-pearlite steels.

2.8.2.2 Precipitation Hardened Martensitic Steels

A class of martensitic steels is strengthened by secondary hardening to impart ultrahigh strength at high-toughness level. AF1410 belongs to this class of steels and contains appreciable amount of nickel and cobalt. Due to high nickel content the steel exhibits a low ductile-to-brittle transition temperature; on the contrary cobalt aids in precipitation hardening and high-temperature strength.[4–6] Another class of steel, AerMet100, is so developed as to impart strength both by precipitation of intermetallic and alloy carbides. Heat treatment of these steels comprises of austenitizing, quenching to room temperature, and then tempering or aging to effect the precipitation of intermetallics and alloy carbides. Alloying elements in these two classes of steel are so chosen that the transformation of austenite may take place at sufficiently low temperatures. The low-temperature transformation products of austenite viz.

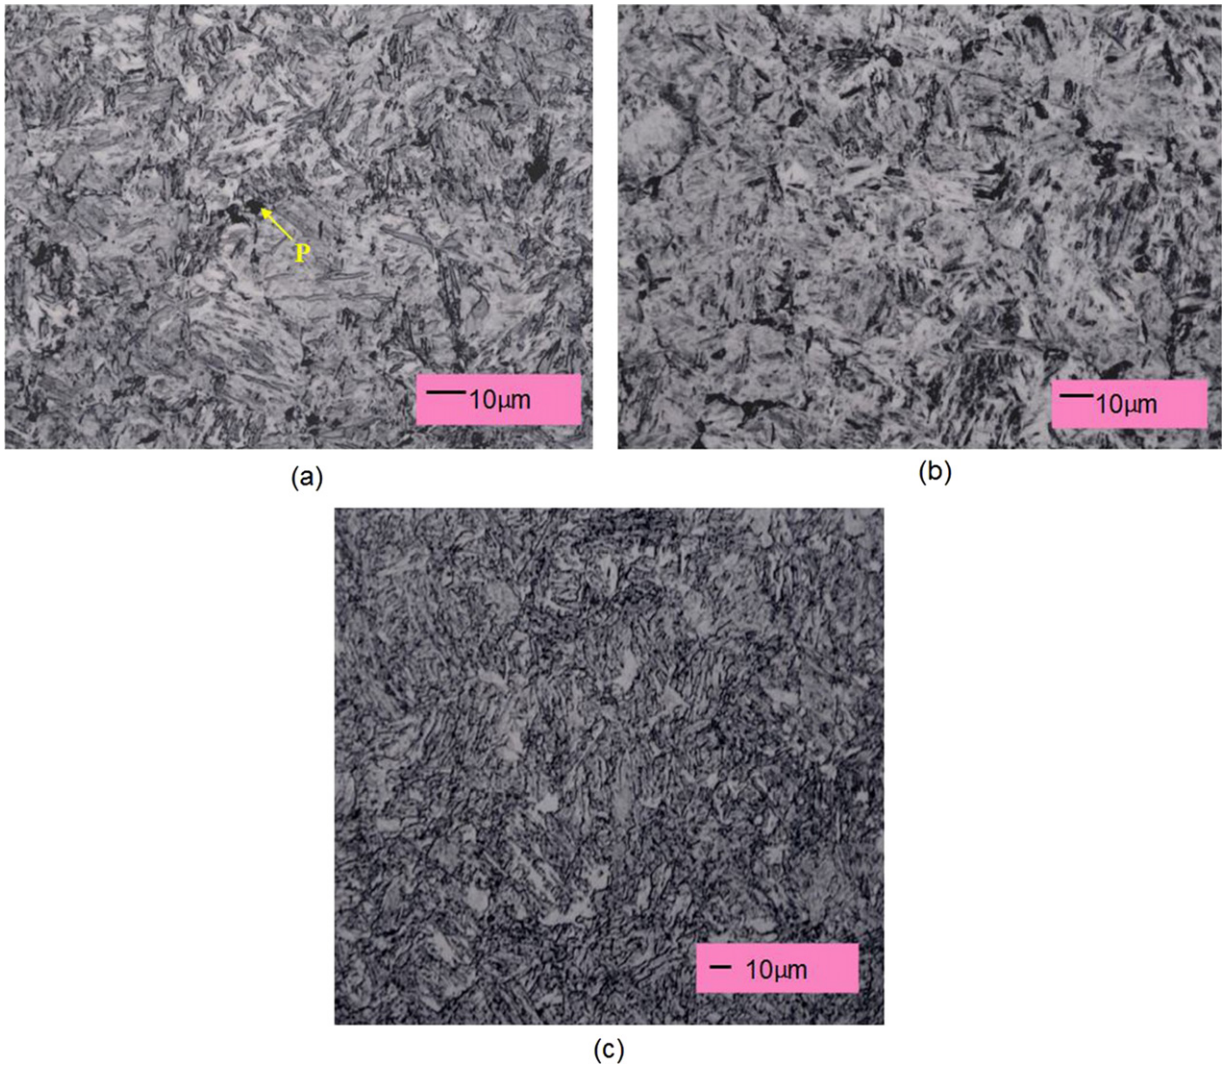

Figure 1 Microstructures of AISI 1045 steel (a) quenched, (b) quenched and tempered at 200 °C, and (c) quenched and tempered at 540 °C. (d) Microstructure of the heat-treatable 42CrMo4 steel for cooling rate 15 Ks^{-1} (left) and 0.07 Ks^{-1} (right); above – without deformation, middle – deformation level 30%, and below – deformation level 60%.[2] Vander Voort, G. F. *Microstructure of Carbon and Low-Alloy Steels*.

lower bainite/martensite are generally produced after quenching of these steels. Aging of these steels are carried out at sufficiently high temperature so that slow diffusing substitutional alloying elements can have adequate mobility to form their carbides or intermetallic compounds with elements other than carbon. The heat treatment of these steels is controlled in such manner that a fine-scale microstructure is achieved to insure higher fracture resistance.

The other steels of this type include HY180 and HP 9–4–20 which led to further development of similar type of steels with improved properties. HY180 steel contains 0.10 wt% carbon, 10 wt% nickel, 8 wt% cobalt, 2 wt% chromium, and 1 wt% molybdenum. After heat treatment, the mechanical property of this steel becomes significantly superior to many high-strength steels.[7–8] A 5 h tempering at 510 °C achieves yield strength of 1250 MPa. The Charpy impact energy of the said steel is found to decrease with increasing tempering temperature above 300 °C till 425 °C; Charpy impact energy attains its minimum value at 425 °C. However tempering at temperatures greater than 425 °C leads to increase in its Charpy impact energy value; its maximum value is attained by tempering the steel at 510 °C. It should be noted that tempering above 425 °C produces intra-lath carbides of type M_2C, which is beneficial to impact strength. Cementite does not form and the needles of these alloy carbide particles are very fine with length being around 10 nm. However multiple heat treatments of HP 9–4–30 steels can lead to further structural refinement with associated improvement in properties. The microstructures of these steels are shown in **Figure 3**.

Cobalt is known to delay recovery processes till a high temperature like 500 °C; the delay in recovery helps to retain the dislocation structure within the material. Thus sites for nucleation of alloy carbides increase many folds and hence numerous fine sized carbides result in the microstructure. Also cobalt increases the activity of carbon in ferrite and thus helps in formation of more carbide. It is also known that higher chromium content in the steels results in more rapid coarsening of the alloy carbides and shifts the secondary hardening

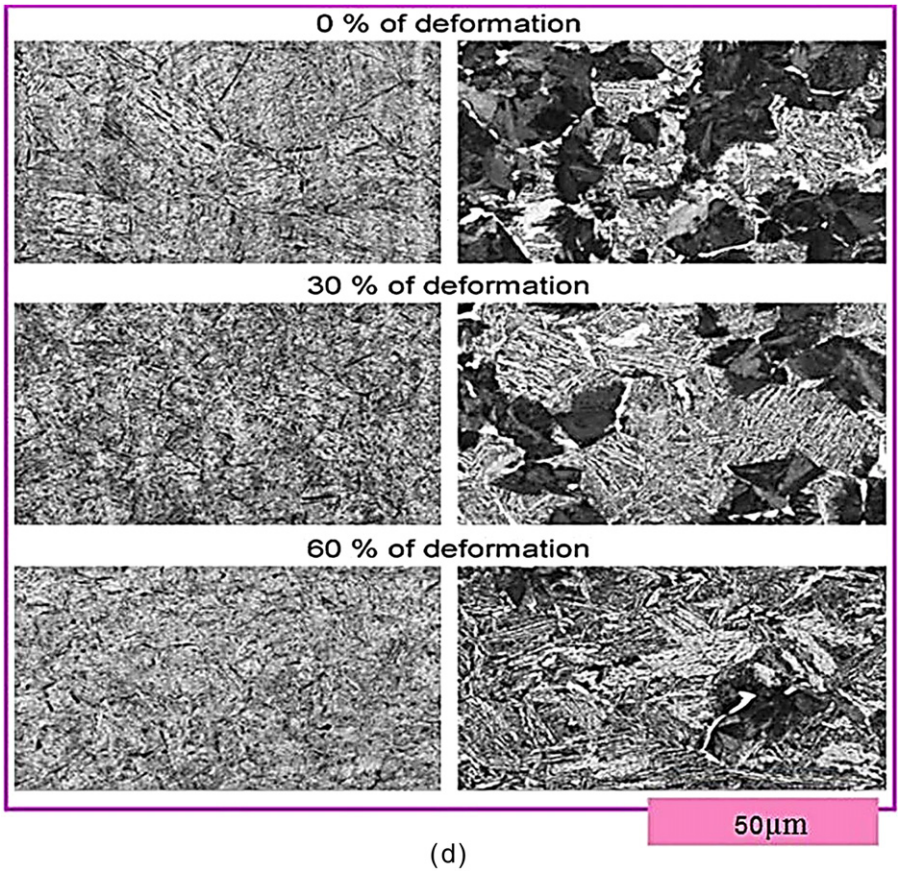

Figure 1 (Continued).

Table 1 Chemical composition of forging quality steel (wt %)

Type	*C*	*Si*	*Mn*	*Cr*	*Mo*	*Nb*	*Ti*	*V*	*Fe*
AISI1045	0.43–0.50	0.15–0.30	0.60–0.90	–	–	–	–	–	Balance
42CrMo4	0.42	0.30	0.80	1	0.20	–	–	–	Balance
38MnVS6	0.38	0.60	1.40	0.04	0.03	–	–	0.10	Balance
PHFP-M	0.36	0.70	1.45	0.15	0.03	0.03	0.02	0.2	Balance

peak to lower tempering temperatures. Increasing the molybdenum content has the opposite effect. This has led to the discovery of AF1410 whose chemical composition approximates 0.16 wt% C, 14 wt% Co, 10 wt% Ni, 2 wt% Cr, and 1 wt% Mo. Alike HY180, AF1410 steel is tempered for 5 h at 510 °C and achieves a yield strength of about 1500 MPa presumably due to higher carbon and cobalt content.

However, AF1410, achieves its maximum yield strength after tempering at 475 °C, not at 510 °C as it is for HY180. This minimum in the toughness as experienced after tempering at 425 °C is ascribed to availability of minimum amount of retained austenite due to its decomposition with the precipitation of cementite. Carpenter Technology developed still higher strength version of this alloy in the name of AerMet100, with a chemical composition of 0.25 wt% C, 13.4 wt% Co, 11.5 wt% Ni, 2.5 wt% Cr, and 1.2 wt% Mo.

Similar to AF1410, the maximum in the yield strength of AerMet100 is obtained after tempering at 475 °C. AerMet100 steel also records the minimum Charpy impact energy on tempering at about 425 °C. AF1410 steel can be strengthened more at higher cobalt content as it ensures higher scope for increasing the carbon content of the steel; it is known that higher carbon content in martensite is responsible for higher hardness of iron–carbon martensite. However the disadvantage of increase in carbon content is realized in having the M_s and M_f temperatures depressed to below room temperature; it is required to elevate these temperature to above room temperature so that one can secure 100% martensite after quenching the steel. Cobalt is an alloying element which, unlike most of the alloying elements in steel, is capable to raise the M_s and M_f temperatures. So cobalt content is increased from 8 to 14% to achieve M_s and M_f temperatures at 327 and 166 °C respectively. Thus a window for increasing the carbon content is now available and this is how AF1410 steel could be modified with composition of 0.17C–10Ni–14Co–2Cr–1Mo with varying amounts of titanium. This gives rise to better

mechanical properties than AF1410 steel which contains 0.13% carbon at 8% cobalt level. The same strategy is employed to design the steel, AerMet100,[9–10] with the chemistry, 0.23C–14Co–12Ni–3Cr–2Mo; here higher carbon content with simultaneous increase in carbide formers can give rise to very high strength upon quenching from 900 to 950 °C followed by tempering at 620–650 °C. The strength of this steel can go as high as 1950 Mpa with K_{Ic} around 126 Mpa $m^{1/2}$.

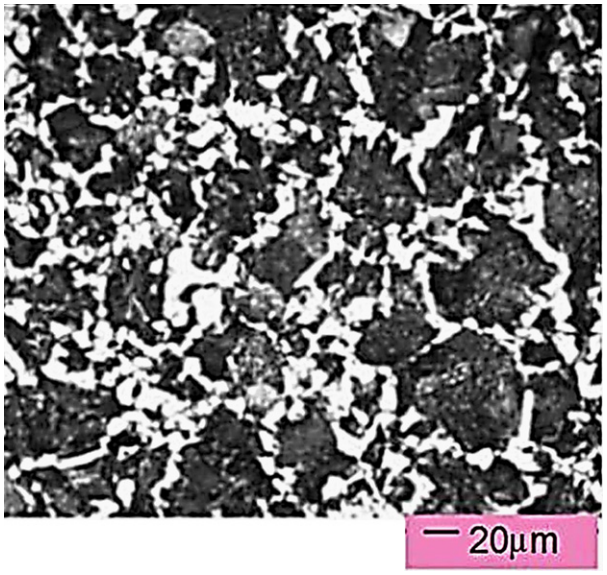

Figure 2 Typical pearlite and ferrite microstructure of air-cooled microalloyed forging steel.[3] Caminaga, C.; Button, S. T. Mechanical Properties of Ausforged 27MnSiVS6 Microalloyed Steel. *Metall. Mater., REM:R.Esc Minas, Ouro Preto* **2013**, *66* (3), 331–338.

2.8.2.3 Heat Treatment of 9Ni4Co Steel

This type of steels has emerged in early 1960s, due to requirement of high fracture toughness at high strength. Commercially known steels under this category are HP 9–4–20 and HP 9–4–30. HP 9–4–20 contains 9% Ni, 4% Co, with 0.20% C; whereas the carbon content is 0.30% in the other variety. These steels possess very high hardenability and presence of 4% Co help to minimize the retained austenite amount in hardened microstructure as cobalt is known to raise the M_s temperature.

The heat-treatment cycle of HP9–4–30 steel is as follows:

- Normalizing is done from 900 °C, after holding at the normalizing temperature for 1 h. per 25 mm thickness.
- Spheroidizing annealing is performed by way of heating to 620 °C and holding it there for 24 h followed by air cooling.
- Alternately multiple annealing from temperature of 700–630 °C with holding time of 4 h at each annealing temperature may be used to produce spheroidized structure. The objective of spheroidizing treatment is that homogenization of austenite for hardening can be facilitated by prior spheroidized microstructure.

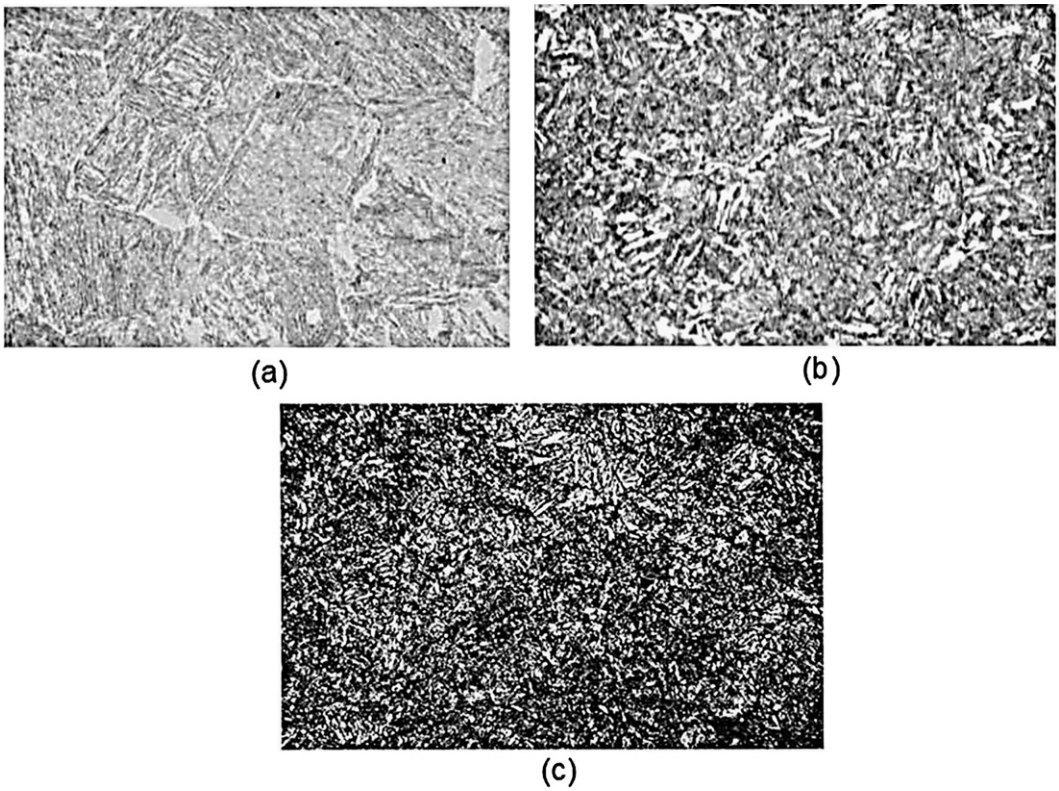

Figure 3 Microstructure of (a) HP 9–4–20 showing tempered martensite, (b) HP 9–4–30 showing tempered martensite, and (c) HP – 9–4–30 grade showing grain refined structure after multiple heat treatment, X400. Rush, H. F. *NASA Technical Memorandum 85816, Grain Refining Heat Treatment to Improve Cryogenic Toughness of High Strength Steel*, 1984.

- For hardening, the steel is austenitized at 850 °C and soaked for 1 h for each 25 mm thickness. This homogenous austenite may be water quenched to ensure complete martensitic transformation. These steels may be subjected to subzero treatment at − 75 °C with a holding time of 1 h and then bringing back to room temperature.
- Tempering is carried out between 300 and 600 °C depending upon the desired strength and ductility property. Most widely used tempering process is a double tempering between 550 and 575 °C, with sufficient hold time at that temperature. Stress relieving at 560 °C for 24 h may be carried out if steel is required to be welded prior to heat treatment. Stress relieving annealing should be carried out by holding for prolonged period of time at elevated temperature and then cooling to room temperature in still air. The micro structures of these steels under various heat-treatment conditions are shown in Figure 3.

2.8.2.4 Heat Treatment of AF1410 Steel

The steel of chemical composition, 0.13–0.17% C; 0.1% Si; 1.8–2.2% Cr; 9.5–10.5% Ni; 0.9–1.1% Mo; 13.5–14.5% Co is described as another variety of ultrahigh strength steels with high fracture toughness and has been developed by US defense for application in submarine structures. The microstructure of this steel consists of lath martensite with dispersed carbides; the general optical microstructure shown in Figure 4 exhibits tempered martensite. The carbide precipitates are formed during tempering and thus give rise to precipitation strengthening. The steel may also subjected to secondary hardening by tempering the workpiece at high temperature above 550 °C which gives rise to the formation of reverted austenite; this improves the impact strength of the steel.

The recommended heat-treatment practice for this steel is as follows:

- Normalizing is carried out as usual to achieve higher machinability. The component is heated in the temperature range 880–900 °C, held there for 1 h per 25 mm thickness of section and then air cooled. Following air cooling the steel can be aged at 650–675 °C for 3–6 h. After machining the stress relieving annealing is carried out at 675 °C, to relieve the mechanical stresses induced due to machining.
- Hardening heat treatment consists of austenitization at temperature of 880 °C where the steel is to be held for 1 h per 25 mm section thickness; then the steel is quenched in oil, if the maximum section size of the article is more than 75 mm. If the maximum section size is 50 mm or less, air quenching can be employed to produce martensite in the hardened steel. The subzero treatment at − 70 °C may be practiced if 100% martensite formation is not possible due to large section size of the heat-treating component.
- Tempering is carried out at 550–570 °C, and holding time at this tempering temperature is normally 5–6 h. It appears from Figure 5 that secondary hardening peak is attained at 480 °C and aging beyond this temperature tends to soften the material with concurrent improvement in impact strength. Also at a temperature of 510 °C maximum improvement in impact property is obtained. This is ascribed to the fact that aging at such high temperature for a prolonged period of time like 6 h leads to the formation of solute rich austenite due to competitive austenite formation. This high solute austenite has a low M_s temperature and therefore after cooling from the tempering temperature to room temperature, the reverted austenite exists in the microstructure. This reverted austenite does not transform to martensite upon cooling from the tempering temperature. The reverted austenite present in the microstructure confers very high-impact strength in these materials. The same features are observed in AerMet 100 steel which contains higher carbon than AF1410. The microstructures of AerMet 100 steel under different heat-treatment conditions (Figures 6 and 7) clearly show that increasing

tempering temperature leads to the coarsening of needle-shaped M_2C precipitates with concurrent formation of reverted austenite.

The dark-field TEM image in Figure 7(b) gives clear evidence of reverted austenite which is stated to be responsible for high-impact strength of AerMet100 or AF 1410 steel after tempering at high temperatures.

2.8.2.5 Press Hardenable Ultrahigh-Strength Steel

A new-generation martensitic steel of composition, 0.25C–0.40Si–1.40Mn–0.5 (Cr + Mo)–0.005B–0.05Ti–0.05Nb possesses a very high strength. The steel is quenched during pressing and then followed by controlled tempering. The quenched and tempered microstructure showing the presence of martensites is shown in Figure 8. The quenched and tempered steel derives its strength from precipitation hardening along with transformation hardening due to formation of martensite. Molybdenum strengthens the grain boundaries; also it lowers the activity of carbon in ferrite which makes it less susceptible to grain boundary precipitation. Niobium is used for grain refinement of austenite. The fine grained austenite, while being quenched to undergo martensitic transformation, would give rise to smaller martensite packet size. This is highly favorable in imparting extra strength to the steel.

The emerging concept of light-weight technology, has led to the birth of press hardened steel which is invoked recently as a token of new-generation technology in automobile industry.

Addition of Titanium helps to avoid segregation of boron nitride at the grain boundaries. Free boron is now available to segregate at the grain boundaries; thus boron does not leave much space for the nucleation of proeutectoid ferrite and it is how boron may exert its hardenability raising effect. 22MnB5 is the commonly used press hardenable steel. Shift of Bs temperature to longer times and lower temperatures is

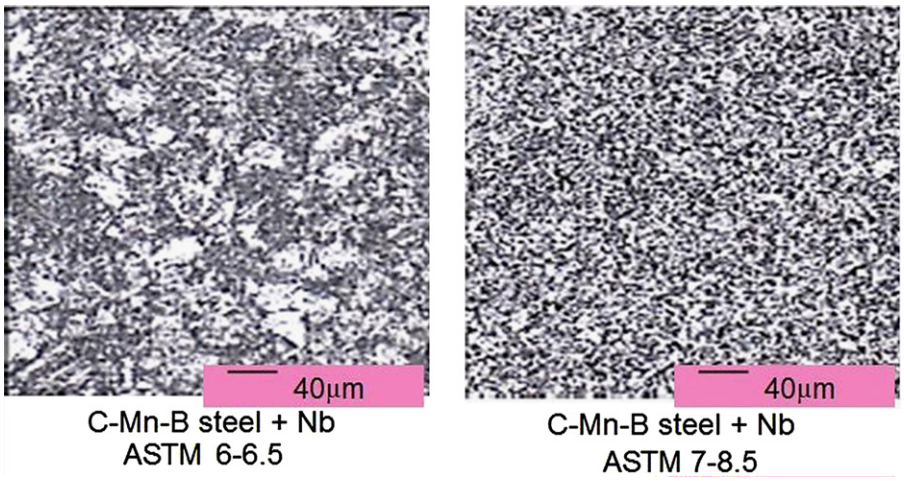

Figure 8 Microstructure showing martensites of fine packet size; prior austenite grain boundary is also revealed in the steel after typical press hardenable steel heat treatment.[12] Bian, J.; Mohrbacher, H. Novel Alloying Design for Press Hardening Steels with Crash Performance. In *International Symposium on New Developments in AHSS*, PR-294–026–2013, USA. Available at: www.niobelcon.com/NiobelCon/publications_files (accessed February 17, 2016).

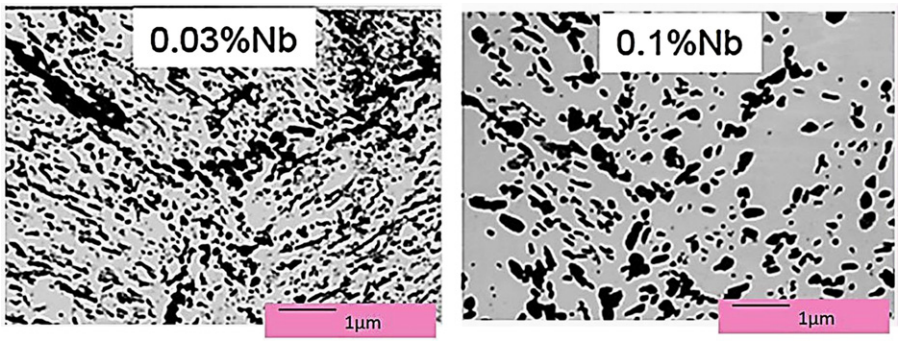

Figure 9 Microstructure of 22MnB5 steel optimized with Nb addition, quenched, and tempered. Microstructure shows distribution and morphology of precipitates in quenched and tempered steel.[12] Bian, J.; Mohrbacher, H. Novel Alloying Design for Press Hardening Steels with Crash Performance. In *International Symposium on New Developments in AHSS*, PR-294–026–2013, USA. Available at: www.niobelcon.com/NiobelCon/publications_files (accessed February 17, 2016).

possible due to addition of elements like C, Mn, Cr, and Mo; thus insurance of martensitic transformation at a slower cooling rate such as, 30 K s^{-1} aids in avoidance of formation of soft diffusinal decomposition product of austenite. This is further accentuated by synergistic effect of Mo and B to delay of austenite to ferrite transformation. All these factors are responsible for production of 100% martensite quite easily after quenching. Moreover the role of microalloys in conferring precipitation strengthening is very important. Microstructure of 22MnB5 steel optimized with Nb addition clearly records a high-population density of nano-sized niobium carbide precipitates distributed uniformly throughout the matrix (**Figure 9**).

2.8.2.6 Nanoscale Precipitations Hardenable Steel

Another ultrahigh-strength steel of 1.9 GPa strength with 10% elongation and 40% reduction in area is developed with newer strengthening strategy accomplished by judicious heat-treatment practice. The chemical composition of the steel is say, Fe–xNi–yAl–1.5Cu–1.5Mo–1.5W–0.07Nb–0.05C–0.01B.[13] The strengthening of this steel is envisaged by co-precipitation of intermetallic like NiAl, and of copper. Both these phases are capable to provide significant precipitation hardening. When the Ni/Cu and Al/Cu ratios are kept at lower level (0.6–1.3 and 0.02–0.5, respectively), precipitation of copper is known to lead the process of co-precipitation. Copper atoms are precipitated first and then the segregation of nickel and aluminum atoms takes place at the interfaces between copper and the matrix; finally the precipitation of NiAl forms at these interfaces upon continued aging at 550 °C. The steel is normally quenched from 900 °C and then it is tempered/aged at the predetermined temperature ~550 °C.

Experienced some shortcomings in respect of its achievable mechanical properties, the magnitudes of Ni/Cu and Al/Cu ratios are now a day increased to 3.3 and 1.3 respectively. This alteration of chemical composition causes nanoscale precipitation of NiAl at first; these precipitates are distributed uniformly throughout the matrix. This is then followed by precipitation of elemental copper at the interface of NiAl and matrix. Thus

co-precipitates (NiAl + Cu) are formed at many locations; however singular precipitates NiAl also remain present at different locations. Both these two types of precipitates confer high strength to the steel.

It is also noted that carbides of the form $Fe_3(Mo,W)C$ and NbC are formed during heat treatment of these steels. These fine carbide particles have significant contribution to the ultimate strength of the material. Therefore it is inferred that martensite matrix of high-dislocation density is infested with numerous highly dispersed nanoscale precipitates of NiAl and co-precipitates of NiAl and copper.[14] As stated, the precipitates of NbC and Fe–Mo–W carbides are also formed in the microstructures. These microstructural constituents make it possible to achieve a very high hardness of around 625HV and ultrahigh strength of 41800 MPa in the above steels.

2.8.2.7 Medium-Carbon Low-Alloy Steel

Medium-carbon low-alloy steels are high-strength, high-toughness steels, the properties of which depends upon the chemical composition and heat treatment. In general these steels contain average carbon of 0.30 or 0.35 wt.%. AISI 4130 or 4140 contains chromium of (0.8–1.1 wt.%) with molybdenum (0.15–0.25 wt.%), whereas AISI 4340 and its modified version are Ni–Cr–Mo steel. In some varieties of this class of steel, vanadium is added to a small amount (0.05–0.1 wt.%). In nickel–chromium steel, the hardenability is quite high as nickel and chromium exhibits synergism in shifting the time temperature transformation (TTT) diagram toward right. In majority of steel of this class the Ni to Cr ratio is maintained at or above 2:1 with Ni ranging from 1.6 to 2 wt%. Commensurate with the application of these steels, machining is required before hardening. For a low-hardenable alloy like AISI4130, 4240, 4330, 4340, and their modified versions, normalizing followed by tempering is required to improve the machinability of steel. Within this class of steels, there are some steels which are of air hardening type. These steels are medium-carbon medium-alloy steel with Cr ~5 wt.%, Mo ~1–3 wt.%, and V ~1.6–1.8 wt.%. The stated compositions are just nominal and may vary according to specification given in the standard hand book. For these steels annealing is preferred before machining. Sometimes severe mechanical working is required and for those situations spheroidization annealing is carried out. These medium-carbon ultrahigh-strength steels contain low to medium alloy contents and are in general hardened and tempered. However before hardening, machining may be required. Normalizing and annealing are the heat-treatment processes preceding the machining operation. Also post-weld stress relieving may be required before hardening and tempering. Some of the steels which have strength higher than 1400 MPa are often exposed to hydrogen during pickling or electro plating. In those cases diffusion annealing to drive out hydrogen is also carried out.

- Normalizing: Whenever normalizing operation is required before machining it is carried out at a temperature 870–900 °C, held there for 1 h 25 mm^{-1} of section size and cooled in steel air. The normalized steels are tempered at 650 °C and then subjected to machining.
- Annealing: Whenever annealing is required it is carried out at a temperature 830–870 °C followed by furnace cooling to about 450 °C at a rate of 10–15 °C per h.

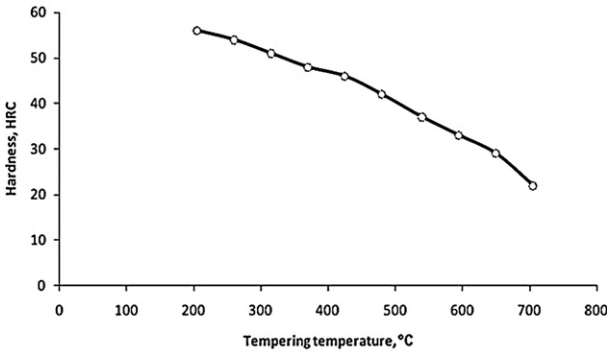

Figure 10 Variation of hardness with tempering temperature. UG Project report, MNIT Jaipur, India after *ASM Handbook*, Vol. 4; p. 506.

- Hardening: The medium-carbon low-alloy steels are generally quenched in oil. The hardening temperature is around 850–880 °C and the soaking time is decided as usual by 1 h 25 mm^{-1} of section thickness. The steel is then quenched in oil bath kept preferably at a temperature 80 °C so as to produce 100% martensite. Following the hardening operation, the tempering is done for sufficient period of time at a temperature ranging from 200 to 650 °C. It may be noted that the tempering temperature is to be decided by the degree of reduction in hardness envisaged to achieve by tempering. A tentative guideline for reaching at a particular hardness value can be obtained from **Figure 10**.
- Spheroidizing: Whenever required, spheroidizing annealing is carried out by heating the steel to 760 °C, holding it there for 12–14 h, and cooling slowly in the furnace.
- Stress relieving annealing: As stated earlier the stress relieving operation is carried out at 650–675 °C if the steel components are welded prior to hardening operation. Whenever the steel is electroplated, the diffusion annealing to drive out hydrogen is carried out by heating it to 200 °C keeping it there for prolonged period of time say 8–10 h depending upon the thickness of the work piece.

However it is to be kept in mind that these annealing operations must not be carried out at a temperature higher than the tempering temperature, if tempering operation is already accomplished. Going above the tempering temperature will lead to degradation of mechanical properties of the steel.

Sometimes polymer quenching such as glycol-based quenchant is used in preference to oil because, it has higher flexibility in adjusting cooling rates and it does not catch fire as easily as oil does. The Microstructural changes accompanying hardening and tempering of AISI 4140 is shown in **Figures 11(a)–11(c)**.

2.8.2.8 Si-Modified 4340 Steel

It is designated as 300 M and contains Si 1.4–1.8 wt%. This steel is normalized by heating to 930 °C, holding there for 30 min per 25 mm of thickness size and then air cooled. If normalizing is a prerequisite for machining, the steel has to be tempered at a temperature of 650 °C. This steel is austenitized at about 860 °C, quenched in oil at 80 °C. Following

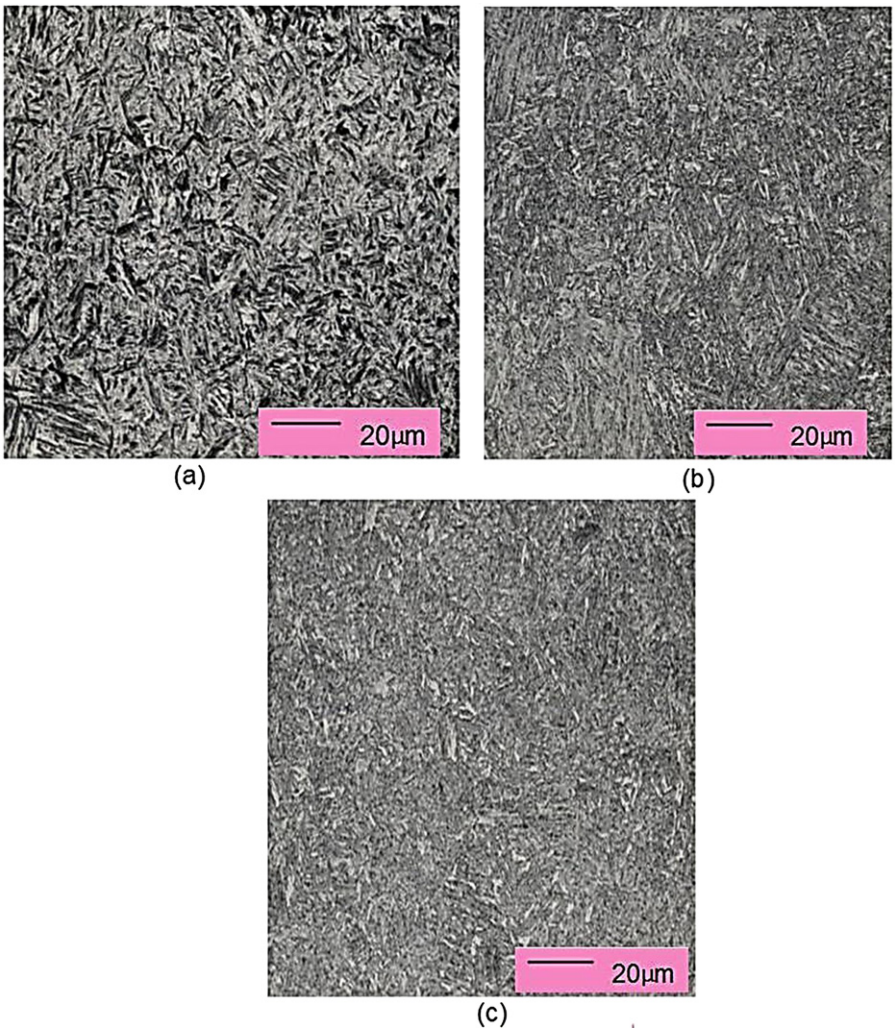

Figure 11 Microstructure of 4140 alloy steel (a) In quenched condition showing martensite, (b) quenched from 900 °C and tempered at 420 °C showing tempered martensitic structure with some acicular product, and (c) tempered at 650 °C showing fully tempered martensitic structure, (all at 20 μ). Courtesy: George F. Vander Voort, Consultant – Struers Inc USA. Vander Voort, G. F. *Understanding Heat Treatment Results using Metallography*. Book on stainless steel; ASM: Metals park, OH, 1935.

quenching operation, tempering is carried out at about 320 °C for 3–4 h. Tempering must be done above 300 °C and the exact temperature is to be decided by final property requirement. Double tempering is recommended for best combination of strength and toughness, because it minimizes the retained austenite content and produces a mixed mode of microstructure comprised of relatively coarse and fine constituent.

2.8.2.9 Ni–Cr Structural Steel

The nickel–chromium steel has wide range of applications. Low carbon chromium–nickel steel is usually subjected to surface hardening treatment to produce a hard and wear resistance surface. These steels are used in heavily loaded gears, shafts, etc. The TTT-diagram of steel containing 0.12% C, 2% Cr, and 4% Ni is shown in the **Figure 12**. After carburizing the composition of the steel at its surface becomes such that M_s–M_f temperatures are considerably lowered due to enhanced stability of austenite caused by alloy addition. When the carburized components are air cooled to room temperature, these are partially hardened. Thus subsequent machining of the parts becomes difficult. So the steels after carburizing must be heated for tempering at a high temperature, viz. 650 °C. Due to presence of high amount of retained austenite the carburized case exhibits a somewhere lower hardness values, RC55.

A single hardening operation is normally carried out for this steel. The steel is heated to 800–830 °C and held for suitable time period. Finally the steel is oil quenched and tempered. Tempering is carried out at such temperature which can give rise to required mechanical properties.

Medium-carbon chromium–nickel steels are often employed for improved structural application. The steel contains 0.37% C, 1.4% Cr, and 3.25% Ni. The hardenability of this steel is quite high and thus this steel is employed for production of heavy forgings, shafts, high-strength crankshafts, etc., without much difficulty in through thickness hardening. It is to be noted that

chromium–nickel steels are highly prone to temper embrittlement, when tempering is carried out at 500 °C followed by slow cooling. Hence after oil quenching these steels are tempered at temperature less than 300 °C (say 230–240 °C). This help to achieve high strength with adequate ductility.

Molybdenum and tungsten further strengthen the steels without loss of ductility. These elements resist softening and lessen the quantum of temper embrittlement. Molybdenum reduces temper embrittlement by delaying the kinetics of precipitation; however this element does not put any thermodynamic constraints to the formation of chromium carbide which are supposedly responsible for temper embrittlement.

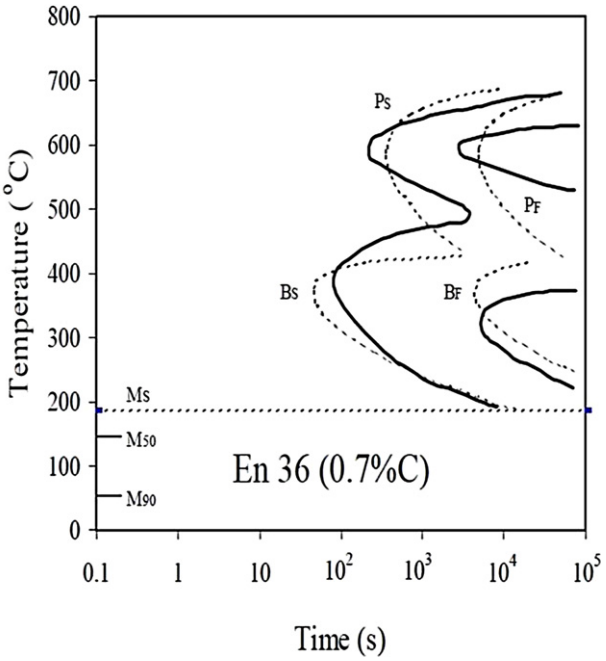

Figure 12 Time temperature transformation diagram for Ni–Cr structural steel.[15] Saunders, N.; Guo, Z.; Li, X.; Miodownik, A. P.; Schille, J. P. *The Calculation of TTT and CCT Diagram of General Steels*. Available from: http://www.sentesoftware.co.uk/media/2540/ttt_cct_steels (accessed July 4, 2011); Atlas of Isothermal Transformation Diagrams of BS En Steels, Special Report No. 56; The Iron and Steel Institute: London, 1956.

Ultrahigh-strength steels (Table 2) containing 5% Cr are known as hot-work die steel. In this category, H_{11} and H_{13} are commercially important.

The chemical compositions of these two steels (H_{11} and H_{13}) are very much similar; hence their heat treatment and ultimate mechanical properties do not vary much. These steels are also known as deep-hardening steel, which imply that they can be hardened by simple air cooling. Air hardening minimizes the thermal stress and thus the chances of distortion or cracking are reduced. The modified H_{11} steel differs from conventional H_{11} steels in respect of carbon content. Both H_{11} and H_{13} are capable to achieve secondary hardening and so the best properties of these steels will be achievable by tempering at temperature higher than 500 °C, that is beyond the secondary hardening peak. The microstructures of these varieties of steel after suitable heat treatments comprise of tempered martensites of desired fineness as shown in Figures 13(a)–13(c). This high-temperature tempering insures stabilization of microstructures. For air-hardening steels like H11 modified or H13, the cooling after forging must be done quite slowly, else there will be considerable martensite transformation, which may lead to crack formation due to high-transformational strain.

Therefore after forging the component should be charged in furnace kept at 800 °C and should be soaked until the equalization of temperature, throughout the section of component is attained. After this the component is cooled very slowly within the furnace.

The heat-treatment schedule for modified H11 is as follows:

- Normalizing: Normally it is not recommended for these steels because these are air hardening steels.
- Annealing: Annealing is carried out after forging. The component is heated to 800 °C in a furnace in controlled atmosphere, and held there for sufficient period to achieve homogeneity of temperature and microstructure. Following soaking the component is cooled slowly within furnace up to a temperature of 450 °C and then rapid cooling to room temperature may be performed. This will ensure freedom from carbide network at grain boundaries.

Table 2 Chemical composition of some ultrahigh-strength steels

Type		*C (wt.%)*	*Mn (wt.%)*	*Si (wt.%)*	*Cr (wt.%)*	*Ni (wt.%)*	*V (wt.%)*	*W (wt.%)*	*Mo (wt.%)*	*Co (wt.%)*	*Al (wt.%)*

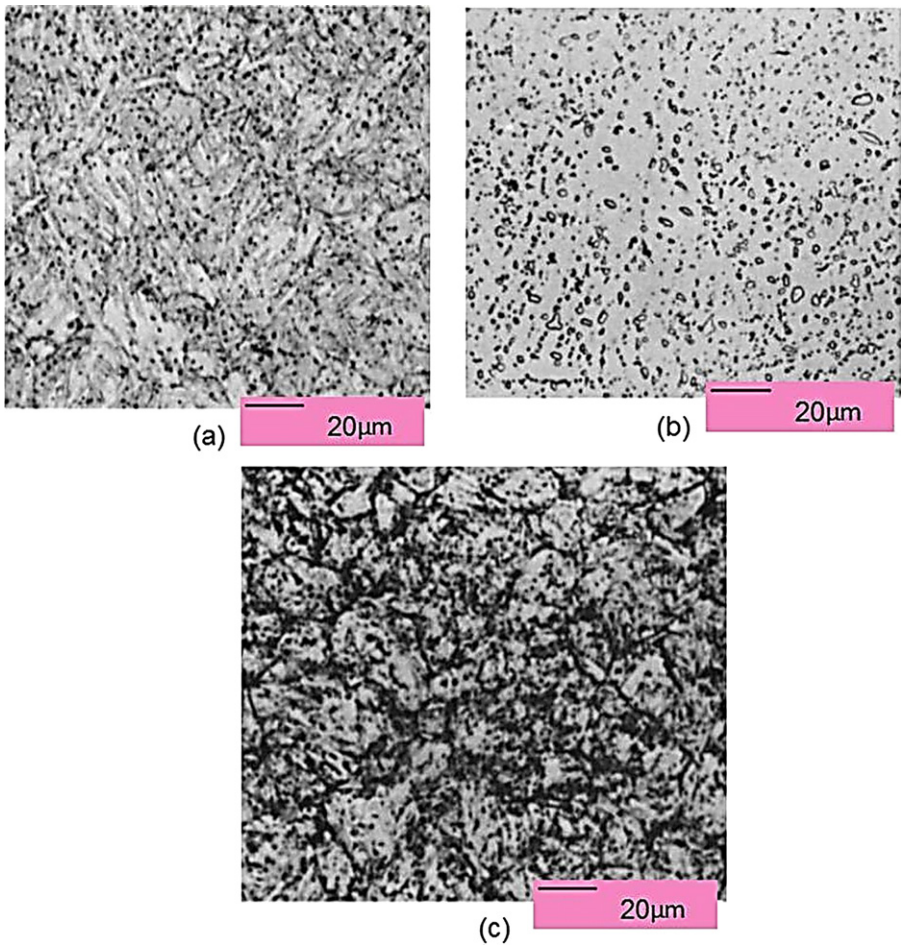

Figure 13 Microstructure of (a) AISI H11 steel austenitized at 1010 °C, air quenched, and double tempered at 510 °C showing fine carbides in martensitic matrix, (b) microstructure of AISI H13 steel, after spheroidizing annealing, and (c) H13 Steel austenitized at 1025 °C, air quenched and double tempered at 595 °C showing small amount of very fine undissolved carbides in a martensitic matrix. *ASM Hand Book*, Vol. 9; p. 1566, 1549, 1567.

- Hardening: For this the components are heated to 760–790 °C at a moderate heating rate of 100 °C per hour, and held there for half an hour until the temperature from surface to center equalizes. This will minimize the thermal stresses in the component. Again, following the preheating treatments the temperature of component may be raised to above 1000 °C, held for about 30 min (however the soaking time is to be suitably adjusted as per the maximum thickness size and total mass of a particular charge in the heat-treatment cycle). After soaking the components are quenched in still air. During air hardening, the distortion due to heat treatment is negligibly small.
- Tempering: Tempering of these steels is carried out at such high temperature where secondary hardening may take place efficiently. In the majority of cases the tempering temperature should be about, 550 °C. At this peak secondary hardening temperature maximization of strength occurs. However tempering the steel at slightly higher temperature beyond the secondary hardening peak is considered to be a better option, because this improves ductility with minimum sacrifice in hardness.

Multiple tempering operations are sometimes carried out in this type of steel. The first tempering is carried out at 550 °C, and held there for 1–2 h depending upon their section size. After this, the component is cooled to room temperature and again heated to tempering temperature which should be 15 °C higher than the previous tempering temperature which means 565 °C and is held there for 2 h, following which the component is again cooled to room temperature. This may be carried out for the third time if it is required to improve ductility to a greater extreme.

- Stress relieving: After rough machining prior to heat-treatment stress relieving anneal is practiced for these steels. Stress relieving is carried out at a temperature of 650 °C for preselected time and then cooled very slowly to room temperature. The stress relieving following rough machining helps to achieve higher dimensional accuracy in the heat treated parts.
- Nitriding: This is often required for achieving high-wear resistance for this variety of steel. In that case the components after finish machining and heat treatment are subjected to nitriding operation. Nitriding is carried out at a

temperature of around 525 °C or at slightly higher temperature, and this treatment may be considered to be second tempering of a double tempering operation.

It serves two purposes:

- double tempering to produce more favorable microstructure and
- formation of nitrides at the surface ensures very high-wear resistance.

Exactly identical heat-treatment schedule with similar requirements will be performed for H13 variety of steel, with only difference is in their tempering temperature. H13 steel is tempered at temperature lower than H11 modified due to existing difference in their composition.

2.8.2.10 Medium-Carbon Chromium–Vanadium Steel

These steels contain above 0.4 wt% carbon with about 1 wt% chromium and are common structural steels, used in automobile sector. However the addition of vanadium by 0.2 wt% is found to increase the resistance to softening upon heating to elevated temperature. This steel is very much suitable for crank shaft, spindle, shaft, etc. Increasing the carbon content to 0.50 wt%, makes the steel become suitable for applications as heavy duty springs.

Heat treatment of medium-carbon chromium–vanadium steel

- A normalizing treatment is carried out by heating the steel to 900 °C, held for suitable time period and then it is cooled in still air.
- Normalizing is followed by hardening process. Hardening is carried by heating at moderate heating rate till 700 °C, holding there for 15 min to relieve thermal stress and then heating at a faster rate, 100–150 °C h^{-1}, to a temperature of 880–890 °C. The steel is held there for 1 h for each 25 mm of maximum section thickness. For heavy duty spring steel with the high carbon content, ($\sim$0.5 wt%); a slightly lower austenitizing temperature is recommended; the temperature of austenitization may be kept at 850–860 °C. The austenitized steel is quenched in oil.
- Following oil quenching, the structural steel for use as crank shaft (0.4 wt%C) is tempered at high temperature just beyond the secondary hardening peak. The tempering temperature for this steel is around 650 °C whereas tempering temperature for heavy duty springs is kept somewhat lower, $\sim$450 °C. The idea of high-temperature tempering for structural steel stems from the requirement of high fracture toughness of the steel at relatively high-strength level. Hence attempt is made to achieve a strength of 900 MPa at 50% reduction in area. For spring steels however the strength requirement is rather high and a low-tempering temperature enables to achieve strength of 1300 MPa.

2.8.2.11 Chromium–Molybdenum Steel: Steel for High-Temperature Boiler Application

Molybdenum bearing steels are generally employed for heat resistance application. Steels containing lower carbon of 0.15 wt% with 0.5 wt% Mo can retain its strength quite satisfactorily till 550 °C. Another variety of the steel containing 0.15 wt% carbon, 0.5 wt%Mo with 1 wt% Cr has excellent weld ability. Its weldability is good because of low carbon content. Since Molybdenum is present in substantial amount, the steel possesses excellent high-temperature properties. Moreover presence of chromium imparts good corrosion resistance. This steel is a good choice for boiler drum, boiler tubes, and super heater pipes. In the present day's boilers, high-temperature steam is in use. The super heater materials of today's boiler plants must have very good high-temperature properties; resistance to deterioration of mechanical properties due to rise in temperature must be quite high in the materials to be used in modern super heater pipes.

Another medium-carbon steel of composition 0.30 wt% carbon, 0.25–0.3 wt% Mo, and 1 wt%Cr is employed for manufacturing of critical components of turbine such as rotor, shaft, etc. Fastening parts of high-temperature boiler are preferentially made from the same type of steel but with a high chromium content, i.e., 1.6–1.8 wt%. The steels belonging to this group are used in hardened and tempered condition.

Heat-treatment schedules of Cr–Mo steel:

- Normalizing from a temperature of 900–925 °C.
- Holding at the austenitizing temperature, 840–880 °C for suitable time, followed by oil quenching with oil temperature at 50–60 °C.
- Tempering is carried out at the preselected temperature; the selection of tempering temperature depends upon the final mechanical strength to achieve.

2.8.3 Spring Steel

To ensure good performance as a spring material, the important factors are the elastic limit, or the proportional limit in tension and that under torsion which must be quite high. If loading is done upto higher stress values, it would result in permanent set and in such case the material will not return to its original state.

Impact loading, rapid cycling, extreme temperature, i.e., where creep is important, adversely affect the spring properties of the steel. The corrosion or stress corrosion is the other issue creating constraints to the performance of spring steel. A typical composition of spring steel is provided in the **Table 3**.

Table 3 Composition of heavy duty spring steel

The factors influencing allowable working stress of spring steels are:

- range of working stress,
- frequency of deflection or oscillations that the spring is to undergo, and
- temperature of operation.

If operating temperature of a spring is increased, its load bearing capacity is decreased. This is reflected by the relaxation or load loss as shown in **Figure 14**.

Different types of spring steels used for various applications are plain carbon manganese steels, silicon–manganese steels, and different types of alloy steels including stainless steels. The steels which are capable to release the stored energy responsively are normally used for spring application. It is emphasized that limited use of spring under load does not give up their original dimension; thus for these steels, high-elastic modulus, high-yield strength, and precipitation hardening are preferred. Further, spring steels must have high-fatigue strength as they also experience fluctuating stresses and sometimes overloading. Its plasticity must be sufficiently high so as to enable the manufacturer to form springs of appropriate shape. High-carbon steels with suitable alloying elements are required to be judiciously heat treated in order to achieve above properties.

As stated earlier, the modulus of spring steels should not be less than 21×10^4 MPa, with a modulus of rigidity higher than 8×10^4 MPa. The failure of spring steels is commonly a fatigue failure initiated by stress raisers. Therefore the spring steels must be made up of very hard and strong materials.

In order to get these properties, most spring steels except stainless steel variety, are used in hardened and tempered condition. Schematic heat-treatment schedule for particular spring steel is shown in **Figure 15(a)**.

In the hardened condition the spring steels must achieve 100% martensite at the center of the section. It is important to avoid retained austenite in hardened condition, which creates soft spots and affects the properties of spring. Therefore judicious selection of alloying element is made to design spring steels, so that M_s temperature does not go below room temperature.

However hardenability of spring steels must be sufficiently high to produce 100% martensite at the center. This allows high-carbon steel with suitable alloying elements to compose a good spring material.

The heat treatment of spring steel should be carried out very carefully, because the spring characteristic is inherently dependent on the heat treatment which ensures achieving the desired microstructure.[15–17] Microstructures of the above spring steel are seen to be tempered martensites of varying fineness when oil quenched and tempered at different temperatures (**Figure 15(b)**).

The successful heat treatment of spring steel must envisage:

- Complete absence of non-martensitic product of transformation of austenite in its hardened state; this is possible only if a compositionally homogeneous austenite is produced in the heating stage and sufficiently rapid cooling, commensurate with hardenability of the spring steels is employed.

  If there is any quench delay because of material handling difficulties, the austenite phase in steel may undergo slow air cooling and may reach such a temperature from where it becomes difficult for the inner section of the material to avoid softer components to form. Thus in industrial situation, delay in quenching must be prohibited. The quality achieved by stipulated heat-treatment cycle is equally important and so the hardness testing of hardened material must be checked to ensure if 100% martensite is formed up to center of stock.

  Because the spring steels are generally of high carbon content, extremely high-temperature austenitization is also discouraged. Moreover furnace atmosphere for high austenitization temperature must not be too much oxidizing so as to effect decarburization beyond the level of acceptance.

  Owing to the fact that decarburization takes place at high temperature, there is a chance that fatigue strength of material may be adversely affected. Normally the spring steel requires appropriate shaping by way of hot working at elevated temperature of around 925 °C, preferably in controlled atmosphere. However the exact temperature of working depends upon the chemical composition of steel. Any difficulty during shaping can be taken care by intermediate annealing for softening the material. Sometimes cold working followed by subcritical annealing around temperature of 650 °C, in neutral atmosphere is performed. Permitted by the cold deformability, this kind of recrystallization annealing for softening the material is a better choice because it prohibits decarburization. Silicon present in the steel increases the activity of carbon in iron and therefore a silicon alloy steels is very prone to surface decarburization. In order to take care of this difficulty the silicon bearing steels are annealed for shortest possible time at the lowest possible temperature.

  It is advisable to normalize the spring steel, which are generally exposed to high-working stress during shaping. In fact the steels which are hot worked by forging are always required to be normalized prior to final heat treatment.

  This is because of sudden energy input in such type of metal forming operation which may lead to adiabatic heating

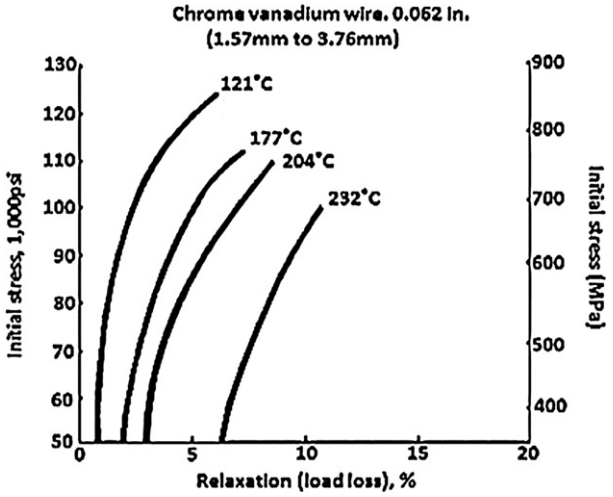

Figure 14 Load loss diagram. www.centuryspring.com.

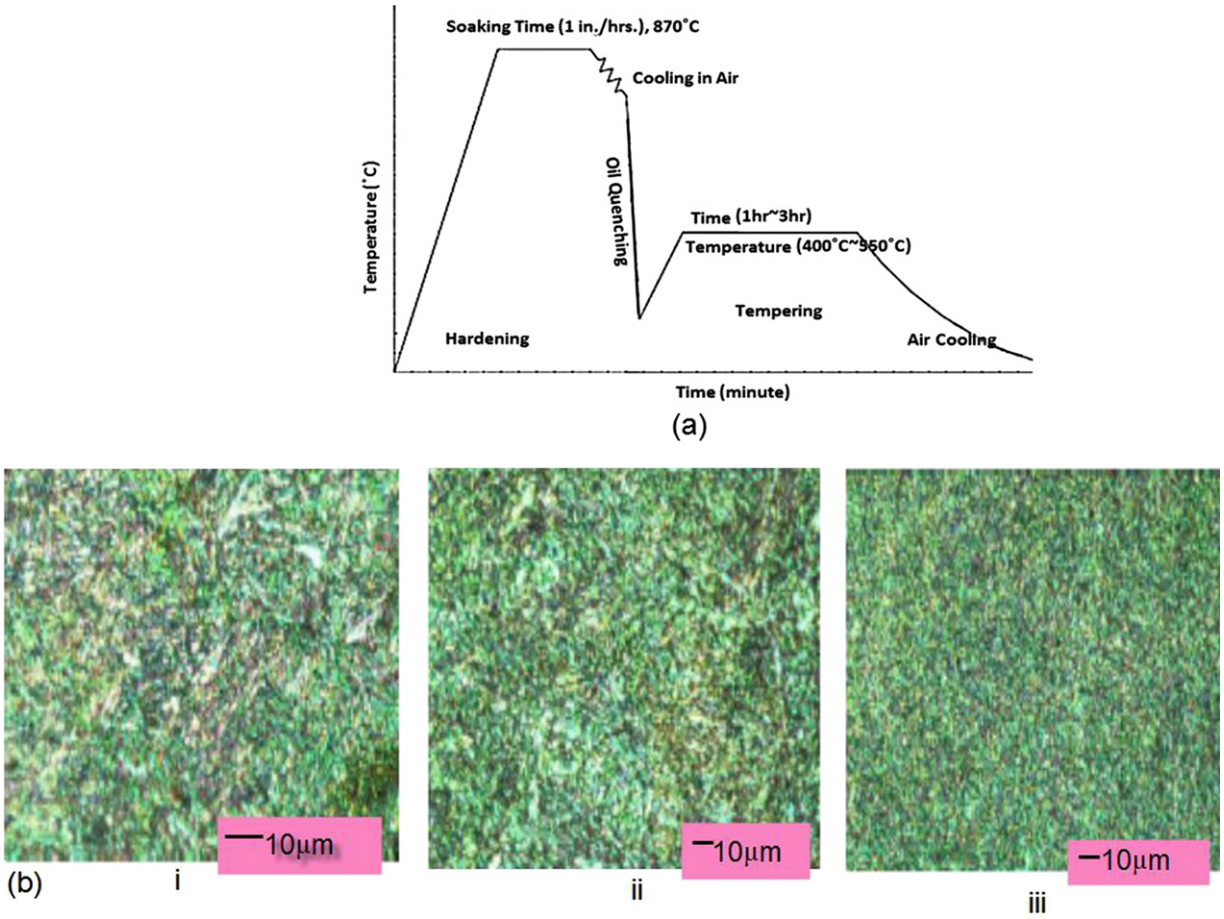

Figure 15 (a) Heat-treatment cycle and (b) The microstructure of spring steel oil quenched and tempered for 2 h at (i) 450 °C, (ii) 500 °C, and (iii) 550 °C.[17] Htun, M. S.; Kyaw, S. T.; Lwin, K. T. Effect of Heat Treatment on Microstructures and Properties of Spring Steel. *J. Min. Met. Mats.* **2008**, *18* (2), 191–197.

thereby leading to the formation of unacceptable structure. Normalizing leads to structural refinement and can be a good starting material for the subsequent heat-treatment operation. In general the steel is heated to a temperature of 850–880 °C, held for certain period of time following the rule of 1 h 25 mm^{-1} section thickness and then cooled in still air.

The hardening operation for the spring steel is extremely critical. Springs are required to be heated quite uniformly throughout the section while attaining the stipulated hardening temperature. It is very important that during heating of steel, there is no change in dimension or shape of the charged material. It is therefore advisable to load the spring within the furnace in horizontal position. Vertically loaded springs for heating may be deformed due to its own weight; when it becomes quite hot during austenitizing the flow stress reduces and the spring deforms. To avoid distortion of long spring, the furnace wall must be plain and smooth without creating any imbalance in load throughout the length of the spring. For a long spring, change in radial dimension is also a concern and it is advisable to insert a mandrel inside the spring. As discussed earlier, holding time depends upon the maximum cross section and also on the total charge placed in a furnace. Springs of smaller dimension are heated to the lower limit of the temperature range for hardening, whereas the upper limit of hardening temperature is normally employed for the springs of larger dimension. It may be recalled that too high a hardening temperature or a prolonged holding time at the hardening temperature gives rise to grain coarsening and excessive decarburization, whereas too low hardening temperature is not desirable as it adversely affect proper hardening.

After holding for suitable period of time at the hardening temperature, the spring is taken off from furnace and then quenched in oil or water depending upon their composition and the final properties required. The temperature of water should be maintained to 30–40 °C so that a slower cooling rate within M_s–M_f can be achieved. The quenching bath must be agitated for improving efficiency of quenching.

For high-carbon high-alloy steels, oil quenching is preferred over water quenching because water quenching leads to the formation of quenching cracks. However the quenching oil should be heated to a temperature of 80 °C, at which it will have adequate fluidity for effective quenching within the M_s–M_f region. Similar to water quenching, the oil quenching bath is also to be subjected to agitation when heat treatable items are put to the quenching medium.

Sometimes very high-hardenable steels are used to impart suitable properties by suitable heat treatment of steels. In

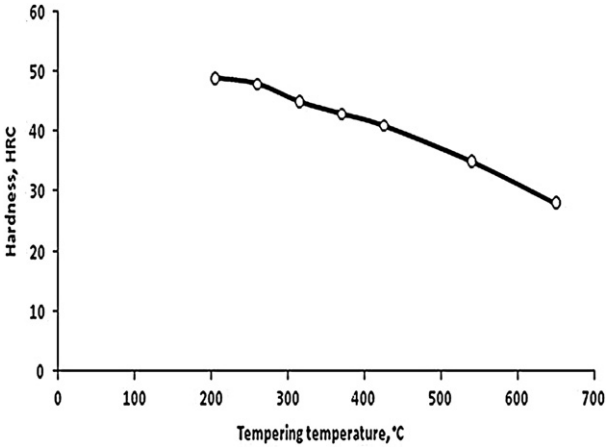

Figure 16 Reduction in hardness due to tempering of spring steel.

this case the work pieces are tempered immediately after quenching as it helps to avoid the quench cracks.

Tempering temperature is decided by the final properties desired in the material. The reduction in hardness due to tempering of a spring steel of different composition at different temperatures is shown in Figure 16. It is experienced in general that beyond a tempering temperature, degree of reduction in hardness value decrease due to increase in temperature. It is apparent from the figure that the reduction in hardness during tempering is a function of tempering temperature for a particular tempering time. It is important to note that the magnitude of reduction in hardness during tempering is a deciding factor of finally achievable toughness properties in the materials. To acquire a good spring characteristics the hardness reduction by tempering must not be less than R_C15. For successful heat treatment of a particular spring steel of similar specification, such type of master curves are to be generated by experimental trials. Sometimes some spring steels are also subjected to patenting operation. Austenitization is carried out at sufficiently high temperature above Ac_3; it is then cooled in molten salt bath kept at fixed temperature near the nose of continuous cooling transformation (CCT) diagram so that a fine pearlitic microstructure or a combination of pearlitic and upper bainitic structure can be produced.

Specific heat-treatment cycles of some common spring steels are given below:

- AISI 1065: (C-0.6–0.7 wt%; Si-0.35 wt% max; Mn-0.60–0.90 wt%; S,P-0.035 wt% max)
  - It is mainly used for light flat spring, for example, seat cushions spring for vehicles.
  - Heat-treatment cycle comprises, of soft annealing at 660 °C, hardening by oil quenching from 825 °C followed by tempering at around 500 °C.
  - Tempered hardness to be achieved is R_C45.
- AISI 1074: (C- 0.7–0.8 wt%; Mn-0.5–0.8 wt%; S, P-0.03 wt% max.)
  - These are used for flat and coiled spring for automobile and vehicles.
  - Soft annealed at 650 °C oil quenching from 800 °C and tempering at 625 °C.
- AISI 1084: (C-0.8–0.9 wt%; Si-0.35 wt%; Mn-0.6–0.9 wt%; S,P-0.04 wt% max.)
  - These are mainly used for flat and coiled spring for automobiles and railways.
  - Heat-treatment cycle comprises, soft annealing at 650 °C, oil quenching from 800 °C, and tempering at 625 °C.
- AC22–76: (C-0.5–0.6 wt%; Si-1.8–2.2 wt%; Mn-0.7–0.95 wt%; S,P-0.035 wt% max.)
  - Silico–manganese steel: Normalizing followed by hardening from 850 °C and then oil quenching with oil at 80 °C, and then tempering at 600–625 °C.
- AISI 1095: (C-0.92–1 wt%; Mn-0.05 wt%)
  - Annealing at 810 °C; Normalizing at 880 °C; Hardening at 800–820 °C.
  - Oil quenching and tempering to RC50.

2.8.4 Silicon Steel

The steel used as the core material of electrical transformers is generally a soft magnetic material viz. grain-oriented silicon steel.[17–18] After due processing, this material exhibits a pronounced Goss texture, i.e., a {110} ⟨001⟩ texture, which is indicative of preferred orientation of grains. High-temperature annealing during the processing of this steel leads to abnormal growth of grains with Goss orientation. Till date universally accepted reasoning is yet to be put forward in respect of the origin of preferred growth of the above Goss grains. It is conjectured that the Goss orientation is inherited since early stages of the production of this material and at later stages of processing it grows at the expense of others, due probably to the strain energy factor.

It is known that the Goss orientation owes its origin to shear deformation during hot rolling. The deformation confined to the surface is responsible for evolution of Goss texture.

The general processing of transformer steels include the production of ultraclean steel with the available technology; the strip is then subjected to first cold rolling to reach to an intermediate thickness. Decarburization re-crystallization annealing is done with cold-rolled strip in continuous annealing furnace. Second cold rolling is done to achieve the final thickness. Then a heat-resistant coating is applied (MgO) and following this, high-temperature batch annealing is accomplished. During this annealing strong Goss texture develops. The microstructure of the annealed steel is shown in Figure 17.

Soft magnetic material possesses minimum coercive force and maximum magnetic permeability. For this, a homogenous single phase microstructure is required. The material must not contain any residual stress which adversely affects the performance of the material. In electrical industries low-carbon silicon steels are widely used as soft magnetic material. Silicon goes in solution in iron and expectedly increases the electrical resistivity. The electrical resistivity is due to the incoherent scattering of electrons at the small-scale irregularities within the crystal. Substitutional Si-atoms are the irregularities of atomic scale of magnitude and hence increase the resistivity. At the same time it reduces the eddy current losses and improves magnetic permeability. The hysteresis loss is minimized in

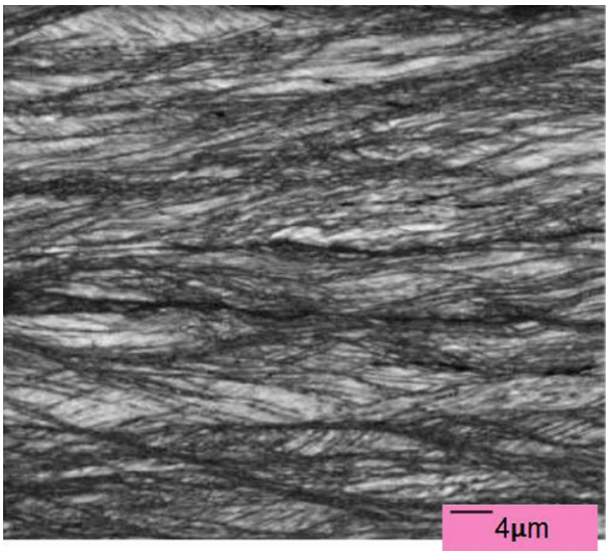

Figure 17 Microstructure of grain-oriented silicon steel after annealing.[19] Dorner, D.; Zaefferer, S.; Lahn, L.; Raabe, D. *Magn, J. Magn. Mater.* **2006**, *304* (2), 183–186.

steel containing 4% Si at a carbon contain below 0.02%. This kind of electrical-sheet steel requires special heat treatment. Batch annealing is carried out in a reducing atmosphere at a very high temperature like 1200 °C. This high-temperature annealing is carried out in inert environment or in vacuum; such a high-temperature annealing for a long period of time, i.e., 15–30 h aims at recrystallization followed by grain coarsening and also deliberate decarburization to burn out carbon at high temperature. The development of a textured material gives a high initial permeability and ensures easy magnetization.

For application as permanent magnet hyper eutectoid chromium steel containing 0.9–1% of carbon with 1.2–1.5 wt% of chromium, is commonly used. Chromium content may be varied up to 3.5 wt% in special cases. Maximum value of coercivity is obtained after hardening of steel. Quenching stresses are relieved by tempering the steel after hardening. The general heat-treatment process for this kind of steel for use as a permanent magnet consists of heating the material to around 850 °C, holding there for 1 h per each 25 mm of maximum section thickness and then quenching in oil or in suitable polymer quenching medium. After hardening, the steel is tempered at a low temperature of 100–120 °C for a prolonged period, even up to 20–25 h; this first stage of tempering stabilizes the microstructure and hence the magnetic properties. Magnetic properties can be improved by alloying the above steel with tungsten by around 5%. It is to be remembered that the steels meant for application as permanent magnet must not be held above Curie temperature for the sake of softening of the steel or as a strategy for preheating before forging, as this will exert a permanent detrimental effect to the microstructure and hence the properties. It should be understood that the ferromagnetic iron requires the favorable alignment of magnetic domains containing parallel spins. This is also possible in a iron–carbon alloy where a single phase exists. Magnetic spoiling due to annealing at 800 °C is ascribed to the coarsening of carbide particles which will not dissolve properly during austenitization. Thus the quenched microstructure is not a single phase and is comprised of carbon depleted martensite and undissolved carbides. These carbides restrict the movement of the domain boundaries required for getting the correct alignments in favorable directions in respect of the externally applied magnetic field.

If the same steel is normalized at a very high temperature like 1200 °C, the carbides go into solution and a single phase microstructure is obtained with the resultant removal of magnetic spoiling. In some cases due to the advantage of cobalt to improve magnetic property (Co is a ferromagnetic material), the steel containing 8–10 wt%Cr and 13–15 wt% Co are used as permanent magnetic material. However Cobalt steels are very prone to magnetic spoiling mainly because the cobalt steels are extremely hard and require a high temperature of 800 °C to get softened. Thus magnetic spoiling is an inevitable consequence of manufacturing of cobalt bearing steel.

The recommended heat treatments for these steels are

- Heating the steel to 1200–1230 °C for austenitization accompanied by complete dissolution of carbides; the steel is held for suitable time at these hardening temperatures.
- Quenching it in air to reduce the thermal stress yet producing a completing single phase martensitic microstructure.
- Tempering the steel at 700–750 °C for 1 h per each 25 mm of section size followed by air cooling.
- Raising the temperature of the steel to around 1050 °C and holding there for a selected period time; the steel in austenitic condition is quenched in oil and finally aged at low temperature, like 100 °C.

Austenitizing for the first hardening leads to complete dissolution of the preexisting carbide particles. Tempering the hardened steel at 750 °C leads to the formation of uniformly distributed fine carbide particle in a matrix of low-carbon martensite. Dissolution of these fine carbide particles in austenite becomes very easy and therefore the second hardening from a low temperature gives rise to the required homogenization effect without the risk of other microstructural damages affecting the magnetic properties.

- The alloy containing 14Ni8Al20Co3Cu is a very good magnetic material. The alloy is extremely hard and so produced by casting. The heat treatment of these alloys is quite complex and is as follows.
  - o Heating to 1300 °C at a very slow rate of the order of 20–30 °C per hour under a magnetic field of intensity 3000 Oe (oersteds).
  - o After this treatment material achieves a very good magnetic property.

2.8.5 Bearing Steel

A bearing is used as a support and allows relative movement to take place between two bodies. In a diesel engine, the principal bearings are those which allow rotation of the crankshaft about its own longitudinal axis in the main engine and those between the connecting rod and crankshaft.

The surface undergoing relative movement, the lubricant to be used and the environment are the deciding factors of property requirements in bearing steel. The steel must have

- resistance to fatigue and crack growth,
- high hardness and strength,
- resistance to hydrogen cracking,
- high corrosion resistance, and
- high toughness.

Types of bearing:

There can be several types of bearings for commercial application depending upon the nature of contact. These are:

- solid contact bearing or journal bearing:
  a) hydro dynamically lubricated bearing
  b) boundary lubricated bearing.
- rolling contact bearing:
  a) ball bearing
  b) roller bearing.

Ball-bearing steels are a special class of steel. The nominal compositions of this variety of steels are given in the Table 4.

In practice the materials of bearing, like the balls, rings, and the rollers are subjected to abrasive wear and corrosion. It is known that chromium in high-carbon steel is introduced to impart aforesaid of the properties. High strength of the material is normally obtained by hardening and tempering.[20–22] This ensures a high fatigue limit, good contact fatigue resistance at high-abrasion resistance. Normally the starting microstructure of this steel is fine pearlite with dispersed cementite particles. The procedure to be adopted for hardening is dependent upon the sizes of the bearing component. The small balls are quenched in oil whereas water quenching may be involved for large sized balls. It is to be recalled that volume expansion due to martensite transformation in a ball will be mostly isotropic and there will be less propensity for cracking even when it is quenched in water. However a polymer quenching with suitable concentration of polymer may be a more reliable quenching medium. The hardened balls are subjected to tempering at relative low temperatures that is around 150–160 °C so that fine low-carbon martensite with dispersed carbide particle constitute the microstructure. However better results can be obtained if the thermal stresses accompanying quenching can be taken care by employing martempering process. The materials austenitized at 850 °C may be quenched in a salt bath maintained at a temperature of 180–190 °C. Formation of matrensite and its first stage of tempering take place simultaneously, with the likelihood of the presence of some retained austenite. The retained austenite present in the oil quenched samples may be reduced by subzero treatment at −50 °C for about an hour. This is then followed by tempering at 160–180 °C for 2 h. The microstructure of ball-bearing steel of type 52 100 is shown in Figure 18.

2.8.6 Hadfield Steel

Hadfield manganese steel is essentially high-carbon high-manganese steel where carbon content is around 1.1–1.4% with 11–14% manganese. The alloy is principally made for high-wear resistance application and its high work hardening ability makes it applicable for various applications including armors. Microstructurally Hadfield manganese steel must be fully austenitic without the presence of any carbide in the microstructure. The compositions of some commercial Hadfield manganese steels are given in Table 5.

Fully austenitic steel is non-magnetic. As stated, the microstructure of Hadfield steel is fully austenitic at all the temperatures; thus there is no scope of structural refinement of these steels through conventional heat treatment. The commercial Hadfield manganese steels are required to have the commonly specified grain size of ASTM-4 or finer. Therefore proper melting techniques are employed to achieve the required grain size.

It is very common that the solidified Hadfield manganese steel contains some carbide particles at the grain boundaries. The precipitated carbides are shown in the Figure 19(a). Slower is the solidification rate, higher will be the amounts of carbides present in the microstructure. These carbides are of the type $(FeMn)_3C$.

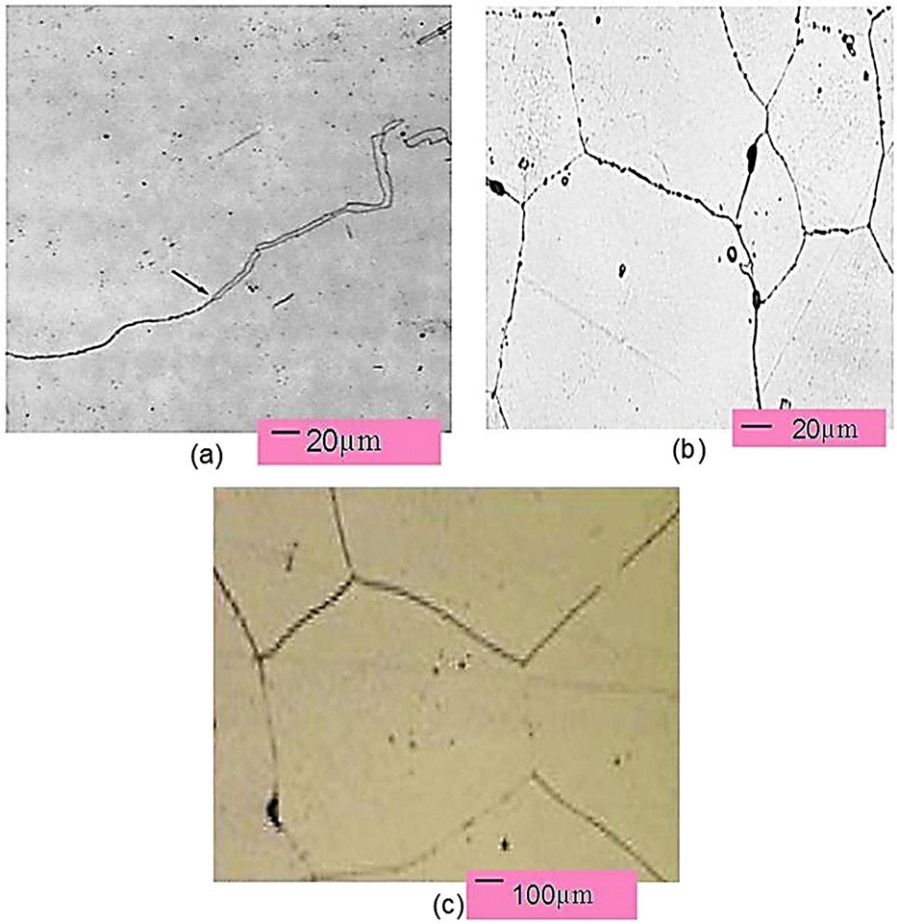

Figure 19 Microstructure of Hadfield steel showing (a) precipitated carbides, (b) undissolved carbide, and (c) clean grain boundaries after heat treatment.[23] (a) and (b) *ASM Hand Book*, Vol. 9; p. 1675, 1678; (c) Hosseini, S.; Limooei, M. B. Optimization of Heat Treatment to Obtain Desired Mechanical Properties of High Carbon Hadfield Steel. *World Appl. Sci. J.* **2011**, *15* (10), 1421–1424.

The heat treatment of Hadfield manganese steel aims at dissolving the precipitated carbides at high temperature and then cooling it very fast to achieve carbide free grains of austenite which is considered to be the ideal microstructure for its commercial application.[23–26] The most commonly stated heat treatment is to heat the steel at a high temperature like 1000 °C, holding it there for preselected time and then quenching it in water. Importantly the complete dissolution of the carbide depends upon judicious selection of heating temperature and the concerned soaking time. The cooling rate is of extreme

importance as a slower cooling rate makes the steel prone to precipitate carbide. So the major points to consider for successful heat treatment of Hadfield manganese steels are:

- Elimination of any undissolved carbide by solutionizing at a high temperature.
- Avoidance of precipitated carbide in the final microstructure.

In industrial situation the control of austenitization temperature and holding time is not so easy in the midst of operational constraints due to inherent difficulty in mechanical handling of the heated objects of heavy weight. From the phase diagram of the steel it may be observed that the formation of carbides is highly probable if the steel is held for sufficient time at temperature below 700 °C. It is for this reason the heating rate at the initial stage is very important. Also this high-alloy steel is very prone to decarburization and demanganization on prolonged holding at high temperature which may lead to compositional degradation and formation of a microstructure that does not secure the desired property of the steel, thereby rendering the component unusable. Thus the suggested strategy of heat treatment may be as follows.

- Heating the component at a very fast rate till a temperature of 750–800 °C is attained by the objects; below this temperature, the probability for formation of $(FeMn)_3C$ is very high. Depending upon the capacity of the furnace, a heating rate of 150–200 °C h^{-1} is also recommendable.
- Because of fast heating there will be thermal shock due to temperature difference between surface and center of stock. However austenite is face-centered cubic (FCC) in structure and is a ductile phase; therefore the chance of cracking due to thermal shock is less. Nevertheless the chance of distortion due to differential volume change at different position of the section cannot be underrated. Therefore the component is held at 750–800 °C for about 30 min. The exact time of holding must be determined through experience of the hardware system and charge quantity of a specified batch under heat treatment in a particular shop.
- The material is then heated to a high temperature like 1050–1075 °C at a moderate heating rate say 75 °C h^{-1}. A slower heating rate is preferred to avoid thermal gradient which may lead to distortion of the material which being austenitic is highly plastic at elevated temperature. On the contrary a slower heating rate implies a higher residence time at a high temperature; this makes the steel liable to decarburization unless the furnace atmosphere is highly controlled. Again the slower heating rate takes a longer time to reach the austenitizing temperature which affects productivity. Therefore proper measures are to be taken while selecting the heating rate.
- The steel is soaked at 1050 °C for 1 h per 25 mm of section size for complete dissolution of carbides. The dissolution of carbides should be completed at a reasonably low temperature but not with prolonged holding time; the idea is to dissolve the carbides rapidly without much chemical degradation at the solutionizing temperature. If solutionizing temperature is too much increased to reduce the socking time, rapid grain coarsening may take place when there is no restrictive agent at the grain boundaries.
- After almost complete dissolution of carbides, the steel is heated as fast as possible up to a temperature of 1100–1150 °C so that
  a) there is insurance of complete carbide dissolution without anything being left to be dissolved,
  b) production of compositionally homogenous austenite is possible,
  c) grain coarsening by unnecessary high-temperature exposure for a long time may be avoided, and
  d) ample provision may be made for inevitable delay in quenching in an industrial situation irrespective of efficacy of material handling system.
- The steel is held at this high temperature for a very short period of time, say for 15–20 min due to above stated reasons. The steel components are then quenched very fast in a circulating bath of water with 4–5% of sodium chloride (NaCl) in it.

A typical microstructure without any carbide is shown in the Figure 19(c).

2.8.7 Stainless Steel

Stainless steels are categorized on the basis of various microstructures. Accordingly different classes of stainless steels are termed as martensitic, austenitic, ferritic, duplex (ferrite with austenite), and precipitation hardening stainless steel. Each variety has a range of composition and within this range a number of steels each with specific designation and different composition from others are available. For example, steels of types 403, 410, 416, 420, 440A, etc., belong to the general class of martensitic stainless steel. Stainless steels are employed in application where corrosion resistance and heat resistance are important. All stainless steels ought to contain chromium as its principal alloying element; the stainlessness is due to the formation of a thin impervious layer of Cr_2O_3 on the surface of the stainless steel component. The passivity of this layer in presence of most of the aggressive environments makes it a versatile corrosion and weather resistant material.

2.8.7.1 Martensitic Stainless Steel

Martensitic variety of stainless steel contains 12–18 wt% of chromium. The composition of some commercially important steels falling under this class is given in Table 6.

Being martensitic, these steels are magnetic and are amenable to cold working at low-carbon concentration; the heat

treatment of martensitic stainless steel envisages the production of martensite from austenitic phase field.[27–29] and therefore the heat-treatment process is similar to those practiced for plain-carbon or low-alloy steels where strength of the steels are required to be obtained from the hardness of martensite that forms due to rapid cooling of high-hardenability austenite.

It is to be noted that stainless steels are high-alloy steels and due to characteristic effect of alloying elements the hardenability of this class of steel is very high; this entails the possibility of formation of martensite even under the ordinary air cooling. However chromium being a strong ferrite stabilizer raises the upper critical temperature by constricting the austenite phase field. The constriction of austenitic loop in the equilibrium diagram of high-chromium steels requires a judicious selection of temperature to produce austenite at a particular carbon level. The cross section of Fe–C–Cr phase diagram at 12% Cr is shown in the diagram in Figure 20. From this diagram it is possible to determine the austenitizing temperature for a martensitic stainless steel of 12% Cr.

Thus martensitic stainless steels are normally heated to a temperature above 1020 °C for austenitizing. However the time at holding temperature must be kept to minimum because at such high austenitizing temperature, there is a great risk of fast grain coarsening just after the dissolution of carbides is completed; at the same time decarburization at the surface of the steel component may take place in martensitic stainless steels which contain appreciable amount of carbon. Following austenitization, the steel is quenched in oil or air. Air quenching, wherever possible, is encouraged due to the potential it bears to minimize thermal stresses. Tempering of the steel follows hardening operation. Tempering of the quenched martensitic stainless steel is carried out at about 580–600 °C so as to take the advantage of secondary hardening. The microstructure of the martensitic stainless steel showing tempered martensite is furnished in Figure 21.

If the carbon content of the martensitic stainless steel is high, tempering must not be carried out too long near 580 °C because it will lead to the precipitation of chromium carbides; consequential formation of chromium depleted matrix will lead to deterioration of corrosion resistance. In the event the carbon content of the martensitic stainless steel is low, the severity of lowering of corrosion resistance property is not so significant as to warrant any special action.

Martensitic stainless steel of high-chromium content with appreciable amount of carbon content must not be tempered within the range of 390–500 °C because there will be significant lowering of impact strength of material. This temper embrittlement is known as 400 °C embrittlement and must be avoided while heat treating martensitic stainless steel.

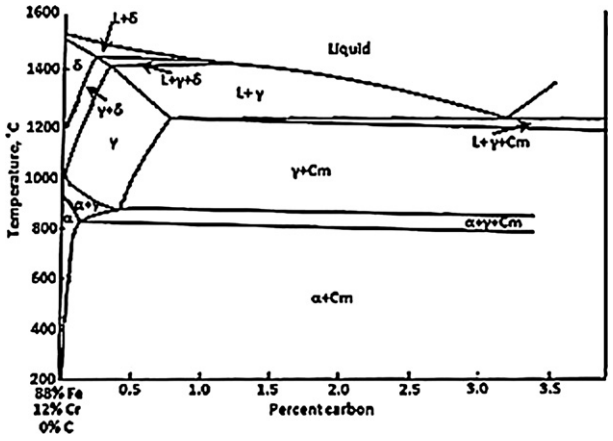

Figure 20 Phase diagram of iron–carbon–chromium alloy for 12 wt% chromium. Thum, E. E. *Book on Stainless Steels*, 2nd ed.; ASM: Metals Park, OH, 1935.

2.8.7.2 Ferritic Stainless Steel

Ferritic stainless steel contains higher chromium content than the martensitic stainless steel. Normally the chromium content of the ferritic stainless steel ranges from 14 to 27 wt%. From the Fe–C–Cr diagram sectioned at 18% chromium, shown in Figure 22, it appears that for a low-carbon level, the austenite is not possible to form until a very high temperature, viz 1200 °C is attained for a carbon content of 0.06%. This implies that the steel of this composition is ferritic from room temperature till 1200 °C and is not amenable to hardening. Ferritic stainless steel may be hardened by only cold working. Microstructure being ferritic, ferritic stainless steel can be readily cold worked and deep drawn. This is why this type of stainless steel is used in food industries and for architectural trims, etc. Annealed steels are very soft and ductile and it possesses a very good formability. In the annealed condition ferritic stainless steels are much stronger then the annealed low-carbon steels and its corrosion resistance is much higher than the martensitic stainless steel. The composition of some ferritic stainless steels is given in Table 7.

Other than annealing, there is no other meaningful heat-treatment practice which may help to improve the properties of ferritic stainless steel. The microstructure of a fully ferritic stainless steel is shown in Figure 23.

However this steel is highly prone to embrittlement if held at temperature within 400–500 °C. This embrittlement leads to sharp deterioration of impact properties and therefore the annealing operation must be carried out at a temperature from above 500 °C till the temperature at which austenite is likely to form. After holding for adequate period of time which is decided by whether there is any carbide phase present in its microstructure and if the carbides can easily go in solution to produce a single phase homogenous ferrite. The steel is then slowly cooled till 500 °C; in any case, long time holding within 400–500 °C is not allowed for the sake of avoiding 400 °C embrittlement. It is advisable to cool the material slowly within the furnace till 500 °C after which a faster cooling must be accomplished to avoid 400 °C embrittlement. The exact cause of 400 °C embrittlement is not known but the recorded observation of enhanced embrittlement with increasing chromium content tends to hint upon that 400 °C embrittlement is related to the formation of harmful carbides while holding the steel at the above temperature region.

2.8.7.3 Austenitic Stainless Steel

In consideration of the means to take care of susceptibility of intergranular corrosion, the austenitic stainless steels are

divided into several groups. The conventional austenitic steel contains around 0.15% carbon which in stabilized group is managed by addition of carbide formers. The low carbon variety directly avoids the formation of carbide which is known to be the main cause of intergranular corrosion. There are high-nitrogen steels where nitrogen is employed as austenite stabilizer; however nitrogen also imparts a better surface property. Some of the austenitic stainless steels are alloyed with other alloying elements to incorporate special properties. The general composition of a few commercially important austenitic stainless steels encompassing all the varieties as stated above is furnished in **Table 8**.

The coefficient of thermal expansion of austenitic stainless steel is very high, so extra precaution is to be taken while loading the heat-treatment furnace with a number of components. There should be proper spacing to accommodate thermal expansion between two adjacent components; because austenite is soft and highly deformable, stacking of items must be done judiciously so as to avoid such deformation. The conventional austenitic stainless steels are supposed to be austenitic at all the temperatures, therefore are not amenable to quench hardening. However hardening can be obtained by

cold working the steel. If welding is done, then the steel must be subjected to heat treatment. In general the conventional austenitic stainless steels are heated to a temperature above 1000 °C, within a preferable range of 1050–1150 °C, held there for sufficient time to dissolve the carbides originally present in the microstructure and then cooling very fast. The annealing temperature may somewhat vary for steels of different compositions and a higher temperature is recommended for those compositions where the chances of presence of carbides in the original microstructure is high. The soaking time to be spent for annealing operation depends upon the section size. However 50–60 min for 25 mm of the section size is the thumb rule which is normally followed to determine the holding time at the annealing temperature. In general water quenching is recommended for achieving maximum amount of corrosion resistance. Although in some variety of steels, oil quenching is also done. Conventional austenitic stainless steel experiences the precipitation of Cr-carbides between 425 and 900 °C if the steel is exposed within this temperature region for a long period of time. Thus the annealing temperature must be considerably above 900 °C so that all the carbides can be fully dissolved in austenite before it is subjected to quenching treatment; moreover the rate of dissolution of chromium carbide being quite sluggish, a high-annealing temperature around 1100 °C is generally recommended for successful implementation of commercial heat treatment of austenitic steel. In order to limit the grain growth to an acceptable limit, the annealing temperature must not be much higher than 1100 °C. The microstructure of AISI 304 steel in Figure 24 exhibits a fully austenitic structure.

As stated earlier the quenching must be done very rapidly; if size, shape, and weight put a concern for distortion due to rapid cooling then quenching in forced air blast may be recommended. In some cases extremely thin sectioned parts cannot withstand a forced air blast without having excessive distortion; in such cases, normal air cooling is recommended. In cases of ultrathin components a slow air cooling may bring down the temperature of the component from annealing temperature of 1100 °C down to room temperature within a very short time. This short duration may not trigger the precipitation of chromium carbides in steels whose carbon content is relatively less to exceed the solubility product of carbon and chromium in FCC austenite. But in cases where the composition is such that this type of air cooling cannot prevent the precipitation of carbides then corrosion resistance is required to be sacrificed. To avoid this situation stabilized grade of austenitic stainless steel or extra low-carbon steels are to be invoked.

In the stabilized grade, the presence of Ti or Nb inhibits intergranular precipitation of chromium carbide and thereby helps to avoid sensitization. Nevertheless these alloys must be annealed to relieve the stresses present in the material and to increase the ductility properties of the same with additional stabilization of austenite.

Normally the steel is heated to a temperature up to 1000–1050 °C followed by a rapid cooling. In this particular case the dissolution of carbide is a greater concern than the precipitation of these carbides during cooling. Thus the annealing temperature and the soaking time are more important for consideration than the cooling rate. Heating temperature must be high enough to dissolve all the carbides in least possible time and with limited grain growth. In this respect a maximum temperature of 1050–1060 °C is reasonably acceptable with a time consideration of 50–60 min per 25 mm thickness. Whenever maximum corrosion resistance from stabilized variety is required to be obtained, the recommendable heat treatment should comprise of heating the material to 1000 °C and holding at this temperature for 5 h and then followed by rapid cooling to room temperature.

The extra low-carbon austenitic stainless steel does not have the problem of sensitization because of the fact that there is no scope for carbide formation and hence unlike non-stabilized grades this variety of steel does not require any rapid quenching from a high temperature (Figure 25). Nevertheless

this steel should not be employed for long-time service within the sensitizing region, 540–760 °C.

Stress relieving of austenitic stainless steel is required if parts made of this steel is exposed to stress-corrosion environment. The steel is then heated to 900 °C or above and a slower cooling is more effective to remove stresses, as the fast water cooling may induce thermal stresses.

Selection of heat-treatment process is quite critical; the processes which aim to avoid sensitization and hence to improve corrosion resistance are those which act in opposition to stress relieving. So stress relieving is to be judiciously applied with an eye to compositional response to such treatment without bringing about sensitization.

The following factors are required to be given consideration during heat treatment of austenitic stainless steel:

- Heating in the range of 470–850 °C envisages carbide precipitation at the austenite grain boundaries. In ferritic stainless steel carbides first form discontinuously within the ferrite grains and then at the grain boundary.
- In high molybdenum-bearing steel σ (sigma) phase form within 550–900 °C. This deteriorates corrosion resistance and ductility.
- Slow cooling of non-stabilized grades may experience sensitization or σ-phase formation or both.
- Heating above 1000–1130 °C enables dissolution of all carbides in austenite.
- Stress relieving may be required only in special situation, and should be practiced only if it is otherwise favorable in respect of retaining corrosion resistance.

Due to presence of molybdenum, 316L and 317L are prone to σ phase embrittlement due to a long-time exposure between 660 and 860 °C; corrosion resistance can however be improved by stabilization annealing at 900 °C for 2–3 h; after this any stress relieving operation at 640–650 °C will not deteriorate the

corrosion properties. Heat treatment of high-nitrogen austenitic steel is exactly similar to conventional austenitic stainless steel as problems encountered due to sensitization and distortion are identical in either case. The steels like 316N or 304N are austenitized at 1020–1100 °C and following holding for 1 h per 25 mm section thickness the jobs are rapidly cooled in water. High alloy grade steels are heated to higher temperature range 1125–1150 °C with a specific purpose. Due to addition of high amount of molybdenum to reduce pitting corrosion and to improve high-temperature resistance, the concerned alloys are produced with very low carbon; nevertheless the steels are prone to δ ferrite formation at a high temperature of austenitization. Again at temperature just below 900 °C, these steels are susceptible to σ phase formation. Therefore neither a low temperature nor a high temperature is convenient for avoidance of property degradation. So austenitization is carried within narrow temperature regime. If stress relieving is to be carried out at a temperature lower than the annealing temperature, holding time must be of minimum possible value.

2.8.7.4 Duplex Stainless Steel

This type of steel is a combination of ferrite and austenite; in some compositions ferrite content is higher and in others austenite content is higher. Also ferrite and austenite contents may balance in some steels. Table 9 gives some typical composition. Duplex steels like 329 are austenitized at temperatures between 925 and 975 °C, held there for predetermined period of time and then cooled quite rapidly but rapidity of cooling must be consistent with limitations of distortion.[30,31] For the molybdenum bearing duplex steels (>6% Mo), the austenitization temperature is kept at higher level say 1000–1050 °C and then the steel in quenched rapidly to room temperature. A typical micrograph of the same steel is shown in Figure 26.

2.8.7.5 Precipitation Hardenable Stainless Steel

Chemical composition of precipitation hardenable stainless steel is given Table 10.

In the heat treatment of precipitation hardenable stainless steels the processes to perform are:

Cleaning: All parts to be heat treated are first subjected to cleaning operation prior to heat treatment. The chemical composition of precipitation hardenable steels is selected very judiciously and therefore it is important that the composition does not alter due to any impurity at the surface. For example, if surface of component contains any lubricants, such as oil, etc., carburization may take place during heat treatment and this will lead to unpredictable product. The cleaning of components is carried out by techniques like abrasive blast cleaning.

Furnace atmosphere: Heat treatment of precipitation hardenable stainless steels cannot be done in any furnace which is fired with oil or natural gas as this will alter the composition of the steel, most commonly carburization. Induction furnaces or gas fired radial tube furnaces are suitable in heat treating this kind of steel. Creating controlled reducing atmosphere either in the form of dissociated ammonia or by any other means bears a risk of nitriding or carburizing, which are detrimental to the final properties of the product. Argon or helium atmosphere may be used for austenite formation at temperature 950 °C or higher. The procedures consisting of full annealing, austenite conditioning, effecting the phase transformation, and finally aging of the steel are narrated below:

- Solutionizing is carried out at temperature of 1050–1070 °C, and held there for 1 h per each 25 mm section for annealing and cooling to room temperature in water.
- Austenite conditioning is generally carried out at a temperature of 900–950 °C for a period of 1 h per 25 mm

thickness followed by air cooling or oil quenching for heaviest section.
- The transformation cooling is carried out from the solutionizing temperature by water cooling to room temperature and then cooling to subzero temperature within the range of −70 to −80 °C.
- The aging is carried out at temperature of 520–550 °C for the time period as predetermined by the final properties required, followed by air cooling.

In all cases of heat treatment of this stainless steel, furnace atmosphere must not carburize the steel under any condition. An excessive oxidizing environment is not very welcome; the carbonaceous environment inside the heat-treatment furnace is also prohibited, as this leads to carbon pick up; higher carbon pick up implies greater risk of sensitization.

Due to presence of molybdenum, 316L and 317L are prone to σ phase embrittlement[32] due to a long-time exposure between 660 and 860 °C; corrosion resistance can however be improved by stabilization annealing at 900 °C for 2–3 h; after this any stress relieving operation at 640–650 °C will not deteriorate the corrosion properties.

Heat treatment of high-nitrogen austenitic steel is exactly similar to conventional austenitic stainless steel as problems encountered due to sensitization and distortion are identical in either case. The steels like 316N or 304N are austenitized at 1020–1100 °C and following holding for 1 h per 25 mm section thickness the jobs are rapidly cooled in water.

High-alloy grade steels are heated to higher temperature range 1125–1150 °C with a specific purpose. Due to addition of high amount of molybdenum to reduce pitting corrosion and to improve high-temperature resistance, the concerned alloys are produced with very low carbon; nevertheless the steels are prone to δ ferrite formation at a high temperature of austenitization. Again at temperature just below 900 °C, these steels are susceptible to σ phase formation. Therefore neither a low temperature nor a high temperature is convenient for avoidance of property degradation. So austenitization is carried within narrow temperature regime. If stress relieving is to be carried out at a temperature lower than the annealing temperature, holding time must be of minimum possible value. Figures 27 and 28 show the microstructure of 17–4PH steels under different treatment conditions.

2.8.8 Maraging Steel

Maraging steels are ultrahigh-strength steels containing high amount substitutional alloying element at very low-carbon content. These steels are very much suitable for high-strength high-toughness applications. It is known that carbon steels with or without alloying elements derives its strength and toughness at a balanced amount by first forming martensite which is an extremely hard phase in Fe–C alloy system and is a super saturated solid solution of carbon in body centered tetragonal ferrite, this hard constituent is subsequently tempered where fine scale precipitation of carbide enables

martensite to get rid of super saturation and intimate mixture of fine ferrite and carbide particles in the microstructure confers a good amount of toughness. In contrast maraging steel produces a very soft martensite. Fe–18Ni alloy produces body centered cubic martensite which is very soft. This soft martensite is strengthened to a very high magnitude by the way of aging the martensite at an elevated temperatures; aging leads to the formation of precipitates of different kinds of thermally stable intermetallics to ensure a very high strength at a high ductility level.[33–35] Ternary or quaternary elements are added to form different intermetallics as the hardening phases.[36] It is quite easy to achieve a very high fracture toughness $\sim 150\ \text{MPa}\sqrt{m}$ at ultrahigh strength level around 1650–1700 Mpa. The nominal composition of some standard commercial maraging steels are given in **Table 11**.

Martensitic reaction is reversible; however due to large thermal hysteresis the reversion from martensite to austenite transformation is considerably delayed. It is for this reason, heating of martensite to about 600–650 °C enables intermetallic precipitates to form; these intermetallic phases are the chief hardening phases in maraging steel.

The martensite in maraging steel is formed after cooling the material from the austenitizing temperature which can be selected from the metastable equilibrium diagram **Figure 29** and the steel is held at the austenitizing temperature for sufficient time so as to make up homogenous austenite phase. This austenite is of FCC crystal structure and after cooling it transforms to BCC martensite through diffusion less shear transformation.

The transformation takes place until M_s temperature is reached and the M_s temperature of most of the varieties of maraging steel ranges between 200 and 300 °C. This implies that maraging steels are fully martensitic at room temperature. These martensites are internally faulted with dislocations due to lattice invariant deformation. The lath martensites in maraging steels do not contain any reversible faults like twins. The alloying elements added to maraging steels influence the M_s temperature but the CCT diagram of the steel would indicate that diffusional decomposition of austenite in this maraging steel is not possible (*ASM Metal Hand Book, Vol.4*). Thus the microstructure of Fe–18%Ni maraging steel is comprised of lath martensite. If nickel percentage is increased beyond 25 wt.%, the martensite becomes internally twinned so as to accommodate macroscopic shape deformation accompanying martensitic transformation.

Most of the maraging steels contain cobalt, which enables the addition of those alloying elements which lowers the M_s temperature but can form intermetallic phases. The main task of strengthening maraging steels is to produce 100% martensite, which upon aging must experience adequate amount of precipitate formation. This leads to age hardening. To assist the formation of different intermetallics, addition of titanium, aluminum, molybdenum etc., are mandatory. However all these elements are known to lower the M_s temperature. Unless M_s temperature is kept at a high level it is not possible to produce 100% martensite; the M_s temperature must be kept around 200–300 °C and cobalt assists in achieving the desired M_s temperature.

Cobalt is the only alloying element, known to raise M_s temperature in maraging steels; so addition of cobalt up to 6–8% nullifies the effect of other elements in depressing the M_s temperature, which otherwise are considered to be very important alloying elements to give rise to precipitation hardening. Since retained austenite is not a concern in most of the commercially available maraging steels, subzero treatment prior to aging is not needed. However if addition of alloying elements like Mo, Ti, and Al are done at a high level, retained austenite may occur in the microstructure and this retained austenite is considered to be a highly unwanted phase in maraging steel.

There are two possibilities during aging of maraging steels, which are:

1. Firstly, the reversible transformation of martensite to austenite, if the selected aging temperature lies above the austenite start temperature.

2. Second, formation of aging precipitates, while the martensite is heated to a temperature below the austenite start temperature.

Aging for a prolonged period of time at a relatively high temperature may lead to formation of high-alloy austenite, known as reverted austenite. This kind of reversion reaction takes place quite significantly, if aging is done at a temperature higher than 550 °C.

Like all other age hardening systems, maraging steels have their own characteristic aging sequences. The elements like Ti and Be act as strong hardeners, whereas the alloying elements like Al, Ni, Mo, Mn, Si, tantalum, tungsten, and niobium leads to moderate hardening. Again there are elements like Co, Cu, and Zr which are known as weak hardeners.[37,38]

In a molybdenum bearing alloy, metastable Ni_3Mo of orthorhombic crystal structure is commonly observed as precipitate phase; this forms on dislocations or at the lath boundaries. In case of titanium containing steels the precipitated phase is identified as Ni_3Ti which has high potential for strengthening the steel.

Cobalt does not directly take part in aging reaction but a phenomenon called Co–Mo interaction lends a definite contribution to the aging effect of maraging steels. Cobalt is known to reduce the solubility of Mo in BCC matrix; as a result higher volume fraction of fine sized Ni_3Mo precipitates are formed in maraging steel containing cobalt and molybdenum. Molybdenum and cobalt exert synergistic effect on strengthening of maraging steels.

2.8.8.1 Heat-Treatment Sequence of Maraging Steels

The different steps followed in the heat treatment of maraging steel is shown schematically in the **Figure 30**.

Solutionizing: As stated earlier the first stage of heat treatment of maraging steels is solution-annealing treatment, carried out at a temperature sufficiently above the austenite finish temperature. In general the commercial variety of maraging steels is solutionized at 815–825 °C for 1 h per each 20 mm thickness of workpiece. It is advisable to have controlled atmosphere furnace and many a times inert gas atmosphere like jet of nitrogen and argon at a positive pressure is considered suitable for the heat treatment of maraging steels; this is because maraging steels are prone to the chemical degradation during heating at a high temperature.

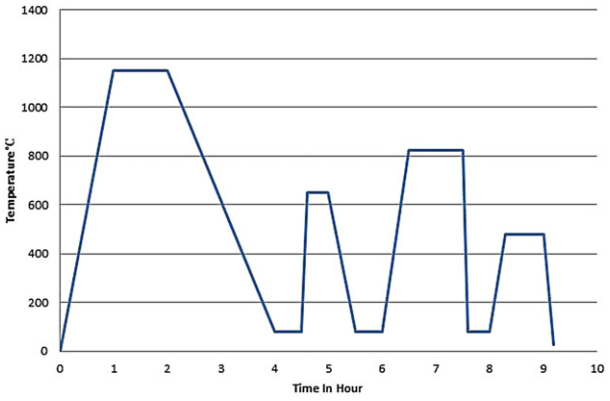

Figure 30 Heat treatment of maraging steel.

Casting of maraging steels are subjected to annealing treatment by heating them to a high temperature like 1150 °C followed by air cooling. Subsequent to this high-temperature treatment the material is reheated to 600 °C held for 1 h and then cooled in air.

The 600 °C heating realizes the formation of reverted austenite which gets distributed throughout the matrix. These reverted austenite particles act as the nucleation sites during the following solutionizing treatment, so that a fine grained austenite can be formed.

After solutionizing, maraging steels are cooled to room temperature. The rate of cooling is of less significance because formation of martensite in maraging steel is inevitable as per dictates of CCT diagram. However it is to be understood that the cooling must be carried out till room temperature, so that 100% martensite formation is envisaged. Because maraging steel is quite strong and the volume change in martensitic transformation of maraging steels is quite small, these steels are not susceptible to quench cracking. Martensite formed after cooling is aged at a temperature between 480 and 500 °C. The microstructure of quenched and aged maraging steel of type of grade 18Ni250 is shown in **Figure 31**. The two microstructures of the same sample at different magnifications essentially demonstrate the presence of martensite phase without any evidence of reverted austenite phase; the presence of precipitates, though hinted in **Figure 31** must require confirmation by high-resolution microscopy. As stated earlier the aging temperature should be kept below 500 °C so as to avoid reversion reaction. By aging at this temperature the commercial maraging steels attain a hardness value of HRc 52–54. The properties of the maraged alloys are shown in the **Table 11**.

2.8.8.2 Embrittlement in Maraging Steel

If maraging steel contains carbon in excess of 0.03 wt% and is alloyed with Ti, there is a great chance of forming precipitates of titanium carbides and titanium carbonitride phases which form at the prior austenite grain boundaries.[39,40] However proper heat treatment can avoid this unwanted precipitation. Nevertheless, embrittlement becomes inevitable due to heating maraging steel at high temperature, i.e., 1180 °C and above, where all carbon atoms in maraging steel go in solution in austenite followed by slow cooling or holding the steel at a temperature region of 750–1050 °C. Precipitation of carbon takes place as grain boundary phase and thus embrittlement results. However if it is required to heat this steel to such a high temperature as in casting, the cooling of the steel from the high temperature must be quite rapid through the temperature region of 1100–750 °C so that the precipitation of carbon at grain boundaries can be avoided and hence the problem of embrittlement can be overcome.

The typical age hardening temperature ranges between 450 and 550 °C with long holding time say 4–12 h; subsequent cooling is done in air. However the time and temperature used for tempering of maraging steels are quite important to determine the final properties of the steel. In initial period of aging the hardening is quite rapid but beyond a definite period

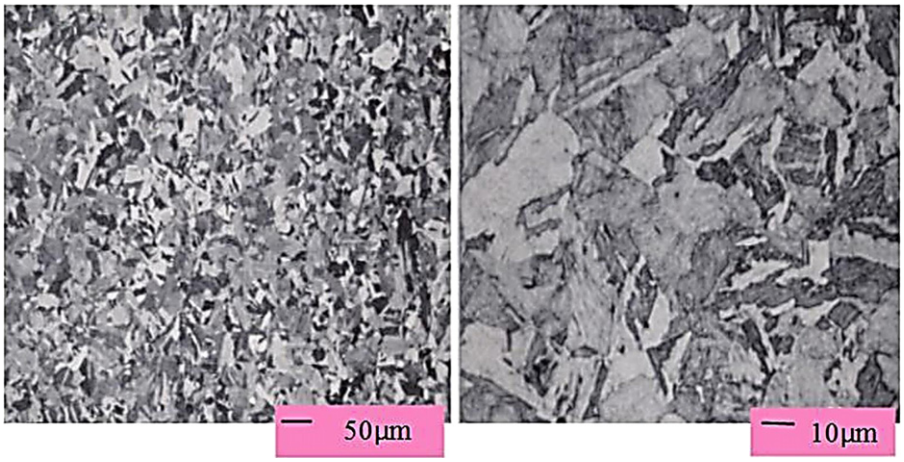

Figure 31 Microstructures of 18Ni250 maraging steel showing martensite after solutioning and aging. Courtesy: George F. Vander Voort, Director, Research and Technology Buehler Ltd. Vander Voort, G. F. *The Microstructure of Ferrous Alloys*.

of aging, particle coarsening takes place and the hardness of the maraging steel reduces. If aging is carried out at a low temperature, the particle coarsening will not be there and age hardening curve may be seen to be a continuous hardening curve. Nevertheless the hardness of the aged martensite must be kept around HR_C 52–53 in order to achieve the desired tensile strength of the order of 2000–2500 MPa.

2.8.9 Heat Treatment of Transformation Induced Plasticity Steel

Transformation induced plasticity (TRIP) steel is a class of steel with ferrite–bainite microstructure and is capable of providing TRIP. Normally these types of ferrite–bainite steels contain a good amount of retained austenite due to incomplete bainitic reaction. These low-carbon steels containing around 0.15% C with silicon of the order of 1.7%, are intercritically annealed so that under equilibrium at the intercritical annealing temperature, a mixed ferrite–austenite microstructure exists. The austenite in the intercritical region is richer in carbon and is given to react isothermally in the bainitic region. The decomposition of austenite to bainite does not go to completion due to formation of low-carbon bainitic ferrite.

The retained austenite is thermally stable due to high solute content, which decreases the M_s temperature to below room temperature.[41,42] However *Md* temperature, the temperature below which martensite transformation may take place by stress induced mode, is very near to room temperature for this kind of steels and any crack propagating through the material will have high-stress concentration ahead of it. If a moving crack comes across a retained austenite particle present in microstructure, the mechanically unstable austenite undergoes stress induced martensitic transformation. These hard martensites are required to be fractured if crack is to propagate through these particles. Since the stress concentration ahead of crack tip is not so high as to be able to fracture the hard martensite, the crack stops propagating. Thus effective plasticity is artificially improved.

The heat treatment of TRIP steel is therefore as follows:

- Normalizing is done by heating the steel to 900 °C and holding there for suitable period of time followed by cooling in still air.
- Heating at intercritical temperature say 750 °C, holding there for specified period of time which depends upon section size. The holding time must be sufficiently high to achieve equilibrium. At this temperature the microstructure of the steel consists of ferrite–austenite mixture of composition as may be deduced from **Figure 32(a)**.
- The steel is then quenched in a bath kept at temperature 350–250 °C; the austenite transforms to bainite (**Figure 32(b)**). Due to incomplete bainitic reaction some high-solute austenite is retained within bainite and this is responsible to impart TRIP. The heat-treatment cycle is shown in **Figure 32(c)**.

2.8.10 Dual Phase Steels

Duplex ferrite martensite steels are first generation AHSSs and are employed in automotive sectors. The composition of a commercial grade dual phase steel, DP500 is given in **Table 12**.

The microstructure of dual phase steel comprises of martensite islands in a matrix of ferrite. The steel is heated to some intercritical temperature, T_i and held there for sufficient time so as to attain equilibrium between two phases, ferrite and austenite. **Figure 32(a)** shows that at temperature T_i, ferrite of composition Z is in equilibrium with austenite of composition Y and after equilibration the steel is rapidly quenched to room temperature.[44,45] High-carbon austenite transforms to martensite and the microstructure is comprised of islands of martensite in the matrix of ferrite as shown in **Figure 33**.

The CCT diagram of this steel along with heat-treatment cycle is shown in **Figure 34**. It is to be understood that the formation of high-carbon martensite is associated with large magnitude of volume change. This volume change is accommodated with the surrounding rigid matrix by way of dislocation, as shown in **Figure 34**.

The transmission electron microstructure is shown in **Figure 35**. It clearly shows huge dislocation in ferrite matrix

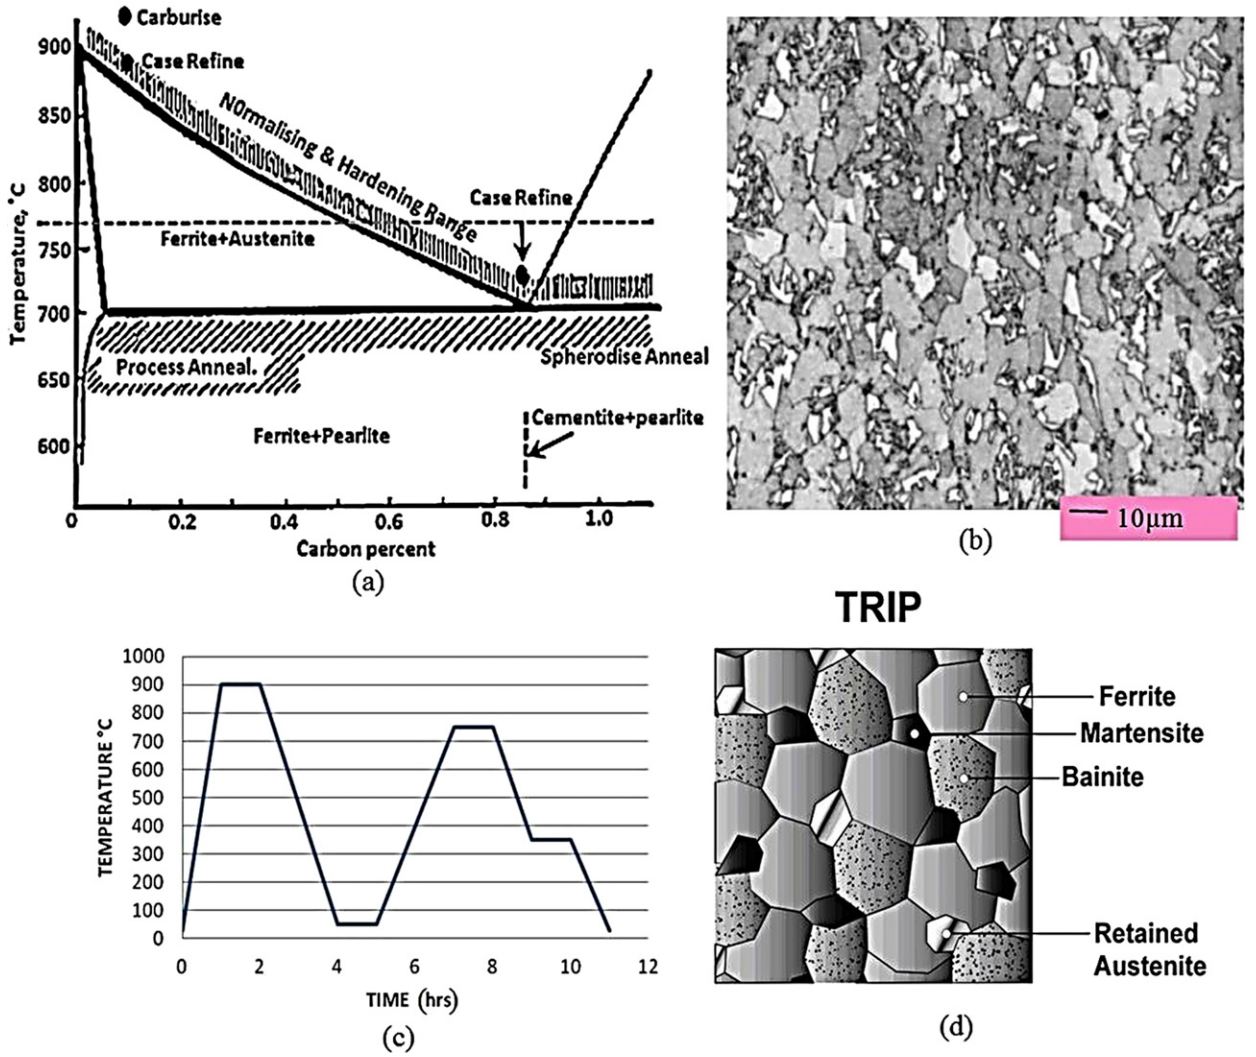

Figure 32 (a) Intercritical annealing temperature shown by a line, (b) Optical photomicrograph of duplex ferrite–bainite TRIP steel,[43] (c) heat-treatment cycle of TRIP steel, and (d) schematic microstructure of TRIP steel. surrounding the martensite crystals. The martensite itself is also highly dislocated due to lattice invariant deformation.

Thus commercial dual phase steel is intercritically annealed and rapidly quenched in water. Due to fast quenching, the ferrite remains supersaturated. These steels are also subjected to another heat treatment called 'Bake hardening.' Bake hardening is a process where the component after being painted is baked at low temperature viz. 160–170 °C. At this temperature the carbon in solution in ferrite becomes more mobile and can migrate to the nearby dislocations if available.

From the heat-treatment schedule of dual phase steel, it appears that the islands of martensite can be made homogeneous and uniformly distributed throughout the matrix. It may lead to a very uniform distribution of dislocations generated around individual martensite particle. The steel is now painted and then baking is carried out by annealing the steel at low temperature of 160 °C. The carbon from supersaturated ferrite starts migrating to dislocations around martensite particles and locks the dislocation. This is typically similar to strain aging and yield strength of steel is improved.[47,48]

2.8.10.1 Rapid Heating Producing Ultrafine Grained Dual Phase Steel

Ultrafine grained duplex ferrite–martensite steels leads to further improvement in properties than the classical dual phase steel. Thermomechanical treatment carried out before intercritical annealing heat treatment has been known to have produced fine grained ferrite in dual phase steels. However through the employment of rapid heating it is also possible to develop very fine microstructures in steels using rapid transformation annealing technique. Steel containing 0.17 wt.% carbon 0.85 wt.% manganese can be subjected to rapid heating technology to produce ultrafine grained ferrite in dual phase steel. The initial microstructure can be fine ferrite – pearlite structure or the tempered martensitic structure. The rapid heating at the rate of 300 C s^{-1} produces austenite at a high degree of superheating; the degree of superheating is the decisive factor in fixing the energy of nucleation ΔG_{max}. Transformation at high superheat reduces the critical nucleus size of austenite as well as the energy of nucleation.[49,50] This leads to formation of ultrafine austenite which upon transformation produces fine microstructure. A low holding time does not allow grain coarsening and so fine structure formation is possible.

2.8.10.2 Bake Hardened Dual Phase Steels

Bake hardening has now been recognized as an effective heat treatment to impart extra strengthening in AHSSs. Bake hardening is essentially a strain aging treatment. The stretch formed steel panels are subjected to a small amount of prestrain; this prestrain introduces dislocations. The ferrite in these steels contains 15–20 ppm carbon in solid solution. The prestrained steel panels are painted and then given to bake at 170 °C. At this temperature the carbon atoms in ferrite become more mobile and migrate to the nearby dislocations. The carbon atoms are segregated there and creates Lomer Cottrell atmosphere; the dislocations are anchored by these carbon atoms. Extra stress is therefore required for dislocations to get away from the above Lomer Cottrell barriers and thus the steels experience extra strengthening, known as bake hardening.[51–54] However it is apparent that for bake hardening to be uniformly effective, the dislocation population should be quite high and should be uniform in distribution. In case of dual phase steel, it is possible to have uniform distribution of numerous martensite islands of high carbon content. The volume strain accompanying Bain distortion creates dislocation around martensite particles. Numerous the martensite regions higher is the uniformity in dislocation distribution and thus bake hardening will be more effective. Similar possibility exists in TRIP aided dual phase ferrite bainite steels. In this case it is required to have a uniform distribution of bainitic regions around which one may expect dislocations to be present. So, proper heat treatment to produce ferrite bainite steels with finely divided bainitic regions throughout the matrix envisages efficient bake hardening.

2.8.11 Heat Treatment of Steel Casting

Heat treatment of steel casting is a tricky job as most of the commercial C–Mn steel castings show cellular dendritic segregation of impurity elements along the grain boundary. In order to achieve a uniform property of steel castings a judicious heat-treatment strategy must be adopted.

Let us take the example of heat treatment of steel castings made of the following composition: 0.28–0.32% C; 1.5–1.7% Mn; 0.4–0.6% Si; 0.25–0.3% Mo; and 0.025% S, P maximum. This steel casting is very commonly used in railways. The heat treatment to secure uniform properties in this steel are:

- Homogenization: Since the impurity elements like Si, Mn, etc., are segregated at the grain boundary, the casting must be homogenized to destroy dendritic structure. To get homogenized microstructure in the casting, component must be heated to a very high temperature, where mobility of substitutional alloying element is quite high and the homogeneous composition of austenite is obtained. The heat treatment is carried out in between 1050 and 1100 °C or higher. If the steel is deoxidized by aluminum or if it contains microalloying element like Ti, V, or niobium, the steel will be inherently fine grained and will exhibit resistance to coarsening. The fine precipitation of AlN or Ti(C, N) inhibits grain boundary movement and hence retard tendency for grain coarsening.

However choice of avoidance of grain coarsening and decarburization is not included in the concept of homogenization, especially when major target of the process is to completely eliminate the microsegregation. Sufficient time is allowed for soaking at high-homogenizing temperature and the exact time is to be decided under the perspective of plant condition. The total charge, with spacing between the charges, the weight of individual item will all decide the total time for homogenization. After soaking, the steel casting should be allowed to cool slowly. The cooling rate is to be as slow as possible. Cooling process may be stopped when temperature of charge inside the furnace reaches 400 °C.

- After the homogenization, conventional annealing is done for which the steel castings are heated within the temperature range of 880–900 °C and held there for 1 h per each 25 mm section thickness; following this the castings are cooled in furnace. Where conventional annealing is not required, the casting may be normalized after homogenization annealing. For this the charge is heated to 860–880 °C and held there for 1 h per 25 mm of thickness.

  After soaking at a higher temperature, when the pallet/tray is taken out for quenching, there may be quenching delay irrespective of the efficacy of the available material handling system, unless the entire process is automated through robotics. Heat treater must raise the temperature of the charge by 20–30 °C higher than the stipulated temperature such that the unavoidable delay in quenching can be taken care.
- In normalizing special care must be taken during cooling. If castings are stacked in layers, the cooling of the over lying casting, releases heat which interferes with the cooling of the adjoining casting thereby creating a very complex situation in respect of achieving predictable cooling rate for all the castings put inside the furnace.

  It is wiser to make use of adequate number of cooling fans positioned at different location, which may ensure a better cooling of castings during normalizing. Sometimes forced air quenching is a recommended heat-treatment process.
- After normalizing, tempering is required to be carried out to achieve desired properties. The castings are then put in tempering furnace and tempering is performed normally in the temperature range of 500–550 °C and held there for the preselected period of time. As discussed earlier, the time and the temperature of holding are decided on the basis of final property requirements.

The above example is a generic heat-treatment cycle of steel casting as can be seen in Figure 36. The time, temperature, or

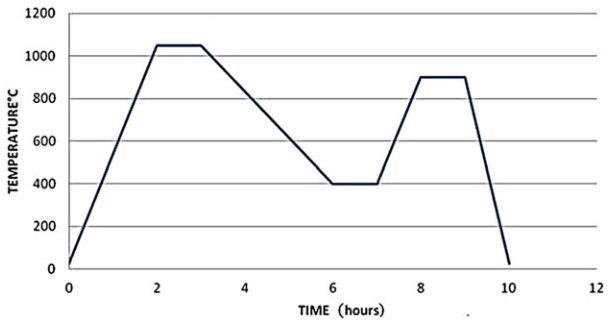

Figure 36 Heat-treatment cycle for steel casting.

the nature of process may be different in cases where different kinds of alloy steels are heat treated. Nevertheless, homogenization at high temperature, conventional full annealing, normalizing, and finally tempering are the basic steps in heat treatment of steel casting.

In industrial situation another major problem is related to material handling.

This particular issue is very critical in case the heat treatment of casting which requires quenching in oil, water, or any other solvent.

2.9.1 Introduction to Tool Steels

2.9.1.1 Definition

Tool steels are alloys used in the manufacture of tools, dies, and molds that shape or cut other materials including steel, nonferrous metals, and plastics. This tool steel definition has its explanation in steel tools section of the manual of Iron and Steel Society[1]

> "Tool steels are carbon steels, alloy steels and high speed steels capable of being quenched and tempered. Usually they are melted in electric arc furnaces and produced under certain practices to meet particular specifications. They can be used in certain hand tools or mechanical fasteners in cutting and shaping material at room temperature or at elevated temperatures. Tool steels are also used in a wide variety of other applications where resistance or wear, toughness, mechanical strength and other properties are selected for optimum performance."

 doi:10.1016/B978-0-12-803581-8.09191-8

In this definition, in addition to the alloying elements tool steels are considered special for its heat treatment characteristics and manufacturing. In the first aspect, there is no exaggeration to consider that without proper heat treatment tool steels are not different from ordinary carbon steels. Manufacturing is also of particular interest because these materials are typically difficult to be produced, requiring the highest quality at every stage of processing.

Peter Payson, in his book *The Metallurgy of Tool Steels*, published in 1962,[2] reported the importance of processing to support the separation of tool steels and steels of 'mass production':

> "Even tool steels are not perfect, but they are much superior than those denominated "tonnage steels", regarding the absence of porosity, morphology of undesirable non-metallic inclusions, chemical segregation and surface defects. Various physical methods are used for inspection and macro metallographic procedures for micro inspection, to ensure that the tool steel is according to consumers' demands."

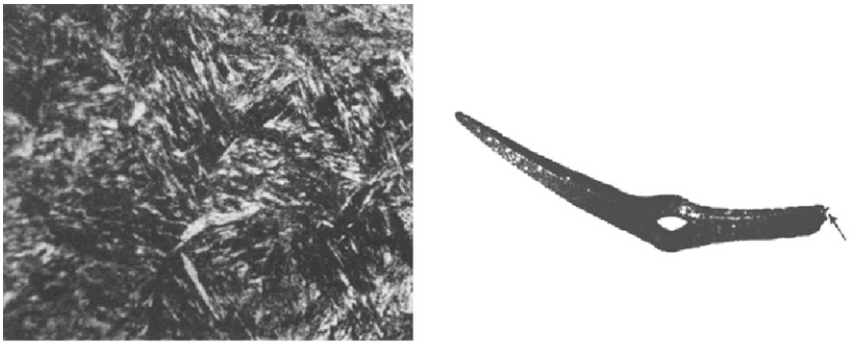
2.9.1.2 Historical Development of Tool Steels

The first uses of steel were for tools and weapons, and since high hardness and durability were the valuable properties for such application. The attainment of high hardness was followed by three facts: the ability to produce iron, the introduction of carbon in the iron to form steel, and heating and tempering to produce martensite. Maddin[3] explored the first hardening steel and described a mining pick – the first known example of martensitic steel tool. The pick (**Figure 1**) dates from the late thirteenth century or 12 BC. **Figure 1(b)** shows the microstructure of the hardened martensite. Older objects had previously been documented, but had pearlitic microstructure, indicating that annealing was not yet used.

The first knowledge and skills to produce high performance steels were used in the production of swords in China, Damascus, and Japan. **Table 1** lists the chronological developments in steels, emphasizing the important dates or periods of tool steels technology and high speed steels (HSS).

2.9.1.3 Tool Steels – Families and Classification

The tool steels come in a wide range of compositions and are classified by different rules in different countries. Many manufacturers also have their own compositions and denominations, some developed by themselves or even patented. The result is the existence of a large number of compositions and tool steels names. The ASTM A681-94 Standard[5] presents the steels most used worldwide, including those separated by their denominations.



2.9.1.4 Names and Classifications Employed in the World

The most used classification is the one given by American Iron and Steel Institute (AISI)[6–8] and the literature offers the similar products in other standards.[9] Another classification is the German DIN,[10] wherein the numbers are usually employed (W. Nr.). For example, AISI M2 corresponds to W.Nr. DIN 1.3343. The DIN standard is the most used in Europe and was the base for the unified Euronorm where the designation starts with EN. Because of the ease of comprehension and its increased use in many countries, this chapter basically addresses the AISI classification.

AISI classification system arranges tool steels into groups based on prevailing properties, applications, or heat treatment. **Table 2** lists the nine major groups of the AISI. Groups are followed by numbers classifying the steel in question. A list of these steels is given in **Table 2**. In addition to AISI (American) and DIN (German), there are other classifications used worldwide such as the Japanese, British, French, and Swedish (**Table 3**).[9] A cross-reference between them is shown in **Table 4**.

2.9.2 Tool Steels Families

There are several ways of grouping tool steels. One of the AISI has been described in terms of the application or heat treatment. However, for teaching purposes and also focusing on the application, a more interesting way is to classify tool steels according to the branch of application. Thus it can be distinguished into four classes: (1) tool steels for cold working, (2) for hot working, (3) for plastic molds, and (4) HSS. The class of HSS has very peculiar properties and some authors prefer to treat them separately from tool steels. This chapter, however, includes them in tool steels because they have many similarities and these can often be employed in molds or dies

1903	0.76–14W–4CR – prototype of modern high speed steels (HSS)
1904	Adding to 0.4% V alloy
1906	Introduction of fusion in an electric furnace
1910	Introduction of HSS T1: 18W–4CR–1V
1912	Adding 3–5% Cr to give hot hardness tool steels
1923	12% Cr Steel for machining at high speed
1939	Super high-speed steels with high C and high V (M4 and T15)
1940	Start of W replacement for Mo. Rise of M2
1953	Resulfurized HSS
1961	HSS with hardness up to 70 HRC (M40 series)
1970	Introduction of high-alloyed HSS steel by powder metallurgy
1973	High levels of Si and N to increase hardness of the M7
1975	First Nb containing HSS developed
1980	Development of super high-speed steels without Co
1980	Coating tool steels with TiN
1982	HSS modified to Al
1992	8% Cr tool steels with high toughness
2000	Low silicon hot work tool steels

Table 2 Main tool steels families according the AISI classification with letter symbols[10]

Family	*Letter symbol*
Water-hardenable tool steels	W
Shock-resistant tool steels	S
Oil-hardenable cold work tool steels	O
Air-hardenable tool steels, moderately alloyed	A
High-carbon and high-chromium cold work tool steels	D
Plastic mold steels	P
Hot work tool steels alloyed with chromium, molybdenum, or tungsten	H
Tungsten HSS	T
Molybdenum HSS	M

with high demand. In the following sections a brief discussion on these four classes will be presented.

2.9.2.1 Cold Work Tool Steels

This class of tool steel is used in dies for metal forming at temperatures below 200 °C, typically at room temperature. The cold shaped materials are low-carbon steels, mainly used in plates or billets, in coinage operations, stamping, shear cutting, etc. In these applications good properties are required in the tool steel, especially high strength and wear resistance. Examples of cold-formed parts are shown in **Figure 2**.

2.9.2.2 Hot Work Tool Steels

The hot work tool steels are mainly used in metal forming at temperatures above 600 °C. The main processes of hot forming are steel forging and extrusion and casting of nonferrous alloys, especially aluminum alloys. During the work, the dies are simultaneously subjected to mechanical stress and exposure to high temperatures. Thus, the employed tool steels must have properties such as hot strength, toughness (shock resistance), and resistance to thermal and mechanical fatigue. **Figure 3** shows examples of forging dies and casting dies (also known as injection process) and some parts obtained by hot working process.

2.9.2.3 Plastic Mold Steels

The steels of this class are applied to the forming operations of thermoplastic polymers in injection, extrusion, and blow molding. The plastic molds are made of a special class of tool steels, in which the processing characteristics of the steel are crucial. Properties such as machinability, polishability, behavior during texturing, and in some cases, corrosion resistance is usually very important for the proper production of the mold. The application of **Figure 4(a)**, for example, requires perfect polishing of the mold and, therefore, the steel tool must meet a number of special requirements. As shown in **Figure 4(b)**, plastic molds are typically complex and therefore have high costs. Therefore, the use of high-quality steel is critical in order to not compromise the performance of the mold.

2.9.2.4 HSS

The HSS have noticeably different metallurgy from the others tool steels. They are mainly used in cutting tools such as drills, taps, milling cutters, hand saws, etc. Its application in molds and dies is limited, but can be used; especially in cold forming, where high wear resistance is required. The microstructure of HSS produced by conventional metallurgy is composed of a tempered martensite matrix of high hardness, reaching levels above 64 HRC, and undissolved primary carbides, some rich in Mo/W (M_6C type) and others rich in V (MC type) (see **Figure 5**). As shown in **Table 5**, the MC carbides have very high hardness, significantly higher than the carbides of Cr of the type M_7C_3 present in the steels of the D series and even higher than the abrasive particles of alumina. Being harder and being present in a high-toughness matrix promotes high wear resistance.

Some factors limit the application of HSS for cold work. The first is the low toughness of these materials when obtained from bars produced via conventional metallurgy process with diameters above 60 mm, exhibiting relatively coarse microstructure. To minimize this fact, the cold working tools are usually treated to lower hardness than the maximum usually obtained; generally, around 60 HRC. The second factor is economical, because the HSS have high amount of alloying elements and substantially more complex heat treatment (austenitizing temperature of 1200 °C range). **Figure 6** shows examples of tools made of HSS. In some very high demanding situations it is recommended to apply the modern HSS produced via powder metallurgy due to the microstructure

refining obtained in this production route leading to higher toughness.

2.9.3 Tool Steels Heat Treatment Concepts

The heat treatment of tool steels is essential for their good performance. Many low-performance problems and unexpected failures found in practical situations are caused by heat treatment errors. Furthermore, the right properties of the tool steels can only be achieved after heat treatment.

The aim of this chapter is to provide simplified and concise information about heat treatment used in the manufacture of tools. Standard normalizing and annealing treatments will not be covered since the users and toolmakers and mold and die industry usually do not perform them. Rather, these treatments are usually performed in the production plants of tool steels. They are an essential part of the material supply condition because they prepare the microstructure to provide adequate response to the final heat treatment and thus optimal performance. **Figure 7** summarizes the change in microstructure (in terms of L, A, C, and F phases, which are defined in **Figure 7**) as a function of temperature and time during the production of tool steel.

2.9.4 Physical Metallurgy Principles

2.9.4.1 Iron Allotropy

Pure iron in solid state has three equilibrium phases: α, γ, and δ. The δ phase is hardly relevant to tool steels. However, α and γ phases are the basis for all the understanding of the structure and properties of iron and hence the steel. These two phases are stable, depending on the temperature. As shown in **Figure 8**, at low temperatures there is only one stable phase called ferrite or α phase. Above 912 °C, the nature (or more precisely the thermodynamics) of Fe identifies that this phase

is no longer stable. Therefore a phase transformation begins in the solid state, in which the iron changes its structure from ferrite (α) to austenite (γ).

The crystalline structure of the α and γ phases are shown in Figure 8. The α phase has body centered cubic symmetry and the γ phase is face centered cubic. The arrangement of the Fe atoms in the two phases is significantly different and the transformation from one phase to another involves atoms movement by diffusion, which means that it takes some time to transform. On heating, the α–γ transformation begins to take place with the formation of a small portion of γ (termed nucleus) that grows consuming the α phase. The same occurs when cooling by a nucleation and growth reaction, the austenite is transformed to ferrite.

2.9.4.2 Carbon Steels

In carbon steels, the phases present are provided by the iron–carbon equilibrium diagram (Figure 9). The eutectoid equilibrium line determines the transformation of the austenite to ferrite. However, the introduction of carbon gives rise to the appearance of a new phase – the cementite, with Fe_3C stoichiometry. For steels having less than 0.77% of carbon, the A_1 line determines the dissolution of the cementite and the transformation of a microstructure in which ferrite and cementite ($\alpha + Fe_3C$) coexist to a microstructure containing austenite and ferrite ($\alpha + \gamma$). After the temperature exceeds the A_3 line, the microstructure will contain only the austenitic phase.

Carbon is much more soluble in austenite than in ferrite. As shown in Figure 9, the maximum solubility of carbon in ferrite is only 0.0218% (at 727 °C). However, in the austenite up to 2.11% of carbon can be dissolved (at 1148 °C). For a composition of 0.4% C, for instance, the phases observed at room temperature are $\alpha + Fe_3C$. This is because the carbon cannot remain in solid solution and thus forms Fe_3C carbide with iron. However, above 750 °C, the equilibrium diagram shows only the presence of austenite. All carbon that was not soluble in the ferrite was dissolved in the austenite.

2.9.4.3 Martensitic Transformation

Continuing in the example of the 0.4% C steel, if cooled from 750 °C slowly, the thermodynamics determines that the diagram phases are reversible and, at room temperature, $\alpha + Fe_3C$ will again be formed. These transformations in the solid state occur by nucleation and growth, which in turn require time for the movement of C and Fe atoms for the formation of Fe_3C. In other words, it takes time to occur, and depends on the atomic diffusion process.

M_2C in high-speed steel	Rich in Mo and/or W	2000
MC in high-speed steel	Rich in V	3000
Alumina abrasive particle	Al_2O_3	2200

Suppose that the same steel is heated, for example at 800 °C, resulting in only one phase – austenite (γ). If this material is quickly cooled from this temperature, for example, in water, there will be no time for all the carbon to get out of the austenite and then the austenite decomposes in the equilibrium phases and Fe_3C. In this situation, the most important transformation of the carbon iron system occurs – the 'martensitic transformation.' This is a kind of transformation that does not need diffusion (it is diffusionless) and thus occurs very quickly.

The martensitic transformation depends only on the temperature to occur. It starts when the steel reaches the temperature of the beginning of martensitic transformation, or M_s line, and ends when the temperature drops down up to the end of martensitic transformation, or M_f line. In some steels M_f temperature is below the room temperature, resulting in not all austenite is transformed into martensite. The portion of untransformed austenite is called 'retained austenite.'

The martensite has next to the ferrite symmetry, but with the *c*-axis bigger than the others (the crystalline structure is characterized by a 'cube' with a side larger than the others and therefore it is no more a cube). It has body-centered tetragonal symmetry and the size of the *c*-axis depends on the carbon content.[14] Due to its structure, martensite has high hardness and also high brittleness. The hardness of the martensite depends on the carbon content, as shown in **Figure 10(a)**. The microstructure of a quenched steel is shown in **Figure 10(b)**.

2.9.4.4 Austenitization and Quenching

Considering the above basis, quenching can be defined as: "the rapid cooling of the steel from a temperature above its critical temperature (A_1 temperature) in a medium such as oil, water, brine or even air."[14] The purpose of quenching is to obtain the martensitic structure and, therefore, the cooling curve must pass on the left elbow of the continuous cooling transformation (CCT) curve, thus preventing the transformation of austenite into ferrite and pearlite.

The CCT curve corresponds to a schematic representation of the phases and morphologies formed as a function of the cooling speed. Obviously, in slow coolings the formed phases are ferrite and carbides, in a spheroidized morphology or pearlite. In rapid coolings, the phase formed is martensite. For intermediate coolings, there are other morphologies, such as bainite and fine pearlite. The alloying elements generally increases the possibility of formation of the martensite, making it possible even at not very rapid coolings; in high-alloy steels, martensite can be obtained even in air cooling. Therefore, it is said that the alloying elements increase the hardenability.

Figure 11 shows two examples of CCT curves for two tool steels, one with low and the other with high alloying elements. For both steels, as the cooling becomes slower martensitic transformation can no longer occur, appearing as pearlite, bainite, ferrite, and carbides. The big difference between the two steels is that for high-alloy steels, this only occurs at much slower cooling rates than for low-alloy steels. In other words, the high-alloy steel does not need rapid coolings such as that for the low-alloy steel in order to obtain martensitic phase.

An important factor to consider in the quenching operation, due to the action it exerts on the final structure of the steel, is the heating temperature, or more specifically the austenitizing temperature. Take the example of a 0.4% C steel

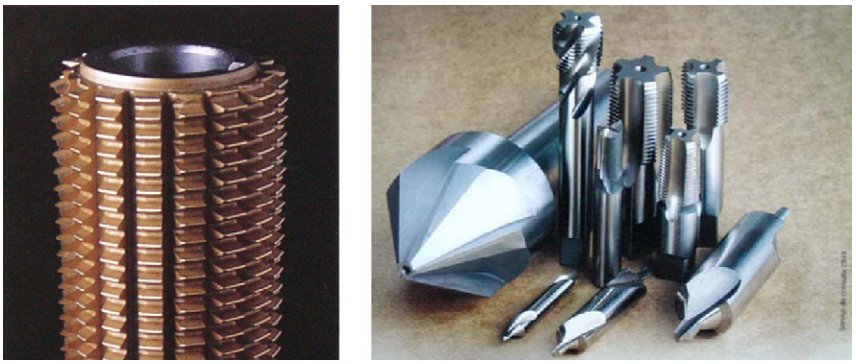

Figure 6 Cutting tools made of high speed steels.

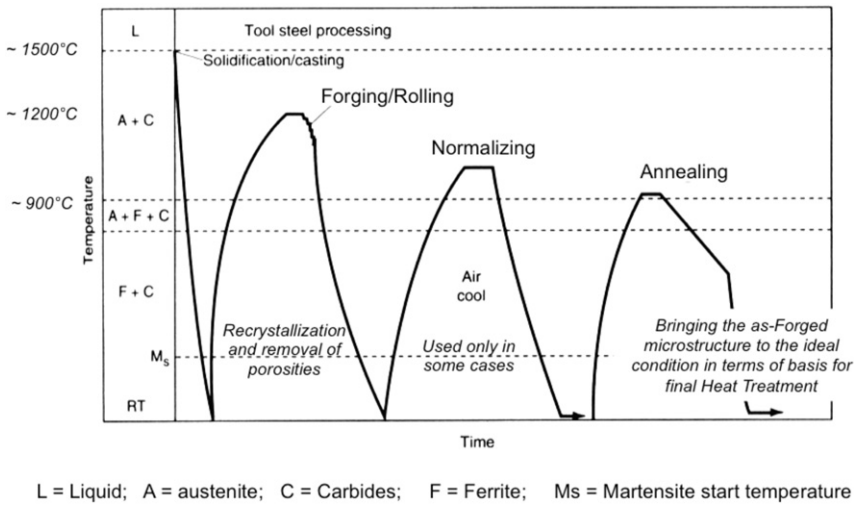

Figure 7 Schematic representation of the transformations that occur in manufacturing of tool steels, from solidification until annealing.[12]

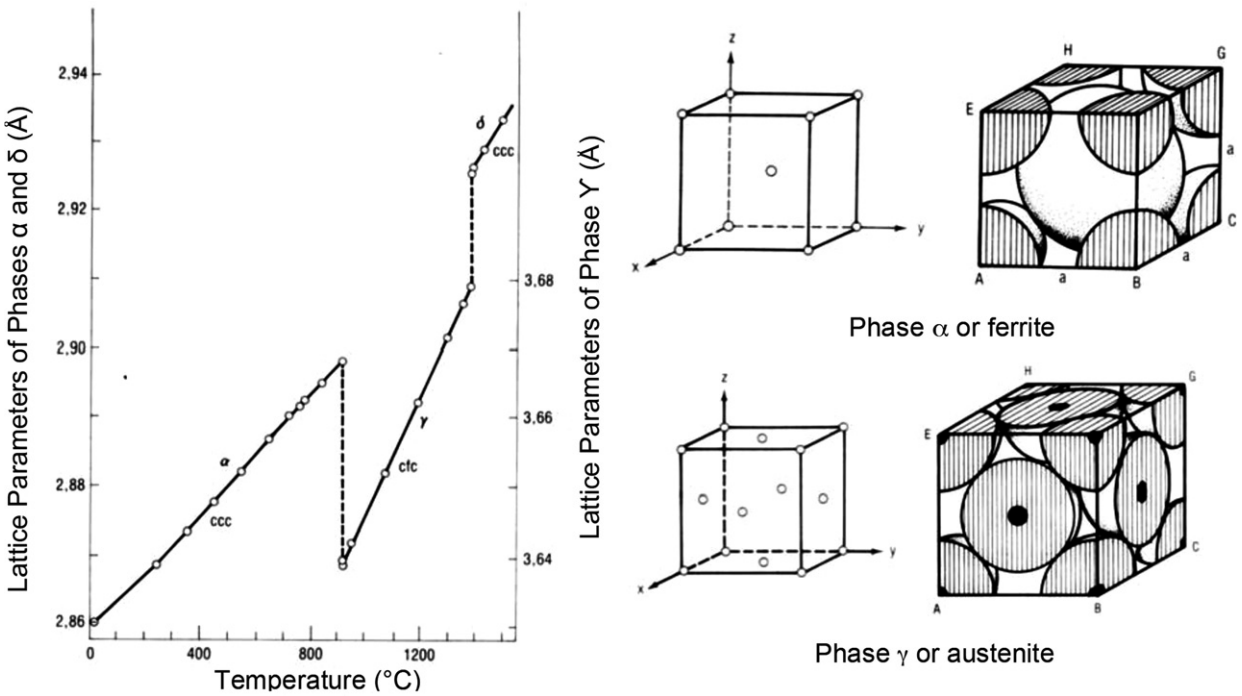

Figure 8 Equilibrium phases of pure iron and their respective crystalline structures.[13]

austenitized at 750 °C (see Figure 9). At this temperature, besides the austenite, ferrite grains will also be present. When quenching in water (assuming a small sample) martensite will be present along with ferrite, because the latter was present during the austenitizing. There is, therefore, incomplete quenching or incomplete hardening. As a result, when heating hipoeutectoide steels for quenching, the temperature must be raised just above the upper limit of the critical zone – A_3 line – and then its structure will consist solely of austenite to be transformed into martensite in the subsequent rapid cooling.

In tool steels, annealed microstructure prior to quenching consists of ferrite and carbides. The austenitizing should promote necessarily the transformation of the whole ferrite into austenite. However, it is not always possible for (and also it is not necessary or desirable) the total dissolution of the carbides in the austenite. The higher the temperature, the greater the fraction of carbides that can be dissolved. However, the austenitizing temperature cannot be too high. This is because the excessive increase in the temperature also promotes strong growth of austenitic grain, which impairs the properties and reduces the toughness of the tool steel. Furthermore, in extreme cases, the use of excessively high temperatures can reach the point of forming liquid, a phenomenon known as overheating or burning. Unlike carbon steels, the austenitizing temperature of tool steel varies considerably between different compositions and types of steel. Adequate temperatures for each steel are provided in books specialized in tool steels and also in tool steel manufacturers catalogs.

In summary, the purpose of austenitizing and quenching is to increase the strength and hardness of the steel. Also resulting from quenching, or rather from the formation of martensite are the reduction of the ductility (low values of elongation and necking),toughness, and appearance of considerable internal stresses. Such drawbacks can be mitigated or eliminated by tempering.

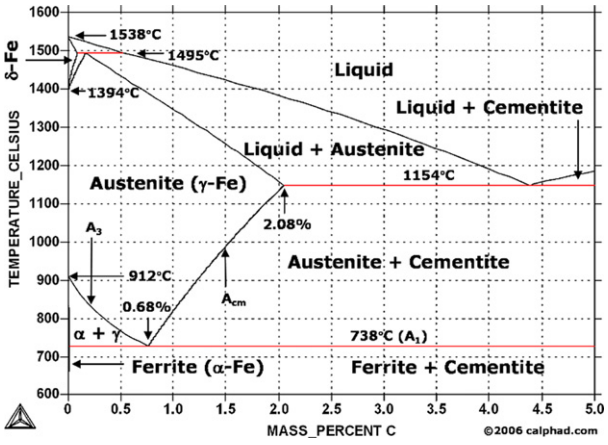

Figure 9 Fe–C equilibrium diagram.

2.9.4.5 Tempering

Tempering is a heat treatment that normally follows the quenching in order to eliminate most of the drawbacks produced by: correcting excessive hardness and brittleness of the material, and increasing its ductility and impact resistance (see Figure 12) in addition to relieving or removing internal stresses.

The heating of martensite allows the reversal of the unstable crystalline lattice to the stable body centered cubic lattice, produces internal adjustments that relieve stresses and also gives rise to precipitation of carbide particles which grow in accordance with temperature and time.

According to the tempering temperature, this heat treatment promotes the following changes, divided into four stages[14]

i. first tempering stage – occurs with the precipitation of iron carbide of epsilon type (ε) with $Fe_{2-3}C$ formula and hexagonal lattice; this carbide may be absent in low-carbon steels and low-alloy steels; Rockwell hardness begins to fall, reaching 60 HRC;
ii. second tempering stage – occurs during transformation of retained austenite into bainite (in carbon steel); Rockwell hardness continues to fall;
iii. third tempering stage – forms a metastable carbide, with Fe_5C_2 formula; when this transformation occurs in

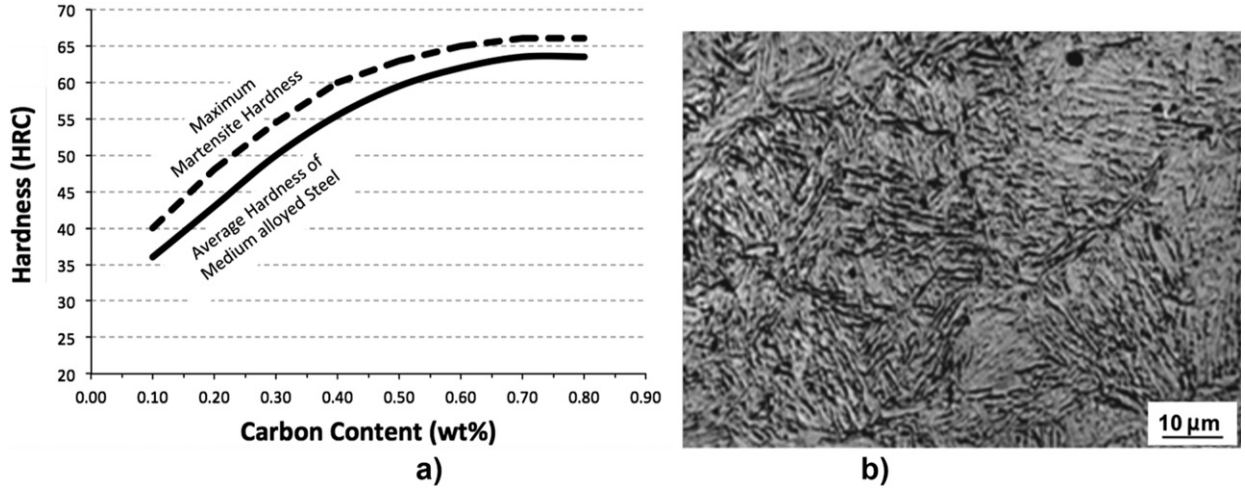

Figure 10 (a) Effect of carbon content on the hardness of the martensite; (b) micrographic aspect of 0.8% C steel quenched: martensite.[14]

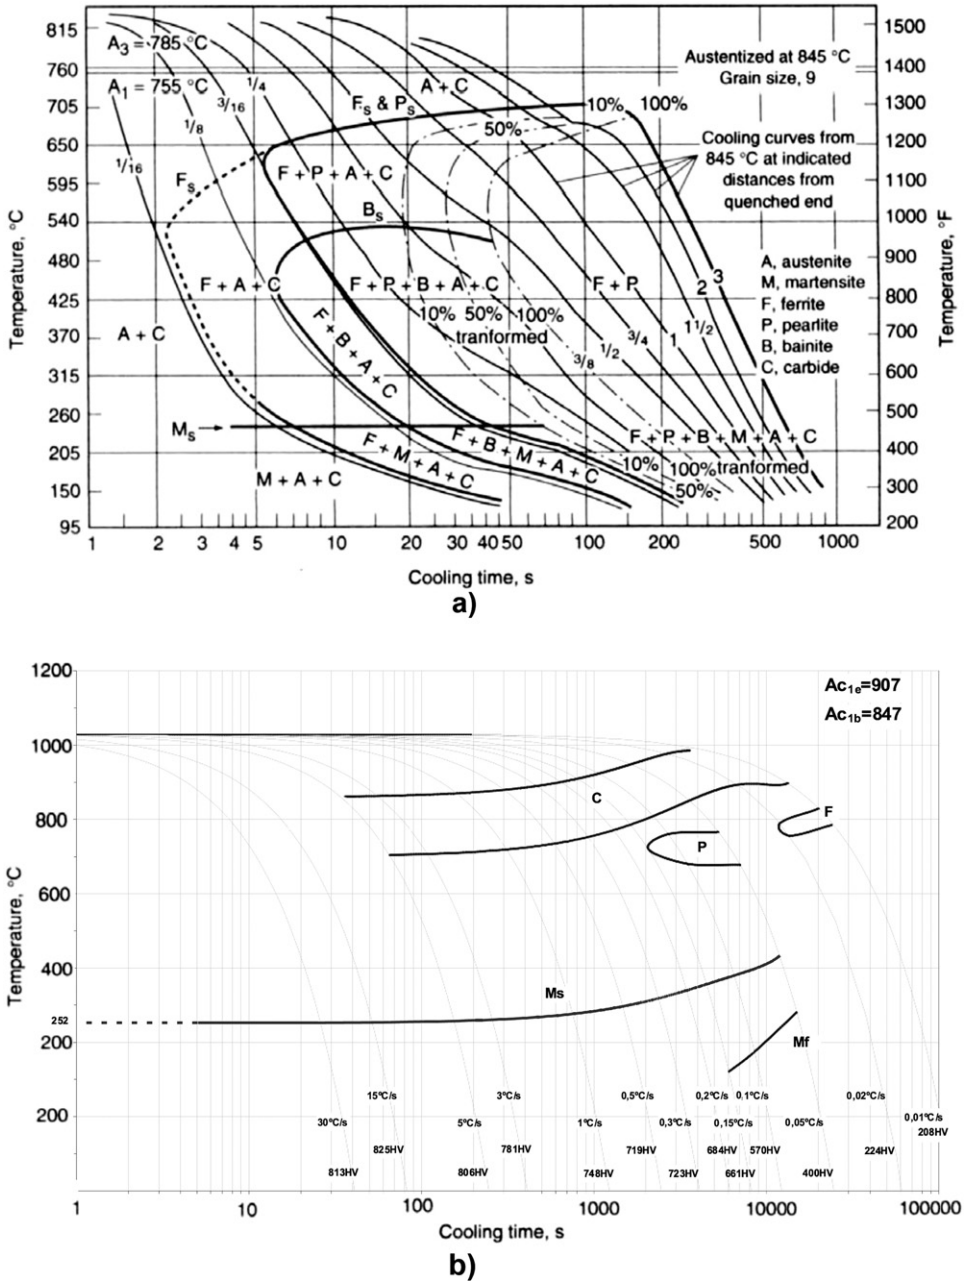

Figure 11 CCT curve of steels (a) low-alloy steel (1.06C–0.33Mn–0.32Si–0.11Ni–1.44Cr–0.3Mo)[15] (b) high-alloy steel – VF800AT (0.85C–0.4Mn–0.90Si–8.5%Cr–2.0Mo–0.6V–0.15 Nb).[16]

high-carbon steel, a dark microscopically visible structure is observed that was called 'troostita' in the past, designation no longer used; Rockwell hardness continues to fall, reaching values slightly greater than 50 HRC; and

iv. fourth tempering stage – between 500 °C and 600 °C only in steels containing Cr, Mo, V, Nb, or W; there is precipitation of alloying carbides and the transformation is called 'secondary hardness' (as discussed in Section 2.9.4.6).

From what has just been exposed, it is noticed that the tempering temperature can be chosen according to the combination of mechanical properties that is wanted in the hardened steel. In this choice, the relationship between hardness–toughness (see **Figure 12**) should be considered in order to meet the application requirements.

2.9.4.6 Secondary Hardness

In the quenched condition, the steels normally consist of martensite, retained austenite, and carbides undissolved during the austenitization. The alloying elements are present either in solid solution in the martensitic matrix or in the form of residual carbides. It is believed that the

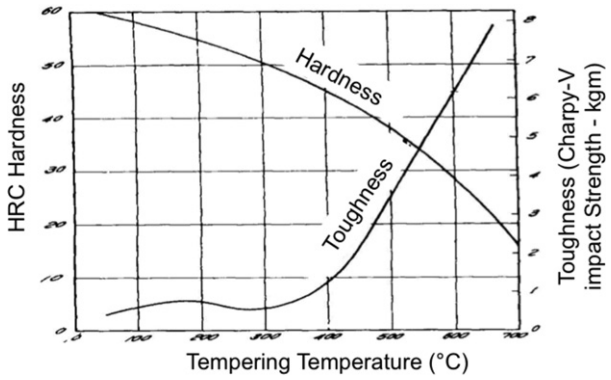

Figure 12 Effect of tempering temperature in the hardness and toughness of a carbon steel.[17]

composition of the retained austenite is the same as martensite, that is, both carbon and alloying elements such as chromium, vanadium, tungsten, and molybdenum are present. When tempering an alloy steel, modifications of its hardness occur which is different from carbon steels, as shown in **Figure 13**.

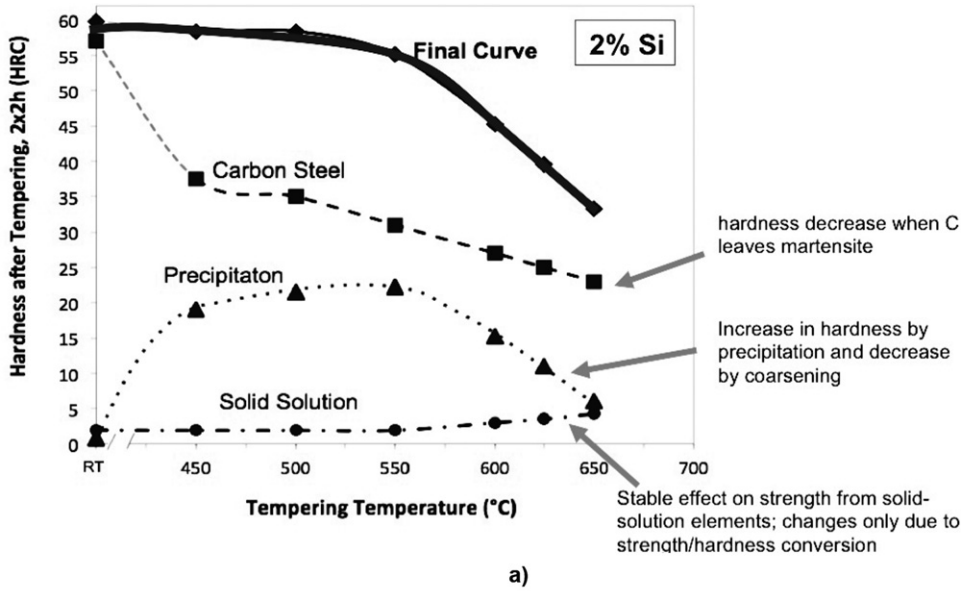
The dotted curve of **Figure 13(a)** corresponds to a common carbon steel, characterized by the continuous drop of the hardness as a function of tempering temperature due to decomposition of the martensite. The dashed curve is related to the hardening by the precipitation of special carbides (commonly known as secondary carbides), which occurs during the heating for tempering and causes an increase in hardness. The continuous bold line curve refers to a high-alloy tool steel (e.g., a HSS) and is the sum of the two other curves. By examining these curves, the following can be pointed out:

- At lower tempering temperatures, the curve corresponding to HSS is more or less parallel to the common C steel;
- At high temperatures, the HSS curve follows the hardening by the precipitation of secondary carbides.

This 'secondary hardening' or the appearance of a 'secondary hardness' – typical phenomenon of many highly alloyed steels and more pronounced in HSS – which develops mainly in the temperature range of 550–565 °C, is assigned to a combination of two processes: (1) transformation of retained austenite into martensite during cooling and tempering (mainly after the first tempering cycle); (2) precipitation of extremely fine dispersion of carbides of alloying elements mainly containing chromium, vanadium, tungsten, and molybdenum. The contribution of retained austenite is verified by tempering at temperatures between 540 and 590 °C; the contribution due to the precipitation of alloying carbides occurs when the tempering is performed between 480 and 650 °C.

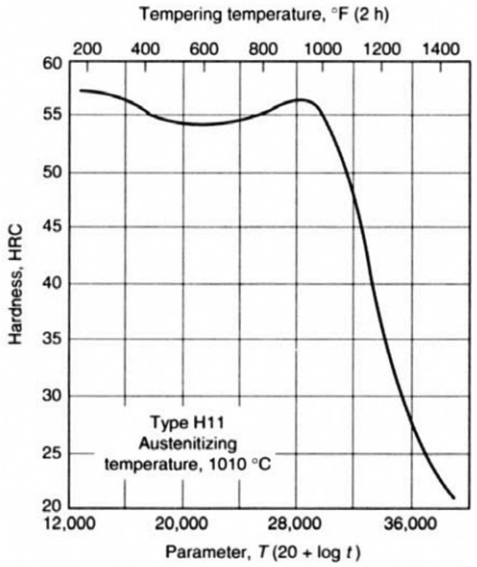
Formation of alloy carbides is slow at low tempering temperature because of 'low diffusion rates.' Diffusion of alloying elements becomes faster with increasing temperature. Tempering alloy steels at a temperature higher than that used in plain carbon steels produces 'fine alloy carbide particles' at a faster rate, so that it gives higher hardness. In other words, the diffusion rate of the alloying element(s) present in these steels is significantly high at higher tempering temperatures (>550 °C) precipitating hard alloy carbides and thus increased hardness is recorded. This type of hardening effect is often called secondary hardening.

The curve that represents carbide precipitation involves two stages, an increase and a decrease in hardness. The increase in hardness is caused by the progressive enhancement of precipitation of carbides, which are extremely small (see **Figure 14(a)**) of nanometer order, i.e., tens of atoms. However, as the temperature increases, these carbides begin to coalesce ('thickening'), as shown in **Figures 14(b)** and **14(c)**, and then the hardness decreases. The coalescence of the carbides occurs by diffusion, depending on the temperature and time. **Figure 13(b)** shows this phenomenon relating the tempering curve as a function of not only the temperature but also a function of time through the tempering parameter, with the formula $T(\log t + 20)$, where 't' is the time in hours and 'T' is the temperature in °F + 460.[12]



Especially for hot work steels or HSS this reduction in hardness is very important, as these materials are exposed to high temperatures (next to those used in tempering) during use. Therefore, in addition to tempering heat treatment, these materials continue tempering (martensite continues decompose) in their applications. Thus, it is always desirable to have greater resistance to this loss in hardness, normally called as 'resistance to tempering.'

The effects of the alloying elements in the secondary hardening can be seen in **Figure 15**. The chromium carbides are typically of the type M_7C_3 and at high temperatures (>650 °C) they are $M_{23}C_6$ (where 'M' is the metal and 'C' carbon). The Cr has less intense effect and the hardness resulted is sufficient just to promote an adequate level up to ~540 °C. From this temperature the hardness drops sharply. W and Mo form carbides of the same type, M_2C type at low temperatures and M_6C at high temperatures. As the atomic weight of W is approximately twice as that of Mo, the effect of 1% Mo is equivalent to 2% W; it is common to use the equivalent tungsten relation: '$W_{eq} = W + 2Mo$.' Considering this, it is verified that the effects of Mo and W in the fraction of the carbides formed are similar. The tungsten and molybdenum carbides promote high hardness and also high resistance to tempering; for high levels of these elements the drop in hardness is observed only after 650 °C. Vanadium also precipitates carbides (MC type) that provide high hardness and resistance to tempering. It acts more intensely than Mo and W; 2% of V generate more pronounced effect than 5% of Mo. Vanadium, even in low concentrations, is effective in promoting resistance to tempering. For example, the steel with 0.26% of V at 760 °C presents 60 HV harder than the composition without V.



Example of the types of carbides formed in H13 steel is shown in **Figure 16**, along with the chemical composition determined by microanalysis.

2.9.4.7 Multiple Temperings

As seen in the Section 2.9.4.6, the tempering of high-alloy steels generally involves precipitation of carbides of alloying elements, which reduces the content of solid solution elements in the martensite. Such precipitation also occurs in the

a)

b)

Figure 13 (a) Response to tempering of a high alloy steel[18]; (b) response to tempering of H11 steel as function of the tempering parameter: $T(20 + \log t)$, where t=time in hours and T=temperature in °F + 460.[12]

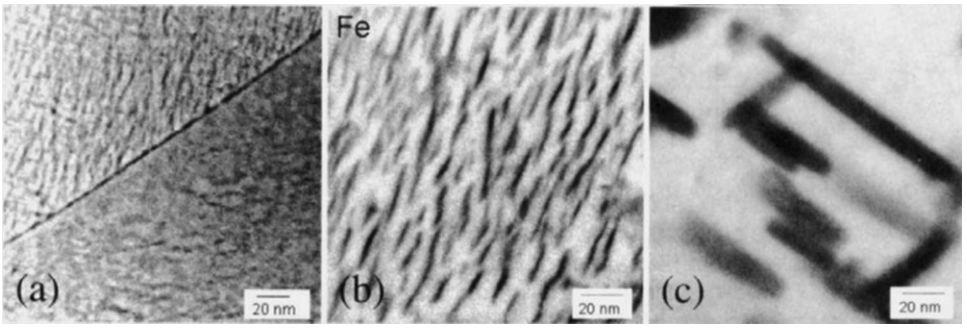


Figure 14 Secondary carbides of the AISI M42 high speed steel after different tempering treatment (austenitized at 1180 °C) (a) 530 °C, triple for 2 h; (b) 590 °C, triple for 2 h; and (c) 680 °C, triple for 2 h.[19] If related to the **Figure 13(a)**, it can be seen that the drop in hardness is accompanied by coalescence ('thickening') of secondary carbides.

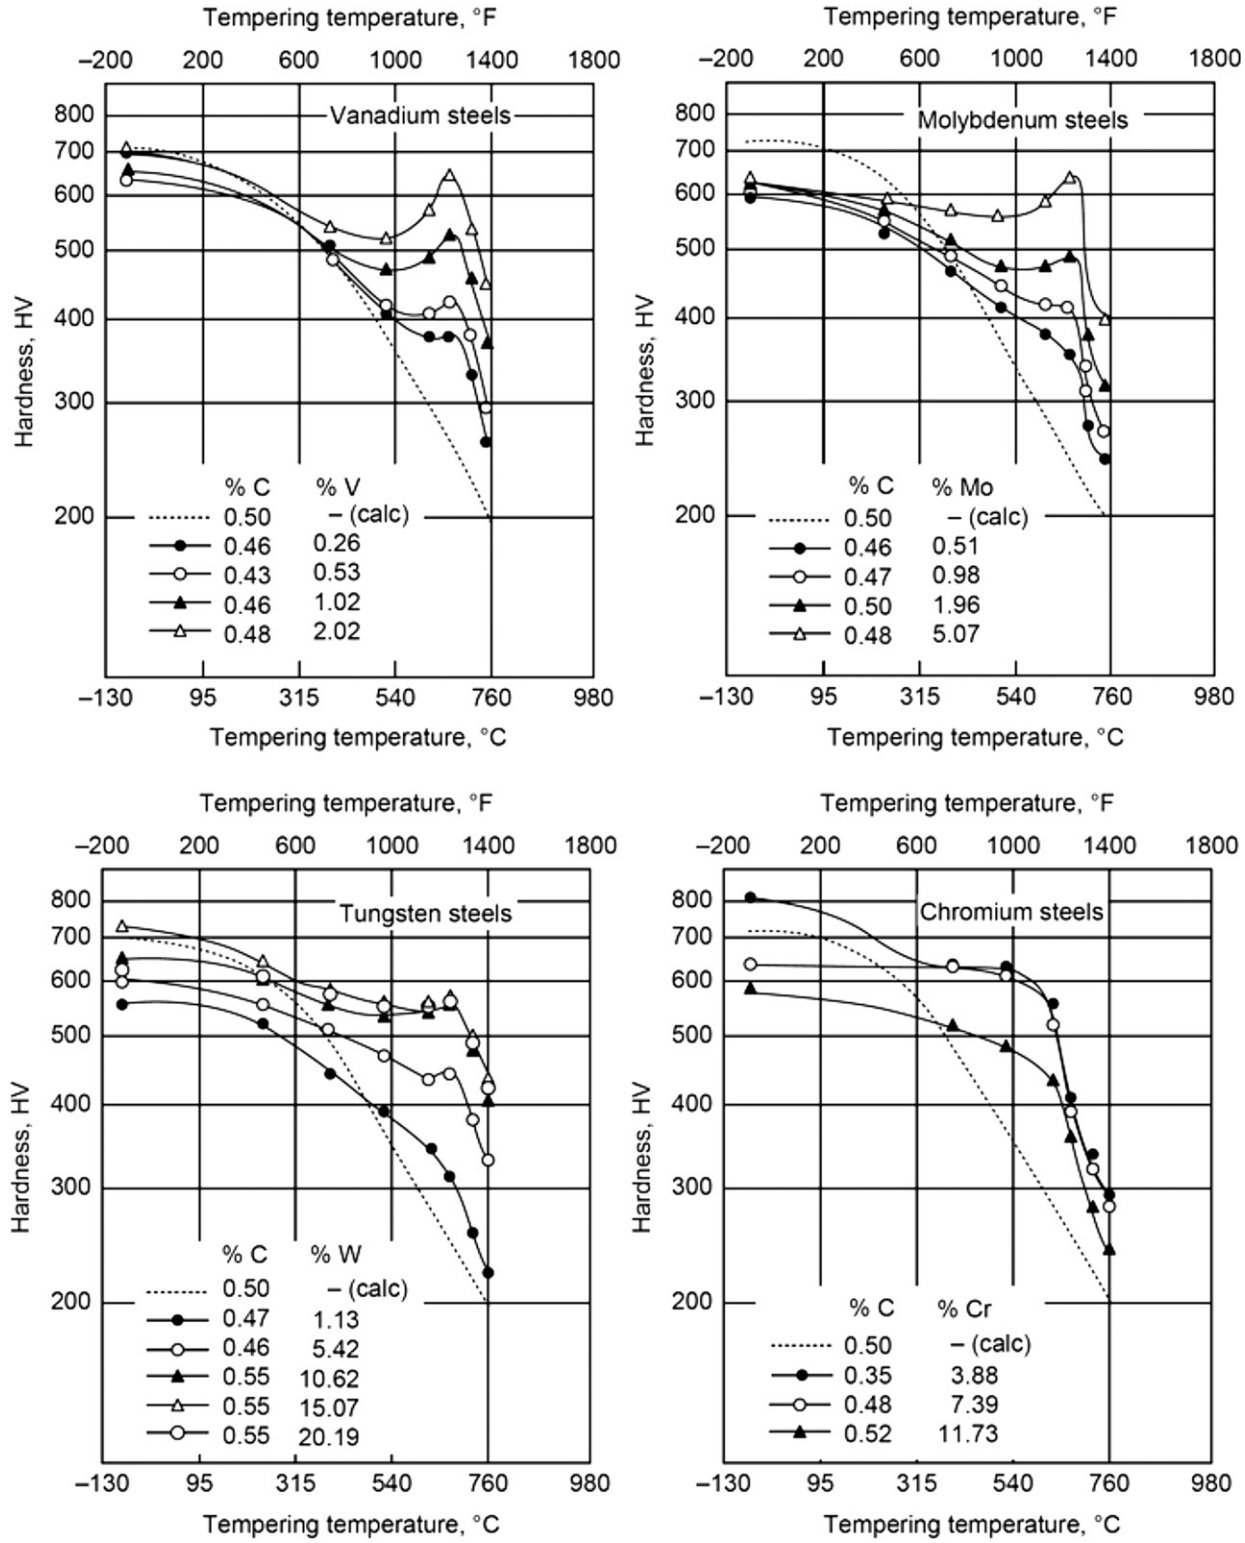

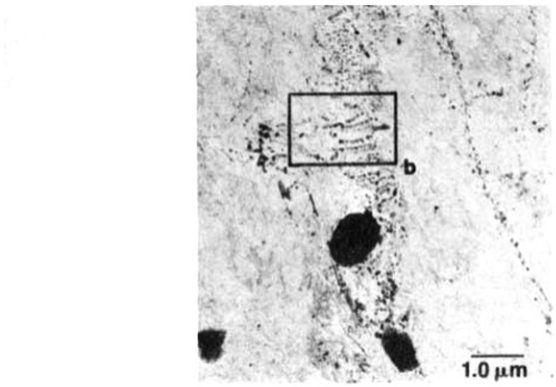

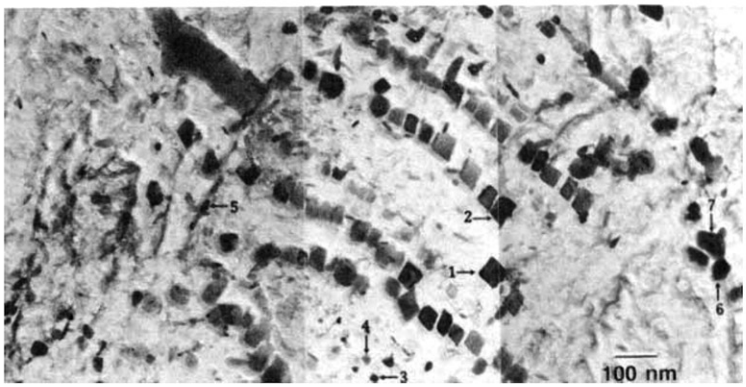

Figure 15 Effect of V, Mo, W, and Cr in the secondary hardness of 0.5% C steel.[20]

retained austenite, making it also poorer in C and alloying elements. The M_s and M_f temperatures depend strongly on the content of elements in solid solution in the austenite. In general, the lower this content the higher are the temperatures of M_s and M_f. Therefore, the precipitation generates rise in the M_s and M_f temperatures.

The most important result is that during the cooling of the tempering, the austenite can transform into martensite (or

Composition of the Metallic Portion of the Carbides Labeled in Figure 18b

Particle I.D.	Type of Carbide	Metal Composition(%) Fe	Mo	Cr	V	Si

+ Analyzed using a Philips 420T TEM/STEM operating in TEM mode with a spot size of 100 nm, E_o = 120 kV, an acquisition time of 300 sec. and a dead time <20%. Specimen was a single stage carbon extraction replica evaluated at 0° tilt.

Figure 16 Secondary carbides analyzed by TEM precipitated in H13 steel after quenching from 1066 °C and double tempering at 593 °C. The chemical analysis and types of carbides identified are presented in the table below the figure.[21]

bainite) as the M_s and M_f temperatures increased. This newly transformed martensite (fresh martensite) has not yet been tempered and therefore is hard and brittle, which may weaken the entire tool. Thus, new tempering should be performed to effectively temper this martensite. Double temperings are needed and it is common in many tool steels. If some retained austenite still remains, the precipitation that occurs in the second tempering may promote its transformation into martensite. Therefore, a new tempering (third) is required. Three temperings are recommended for high-alloyed HSS.

2.9.5 Practical Aspects of the Heat Treatment

Although summarized, the concepts presented in Section 2.9.4 are very important for understanding and for correct application

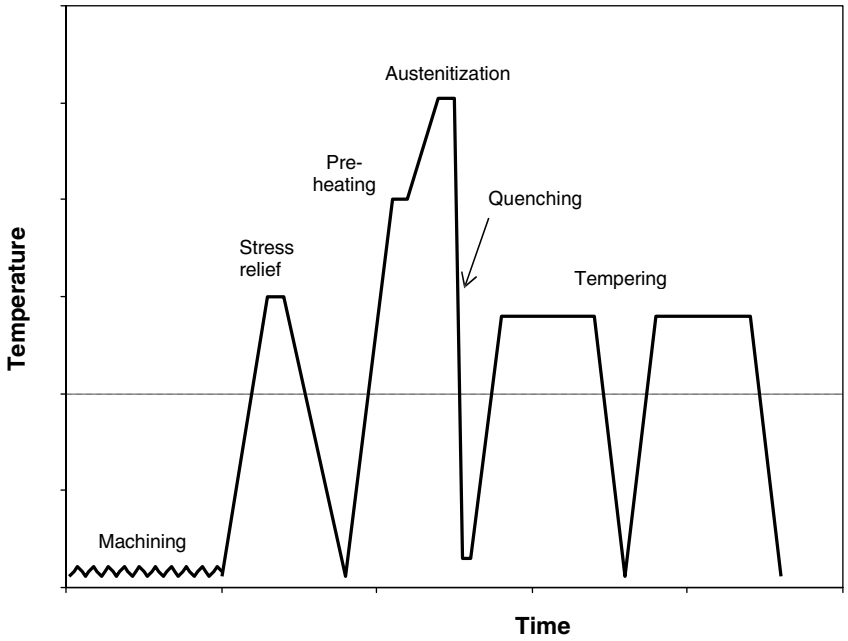

Figure 17 Schematic diagram of the main operations performed by tool steel users in manufacturing of molds, dies, and tools.

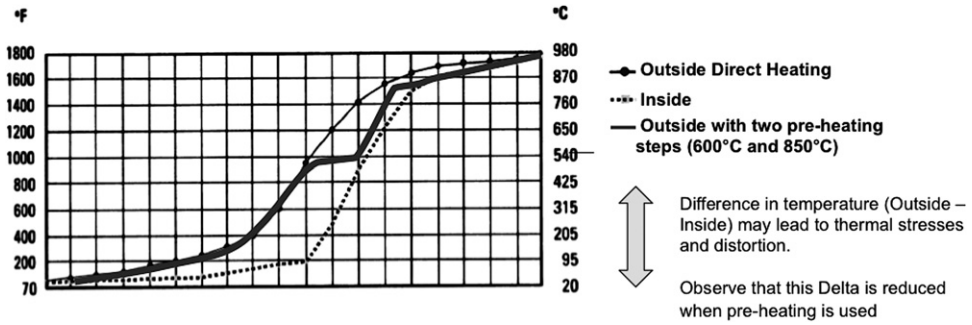

Figure 18 Difference between the temperature of the surface and core of a piece during heating within a furnace.[22]

of heat treatments in tool steels. Following are some important information to obtain desirable results after heat treatment of this kind of steels.

Operations typically performed by the manufacturer of the mold or die steels are shown schematically in Figure 17.

2.9.5.1 Design, Machining, and Stress Relief

The mold or die design is an important part and is closely related to possible problems of the heat treatments. Regions with abrupt variation in the cross-section and sharp corners are points that can lead to cracks or warpage during heating and mainly during quenching. It is not objectified here to describe all design conditions but in project design, all aspects and transformations of heat treatment should be considered.

Despite the finish machining performed after the heat treatment, the prior finish cannot be too rough. Rough machining marks can act as notch and cause fracture of the mold or die during the heat treatment.

In addition to giving shape of a component, machining also introduces stresses in the material. These stresses must be relieved before heat treatment in order to avoid distortion or warpage. This treatment is called stress relief and should be done immediately after machining. Stress relieving is strictly necessary in parts with pictures and profiles, in which the material removal was greater than 30%. The stress relief procedure in tool steels involves slow heating to temperatures between 500 and 600 °C and cooling in the oven until the temperature is 200 °C.

During cutting (work) the tool can also be subject to tensions. In this case, the stress relieving must be carried out at a temperature 50 °C lower than the temperature of the final tempering. The procedure is the same.

2.9.5.2 Heating Furnaces

There are many types of heating furnaces that can be used in treatment of tool steels. Some examples are the muffle furnace,

salt bath furnaces, vacuum furnaces, and fluidized bed furnaces. The description of the types of furnaces falls beyond the objective of this chapter, but can be found in books for this specific topic.

The use of appropriately controlled atmospheres is important to prevent the occurrence of decarburization. This is characterized by the 'loss' of carbon or alloying elements during the treatment, caused by oxidation. It causes decrease in hardness of the surface layer, which needs to be removed by a finishing machining.

An important thing to mention about the heating furnaces is the need of rigorous knowledge and control of the temperature. If the temperature calibration of the furnaces is not properly performed, there may be deviations of hardness and properties in the treated materials. A treatment temperature 15 °C higher or lower can lead to very undesirable consequences, ranging from the low performance to the loss of the mold or die. Moreover, the furnaces used must have adequate capacity to perform the treatment, since the whole piece needs to be treated at the appropriate temperature. There should not be hotter or colder points within the furnaces.

2.9.5.3 Preheating

When ensured that the furnace used is appropriate, heating for quenching can now be realized. However, as shown in **Figure 18**, the surface heats up more rapidly than the core. Considering that the tool steels are treated at relatively high temperatures, this difference can cause distortions.

To avoid these problems, it is recommended to carry out preheating before the austenitization (as shown in **Figure 17**). The time should be sufficient for equalization of the temperature between the surface and the core, usually between 15 and 30 min (assuming that the part is heated with the furnace). The temperature depends on the steel in question, being available in specialized books and tool steel manufacturers catalogs.

2.9.5.4 Austenitization

The temperature and time of austenitization are essential for adequate performance of the tool. As already mentioned, the austenitization is the part of the heat treatment in which ferrite is transformed into austenite, which dissolves the carbides of alloying elements that in turn, will re-precipitate causing hardening. The temperature, therefore, should be high enough to allow these phenomena to occur. Otherwise, the ferrite cannot be completely converted to austenite, and in the end, the required martensite is not formed. Still, if the temperature is too low, there may be low dissolution of carbides, jeopardizing the response to the secondary hardening.

However, the temperature cannot be too high. As shown in **Figure 19**, the austenite consists of grains that grow as the austenitization temperature increases. The excessive grain growth weakens the material and decreases the life of the tools. As already explained in Section 2.9.4.4, very high austenitizing temperatures can cause liquid formation in regions rich in carbides, causing severe embrittlement in the material (burning). This can happen especially in HSS. The austenitizing temperatures also vary widely among tool steels (800–1200 °C). Like temperature, the time of austenitization also cannot be too long or short. Temperatures and times recommended for each steel are given in manufacturer technical brochures.

2.9.5.5 Cooling Mediums for Quenching

Books and tool steel catalogs usually indicate possible mediums of quenching for each steel. The cooling mediums are even used to classify tool steels. It should be stressed that the indicated mediums should be followed as recommended, always taking into consideration the size of the pieces. In case of oil, it must be suitable for quenching and (as in the case of water quenching) be renewed with certain frequency.

For the cases where reduction in distortions is targeted the use of martempering (when possible) is interesting. This treatment makes the equalization of the temperature between the surface and core occur prior to the martensitic transformation, reducing the risk of cracks and distortions.

2.9.5.6 Time and Temperature of Tempering

The tempering temperature should be chosen according to the required hardness for the application, using the correct tempering curve. Contrary to what occurs in carbon steel, the tempering curve of tool steels varies considerably with the austenitizing temperature employed. In this choice, here are some general tips:

- The conditions of austenitization, always use the highest tempering temperature possible. In some steels such as AISI D2 or VF800AT, the tempering curve analysis shows that the hardness of HRC 58 can be obtained by using low temperatures, approximately 200 °C or higher temperatures, 530–560 °C (see tempering curves in the manufactures' catalogs). Higher tempering temperatures are recommended for three reasons: (1) cause elimination of retained austenite, which could transform during operation and cause expansion ('seizure or gripping') and embrittlement of the material; (2) increase in hardness by the secondary hardening, a mechanism that produces tougher pieces (tools) than a little tempered martensite; and (3) make possible the realization of surface treatments such as nitriding, without loss of core hardness.
- When using HSS for cold work with hardness around 60 HRC, keep the tempering near the secondary peak (~560 °C) and get the hardness from reducing the austenitizing temperature. The other possibility would be to use the standard austenitization temperature (~1200 °C) and tempering at high temperature (~610 °C) to obtain the desired hardness. However, using smaller austenitizing temperatures results in lower grain growth, generating higher toughness. Moreover, the adjustment of the austenitizing temperature rather than the tempering provides greater control of the hardness. As shown in **Figure 15**, the hardness rapidly decreases beyond the peak, and an error of 5 or 10 °C can easily modify them in 2–3 points. Other advantages of the smaller austenitizing temperatures

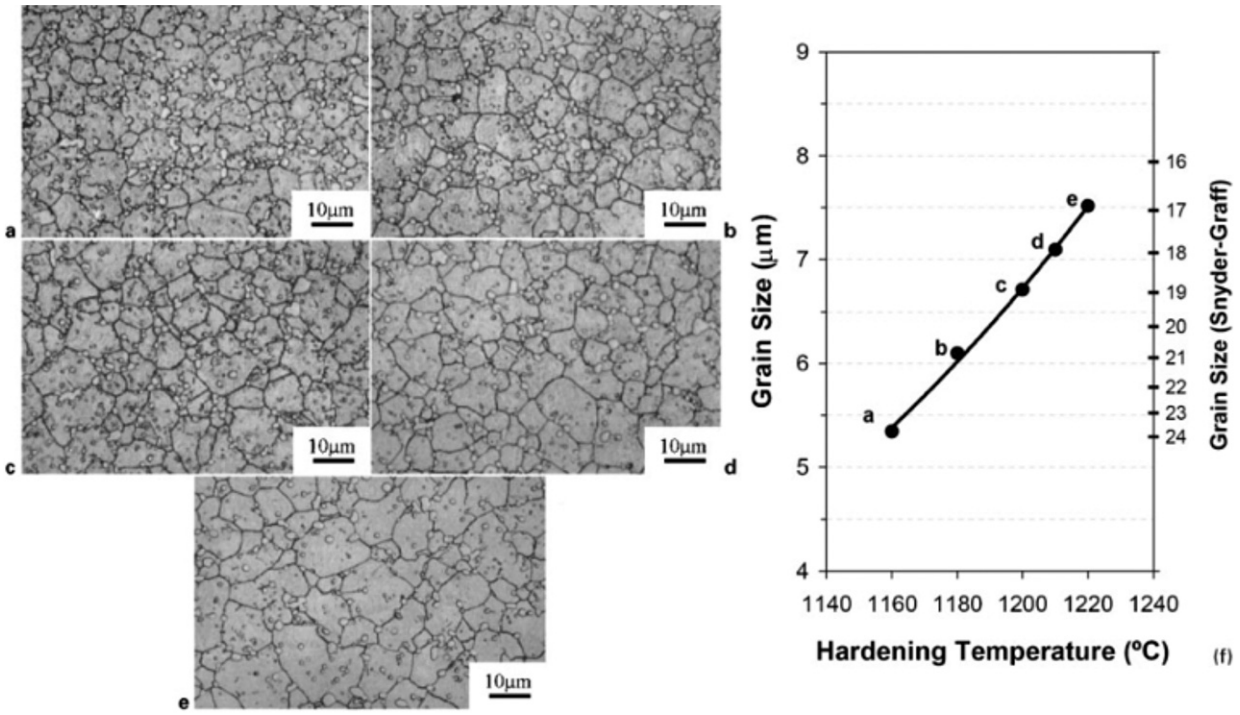

Figure 19 Variation of the austenite grain size of M2 steel as function of the austenitization temperature. Etching: Nital 4% (8 min) and Villela (20 s). Images represent the typical microstructures after hardening (quenching) at: (a) 1160 °C, (b) 1180 °C, (c) 1200 °C, (d) 1210 °C (e) 1220 °C (etching, nital 10% (8 min) and Villela (20 s)), and (f) austenite grain size measured by Snyder–Graff method.[23]

are less deterioration of the furnaces and the lowest energy consumption for heating.

- In steels for hot work, the tempering temperature must always be higher than the temperature of work of the matrix. Explanation: if the tempering temperature is lower than the usage, the material will experience tempering during application, losing hardness in an uncontrolled manner. Moreover, tempering at lower temperatures may not provide the total elimination of the retained austenite, generating the problems already discussed. Lower temperatures are often used on the grounds of promoting greater hardness, and consequently, higher strength and less hot wear (see **Figure 13(b)**). However, this practice is flawed because it must be taken into consideration that the material will work at elevated temperatures. As the hardness of work is the property that determines the hot resistance, there are no direct gains in this practice because the material is tempered again, but this is time uncontrolled (at work), and the hardness will again fall.
- The time for each tempering should be approximately 2 h (at temperature). Unlike austenitizing, there are no problems if the time is a little higher (occurs possibly a slight decrease in hardness). However, if the time is less, the microstructure may not have been sufficiently tempered, causing reduction in properties. This brings an interesting phrase, used routinely, 'hardly the steel can be super-tempered, but can easily be sub-tempered.'[21]
- Another important recommendation is that the tempering should be performed immediately after hardening (quenching), i.e., as soon as the piece reaches approximately 60 °C (this temperature may vary from one steel to another steel). If longer times (more than 1 h) pass before the tempering, stabilization of retained austenite phenomenon will occur. As discussed in Section 2.9.7, the austenite tends to transform again into martensite or bainite after the first tempering. However, if the time between quenching and tempering is excessive, part of the austenite no longer transforms – a phenomenon known as stabilization of the retained austenite. Thus, in practical terms, quenching cannot be performed one day and tempering the day after. It is also important to remember that excessive rush for tempering must be avoided, i.e., tempering cannot be started until the entire piece has cooled. This is because, if the tempering starts above 150 °C for example, great part of the microstructure has not yet been transformed into martensite.

2.9.5.7 Quality of the Heat Treatment

The primary measure of control of the heat treatment is a measure of surface hardness. Although important, however, the hardness can hardly evaluate all aspects of the microstructure. Let's take the example of **Figure 20**, where several microstructures of the VH13 (AISI H13) steel were found, all with similar hardness, between 44 and 46 HRC. In **Figure 20(a)**, the normal microstructure is observed, consisting of tempered martensite and secondary carbides; this is responsible for the high value of toughness identified – 350 J. **Figure 20(b)** shows a typical microstructure of a steel austenitized at too high temperature, showing the high grain size of the austenite. As a result the toughness drops to 42 J, showing that embrittlement has occurred. **Figure 20(c)** presents a steel that was austenitized at very low temperature, which did not

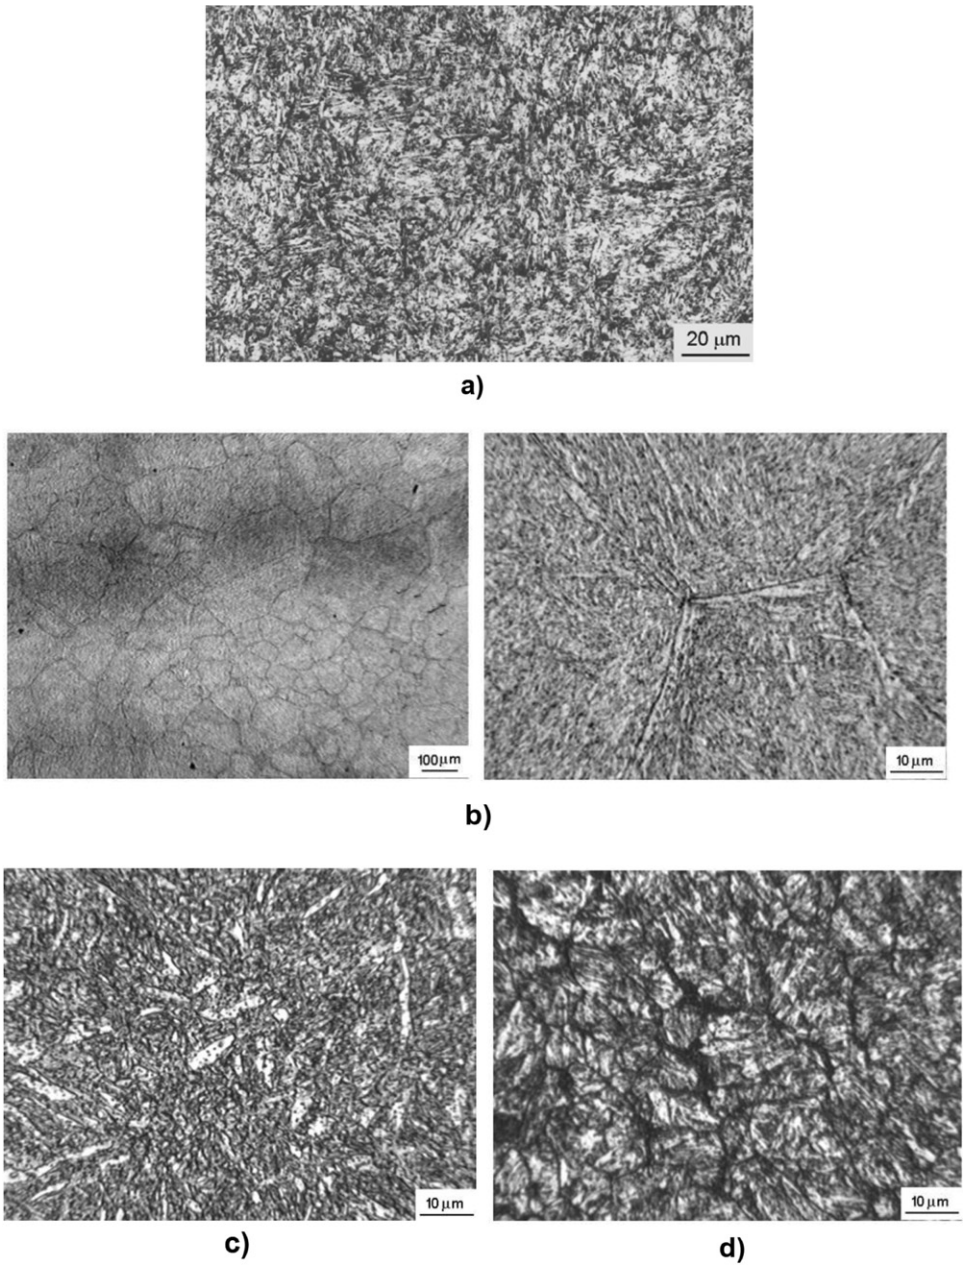

Figure 20 Representative microstructures of the H13 steel, heat treated to a hardness range of 4446 HRC in the following conditions: (a) right condition, austenitization at 1020 °C, quenched in oil and double tempering at 610 °C, impact energy of 350 J and loss in hardness of 0.5 HRC being exposed at 550 °C for 10 h; (b) wrong condition, austenitization at 1150 °C, quenched in oil and double tempering at 630 °C, impact energy of 35 J; (c) wrong condition, austenitization at 890 °C, quenched in oil and double tempering at 250 °C, impact energy of 208 J and loss in hardness of 3 HRC, after being exposed at 550 °C for 10 h; (d) wrong condition, austenitization at 1020 °C, quenched with slow cooling and double tempering at 610 °C, impact energy of 225 J (the darker regions are perlite).

promote total transformation of the ferrite into austenite. The toughness is again lower than expected (210 J). Furthermore, in order to obtain the required hardness, this steel was tempered at low temperature (200 °C). After exposure to 550 °C, a drop of 3 HRC in hardness is observed, although only 0.5 HRC was expected. Thus, the microstructure of **Figure 20(c)**, besides being more brittle, would present poorer hot performance, given its biggest loss in hardness. In **Figure 20(d)**, a microstructure with pearlite traces (dark in the triple points) is seen, confirming an erroneous condition in the cooling for quenching. Again, less toughness is verified.

The microstructures of **Figure 20** can easily be found in practical situations. The situation of **Figure 20(b)** may result from an uncalibrated austenitizing furnace or even an incorrect charge in order to take the load (and temperature!) of a different steel. The microstructures of **Figure 20(c)**, instead, may occur if the furnace temperature is uncalibrated to lower temperatures or occurs even when treated in a furnace with

temperatures not exceeding 1000 °C (which is common). In the case of Figure 20(d), this condition could occur, for example, in a mold or die with large dimension, that instead of quenching in oil as recommended, it was rather cooled in still air.

For the above example it is clear that the hardness is not sufficient condition for an appropriate heat treatment. To be considered an appropriate treatment, their microstructure should be evaluated. However, in practical terms, it is extremely complicated to evaluate the microstructure of a mold or die steel, because it would normally be necessary to destroy the part (e.g., to observe the microstructure of the core). Thus, a good heat treatment can only be guaranteed if all procedures (equipment, temperature, and time) are strictly respected.

It is worth mentioning that different heat treatment routes or when involving thermomechanical processing or processed in a semisolid state[24] the results might be completely different. Cryogenic treatments have also been frequently applied to tool steels either during production (or during the conventional heat treatment)[25,26] or after the conventional heat treatment[27] and on both cases properties enhancement are achieved. Another way to obtain better quality is employing hard coatings[28,29] on them. In this case friction reduction, improved wear and corrosion resistances are usually searched.

2.9.6 Heat Treatment Troubleshooting

2.9.6.1 The Importance of Heat Treatment in Tool Steels

The heat treatment has very important effects on properties, and consequently, on the performance of tool steels. Nevertheless, the vast majority of premature tool failure is a result of an incorrect heat treatment (it is estimated that about 70% of premature tool failure is caused by incorrect heat treatment).

The heat treatment of the tool steel has many peculiarities. For a number of factors, not just metallurgical factors heat treatments of tool steels are very different from heat treatment of plain carbon or low-alloy steels, for example, those applied in large volume parts production. Firstly, there is a high dependence of the final properties of the material with the heat treatment applied. The conditions of temperature, time and heating and cooling rates, the equipment utilized, and finally the entire procedure in most cases will be strongly related to the final performance of the tool. Secondly, the high value of the parts to be treated; in this case, dies and molds in which machining costs and the steel itself are already included. Thirdly, because it is usually one of the last steps of the process. So, if serious problems occur, it will hardly be possible to reset the tool treated within the required procedure. Fourthly, dies and molds are not standardized tools and consequently, the heating time and geometry, and the stress concentrators related to it, are constantly changing. Fifthly, the narrow temperature range, both of austenitizing and tempering as well as the variation of this range between the various types of steels used in tools.

All of these specificities of heat treatment of tool steels, if not well observed, can lead to problems or process failures that consequently cause a low yield of the tool. In terms of failures, it is interesting to divide them into two subgroups. The first are the flaws identified in the process itself, as small or catastrophic cracks, distortions, superficial problems (such as decarburization and oxidation), and other failures visibly observed. Although serious, these failures generally do not compromise the tool life, or at least do not create unexpected results during their use, because they are identified before it enters into operation. The second possibility of deviation in the heat treatment refers to conditions of temperature, time, and cooling rates employed. Quality control of the heat treatment, in most cases, is performed only by hardness measurements on the surface of the tool. This is because normally it is dealt with unique pieces and high values, with no possibility of its destruction for microstructural analysis and determination of properties. Thus, once the hardness is right, it is possible that the heat treatment deviations will hardly be identified before use of the tool and these will only be observed if a smaller tool life is perceived, and the cause of failure can be defined accurately.

Therefore, it is important to have knowledge of possible inaccuracies in the heat treatment. Two types of tool steels and the effect of heat treatment procedures on their properties will be discussed here. The first steel is the VH13ISO, similar to AISI H13, but produced with special manufacturing processes to provide improved toughness and isotropic properties.[30] The second steel, called VF800AT was developed for applications requiring greater toughness than the conventional steel,[31] typically AISI D2 and D6. The compositions of these steels are presented in Table 6.

For both steels studied, VH13ISO and VF800AT, various conditions of quenching and tempering were employed. Some are correct by following the recommended temperatures and times for each steel, and some considered incorrect, for not following these recommendations. The heat treatment conditions used for each steel will be described later, in the results. When not mentioned, the austenitizing times were 30 min and double tempering temperature in 2 h.

To evaluate the toughness, the VH13 steel was analyzed by unnotched impact test, following recommendations of NADCA,[32] because this test relates very well to yield of hot work dies.[30,33] For the VF800AT steel, the four points bending test[34] was used with test samples of 5×7 mm^2, taken in the longitudinal direction. The mechanical results were correlated to the microstructures observed by optical microscopy. For the case study, the failure (fracture surface of impact specimens) of the VHSUPER, another hot work tool steel, was analyzed by scanning electron microscopy.

The following results are described in three parts. In the first one it will be described the simulations of various heat treatments in VF800AT steel. Secondly, the same approach is taken for the VH13 steel. Because of excessive marks of austenite

Table 6 Nominal chemical composition of the steels VH13ISO and VF800AT

	C	*Si*	*Mn*	*Cr*	*Mo*	*V*	*Nb*
VH13ISO	0.40	1.0	0.3	5.2	1.5	0.9	–
VF800AT	0.85	0.9	0.4	8.0	2.0	0.5	0.15

grain boundaries in the latter material its evaluation in laboratory was inaccurate. This would require slow cooling of the sample, but not so slow as in an oven. Being impossible to simulate this slow cooling, it was employed a real case of die failure, held by cooling at too slow quenching. This fact is described in the third part, for a forging die made in VHSUPER steel.

2.9.6.2 Analysis of Several Conditions of Heat Treatment in VF800AT Steel

To study the heat treatment of VF800AT steel, a correct routine was followed as well as an incorrect one. Bending tests of the samples were then carried out. For all materials the hardness was maintained at 60 HRC. The condition A refers to the material treated properly, with 1030 °C quenching and double tempering at 530 °C. All the other conditions refer to incorrect treatments (but would be correct for other materials). Figure 21 shows these results.

The condition B features a double incorrect treatment condition, wherein both the austenitizing and the tempering temperatures were inadequate. Compared to the correct treatment, there is loss in 25% of flexural stress strength and lower rupture energy, indicating less toughness. The condition B is close to the thermal treatment applied to the VC131 (AISI D6) steel, very widespread in cold work applications.

The condition C, on the other hand, has the correct austenitizing temperature, but tempering was applied at a low temperature. This procedure is typical for VD2 (AISI D2) steel, which has higher austenitizing temperature than the VC131, but is tempered at a low temperature, because the secondary peak is not sufficiently intense to promote hardness of 60 HRC. In this case, there is also loss of strength and toughness.

The fourth condition D is typical for heat treating HSS – austenitization at very high temperature and tempering above 550 °C. In this case, the loss in toughness was even more significant.

The above mechanical properties can be understood by analyzing the microstructures obtained in each condition (Figure 22). In the correct condition (A) a microstructure with martensitic matrix and undissolved primary carbides are observed. At that magnification (approximately × 350), the identification of the austenitic grain boundaries is unclear, because they are thin, due to the austenitizing temperature being adequate. It is also observed as a matrix darkened by metallographic etching. This condition of the matrix results from tempering at high temperature, with precipitation of secondary carbides, removing alloying elements from the matrix and providing greater susceptibility for the chemical etching. The mechanical properties are higher, in this case, because the stresses in the matrix, generated by the martensitic transformations, are alleviated and hardness is promoted by secondary precipitations, improving further the mechanical properties.

In the condition B, it is observed that the quenching and tempering at low temperatures are able to promote adequate hardness. However, the microstructure practically consists of crude martensite, i.e., not tempered. In such a condition, the stresses on the microstructural matrix are very high, reducing the strength and toughness of the material.

The condition C is slightly better than the condition B, in terms of mechanical properties. However, the fact of tempering at yet low temperature, promotes better toughness in comparison to the correct treatment (condition A). The microstructure still presents as somewhat less tempered, a fact highlighted by the high resistance of the material to metallographic etching, thus generating low toughness.

In the condition D, on the other hand, the microstructural matrix is more etched by the chemical reagent. However, the obtained toughness is too low because in this case the negative factor refers to the very high austenitizing temperature (typical of HSS). Under these conditions, there is too much grain growth because, unlike HSS, the VF800AT alloy was not designed to withstand as high austenitizing temperatures.

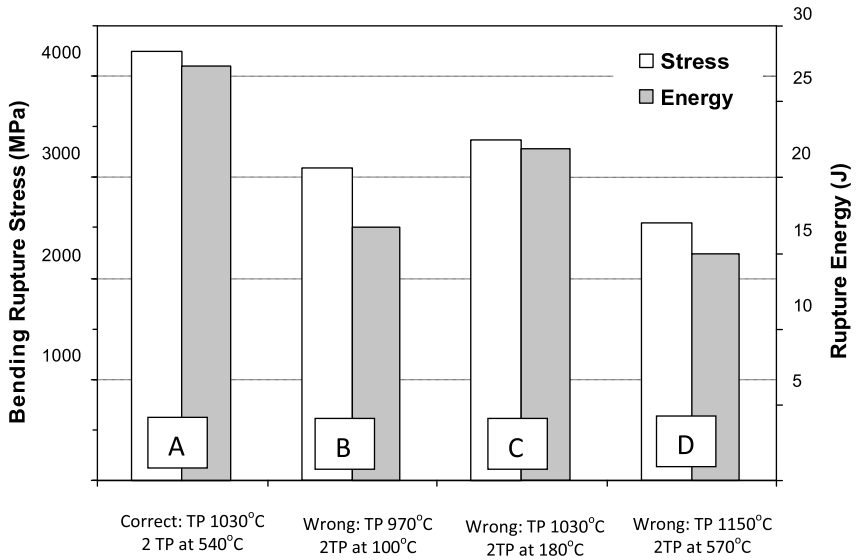

Figure 21 Resistance to bending and rupture energy, for VF800AT steel treated under several conditions, all with 60 HRC. The conditions A–D are described in the text.

The martensite formed during cooling is consequently rough and properties are reduced.

2.9.6.3 Analysis of Several Conditions of Heat Treatment in ISO VH13 Steel

As performed for the VF800AT steel, various heat treatment conditions were also applied to the VH13ISO steel. The conditions are described below and the results of impact are shown in Figure 23.

Condition E: correct heat treatment for the H13 steel, with austenitization at 1020 °C, rapid cooling during quenching, and tempering at high temperature of 610 °C. This condition generates the greatest toughness values.

Condition F: low austenitizing and tempering temperatures. This procedure may be erroneously applied when using low-temperature ovens.

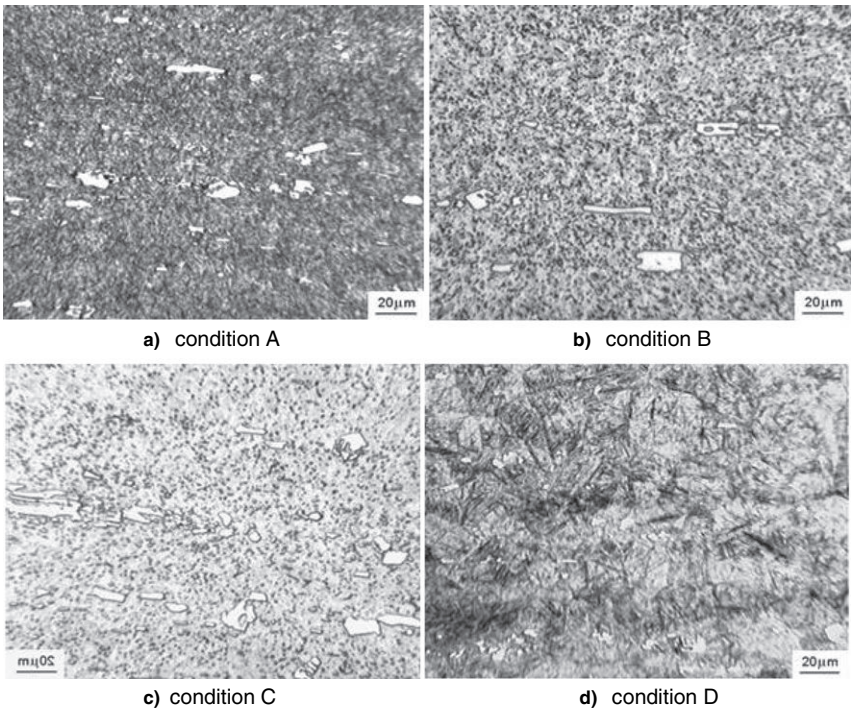

Figure 22 VF800AT steel microstructures resulting from heat treatment under the conditions A–D, described in Figure 21. Magnification of × 350, Villela etching, for 10 s.

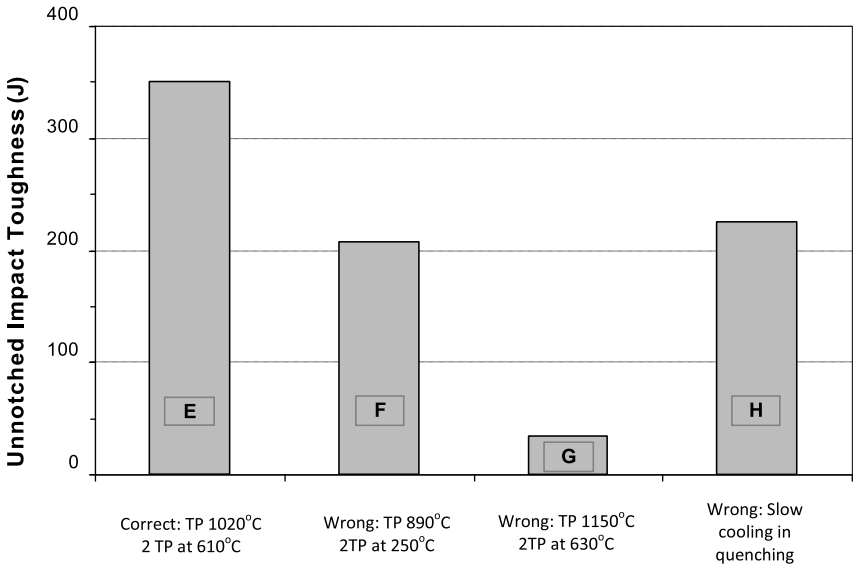

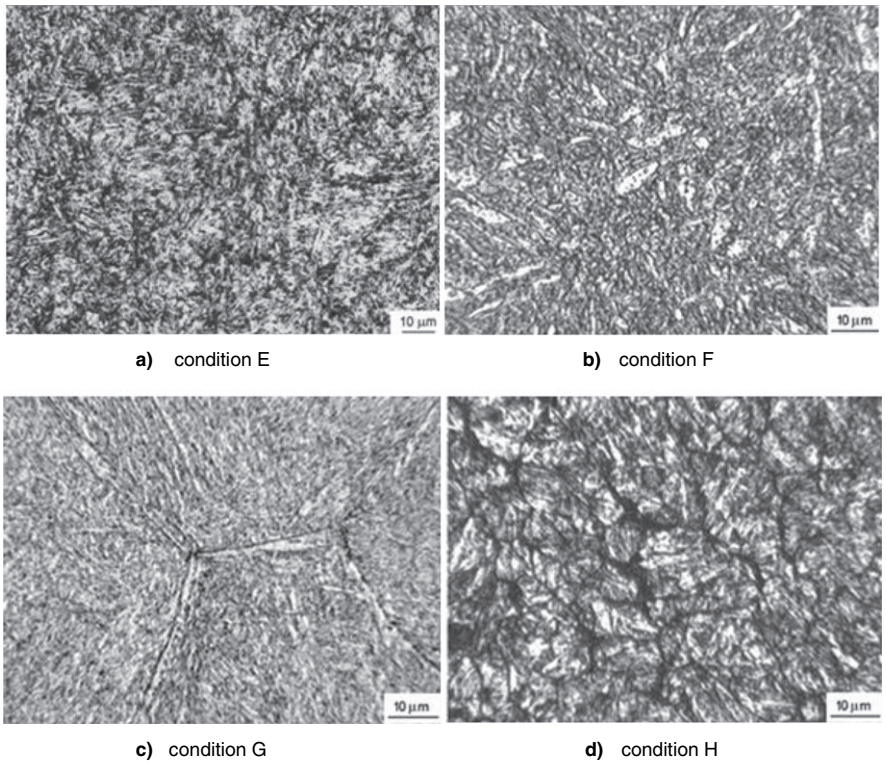

Figure 23 Unnotched impact energy according NADCA[32] for VH13ISO steel treated for various conditions, all 45 HRC. The conditions E–H are described in Section 2.9.6.2 of the text.

a) condition E **b)** condition F

c) condition G **d)** condition H

Figure 24 Microstructures of the VH13ISO steel as a result of the heat treatments under the conditions E–H as described previously (Figure 23). Nital etching (4%).

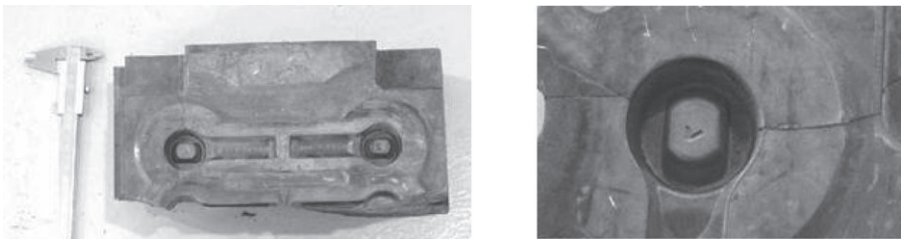
Condition G: too high austenitizing temperature and tempering temperature slightly higher than usual, to adjust the hardness to the required range.

Condition H: normal austenitizing and tempering temperatures, but the material cooled very slowly to room temperature (approximately 6 °C min^{-1}). This procedure may be caused, for example, due to quenching in poor aggressive cooling medium such as quenching in air.

Figure 24 shows the features of the microstructure of each condition of heat treatment. In Figure 24(a), a typical microstructure is observed consisting of tempered martensite and secondary carbide (condition E); this generates high toughness identified value – 350 J.

In Figure 24(b), condition F, the too low austenitizing temperature did not cause the total transformation of ferrite. The toughness is lower than expected (210 J). Furthermore, in order to obtain the required toughness, the steel is tempered at a low temperature (200 °C). After exposure for 10 h at 550 °C, it has reduced 3 HRC points in hardness where only 0.5 HRC were expected. Thus, this microstructure, besides being more fragile, would cause loss in hot performance, given its biggest loss in hardness.

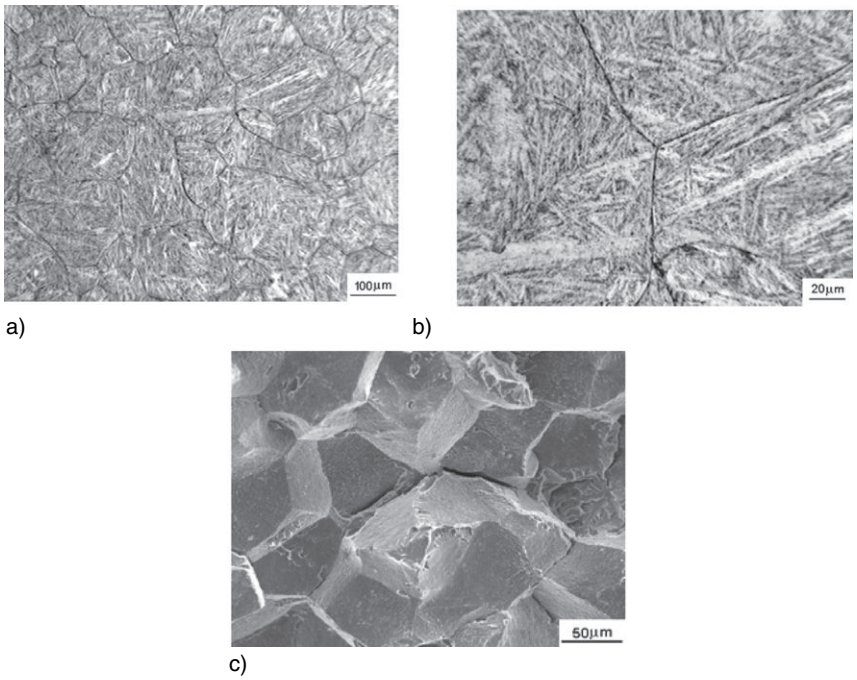
Figure 24(c) shows the typical microstructure of austenitized steel to too high temperature (condition G), evidencing the high austenite grain size. The result is dramatically lower toughness (42 J), showing that the embrittlement occurred. Just as in the condition D of the VF800AT steel, very high austenitizing temperature promotes the formation of coarse martensite and sharp reduction in toughness.



For condition H (Figure 24(d)), the microstructure has traces of pearlite (dark in triple points), showing an erroneous condition in the cooling of quenching. Again, low toughness is observed. Besides the pearlite formation, too slow cooling provides grain boundaries embrittlement, as will be shown in the following item.

2.9.6.4 Case Study – Forging Die with Premature Failure

A practical case of failure similar to the condition H, previously described, was identified in a forging die made of VHSUPER steel. In this case, the matrix had much lower than expected life. The failure occurred by catastrophic cracks, shown in Figure 25.



The microstructure of the material, Figure 26, showed strong marking of austenitic grain boundaries. This results from precipitation of carbides during cooling, due to a too slow cooling rate during quenching. It is also observed as coarse austenitic grain, indicating that the heat treatment was performed with excessive austenitizing temperature or times, which facilitates the precipitation of carbides.

To analyze the toughness, impact test specimen's samples were withdrawn from the fractured die. The results found are much lower than expected for the VHSUPER steel. The energy of rupture was 50 J in unnotched specimens, machined according to the recommendations of NADCA, and the expected rupture value for this steel is more than 250 J. The fractured surface, shown in Figure 26(c), made up of predominantly intergranular, evidencing the fragilizing effect of the carbides.

a) b)

Figure 25 Premature failure of a forging die. (a) whole die and (b) details of the cracked regions.

a) b)

c)

Figure 26 Microstructure observed in the cracked die. Austenitic grain in detail at (a) low magnification; (b) high magnification; and (c) fracture of impact test specimens taken from the die, obtained by scanning electron microscopy, secondary electron.

After this result, a sample of the material was taken and an annealing followed by new quenching and tempering was performed, for the same hardness but with cooling in oil during quenching. The rupture energy increased from 50 J to 360 J.

From the previous examples, Sections 2.9.6.3 and 2.9.6.4, it is clear that hardness is not sufficient information for an appropriate heat treatment. To be considered an appropriate treatment, the microstructure and mechanical properties should also be evaluated.

However, in practical terms, it is unfeasible to evaluate the microstructure and properties of a mold or die, because normally it would be necessary to destroy the part (e.g., to observe the microstructure of the core). Thus, appropriate heat treatment can only be guaranteed if all procedures (equipment, temperature and time) are strictly adhered to.

To summarize, the conditions of heat treatment significantly influence the microstructure and properties of the tool steels and consequently, have a strong influence on the life of the mold, matrix, or the tool used. Either for tool steels for cold working or in steels for hot work, heat treatment conditions vary intensely from steel to steel. So the individual conditions of each material in terms of temperature, time, and heating and cooling rates must be respected for proper performance of the tool. Studies in the laboratory have shown the influence of wrong conditions on the final properties of the tool steels. They therefore confirm the need of using a correct procedure, in order to guarantee an appropriate heat treatment.

2.9.7 Examples of Application and Performance of New Hot Work Steels

Hot forming tools are applied in various industries, focused on the production of parts for mechanical applications, especially automobile parts. The variety of methods used can be divided into three basic operations: tools for hot and warm forging, molds and dies for casting of nonferrous alloys, and extrusion dies of nonferrous alloys.

In forging applications, the hot forging of steel, especially of engineering steels applied in automobile parts, is distinguished. In such operations, the forged billet is heated at temperatures above 1100 °C. During the forming, the die surface is heated; the higher the temperature of the billet and the contact time of the workpiece with the tool, the higher is the temperature of the die. In relation to the contact time, this is higher in press forging and lower in the case of hammer forging. If temperatures reach the surface of the matrix, for example, over 550 °C, the tempering mechanisms start to occur in tool steel promoting loss of mechanical strength in such regions. Thus, a key property is the resistance to tempering (i.e., the loss in hardness) of the tool steel.

In extruding nonferrous alloys, the temperatures used are too high, but the billet is heated to lower temperatures in comparison to forging operations. In the aluminum extrusion, for example, the temperature of the billet is in the order of 600 °C. However, the long contact with the billet with constant friction also generate hardness loss in tool steel. In copper alloy extrusion the temperature is higher than that of aluminum, thus requiring steels with high resistance to tempering. In both applications, nitrided tools are often employed, in order to increase the hot wear resistance. However, long time of exposure to heat promotes diffusion of the nitrided layer, requiring re-nitriding of the tool.

In both forging and extrusion, toughness is also an important property. In local stress concentration, lack of toughness can generate coarse cracks, which depending on the size involved may condemn the tool. In forging, such cracks could be catastrophic, immediately suspending the operation, or be caused by mechanical stresses. The toughness is also important in extrusion operations in parts of auxiliary tools to the die, receiving the impact of the billet or having areas of higher stress concentration.

Other application that requires high performance of the tools and special tool steel properties is the casting of nonferrous alloys, especially aluminum alloys. In the press casting process the main solicitation applied to the dies is thermal cycling. As a result, the normal way to determine the end of tool life is the formation of a network of thermal cracks (heat-checking) in such a severe manner that compromises the surface quality of the part being produced.[35] The main property of tool steel related to the formation and propagation of such cracks is toughness. Physical properties such as thermal conductivity and thermal expansion coefficient are also important because they act in the homogenization of the temperature between the surface and the core of the die and in the expansion generated by the heating, respectively. The increase in these properties decreases, however, the fatigue stresses. But the variation of these physical properties is limited in tool steels.

Therefore, the hot strength, more specifically, the resistance to loss in hardness (tempering resistance) and toughness are the most important properties of the tool steels used in hot forming. Depending on the employed forming process, one or other property, or even both, may be more important. Other properties, physical properties such as conductivity and thermal expansion already mentioned, can also be important, but to a lesser degree in most applications. Yet, there are situations in which the machinability and the reduction of alloying elements may also be important, such as in large forging dies.

Each tool steel has a set of properties, depending on the chemical composition and manufacturing process. As shown in previous studies,[36–38] the modification of H13 steel manufacturing process promotes increased unnotched impact energy (from 60 J to more than 200 J). Special processes, including refining by electro-slag remelting (ESR), may also promote even greater improvements.

Thus, the selection of the best steel for each application must involve the combined analysis of all the previously described properties and the influence of the manufacturing process. For this analysis, it is essential to have good knowledge of the application in question in order to determine the primary failure mechanism and the best strategy to slow it down.

The use of new steels is also related to this purpose. Through the knowledge of the main tool failure mode one can select the new material in order to act in the cause of this failure. In the following section the analysis of application of two new tool steels in hot forming will be shown. The failure modes are analyzed and compared with the main properties of the materials, so as to understand the performance improvement achieved.

2.9.7.1 Properties of the TENAX 300 and VHSUPER Steels

The two new materials and modifications that provided their properties have been described in previous papers.[38–40] However, as the knowledge of such properties will be important in subsequent discussions, they are summarized in Figure 27 and compared to the conventional AISI H13 steel. As shown in Figure 27(a), the main improvement of the TENAX 300 steel is the increased toughness characterized by impact energy. However, in Figure 27(b) it is also observed slight improvement in the hot strength of the material. In the same figure a considerable higher heat resistance of the VHSUPER steel can be seen. In these cases, the hot strength is measured by tempering resistance (or resistance to loss in hardness) which is basic in hot conformation applications.

It is also important to note that such improved properties obtained from chemical composition changes only become effective after production in appropriate conditions. As shown in previous studies,[36–38] the routes of the so called ISO® and ISOMAX® contain major process modifications, to produce improvement in isotropy and mechanical properties of the tool steels. In ISO® process, changes refer to secondary refining of molten steel in ladle furnace, the time of homogenization and forging conditions associated with particular annealing, which prevents precipitation of carbides in the grain boundaries. In ISOMAX® process on the top of all these changes, a refining by ESR is added, greatly reducing the amount of inclusions and increasing isotropic properties.

2.9.7.2 Case Analysis

Following are information about four applications of new steels. Two of them concern the use of VHSUPER steel in forging dies and the other two the use of TENAX 300 steel in forging die and die casting die. Besides these tests, other applications were also analyzed. However, data of the following cases are more complete and therefore, they were

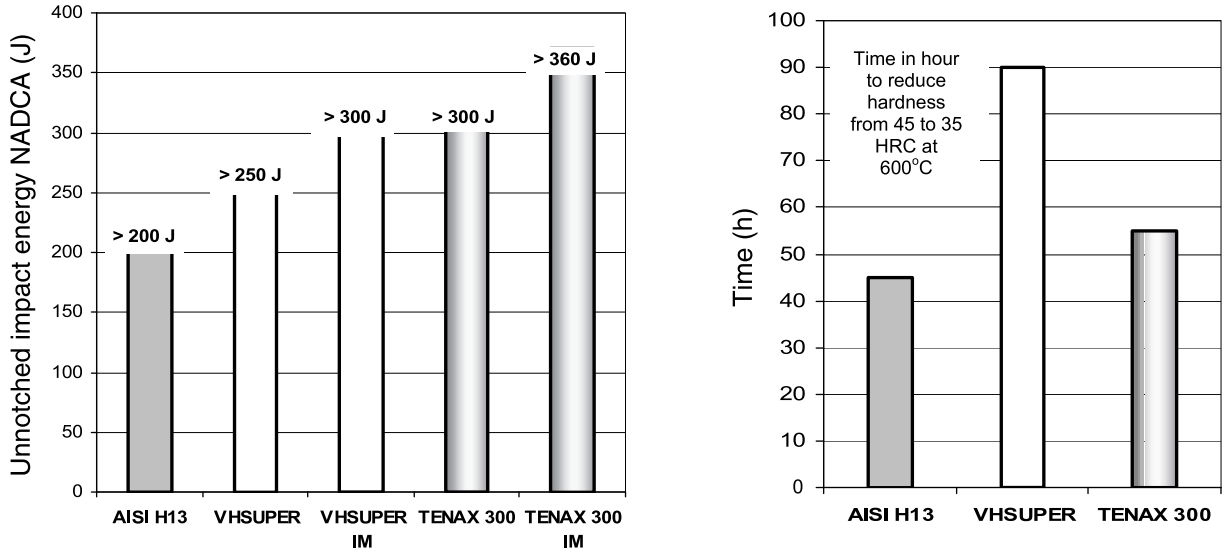


Figure 27 (a) Impact resistance in unnotched specimens for TENAX 300® and VHSUPER® steels, obtained by ISO® processes (not shown) and ISOMAX® (identified by IM). The toughness of H13 steel produced by ISO process is shown for comparison. Test specimens 5×7 mm^2, in the transverse direction, machined and treated to 45 HRC$\pm$1 according to NADCA; (b) resistance to tempering of typical AISI H13 TENAX 300 and VHSUPER, characterized the time necessary for the drop of hardness from 45 to 35 HRC when the materials are subjected to the temperature of 600 °C.

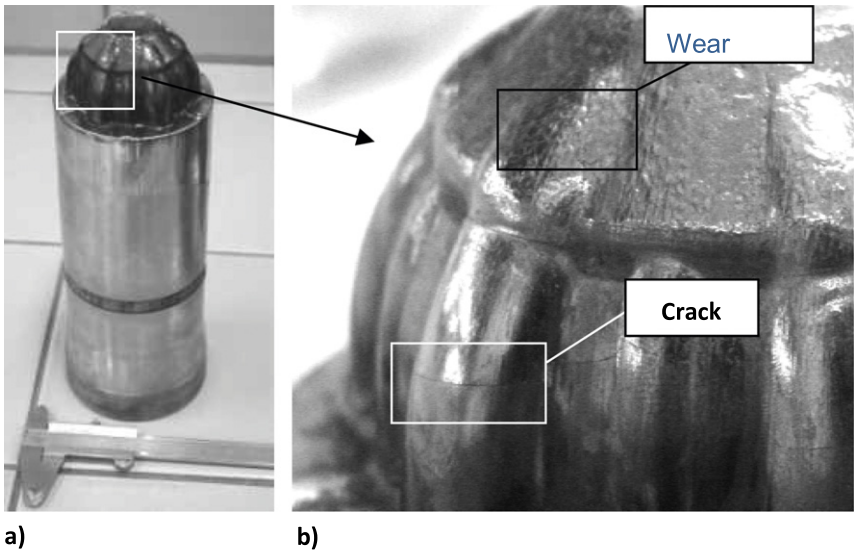

Figure 28 (a) Visual aspect of the punch and (b) detail of the hot worn regions and cracks.

selected to be presented here. In them, the process variables and conditions of use of the tools, including the hardness, were kept approximately constant. Thus, the results can be attributed to the replacement of the steel.

2.9.7.2.1 Warm forging punch – Case 1

The process in question is a high-speed warm forging. Despite the forged billet having a lower temperature than in the usual hot forging, at high speed of the process the contact between the heated billet and the die is bigger, thus heating the surface thereof. The process also employs high cooling, thereby promoting thermal shock in the surface region.

Process data: product: spindle; tool: precision forging punch to warm; forged material: SAE 1045 and modified SAE 1050 steels; billet temperature: 900 °C; cooling: high, with water;

Stroke speed: high; previously tool steel used: AISI H13; tested steel: VHSUPER; gain in tool life obtained by replacement 56%.

Figure 28 shows the punch analyzed at the end of its life. As this type of forging produces parts with high dimensional accuracy (in the order of tenths of a millimeters) deviations compromise the piece produced. Thus, the end of life is caused by wear on the rounded protruding regions and the emergence of thermal cracks (see Figure 28(b)).

In order to get more information, the punch was cut and microhardness tests were performed on the worn area. The results were plotted as a function of distance from the contact surface, as shown in Figure 29. The hardness to depths greater than 1 mm is practically uniform, with the value specified for the material – 53 HRC. However, surface areas, specifically where the wear occurs, the hardness decreases significantly, reaching about 42 HRC. Thus, wear is effectively related to the loss in hardness of the tool during operation and little change in the hardness of the core was observed. The onset of thermal cracking is also related with a loss in hardness because lower hardness regions become more sensitive to thermal crack initiation.[41]

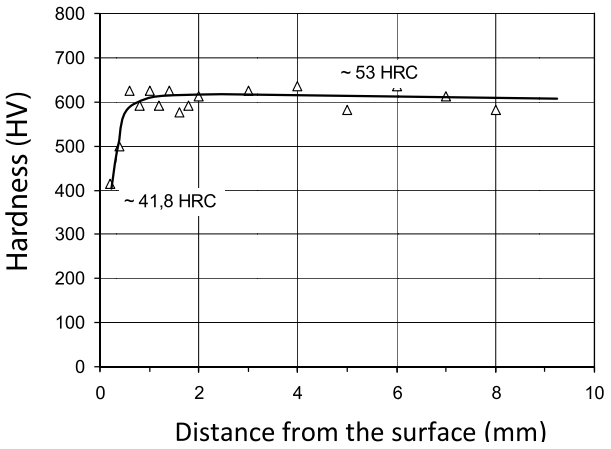

Figure 29 Microhardness measurements of the punch shown in Figure 28, from the working surface downwards to the inner regions in the direction of the die center.

Thus, increasing the tempering resistance of the material becomes essential to promote increased life of this tool. Verified by this fact, the VHSUPER steel was then tested and approved for the application, providing 56% increase of tool life.

The comparative analysis of the tempering curves and the drop in hardness as a function of temperature and time for VHSUPER and H13 steels, Figure 30, allows full understanding of the phenomenon. In both steels there is hardness losses when the steel is subjected to high temperatures. The greater the time and temperature employed the greater is the loss in hardness. However, it can be seen in Figures 30(a) and 30(b) greater stability at high temperature of the VHSUPER steel, as discussed previously. Thus, during the forging process failure will occur after a larger number of strokes, producing the yield gain observed.

2.9.7.2.2 Connecting rod hot forging die – Case 2

The increased hot resistance of the VHSUPER steel was also evaluated in hot forging die for connecting rods, shown in Figure 31(a). In this type of forging, the dimensional requirements

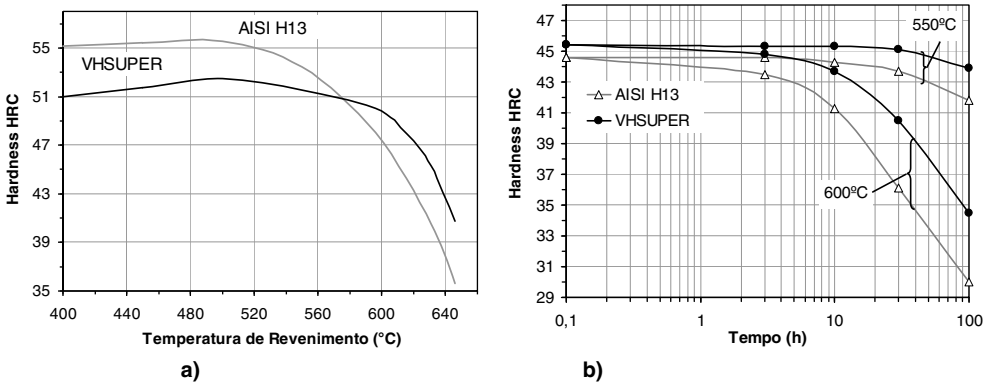

Figure 30 Comparative tempering resistance of the AISI H13 and VHSUPER steels (a) decrease in hardness as a function of temperature, double tempering after 2 h; (b) Hardness versus time in logarithmic scale.

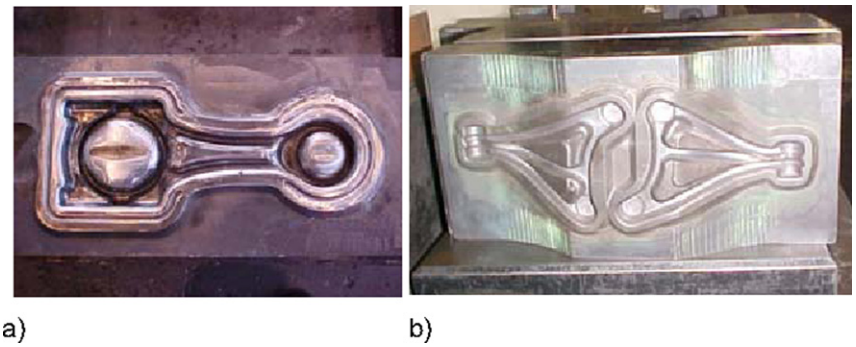

Figure 31 (a) Connecting rod hot forging die, analyzed in case 2, where the steel VHSUPER was tested and (b) engine support hot forging die, where the steel TENAX 300 was tested.

are lower than in the forging described in Section 2.9.7.2.1, but the contact time and the temperature of the forged billet are substantially higher. However, the depth of the surface region of the matrix affected by the heat of the process is worse. Some data indicated that the affected region is about 5 mm and, as shown in **Figure 29**, the hardness of the matrix decreases toward the surface.

Process data: product: forged connecting rod; tool: hot forging preform die; forged material: medium carbon steel; temperature: about 1250 °C; stroke speed: slow, typical of forging press; tool steels previously used: AISI H12 and H13 steels; tested steel: VHSUPER; Gain in lifetime obtained with the substitution: about 50%.

The end of life of the tools is caused by two factors: warm wear associated with the formation of thermal cracks. These cracks have depths greater than those observed in the warm forging punch (**Figure 28(b)**), because of the greater heat and higher temperature of the forged billet, which promotes more intensive thermal shock. The replacement of the AISI H12 and H13 steels by the VHSUPER steel can be understood based on the comparative analysis of resistance to tempering (**Figure 30**) and toughness (**Figure 27(a)**). The improvement in both properties of the VHSUPER promotes reduction in the hot wear. The higher the hardness values the longer is the time of use. Furthermore, the thermal cracks are reduced because of the increased hot hardness and toughness.[35]

2.9.7.2.3 Hot forging die with complex geometry – Case 3

The process analyzed in this case is very similar to that described in Section 2.9.7.2.2. However, the failure mode is quite different, therefore, a different solution has been proposed. It is also about the press hot forging, details of which will be described later. However, the geometric complexity of the die used causes the failure mode be associated with cracks arising due to mechanical fatigue in stress concentration regions (see **Figure 31(b)**). The fundamental property of the tool steel in this case is toughness because it is related to the material resistance to crack propagation when subjected to a stress concentrator. Thus, the use of a high toughness steel is fully consistent with the need of the failure mode.

Process data: product: engine support; tool: hot forging die; forged material: mild carbon steel; stroke speed: slow, typical of forging press; tool steel previously used: AISI H13; tested steel: TENAX 300; life gain with the replacement: approximately 40%.

The application of the TENAX 300 tool steel was suggested by their substantially higher toughness compared to H13 steel, as shown in **Figure 27(a)**. Thus, a useful life gain of 50% was observed.

2.9.7.2.4 Aluminum casting die – Case 4

The end of life mechanism of casting dies is often discussed in the literature[35,38] and is associated with the formation of thermal fatigue cracks, as described in Section 2.9.7.2.1.

The important property of tool steel for this application is the toughness again. Studies show that, for a given hardness, the material's resistance to thermal fatigue damages is greater the higher the toughness, measured by the impact test on unnotched specimens.[41] Consequently, the TENAX 300 steel was applied in an aluminum press casting die. This process is described below. The performance of the die produced with the H13 steel was low because the geometry and the injection process brought many cracks to the die. After application of TENAX 300 IM steel, there was very significant increase in the tool life (greater than 100%!).

Process data: product: engine flange; tool: die cavity of an aluminum press casting die; process: die casting; tool steel previously used: AISI H13; tested steel: TENAX 300; gain in lifetime with the replacement: production of 80 000 shots per die against 200 000 shots.

For this application, the steel produced with ISOMAX process was employed due to the maximum toughness and isotropic properties obtained. So the high toughness of TENAX 300 IM steel, identified by impact energy values greater than 360 J, can be considered the main property responsible for the excellent results obtained in this application.

2.10.1 Introduction

Cast irons primarily are alloys of iron and carbon, the carbon percentage being 2–6.67% and undergo eutectic solidification. Since, high carbon content produce high brittleness, for most commercial applications the carbon content is restricted to 2.5–4%. However, beside carbon, industrial cast irons invariably contains silicon more than 1% with varying percentages of manganese, sulfur, phosphorus, and other alloying elements occasionally added. Binary Fe–C melt may solidify either by metastable Fe–Fe_3C system or by stable Fe–Graphite system. The solidification either by stable or metastable system depends on factors like graphitization potential, inoculation treatment, and cooling rate. These factors also govern the morphology of the stable graphite during solidification. Apart from the carbon, silicon has a contribution to increase strongly the graphitizing potential.[1,2] Silicon also shifts the eutectic and eutectoid compositions to lower carbon contents and pushes up these transformation temperatures (Figure 1). The ultimate properties of cast iron depend on the form of carbon precipitation and the matrix structure. The graphite form during solidification by Fe–Graphite system cannot be changed further by solid-state transformation by heat treatment. However, the cementite (Fe_3C) and the matrix structure can be changed by a suitable heat treatment to achieve desired properties. Important matrix structures and their characteristics and contributions to the iron properties are summarized in Table 1.

2.10.1.1 Types of Cast Irons

The cast irons are classified mainly according to the conditions and physical forms of the carbon present.[2] As stated earlier the carbon in cast iron may be present as graphite in stable system or as combined form of cementite in metastable system. In

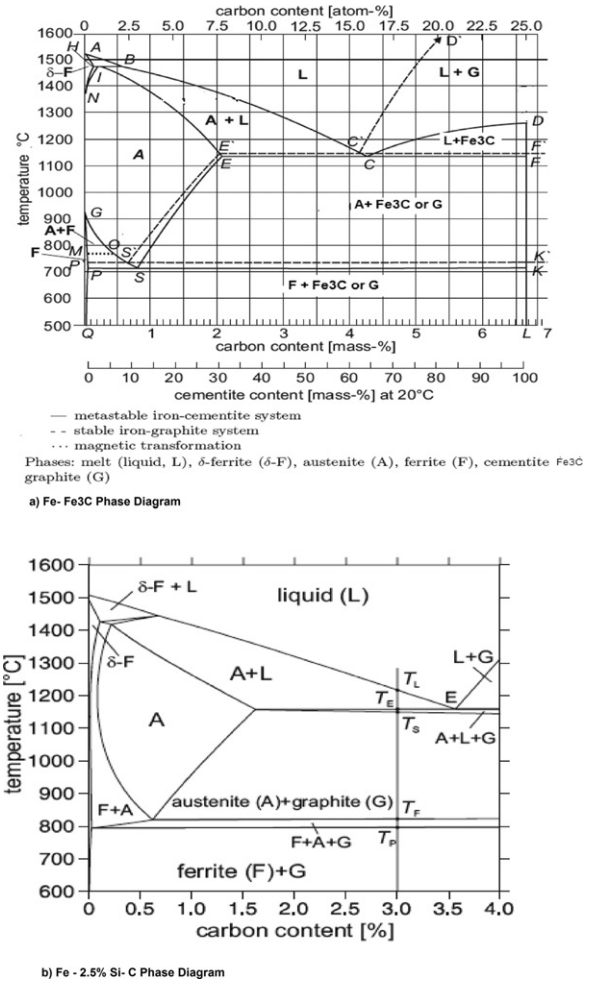

Figure 1 Fe–Carbon phase diagrams. (a) Fe–Fe_3C system and (b) Fe–2.5%Si–C. Modified from Berns, H.; Theisen, W. *Ferrous Materials, Steel and Cast Irons*, 1st. ed.; Springer Berlin; Heidelberg, 2008.

Table 1 Important matrix structures and their characteristics

Matrix structures	*Characteristics*	*Contributions*
Ferrite	Relatively soft, ductile Fe–C solid solution. Other elements viz. Si, Mn, Cu, and Ni may dissolve in the solid solution. Ferrite matrix can be produced either in as-cast condition or by annealing heat treatment	Yields low strength and poor wear resistance but good fracture toughness, thermal conductivity, and machinability
Pearlite	Decomposition product of austenite by eutectoid reaction into alternate lamellae of ferrite and cementite. A relatively hard phase. Carbon content varies depending on the iron composition and cooling rate	Develops moderate toughness, reduced thermal conductivity, and good machinability. The improvements in properties depend on the interlamellar spacing of pearlite
Ferrito–pearlite	A mixture of two phases, ferrite and pearlite	Results in a combination of extreme properties of the constituent phases
Bainite	The structure can be obtained by suitable alloying with Ni and Mo in as-cast condition or by austempering heat treatment	Several mechanical property advantages can be obtained such as combination of strength and toughness, good fatigue resistance, wear resistance, damping capacity, casting properties, formability, and machinability
Austenite	A high percentage of austenite stabilizing elements viz. Ni, Cu, etc., is needed to stabilize the austenite at room temperature	Austenitic matrix yields good toughness and high temperature property up to about 800 °C. Develops heat and corrosion resistance and nonmagnetic properties
Martensite	This hard phase can be produced either in as-cast condition by proper alloying or by heat treatment. Often associated with austenite retained in the microstructure	Martensitic matrix produces high strength and hardness, wear and abrasion resistance

Source: Modified from Elliott, R. *Cast Iron Technology*, 1st ed.; Butterworths: London; Boston, MA, 1988 and Angus, H. T. *Cast Iron: Physical and Engineering Properties*, 2nd ed.; Butterworths: London; Boston, MA, 1976.

stable system graphite may be of different shapes and accordingly the classifications are,

- Gray iron: Graphite is present as flakes and the fracture surface has a grayish appearance and so the name gray cast iron.
- Ductile iron: It is so named because of its good ductility. The graphite is present as spheroid form in which numerous flakes form into ball-like cabbage leaves. It is also known as spheroidal or nodular graphite iron.
- Compacted or vermicular graphite iron: The graphite morphology is intermediate between spheroids and flakes. The graphite phase shows segmented growth features with blunted edges but is interconnected within the eutectic cells.

Other important cast iron categories are:

- White iron: Most of the carbon is in brittle cementite form and the fracture appearance is crystalline whitish.
- Malleable iron: In this type of iron most or all the carbon is in uncombined temper carbon form. The rounded temper carbons are formed by prolonged annealing treatment of white cast iron.
- High-alloy irons: The properties and structure of any of the above types are modified by alloying additions generally over 4%. This class of iron includes wear resistant white irons, the austenitic and ferritic high-alloy heat and corrosion resistant irons.

2.10.1.2 Heat Treatment of Cast Irons: General Considerations

2.10.1.2.1 Critical temperature ranges

The selection of heat treatment temperatures is based on the understanding of the phase diagram and the critical temperature ranges in the phase diagram. In almost all types of heat treatments most important is the selection of austenitizing temperature to develop a single phase austenitic matrix above the critical temperature and below which austenite transforms to ferrite and pearlite /graphite. Silicon, manganese, and phosphorus are the most significant elements which influence the critical temperature of cast irons.[4–6] The location and size of this range is shown in Figure 2. The quantitative effects of various elements on the critical temperature ranges are shown in Table 2.

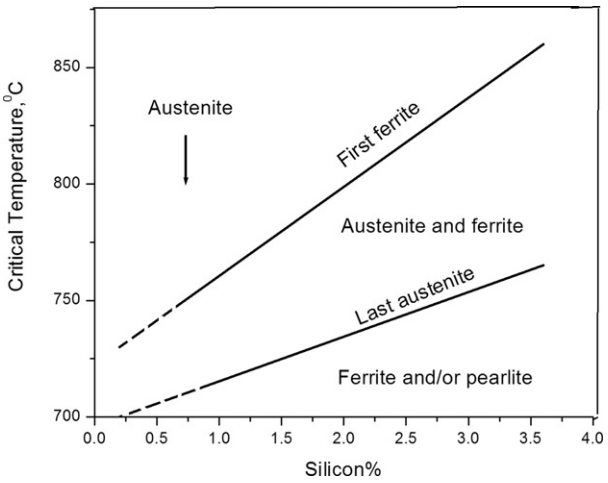

Figure 2 Effect of silicon percent on the critical temperature range of gray, malleable, and ductile irons cooled at 5 °C h^{-1}. Rehder, J. E. Critical Temperature Heat Treatment of Cast Irons. *Foundry*, June 1965; pp. 65–67. American Foundry Society.

2.10.1.2.2 Carbon content in the matrix

The carbon content in the matrix is directly related with the austenitizing temperature, higher the austenitizing temperature

Table 2 Effects of some common elements on the critical temperature ranges

Element (%)	*Upper critical temperature; effect: °C per (%)*	*Lower critical temperature; effect: °C per (%)*
Silicon, 0.3–3.5	37 increase	29 increase
Phosphorus, 0–0.2	220 increase	220 increase
Manganese, 0–1.0	37 increase	130 decrease
Nickel, 0–1.0	17 decrease	24 decrease

Source: Elliott, R. *Cast Iron Technology*, 1st ed.; Butterworths: London; Boston, MA, 1988; Table 4.1, p. 130.

higher will be the carbon content in equilibrium with the austenitic matrix.

2.10.1.2.3 Hardenability

The hardenability is significantly increased by carbon and silicon in conjunction with other alloying elements such as manganese, nickel, molybdenum, copper, etc., which enables cast iron to be quenched in media with low severity of quench viz. air, oil, or a polymer. This is to harden the cast iron to higher strength and hardness. Water as quenching medium with high severity of quench is not commonly employed to avoid distortion or cracks.[2]

2.10.1.2.4 Shape and size of the castings

Heavy and complex shape castings pose difficulties in heat treatment. For homogeneous heating from external surface to the core of the casting the heating rate must be slow enough and steady temperature soaking time must be adequate to avoid any temperature differential. After the soaking the rates of cooling also to be slow enough to avoid any residual stress development.[2] In case of quenched components, immediate tempering treatment is to be followed.

2.10.1.2.5 Surface oxidation and decarburization

Heat treatment furnace atmosphere must be controlled to avoid any surface oxidation and decarburization. Heavily oxidized surface poses machining problem due to the formation of hard oxide scale and hence drastically reduces the cutting tool life.[2] Due to decarburized layer formation proper hardening effect on the surface is not achieved by quenching.

2.10.2 Heat Treatment of Gray Irons

Gray irons are most widely used irons for general engineering applications. As described earlier gray irons undergo solidification as stable Fe + graphite system, the graphite formed are in flaky shape. The chemical composition of this gray iron is usually in the range of 2.5–4.0% carbon, 1–3% silicon, and 0.1–1.2% manganese. The manganese being a carbide stabilizer is kept at lower range for ferritic matrix, while higher range is preferred for pearlitic higher strength matrix. Apart from these, other alloying elements such as nickel, copper, molybdenum, chromium, etc., are added occasionally to achieve desired specific properties.

The most commonly employed heat treatment processes for gray irons include stress relieving and annealing. Through hardening and tempering is occasionally carried out to produce hard martensitic matrix for high strength, hardness, wear, and abrasion resistance. Surface hardening such as flame hardening or induction hardening is often carried out to replace chilled iron or costly alloying.

Other than the stress-relieving treatment, all heat treatments involve phase transformations to improve the properties. As the heat treatment has little or no influence on the graphite flake shape and distribution, matrix phase transformation is responsible for the property improvements. Although the graphite flakes are unchanged, the flake size has influence on the rate of matrix transformation by controlling the rate of diffusion of carbon. Finer the flakes, shorter will be diffusion distance causing a rapid transformation rate.

2.10.2.1 Stress Relieving of Gray Irons

Complex-shaped castings during their solidification may develop residual elastic stresses in the casting due to differential contractions. In contrast, castings with more or less uniform section thickness, the extent of residual stresses are not appreciable. In extreme cases, when the residual stresses are significant it will cause distortion or cracking.[2–4] The extent of residual stress is influenced by the factors like shape and size of the casting, the casting technique, and material properties and composition of the casting.

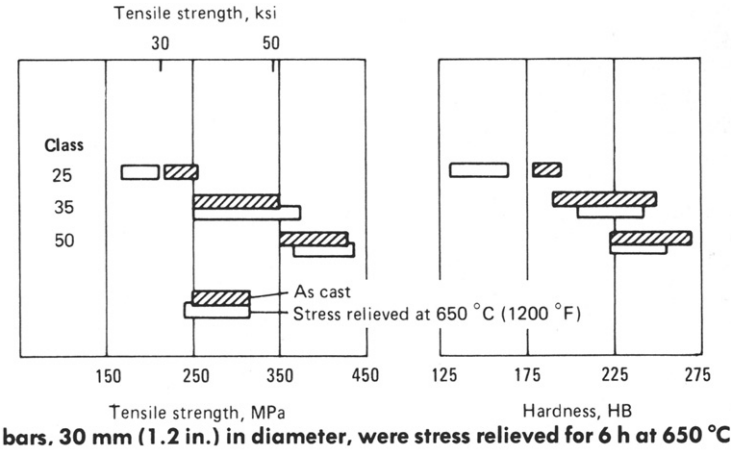
The residual stresses in castings develop due to following reasons:

- Differential contraction in castings with nonuniform sections.
- Restraint of the free thermal contraction of the casting by the rigid mold.
- Introduction of compressive residual stresses during surface cleaning operations such as shot peening.
- Thermal processes such as welding, through hardening or surface hardening.

The extent of stress relieving by stress-relieving heat treatments depends on various factors[3] such as,

- Initial level of residual stress
- The time–temperature relationship for stress-relieving treatment
- The rate of heating
- The rate of cooling
- The chemical composition and the microstructure.

Higher the initial level of residual stress, the more readily the stress will be relieved. The temperature and holding time at the stress-relieving temperature are two crucial parameters. Generally, the temperature is chosen in the range of 565–650 °C much below the critical temperature.[6–9] Selection of higher temperature requires shorter time of holding but will cause a slight structural change with lowering of hardness and tensile strength. However, the economics of the process definitely favors higher temperature process with shorter times. **Figure 3** indicates the effects of stress relieving at 650 °C for 6 h on the tensile strength and hardness variations in different grades of



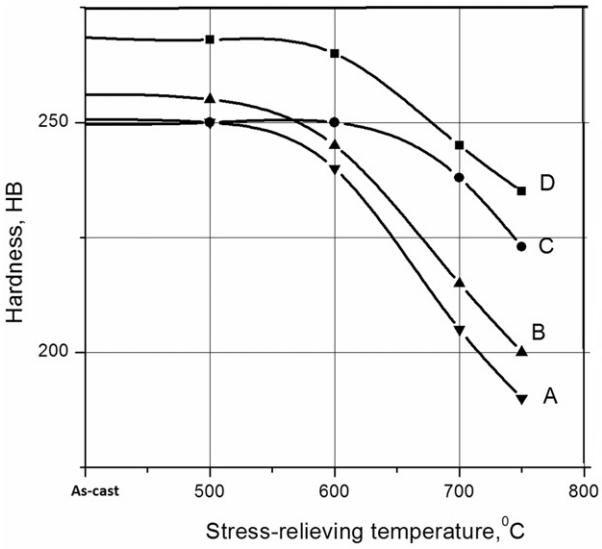


Figure 3 Effect of stress relieving on tensile strength and hardness of gray iron bars (30 mm diameter), stress relieved at 650 °C for 6 h. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Grey Irons; Figure 14, p. 1480.

gray irons. The hardness variations after stress relieving of alloyed and unalloyed gray irons at different temperatures are shown in **Figure 4**. The suitable temperature range as evident from the figure is 540–565 °C with a minimum decomposition of carbides in unalloyed irons. In this temperature range the effects of holding time on the residual stress percentage are depicted in **Figure 5**. Even after 1 h of holding could reduce the residual stress to 75–85%; higher holding times are not very much effective.

Table 3 shows the effects of composition on stress-relieving temperature of unalloyed and high-alloy irons. Alloying elements such as Mn, Cr, and Mo increase the strength at higher temperature range and such alloyed irons need higher stress-relieving temperatures.[10]

The heating and cooling rate of castings are two controlling factors; a slow heating rate of the order of 100–120 °C h^{-1} is optimum to avoid the generation of thermal stress especially for complex large castings. Similarly, a slow cooling rate is desirable after the soaking period at least in the upper range of temperatures. Complex shapes are recommended to cool down in the furnace to about 200 °C and can be subsequently air cooled. In batch type of stress relieving the loading temperature should not exceed 95 °C. A common heat cycle is to heat to 620–650 °C in about 3 h, isothermally soaked at this temperature for 1 h and cooled to 200 °C in 5 h in the furnace and then the castings are allowed to cool in air. In continuous furnace also this type of temperature zones can be adjusted.[6,8]

Iron	Composition, %					
	TC (a)	CC (b)	Si	Cr	Ni	Mo
A	3.20	0.80	2.43	0.13	0.05	0.17
B	3.29	0.79	2.58	0.24	0.10	0.55
C	3.23	0.70	2.55	0.58	0.06	0.12
D	3.02	0.75	2.38	0.40	0.07	0.43

Figure 4 Effect of stress-relieving temperature on hardness of different alloyed gray iron bars (30 mm diameter) held at respective temperature for 1 h and air cooled. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Grey Irons; Figure 15, p. 1481.

2.10.2.1.1 Case studies on stress relieving

Case 1: As-cast clutch plates made of gray iron of composition 3.4%C (0.7–0.9 combined C), 1.3–1.8% Si, 0.25–0.4%Cr, 0.3–0.4%Mo, and Ni and Cu as required, minimum tensile strength 275 MPa and hardness 207–255 HB, are to machined with a flatness tolerance of 0.1 mm. In as-cast condition the tolerance could not be maintained but when castings were stress relieved at 620 °C for 2 h it became alright.[8]

Case 2: A cast transmission case made of gray iron of composition 3.1–3.4%C, 2.15–2.35%Si, and 0.2–0.4%Cr did not follow the usual procedure of slow cooling in the mold before shake-out and some of the castings were cracked (1.3 mm wide) because of fast shake-out needed for a rush order. Other castings developed cracks not after the machining but during final hot washing operation. The problem was eliminated for the remaining ordered pieces by stress relieving at 620 °C for 2 h. When original shake-out practice was followed, no further crack developed and eliminates the need for stress relieving.[8]

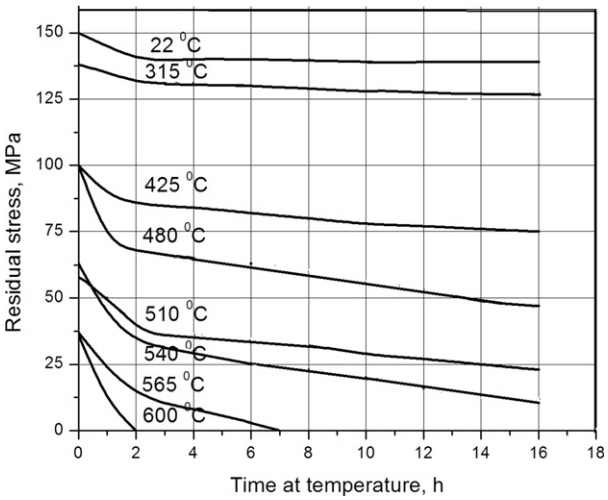

Figure 5 Effect of stress-relieving temperature and time on residual stress in gray iron (Composition: 2.72%C, 1.97% Si, 0.141% P, 0.08% S, 0.51% Mn). *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Grey Irons; Figure 17, p. 1482.

Table 3 Recommended stress-relieving temperature for unalloyed and alloyed gray irons

Gray iron type	*Stress-relieving temperature (°C)*
Unalloyed or alloyed without Cr	510–565
0.15–0.30% Cr	595–620
>0.30% Cr	620–650

Source: Dossett, J. L.; White, C. V. *Heat Treating of Gray Irons, Heat Treating of Irons and Steels*; *ASM Handbook*, Vol. 4D; ASM International: Materials Park, OH, 2014; pp. 493–507.

Case 3: Hot tears and out-of-roundness developed in gray iron as-cast rings and also the flat plane is distorted during machining. A modified gating system which equalized the temperature differentials and controlled the shrinkage distribution resulted in the elimination of hot tears and distortion. Further stress-relieving treatment at 370 °C for 2 h eliminated the machining distortion.[8]

2.10.2.2 Annealing of Gray Irons

The main objective of annealing is to soften the iron by decomposition of eutectic carbides or pearlitic carbides into ferrite and graphite by slow cooling through the critical temperature ranges. The structure promotes increase in ductility and machinability of the gray irons. There are several types of annealing processes in practice namely; (1) ferritizing annealing, (2) full annealing, and (3) graphitizing annealing. The processes are differing on the range of annealing temperature employed.

2.10.2.2.1 Types of annealing

2.10.2.2.1.1 Ferritizing annealing

This is to convert the combined carbon in pearlite to ferrite and graphite. The heat treatment involves heating the iron more commonly above 700 °C and up to maximum temperature of 760 °C, the lower critical transformation temperature. Lower the treatment temperature employed longer will be the time of soaking. The recommended soaking time at 760 °C is 1 h per 25 mm section thickness. The exact ferritizing temperature can be determined for a particular composition by annealing at different temperatures in the range of 700–760 °C for a fixed soaking time; most suitable temperature will be with lowest hardness.[3,4]

For simultaneous stress relieving along with ferritizing, the castings after soaking period are to be cooled slowly at the rate of 110–290 °C h^{-1} especially for complex shapes.

Figure 6 Fully ferritic, annealed gray iron (etched with 2% Nital). George Vander Voort. *Metallographic Procedures for Cast Irons*; Vac Aero International Inc. Newsletter; Figure 4.

2.10.2.2.1.2 Full annealing

A full annealing involves two stages of annealing. The first stage is to process above the critical temperature in the range of 790–900 °C.[8] This is aimed to decompose any small quantities of carbides present in the structure and to homogenize the matrix. The holding times may be same as those in ferritizing annealing. After this holding period the second stage involves a slow cooling through 675–790 °C temperature range to promote a ferritic matrix with graphite (**Figure 6**).

2.10.2.2.1.3 Graphitizing annealing

The graphitizing annealing with a higher annealing temperature in the range of 900–955 °C is employed to convert the intercellular massive carbides into pearlite and graphite. Further softening may be accomplished by a ferritizing annealing. The single graphitizing annealing followed by air cooling is employed if maximum strength and wear resistance are to be retained with a pearlitic matrix. On the other hand, double-stage treatment, i.e, graphitizing and ferritizing is suitable for developing ferritic matrix with maximum machinability.[4,8]

2.10.2.2.2 Effects of alloying on annealing soaking time

Alloying elements present in gray iron have pronounced effects on the annealing temperature and soaking time at the annealing temperature. Alloying elements can be grouped as graphite stabilizing and carbide stabilizing. The formers such as carbon and silicon accelerate the decomposition of pearlite and eutectic massive carbides whereas the later such as antimony, tin,

Table 4 Effect of 0.1% additions of various elements on pearlite decomposition time

Elements	*Increase in soaking time (%)*
Manganese	60
Nickel	30
Copper	30
Chromium	200
Phosphorus	30

Source: Dossett, J. L.; White, C. V. *Heat Treating of Gray Irons, Heat Treating of Irons and Steels; ASM Handbook*, Vol. 4D; ASM International: Materials Park, OH, 2014; pp. 493–507.

vanadium, chromium, manganese, phosphorus, nickel, and copper favors pearlite formation and hinder decomposition. For an example, when silicon content is increased from 1.93 to 2.68%, the decomposition time of pearlite is reduced from 45 to 10 min during annealing at 750 °C.[8] The effects of various carbide stabilizers (0.1% additions) on the decomposition times of pearlite are shown in Table 4.

2.10.2.3 Normalizing of Gray Iron

Normalizing for gray irons is employed to enhance the mechanical properties or to restore the as-cast properties which have been changed by the thermal processes. The castings are austenitized in the temperature range of 880–925 °C for a soaking period of 1 h 25 mm^{-1} section thickness and cooled to room temperature in still air.[6] The austenitization temperature has a great influence on the microstructure, hardness, and tensile properties. The most important compositional and microstructural parameters, combined carbon and interlamellar spacing of pearlite dictate the ultimate properties after normalizing (Figure 7). A higher carbon solubility is attained by a higher austenitization temperature which in turn, increases the volume percent of pearlite in the structure. The higher volume percent of pearlite is responsible for improved hardness and strength. The effects of other elements are also important to change the solid solubility of carbon in the austenite. The combined effect can be assessed by carbon equivalent and the effects of manganese, chromium, nickel, and molybdenum contents in the iron. Figure 8 shows the effect of carbon equivalent and %chromium and % nickel of the normalized hardness of the two different irons. As the austenitization temperature is gradually increased from 800 to 980 °C the hardness increases because of the stabilizing effects of alloy contents. Higher hardness can be achieved with lower carbon equivalent and alloying with Cr, Ni, and Mo.[6]

The interlamellar spacing of the resultant pearlite matrix is influenced by the composition and rate of cooling subsequent to austenitization. The composition effect is mainly due to the combined effect on the carbon solubility in the austenite. So far as the cooling rate is concerned, a fast cooling promotes smaller spacing and results in higher strength and hardness. Very high cooling rate combined with high-austenitizing temperature favor martensitic transformation impairing the machinability. The final hardness after normalizing can be partially controlled by the temperature of removal of components from the furnace.

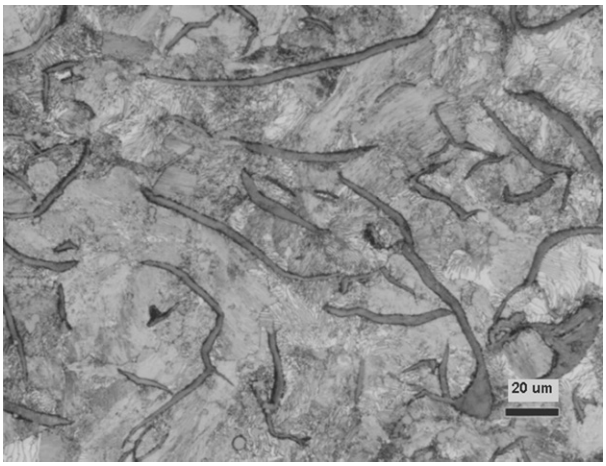

Figure 7 Fine pearlitic gray iron in normalized condition. George Vander Voort. *Metallographic Procedures for Cast Irons*; Vac Aero International Inc. Newsletter; Figure 5.

2.10.2.4 Through Hardening and Tempering of Gray Iron

Objective of the through hardening and tempering treatment is to enhance the mechanical properties particularly the strength and wear resistance. The hardening involves austenitizing above the critical temperature range, soaked at this temperature for adequate time for optimum carbon and alloying elements dissolution in the austenite, followed by quenching in a suitable medium to form martensite (Figure 9).

An optimum austenitization temperature is to be selected to dissolve adequate amount of carbon, a high-carbon austenite on quenching forms high-carbon martensite with high hardness and strength. On the other hand, a very high austenitization temperature causes danger of distortion, cracking, and retention of austenite.[4,6] The minimum austenitizing temperature is about 55 °C above the lower critical temperature A_1 of a particular iron. The A_1 temperature is calculated from the relationship,

$$A_1 = 730 + 28(\%\mathrm{Si}) - 25(\%\mathrm{Mn})$$

The austenitizing time is also an important control parameter. For unalloyed gray irons, the austenitizing time is longer to saturate more carbon in austenite and thus increased quenched hardness is obtained.

The austenitized gray iron castings are quenched in a molten salt or oil or water soluble polymer quenchant. Water quenching is not recommended as quench cracks and distortions are developed. Alloyed gray irons with high hardenability can even be forced air quenched to obtain a high percentage of martensite. Because of the high-thermal and transformation stresses in as-quenched condition, the castings are prone to cracking at room temperature. So, especially complex shape castings are t be withdrawn from the quenching bath in hot condition at about 150 °C and immediately tempered. The as-quenched castings are tempered at an elevated temperature in the subcritical range usually for a time of 1 h 25 mm^{-1} to impart strength, ductility, and toughness. The effect of tempering temperature on the strength, hardness, and impact

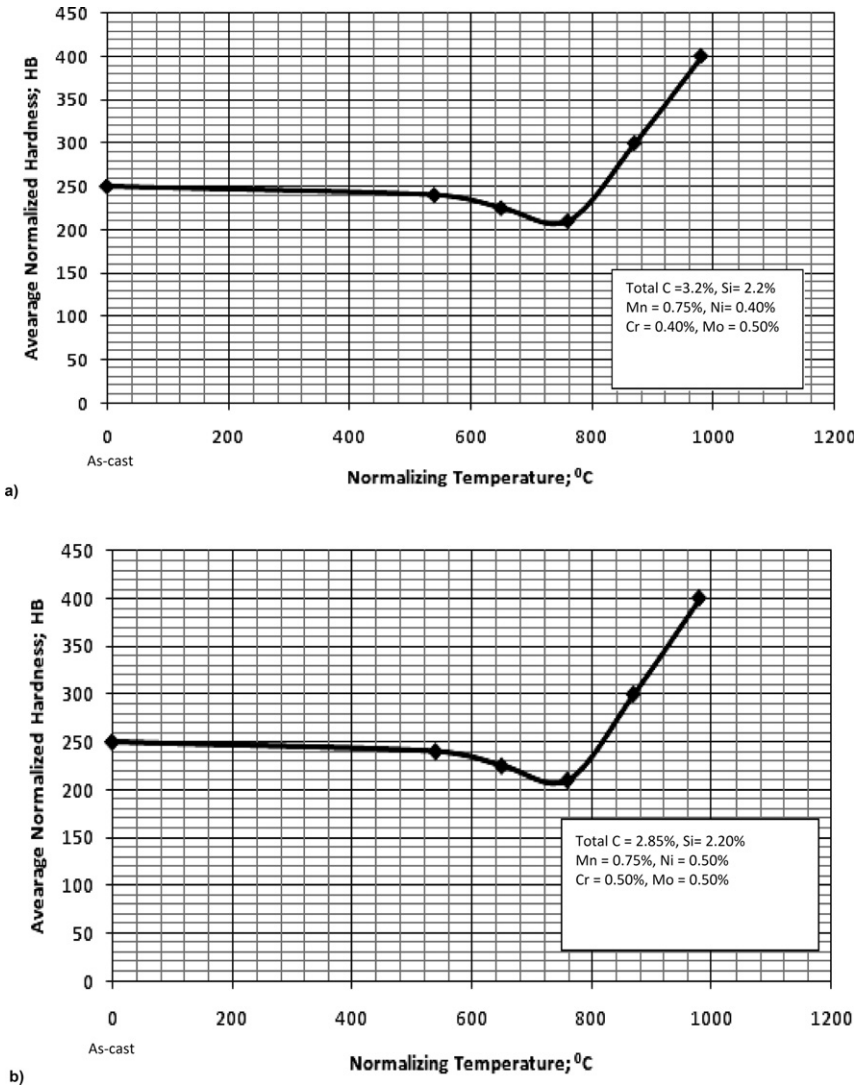

Figure 8 Effect of carbon equivalent (%C and %Si) and alloy contents on the normalized hardness of gray iron. Modified from Davis, J. R. *ASM Specialty Handbook: Cast Iron*; ASM International: Materials Park, OH, 1996; Figure 4, p. 182.

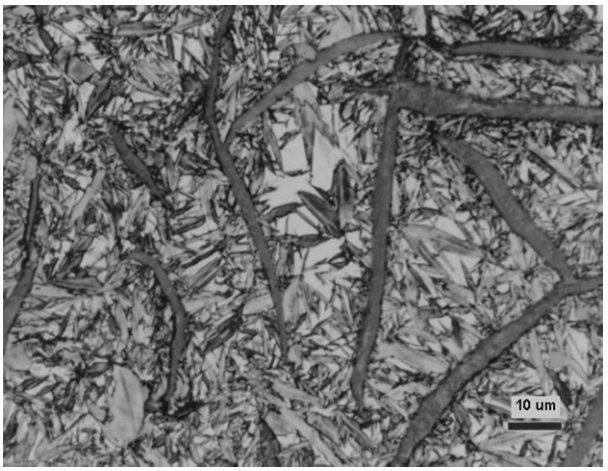

Figure 9 Pearlitic gray iron hardened to form martensite and retained austenite. George Vander Voort. *Metallographic Procedures for Cast Irons*; Vac Aero International Inc. Newsletter; Figure 6.

toughness of low-silicon gray iron are shown in Figure 10. The maximum strength developed depends on alloy content. To achieve high strength for both alloyed and unalloyed gray irons, the usual tempering temperature ranges from 370 to 510 °C.[6]

2.10.2.4.1 Case study on hardening and tempering of gray iron

Case 1: Valve guides made of unalloyed gray iron of which hardness requirement is 30–34 HRC in hardened and tempered condition. To achieve this final hardness the components are austenitized at 885 °C for 1 h followed by quenching in hot oil at temperature of 60 °C. The as-quenched hardness obtained in the range of 45–50 HRC. The quenched valve guides are tempered at 480 °C to achieve the desired final hardness.[6]

2.10.2.5 Austempering of Gray Iron

The austempering is an isothermal tempering process of as-quenched austenite phase in the acicular or bainitic ferrite

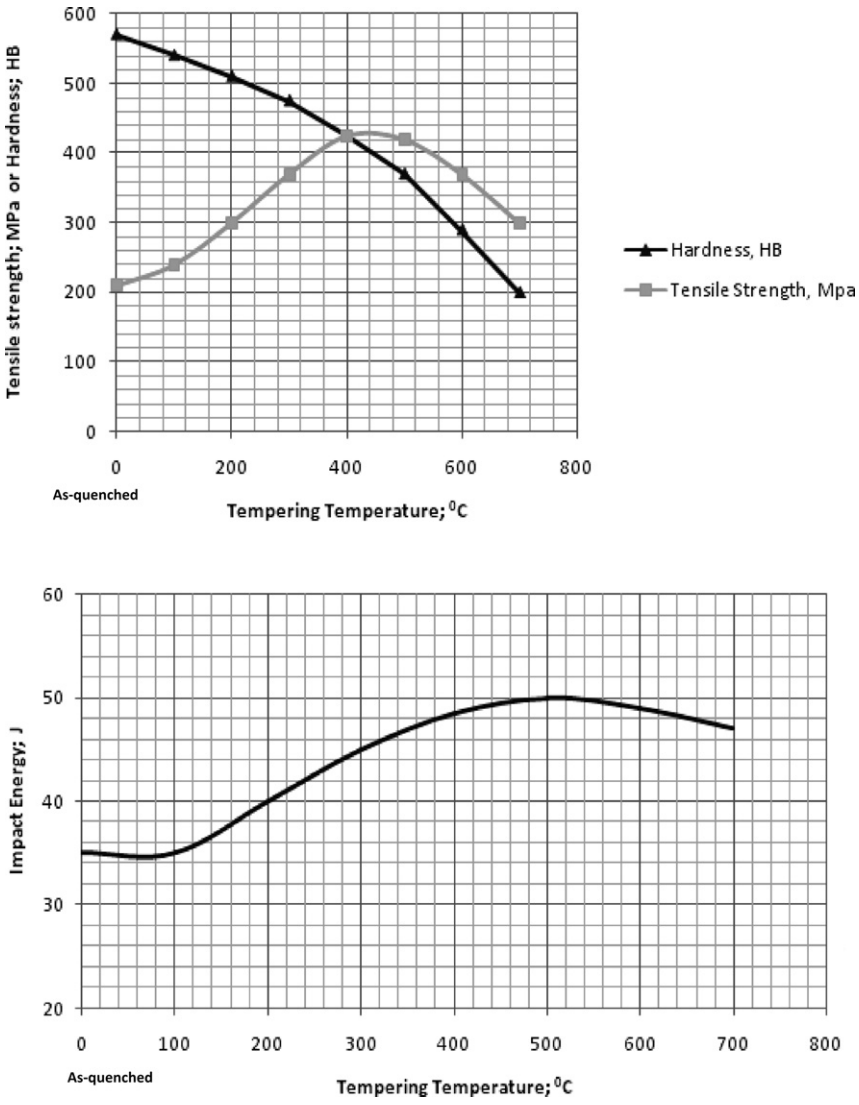

Figure 10 Effect of tempering temperature on the strength, hardness, and impact toughness of low-silicon gray iron. Modified from Davis, J. R. *ASM Specialty Handbook: Cast Iron*; ASM International: Materials Park, OH, 1996; Figure 8, p. 185.

region. The ultimate microstructure is acicular ferrite or bainite with varying percentages of retained austenite (**Figure 11**). The process comprise of austenitizing followed by rapid quenching in an isothermal temperature bath in the range of temperature 250–425 °C and maintained a constant temperature until the austempering transformation is complete. Austempered gray iron components exhibit increased wear resistance, higher strength, and better noise damping properties. **Figure 12** shows the tensile strength of austempered gray iron as a function of hardness for classes 20, 30, and 40 gray irons.

The essential requirement for austempering is to have sufficient hardenability of the iron to avoid the formation of pearlite on quenching to the austempering bath. The section thickness and shape determine the percentages of elements like Ni, Cu, and Mo for sufficient hardenability.[11]

Initial austenitization temperature and time are similar to the conventional hardening temperature and time of holding.

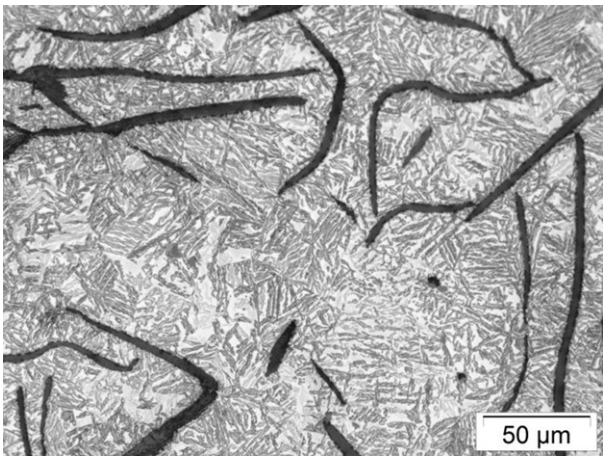

Figure 11 Microstructure of austempered gray iron.

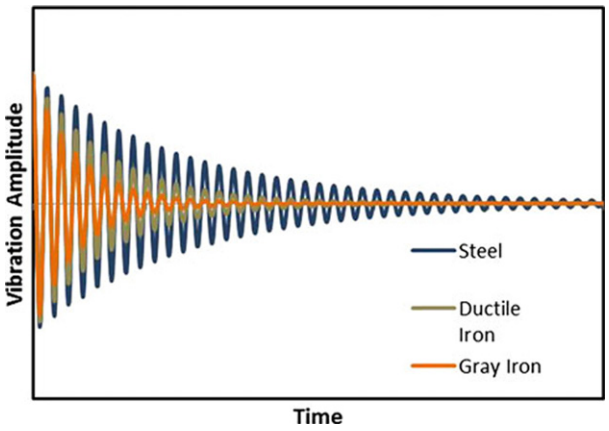

Figure 13 Schematic of vibration characteristics of Gray Iron, Ductile Iron, and Steel. Voigt, R. C.; Loper, C. R., Jr. Austempered Ductile Iron-Process Control and Quality Assurance. *J. Mater. Eng. Perform.* **2013**, *22* (10), 2776–2794.

A suitable temperature range is 840–900 °C for gray cast iron and the holding time is to be determined from chemical composition, size, and complexity of the shape of the casting.

Subsequent to austenitization, the components are usually quenched in salt, oil, or lead baths for austempering. A lower austempering temperature is chosen in the range of 230–290 °C when a high-ultimate hardness is desired. The isothermal holding time is dependent on the bath temperature and composition of the iron. Presence of nickel, chromium, and molybdenum lengthen the transformation kinetics.[11–14]

2.10.2.5.1 Case studies on austempering of gray iron

Case 1: Diesel engine cylinder liners made of gray cast iron are often subjected to austempering to achieve the properties with minimum distortion and cracking as compared to hardening and tempering.[15] The austempering cycle involves in preheating at 650 °C for 5 min and then the temperature is raised to austenitization temperature at 870 °C and held for 8 min. Subsequently quenched in salt bath at 250 °C and isothermally held for 20 min and cooled in air.

Case 2: For power train applications such as gears, shafts, etc., austempered gray iron is a potential material.[15] Along with desirable galling wear resistance, strength, and hardness properties austempered gray iron provides best noise reduction capacity. The vibration damping characteristics of gray iron is increased in austempered condition than its as-cast counterparts. Austempered gray iron with a tensile strength of 414 MPa can have the noise damping capabilities of a fully damped class 20 gray iron with tensile strength of 138 MPa (Figure 13).

2.10.2.6 Martempering of Gray Iron

To overcome the restrictions of conventional quenching and tempering like distortions, cracking tendency etc., martempering is a solution. Martempering involves interrupted quenching – the cooling is stopped at a point above the martensitic start temperature (Ms) to allow sufficient time for homogenization of temperature differential from surface to core of the component to be heat treated. Further cooling is continued through the martensite region of continuous cooling transformation (CCT) diagram followed by the usual tempering to avoid brittleness of the martempered component.

In martempering the casting is initially austenitized above the range of transformation and quenched in salt, oil, or molten lead bath, the temperature of which is maintained just above the martensitic start temperature (Ms). For unalloyed gray iron the martempering temperature is in the range of 200–260 °C. The component is held at this temperature for adequate time to attain the bath temperature and subsequently cooled to room temperature. The holding temperature in the bath depends on the size and complexity of shape of the component.[6]

2.10.2.6.1 Case studies on martempering of gray iron

Case 1: Rey iron cylinder liners or sleeves for engines of chemical composition 3.25–3.50%C, 2.0–2.25% Si, 0.025% P (max.), 0.12% S (max.), 0.55–0.80% Mn, and 0.30–0.40% Cr are subjected to following martempering cycle[6]:

a. Subjected to full annealing in a pusher type continuous furnace at 870 °C, and rough machined.
b. Austenitization for martempering at 870 °C for 1 h in a neutral atmosphere.
c. Quenched in a salt bath of molten nitrate–nitrite at 245 °C for 1 min and air cooled for 30 min.
d. Tempering of cleaned castings at 200 °C for 2 h.

The as-cast sleeves were having flake graphite microstructure with mostly type A graphite flakes and of size 4–6. The matrix dissolves about 0.70%C during the course of austenitization and results in a martensitic matrix after martempering. The bulk hardness in the range of 45–50 HRC with matrix microhardness higher than 60 HRC develops. The martempering reduces the tendency of distortion by 50% of those in conventional oil quenching. Martempering also eliminates the cracking tendency.

2.10.2.7 Surface Hardening of Gray Iron

Surface hardening is an economical method to impart high wear resistance in selected areas of the casting. Most common surface hardening methods include flame and induction hardening.

In flame hardening the form of hardening is due to transformation hardening in which the surface layer is heated above the critical temperature A_1 to austenitize and during subsequent quenching hard martensite is formed. But the inside core temperature being at below the A_1, it is remaining unhardened and so softer.[3,4,6]

For successful flame hardening the combined carbon content is an important parameter. Most suitable range is 0.5–0.7% but a lower combined carbon with 0.4% can even be flame hardened. However, a high combined carbon above about 0.8% is susceptible to cracking. As silicon favors graphite formation it reduces the combined carbon and so a low silicon content (<2.4%) is recommended for flame hardening. A porous and rough surface is generated after flame hardening when the iron contains a high total carbon with coarse graphite flakes. The flakes are burnt out during flame heating.

Because of their higher hardenability alloyed gray irons are better flame hardened with higher surface hardness and depth. Nickel, chromium, and molybdenum additions are often helpful for this purpose. An unalloyed iron containing 3% total carbon, 1.7% Si, 0.6–0.8% Mn develops a maximum hardness of 400–500 HB. In contrast, an average surface hardness of 550 HB can be developed with either 2.5% Ni and 0.5% Cr or 1–1.5% Ni and 0.25% Mo additions.[3]

The surface hardness of flame hardened gray irons is slightly lower than that in the immediate below. This is due to the retention of soft austenite phase at the surface. The surface hardness can be increased by heating at 200–250 °C which also relieves the residual stresses.

Induction hardening is more expensive than flame hardening but it is justified for large number components to be hardened. The hardening is carried out in the range of temperature of 870–925 °C for a short heating cycle. A minimum combined carbon as pearlite ranging from 0.4 to 0.5% is essential for successful hardening. The surface hardness is very much dependent on the carbon equivalent (i.e., %total carbon + %Si), higher the carbon equivalent, more graphite is present in the microstructure causing decrease in the hardness.[3]

2.10.3 Heat Treatment of Malleable Irons

Malleable irons are produced by solid-state phase transformation by annealing of white cast iron components. The metastable iron carbide (Fe_3C) is decomposed to graphitic temper carbon in various matrices such as ferritic, pearlitic, and ferrite–pearlitic depending upon the composition and the type of annealing employed. The starting white iron must be of controlled compositions as various elements have varying response toward malleablizing annealing. Carbon and silicon percentages are so balanced to ensure freedom from graphite formation during solidification. Higher silicon content increases annealing response. Higher silicon content results in rapid annealability and a short-cycle process can be employed.

Table 5 Typical compositions for Whiteheart, Blackheart, and short-cycle Blackheart irons

Element (%)	*Whiteheart malleable iron*	*Blackheart malleable iron*	*Blackheart short cycle*
Total C	3.0–3.7	2.2–3.0	2.35–2.45
Si	0.4–0.9	0.7–1.2	1.5–1.6
Mn	0.2–0.4	0.2–0.5	0.3–0.4
S	0.3 max.	0.05–0.16	0.1–0.15
P	0.1 max.	0.12 max.	0.05 max.
Cr	0.1 max.	0.1 max.	0.1 max.

Source: Elliott, R. *Cast Iron Technology*, 1st ed.; Butterworths: London; Boston, MA, 1988; Table 1.8, p. 14.

Bismuth and tellurium favor white iron solidification while boron and/or aluminum increase the nucleating potency of graphite clusters and increase annealing response. Addition of about 1% manganese promotes pearlitic matrix to develop higher strength. Copper, nickel, and/or molybdenum are often alloyed to improve strength, wear, and corrosion resistances. Certain elements like phosphorus, antimony, tin, and chromium have negative effects on graphitization process and are to be restricted.[3] Typical compositions of various types of malleable irons are shown in **Table 5**.

The malleablizing annealing involves three stages, the initial nucleation of graphitic temper carbon in the first stage of graphitization occur during the holding period at 900–970 °C. In this stage, massive eutectic carbides are decomposed to temper carbon and austenite. Next stage involves rapid cooling to 740 °C and then slow cooling (2–28 °C h^{-1}) through the austenite to pearlite transformation range. Due to very slow cooling the pearlite decomposes to ferrite and temper carbon. This graphitization is known as second stage of graphitization. Faster rate of cooling from annealing temperature such as air cooling produces a pearlitic matrix while oil quenching develops martensitic matrix. There are two types of malleable irons, whiteheart and blackheart, based upon the appearance of the final fracture reflecting the basic difference in their microstructures.

2.10.3.1 Whiteheart Malleable Iron

In the whiteheart malleablizing, the white as-cast iron is decarburized during annealing leaving a structure of iron carbide in a metallic matrix. When fractured the appearance is whitish, giving rise to the name 'whiteheart.' Decarburization is only possible in thin sections; in heavier sections some conversion of carbide to graphite nodules occurs so that the annealed casting has a white rim with core having different structure and mechanical properties. This limits the application to which it can be put.[4]

Malleablizing annealing in this case is a combined decarburization and graphitization process carried out in an oxidizing atmosphere. Originally it was done by packing castings into iron ore mixtures but now it is performed in continuous atmosphere controlled furnaces at about 1070 °C. Small castings may be fully decarburized and are referred to as weldable malleable irons.

Controlled oxidation of carbon in the castings occurs producing a carbon gradient from edge to center. The surface is

deeply decarburized which is fully ferritic but becomes pearlitic further below the surface and the center is pearlitic containing temper carbon (Figure 14). Although, the center of whiteheart castings is normally pearlitic, the presence of decarburized ferritic skin ensures freedom from brittleness and can absorb plastically a considerable amount of energy from a local blow and is freely machinable.[3–5]

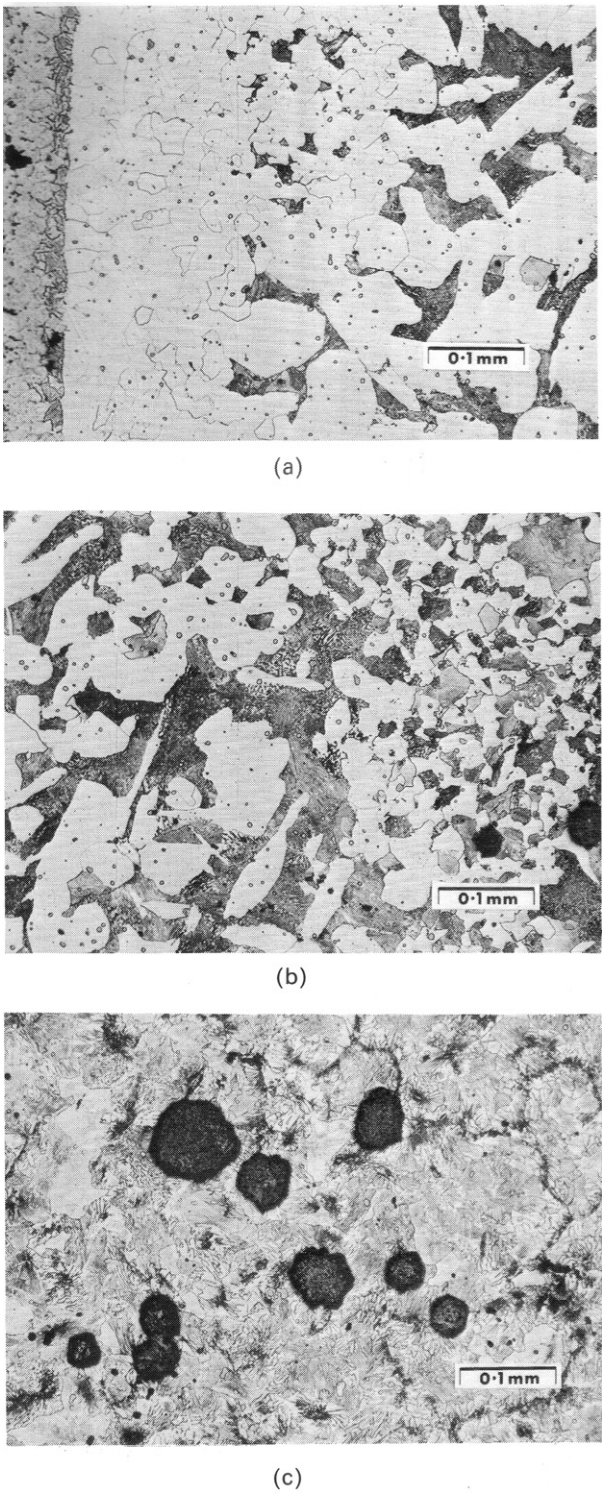

Figure 14 Variation in structure from surface to core (a–c) of a whiteheart malleable iron (3.0%C, 0.75%Si, 0.24%Mn, 0.22%S, 0.06%P). Elliott, R. *Cast Iron Technology*; Butterworths; Figures 6.30 (a),(b),(c), p. 232.

2.10.3.2 Blackheart Malleable Iron

Blackheart malleable irons are produced with lower total carbon content and slightly higher silicon content than whiteheart. Blackheart malleable irons can be with a softer and ductile ferritic matrix or a harder, less ductile pearlitic matrix. Both these matrices are produced by annealing in an inert material like sand or slag packing at 850–950 °C for a prolonged period of 7 days. Alternatively, the annealing is done in a controlled atmosphere furnace with reduced 70 h of soaking. During this soaking period, the first stage of graphitization takes place which is followed by a controlled slow cooling down to 650 °C for second stage of graphitization to occur. As the annealing is performed in neutral atmosphere the chances of decarburization is almost nil (Figure 15) and very slow cooling through the critical temperature range provides the whole of carbon to be deposited as temper carbon and the matrix is ferritic from surface to core. The fracture surface thus appears as blackish in color. Because of its lower hardness, blackheart malleable iron is very freely machinable and with high shock resistance.[3,4]

The higher strength pearlitic malleable irons are produced by (1) increasing the carbide-stabilizing element like manganese to about 1%, (2) by increasing the rate of cooling through the second stage so as to retain the pearlitic matrix, or (3) by annealing, reheating, and air or oil quenching with or without tempering. A wide range of properties can be achieved by transformation of austenite after first stage of graphitization into pearlite, bainite, or martensite.[3,4]

2.10.3.3 Hardening and Tempering of Malleable Irons

The process is most suited in pearlitic malleable iron and involves three consecutive steps, (1) first step is to anneal and air quenching to retain about 0.75% carbon in the matrix; (2) reaustenitization and homogenization of the combined carbon in the matrix at around 885 °C for 1 h, and (3) subsequent quenching in hot agitated oil at temperature of 50–55 °C. A martensitic matrix is developed without any bainite (Figure 16). The selection of austenitization temperature is of utmost importance to obtain the matrix structure (Figure 17). Higher the austenitization temperature and time, more is the amount of dissolved carbon in the matrix and the austenite will be more homogenized. This will result in a homogeneous martensite after quenching but the tendency toward distortion and cracking is increased.[6,16]

The microstructure of air-quenched and tempered malleable iron shows tempered carbon surrounded by ferrite envelops and the pearlites are of broken lamellar pattern. In contrast, the oil-quenched and tempered iron shows matrix of tempered martensite without any ferrite envelop.

The final hardness can be tailored by proper selection of tempering temperature and time in case of pearlitic matrix while for martensitic matrix, temperature is the prime factor

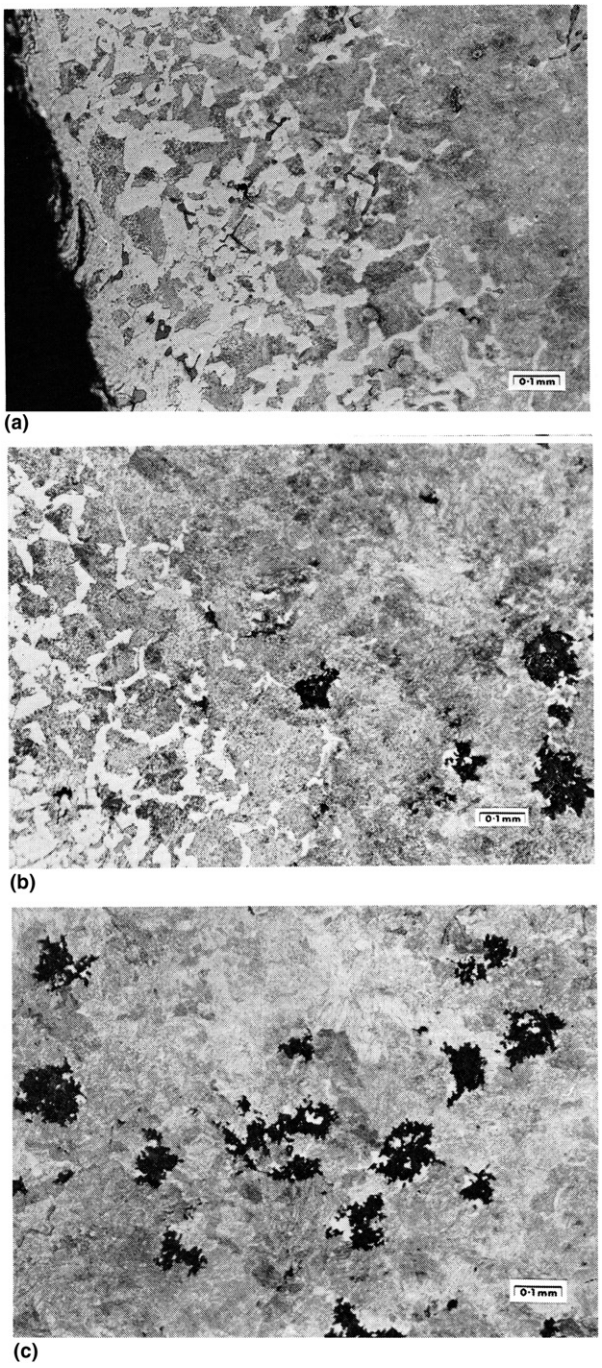

Figure 15 Variation in structure from surface to core (a–c) of a blackheart malleable iron (2.6%C, 1.1%Si, 1.1%Mn, 0.12%S, 0.03% P). Elliott, R. *Cast Iron Technology*; Butterworths; Figures 6.31, 6.32, 6.33, p. 233.

(Figure 18). Tempering times are predetermined on the section thickness and the as-quenched microstructures. Tempering time should be longer than 2 h for uniformity of hardness. The pearlitic structures are tempered at a slower rate than that with martensite. The beneficial effects of alloying on the tempered hardness are shown in (Table 6).

The hardened and tempered malleable irons can also be produced from fully annealed ferritic malleable irons. To obtain a uniform carbon content in the austenite the austenitization temperature and time should be comparatively higher than those in pearlitic malleable iron. During austenitization some of the carbon from the temper carbon is dissolved in the austenite as the initial matrix is carbon-free ferrite. This austenite contains lesser carbon compared to the initial pearlitic malleable iron. Accordingly, the tempering temperature is to be selected at lower range for a desired final hardness.[16]

2.10.3.4 Martempering of Malleable Irons

Pearlitic malleable iron components while subjected to conventional hardening treatment by oil quenching in warm oil are susceptible to quench cracking. These iron components can be martempered to achieve mechanical properties similar to those obtained by oil quenching and tempering typically as, ultimate tensile strength 860 MPa, yield strength 760 MPa, and hardness 300 HB. For martempering, pearlitic malleable irons are first austenitized at 880–900 °C for 1 h and followed by quenching in a molten salt or oil bath maintained at a temperature of 200 °C.[6,16]

2.10.3.5 Bainitic Heat Treatment of Malleable Irons

Isothermal holding subsequent to austenitization of pearlitic malleable iron in the range of bainitic transformation region develop either upper or lower bainite structure depending on the holding temperature. The bainitic structure causes a marked increase in strength and hardness but impairs ductility. For example, a pearlitic malleable iron with 2.6%C, 1.4%Si, 0.5%Mn and 0.11%S when annealed at 930 °C for 16 h, air quenched and tempered at 680 °C for 4 h produced ultimate tensile strength of 650 MPa, yield strength of 460 MPa, elongation of 3.4%, and hardness 217 HB. The iron when austenitized at 900 °C in salt bath for 1 h, quenched in molten salt at 295 °C for 3 h and air cooled produced a much higher tensile strength (995 MPa), yield strength (920 MPa), and hardness (388 HB), but the elongation is only 1%.[16]

2.10.3.6 Surface Hardening of Pearlitic Malleable Irons

For surface hardening by flame or induction hardening, initial pearlitic matrix is most suitable. Ferritic malleable irons respond to the surface hardening provided adequate time is allowed in austenitization for dissolution of carbon from the temper graphitic carbon to the matrix. Response of lamellar pearlitic are more readily, compared to spheroidized structures. For adequate hardenability a minimum 0.5% Mn is effective. A hardness ranging from 55 to 60 HRC can be attained with adequate depth of hardness which can be controlled by the rate of heating and the surface temperature developed. In induction hardening, the controlling factors are power output, operating frequency, heating time, and the alloy content. The heating temperature is critical as the minimum temperature is dictated by austenite homogenization and the maximum temperature is to avoid fusion and burning. A more uniform and deeper case can be obtained with increased

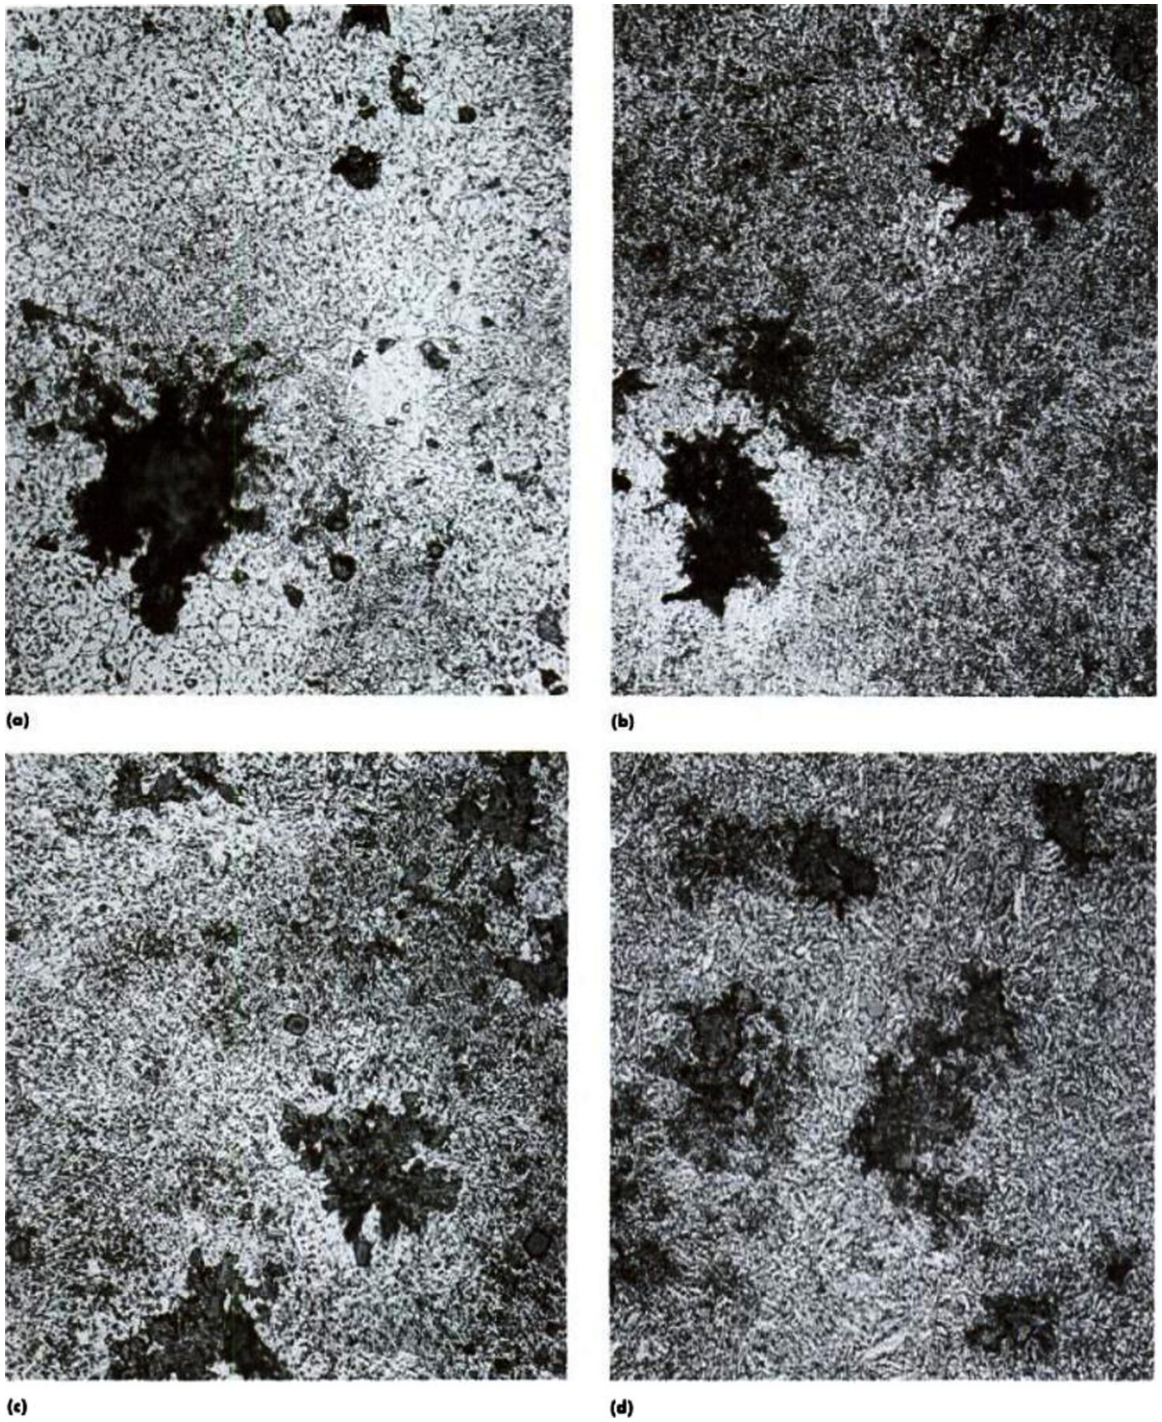

Figure 16 Structure of oil-quenched and tempered martensitic malleable iron, (a) 163 HB, (b) 175 HB, (c) 207 HB, (d) 229 HB. Davis, J. R. *ASM Specialty Handbook: Cast Iron*; ASM International: Materials Park, OH, 1996.

heating time. Generally, quenching in water is necessary to produce high hardness and adequate case depth.[4,6,16]

2.10.3.6.1 Case studies on surface hardening of malleable irons

Case 1: Crimping tool jaws for electrical connectors originally were made of tool steels. Now, it has been possible to replace it by shell mold integral casting made of pearlitic malleable iron (Grade 45010). The intricate contour of the jaws is then surface hardened by induction heating and water quenching to develop required wear resistance. So, the hardening is done in the selected jaw areas and the strength and toughness inherent in grade 45010 are maintained in the arms of the handles.[16]

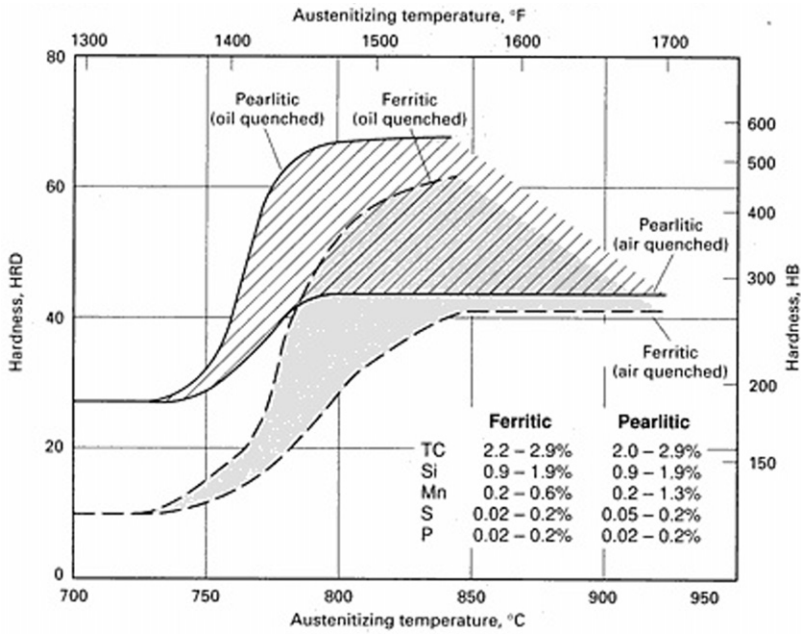

Figure 17 Effects austenitizing temperature and quenching media on the hardness of as-quenched malleable iron. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Malleable Iron; Figure 3, p. 1512.

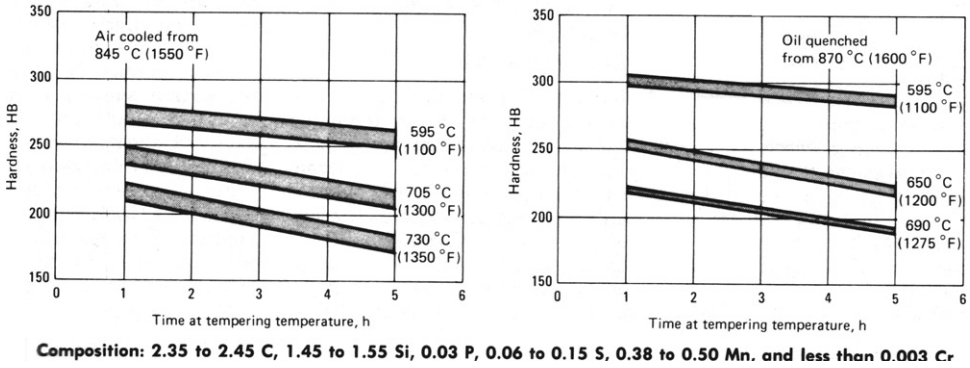

Figure 18 Effects of tempering temperature and time on the hardness of pearlitic malleable iron (composition: 2.35–2.45%C, 1.45–1.55%Si, 0.03%P, 0.06–0.15%S, 0.38–0.50%Mn, <0.003%Cr). *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Malleable Iron; Figure 5, p. 1513.

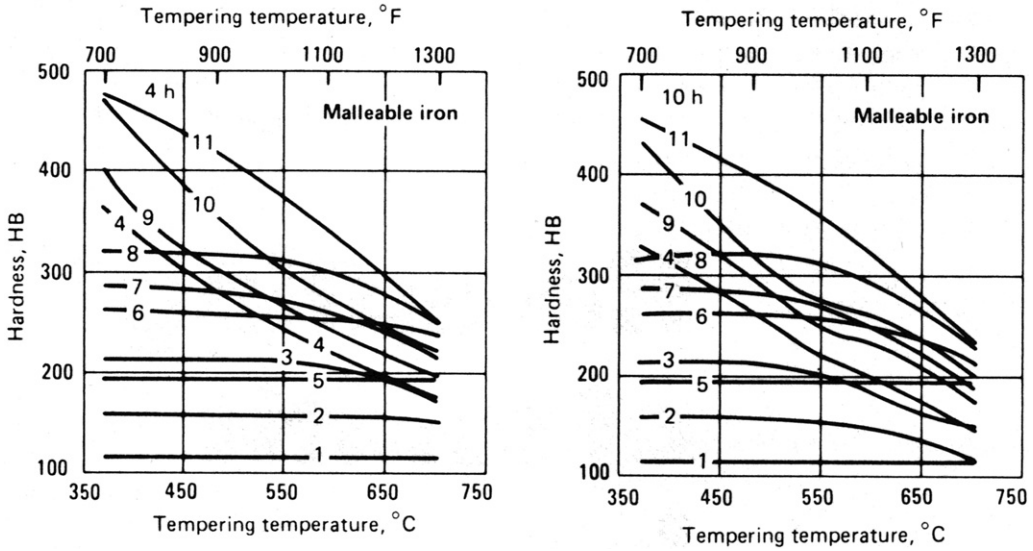

Case 2: Pinion spacers supporting the cups of roller bearings have been made of pearlitic malleable iron and the two ends of the pinion spacers were flame hardened to a hardness above 58 HRC to a depth of about 2.4 mm. It has been possible to eliminate the service failure by this treatment.[16]

2.10.4 Heat Treatment of Ductile Irons

The ductile iron also known as nodular iron or spheroidal graphite iron solidifies as iron-graphite system and the graphite has the spheroid form. Because of its comparable strength and ductility the ductile iron are potential material to replace many structural steels. The as-cast matrix is usually comprise of ferrite, pearlite, or ferrite-pearlite depending on the section size and alloy contents. Although, control of microstructure and properties can be achieved in as-cast condition, the heat treatment is a versatile tool for further extending the range of properties in ductile irons. The most common and important heat treatments and their objectives include[11]:

- Stress relieving at subcritical temperature range to relieve the residual stresses in the castings.
- Annealing to increase the ductility, toughness, and machinability, to decrease hardness and eliminate carbides.
- Normalizing to improve strength with adequate ductility.
- Through hardening and tempering to impart strength and hardness.
- Austempering to develop a microstructure providing high strength and wear resistance and some ductility.

Table 6 Effect of tempering temperature, time, and alloy additions on the hardness

Malleable iron type and conditions	*%TC*[a]	*%Si*	*%S*	*%Mn*	*%Mo*	*Alloying and prior heat treatment*	*Hardness; HB*
Standard ferritic grade 32510	2.4	1.8	0.072	0.3	–	Unalloyed; fully malleablized	116
Pearlitic malleable iron, Grade 45007	2.4	1.8	0.072	0.3	–	Unalloyed; air quenched from 925 °C, tempered 8 h at 695 °C	156
Pearlitic malleable iron, Grade 60003	2.4	1.8	0.072	0.3	–	Unalloyed; oil quenched from 870 °C, tempered 3 h at 650 °C	212
Oil-quenched malleable iron	2.4	1.8	0.072	0.3	–	Unalloyed; oil quenched from 870 °C, not tempered	444
Pearlitic malleable iron, Grade 45010	2.4	1.8	0.076	0.9	–	Alloyed (Mn); air quenched from 940 °C, tempered 34 h at 715 °C	192
Pearlitic malleable iron, Grade 80002	2.4	1.8	0.072	0.9	0.45	Alloyed (Mn and Mo); air quenched from 940 °C, tempered 12 h at 620 °C	262
Air-quenched alloyed malleable iron	2.4	1.8	0.079	0.9	–	Alloyed (Mn); air quenched from 925 °C, not tempered	285
Air-quenched alloyed malleable iron	2.4	1.8	0.076	1.10	–	Alloyed (Mn); air quenched from 925 °C, not tempered	321

- Surface hardening to impart high surface hardness and wear resistance in some selected areas of the casting.

2.10.4.1 Fundamental Considerations for Heat Treatment of Ductile Iron

The presence of high carbon and silicon causes some specific characteristics of ductile iron toward the response to heat treatment. The high carbon content is advantageous to yield a high hardenability without the necessity for expensive alloying additions. The high carbon, on the other hand, is harmful in respect of quench cracking due to formation of high-carbon martensite and/or retention of metastable austenite. Silicon also has an important role to reduce the solid solubility of carbon in the austenite and favors graphite formation in ferritic matrix during slow cooling. The graphite nodules also play an important role in heat treatment. During austenitization carbon from nodules diffuse in the austenitic matrix causing carbon enrichment while during slow cooling carbon

rejected out from the austenite returns to the nodules as 'sink.' This transfer of excess carbon from nodule to matrix and vice-versa favors the easier heat treatment.[6,17]

In general, different heat-treatment processes involve austenitization and subsequent controlled cooling or isothermal soaking or a combination of the two. As a consequence, the structure developed can be categorized according to the matrix phases; (1) thermodynamically stable ferritic matrix and (2) metastable austenitic matrix.

CCT diagram (Figure 19) and the isothermal transformation (IT) diagram (Figure 20) are two important diagrams to predict the ultimate matrix phase for a particular cooling process. From CCT diagram, it is evident that, slow furnace cooling for annealing will produce a ferritic matrix, air cooling or normalizing will produce pearlitic matrix, and quenching will produce martensitic matrix with some retained austenite.[17–22] The corresponding micrographs are shown in Figure 21.

The process sequence in austempering of ductile iron can be explained by the IT diagram. The austenitized iron is subsequently quenched in salt bath maintained at a steady temperature. Isothermal holding will result in a ausferritic (high-carbon metastable austenite γ_H and plate-like ferrite) or a ferrite–carbide aggregate (bainite) with prolonged holding time. After the required holding time the austempered iron is cooled to room temperature.

The presence of high silicon content prevents the iron carbide formation and the carbon rejected in the first stage of reaction ($\gamma \rightarrow \gamma_H + \alpha$), saturate the austenite and the M_s and M_f temperatures are depressed. Thus, on subsequent cooling, austenite will be stabilized and will not transform to martensite. The austempering time in stage I depends on the alloy content and section size and generally ranging from 1 to 4 h. Prolonged austempering will cause stage II reaction ($\gamma_H \rightarrow \alpha +$ Carbides) producing unwanted bainite which impairs toughness and ductility.[17–22]

Except in case of subcritical treatments like stress relieving, for all other heat treatments an initial austenitization is essential for further treatments to follow. As ductile irons are ternary Fe–C–Si alloys, the critical temperature varies with carbon an silicon contents. The austenitizing temperature must exceed the upper critical temperature. The solubility of carbon in the austenite is dependent on the temperature. So, the selection of a particular austenitizing temperature determines the desired carbon content in the matrix and hence the hardenability or austemperability. Most commonly adopted austenitizing temperature is in the range of 900–950 °C with 1–3 h of holding time.

The range of tensile strength and elongation percentage and hardness values obtained with different types of heat treatments are shown in Figures 22 and 23 respectively.[17]

2.10.4.2 Annealing of Ductile Irons

The objective of annealing is to produce maximum ductility and toughness, reduced strength and hardness, improved machinability, and uniform properties. These properties can be achieved by generating a carbide-free ferritic matrix (Figure 24). Certain elements tend to retard the annealing process which include manganese, phosphorus, chromium, and molybdenum and should be restricted in the casting. Table 7 summarizes the details of various types of annealing processes adopted in practice with their individual purpose.[17,22]

The effect of subcritical ferritizing at 705 °C for various length of time on the hardness of four different grades of ductile irons are shown in the Figure 25.

2.10.4.3 Normalizing of Ductile Irons

The normalizing treatment involves austenitizing and subsequent air cooling to room temperature. The purpose of

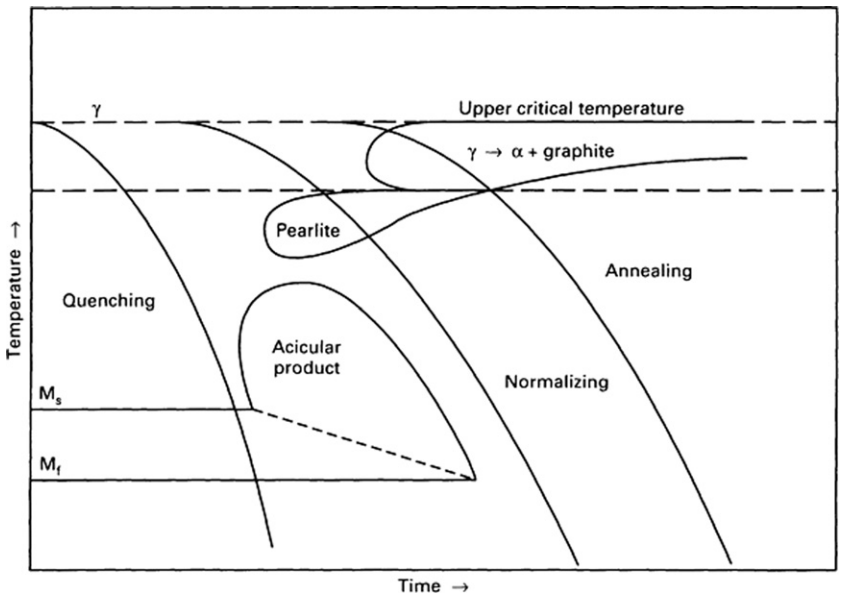

Figure 19 Continuous cooling transformation diagram of ductile irons showing different treatment zones. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 1, p. 1487.

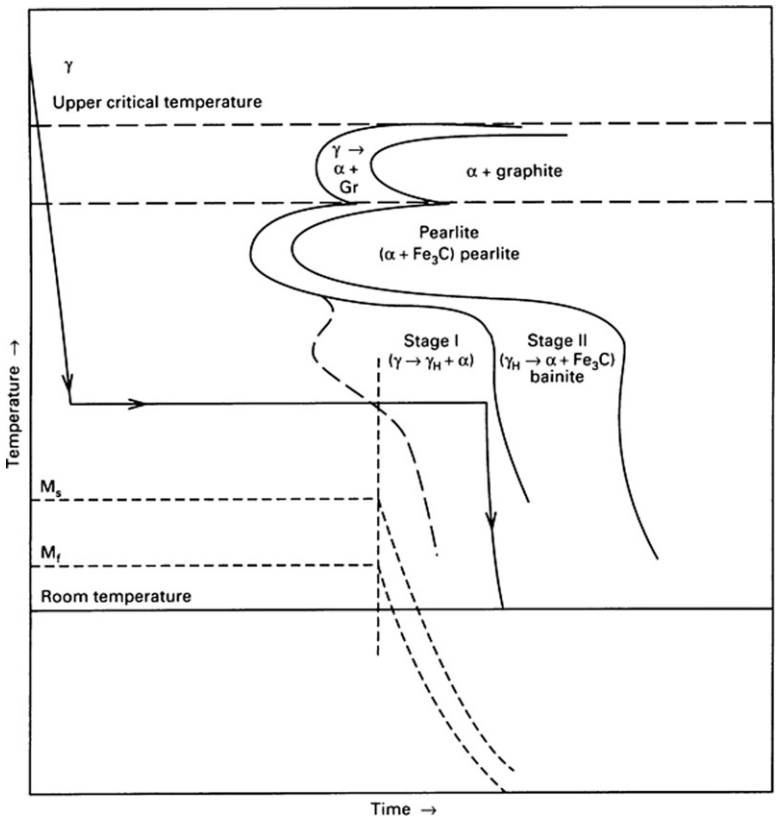

Figure 20 Isothermal transformation diagram of ductile iron showing austempering process sequence. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 2, p. 1488.

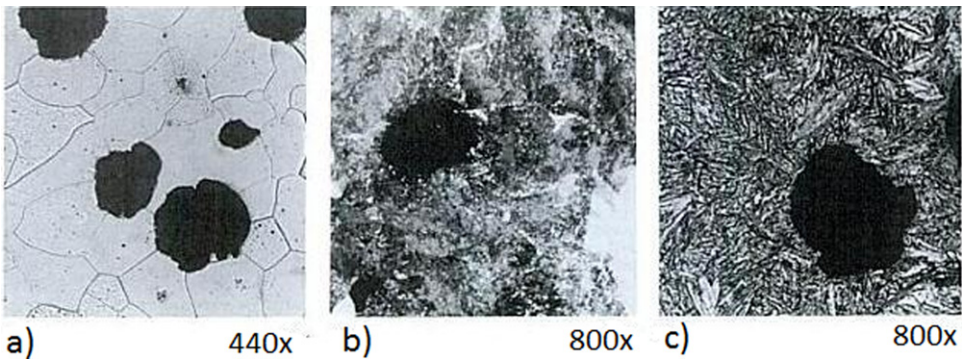

Figure 21 Optical micrographs of ductile iron with different treatments and matrices; (a) ferritic in annealed casting, (b) fine pearlitic in normalized casting, and (c) martensitic in quenched casting. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 3, p. 1488.

normalizing is to dissolve eutectic carbides, increase the strength and hardness, and to develop a uniform structure throughout the casting. The microstructure developed in normalizing depends on the composition of the casting and the cooling rate. According to the composition the continuous cooling transformation diagram changes and hence the critical cooling rate. The actual cooling rate is dependent on the mass of the casting, ambient temperature, and air flow in the surrounding. Adequate fast cooling rate should be provided to develop a fine fully pearlitic matrix without any ferrite (**Figure 26**). Alloying additions such as nickel, molybdenum, and additional manganese are to be made to increase the hardenability of heavier castings so that a fully pearlitic structure after normalizing could be achieved.[17]

Figure 27 illustrates the effect of nickel and other alloy content on the hardness of castings with various section thicknesses.

The normalizing temperature is generally selected as 100 °C above the critical temperature range and typically the temperature ranges between 870 and 940 °C. The standard

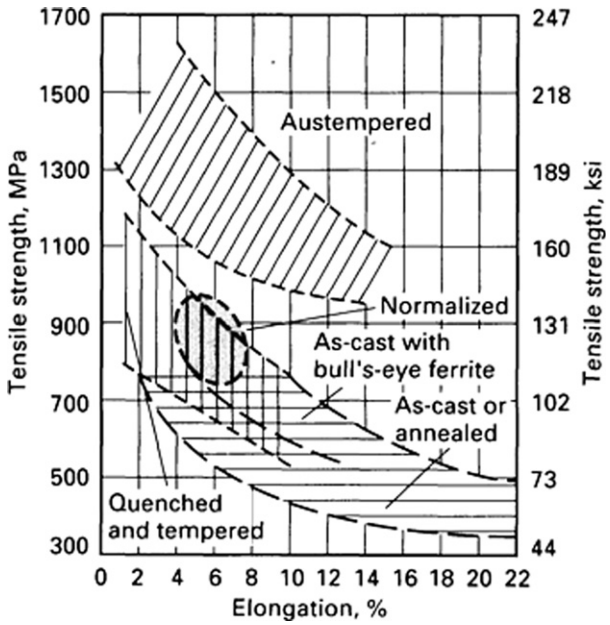

Figure 22 Tensile strength versus elongation percentage of ductile irons with different heat treatments. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 4(c), p. 1490.

holding time for unalloyed castings at this temperature range is 1 h plus 1 h 25 mm^{-1} of section thickness.

Sometimes, tempering treatment is subjected to normalized castings to obtain the desired hardness, toughness, and for stress relieving due to differential cooling rates during normalizing. The actual composition and the normalized hardness value dictate the response of tempering on the final tempered hardness (**Figure 28**). Typical tempering temperature ranges from 425 to 650 °C with a holding time of 1 h 25 mm^{-1} section thickness.[17,23]

2.10.4.4 Hardening and Tempering of Ductile Irons

Hardening treatment includes austenitizing followed by quenching, provides maximum hardness resulting from transformation of austenite to martensite (**Figure 29**). The as-quenched hardness depends on the carbon content in the martensite, volume fractions of martensite, and the retained austenite in the microstructure. Austenitizing temperature determines the carbon content in the austenite and hence in the martensite after quenching. An austenitizing temperature of 845–925 °C is the common temperature range to obtain the optimum carbon content and maximum hardness. The effect of austenitizing temperature on the water quenched hardness of a ductile iron is shown in **Figure 30**. It is evident from the figure that, the highest range of hardness is obtained with austenitizing at 845–870 °C. Above 870 °C the greater percentage of retained austenite is stabilized lowering the as-quenched hardness.[17]

The choice of quenching media is also very important so that the maximum as-quenched hardness, minimum chances of residual stresses, and quench cracking tendency result in. The most widely used medium is oil to meet up these requirements. However, water or brine also may be used for simple shapes. For complex-shaped castings hot oil at 80–100 °C is preferred to avoid any distortions and cracking.

The as-quenched castings are immediately tempered in the range of temperature of 425–600 °C for different length of time. The purpose is to reduce residual stresses and chances of cracking, decrease strength and hardness at the cost of increment in ductility and toughness and to improve machinability. Tempering process is influenced by other factors like alloy content, as-quenched microstructure and nodule count. Low alloy martensitic matrix with high nodule count decreases the tempering temperature and/or time. **Figure 31** shows the effect of tempering temperature and time on the tempered hardness of two different ductile irons. The tempering process in this temperature range involves two stages; (1) precipitation of carbides and (2) nucleation and growth of small secondary graphite nodules at the expense of carbides. This secondary graphite formation causes drop in hardness in the second stage and consequently decrease the tensile and fatigue strengths. **Figure 32** illustrates the effect of tempering on the hardness and tensile properties.[17,24]

2.10.4.5 Austempering of Ductile Irons

Austempering of ductile irons produce a unique material with outstanding properties of high strength and good ductility. Austempered ductile iron (ADI) is twice as strong as standard ductile iron grades with comparable toughness. Apart from these, it is responsive to work hardening surface treatments and posses excellent fatigue and wear properties. Compared to forged steel components ADI offers high strength-to-weight ratio, lower production costs of near net shape castings, and good machinability. The austempering treatment involves following steps[6,14,17,25,26,28–33]:

- Austenitizing the casting normally in the range of temperature 845–925 °C for a holding time adequate to saturate the austenite with carbon.
- Austenitizing followed by rapid quenching in a hot bath maintained at temperature of 230–400 °C to avoid pearlite formation. The temperature range of salt bath is above the martensite start temperature (Ms) of the iron.
- Isothermal holding in the hot bath, i.e, austempering for adequate time to produce an ausferritic matrix, a combination of acicular ferrite and high-carbon austenite.
- Subsequent cooling to room temperature after predetermined austempering time.

2.10.4.5.1 Effect of metallurgical variables on the properties of ADI

2.10.4.5.1.1 Effect of metal composition

The selection of composition for both ductile iron as well as ADI is important. Firstly, the elements which adversely affect the spheroid formation or carbide and inclusion formation or propmotion of shrinkage should be restricted. Secondly, control should be exercised to the elements which affect hardenability and the properties of transformed microstructure. The section size of components, the type of quenching media

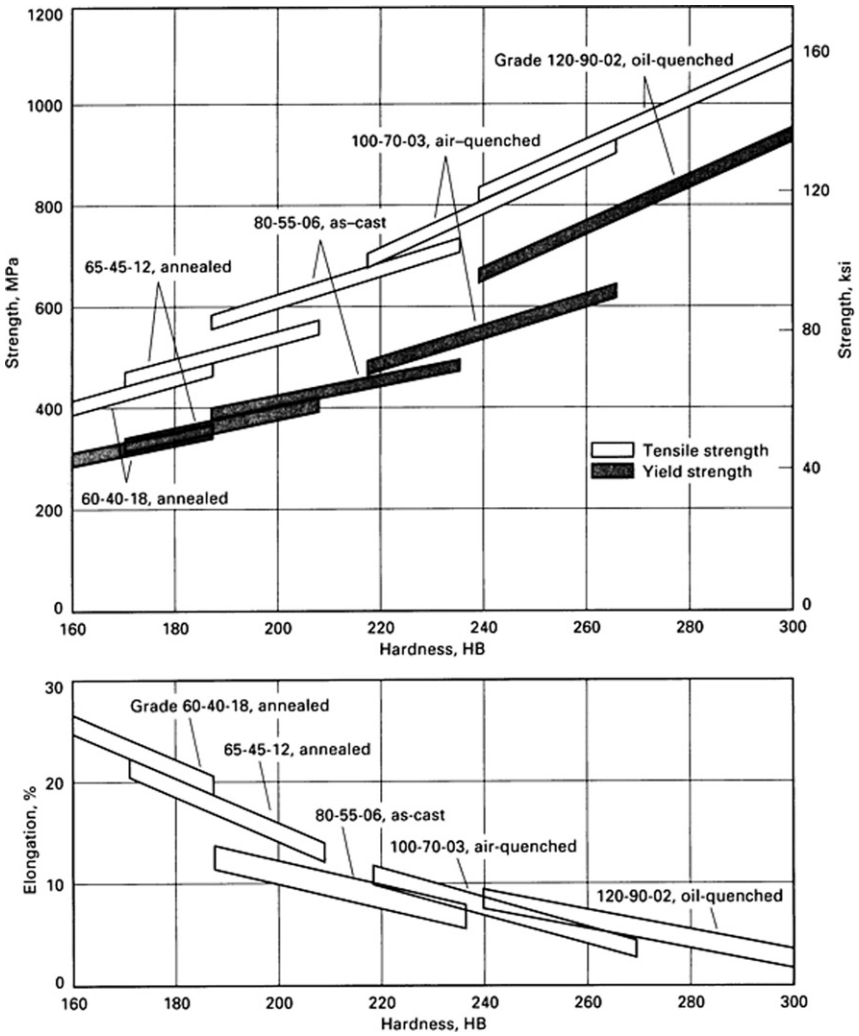

Figure 23 Strength and ductility versus hardness of ductile iron. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 5, p. 1491.

and the severity of quench are determining factors for the optimum alloying requirements.[6]

In an agitated molten salt bath quench, section sizes up to about 10 mm of an unalloyed ductile iron can be successfully through hardened without the formation of pearlite. In an agitated austempering bath with water saturation, section sizes up to about 20 mm can be through hardened for unalloyed iron. Proper alloying is needed to through harden and to avoid pearlite formation in the microstructure. Followings are the effects of carbon, silicon, and other alloying elements like manganese, copper, nickel, and molybdenum.

Carbon: Variation of total carbon in a narrow range (~3.6%) will have little effect on the properties of austempered iron. Since equilibrium carbon content in the austenite phase will not be affected much, the IT characteristics will not be changed.
Silicon: Silicon is a graphitizing element and decreases the solubility of carbon in austenite. It raises the eutectoid temperature and inhibits the formation of bainitic carbide. Increasing the silicon content increases the impact energy of the ADI and lowers the ductile–brittle transition temperature. The Si content should be restricted to 2.4–2.8%.
Manganese: Mn is an element which has a strong effect on hardenability but it has a tendency to segregate at cell boundaries and retards the austempering transformation by forming carbides. This segregating tendency is particularly prominent in the castings with lower nodule counts or thick section castings (>20 mm). The high segregation of Mn causes shrinkage, carbides, and unstable austenite. The ultimate effect is deterioration of mechanical properties and poor machinability. In view of this, the Mn content is restricted in austemepered ductile iron to less than 0.3%.
Copper: Copper is also effective in increasing the hardenablity. However, it has no significant on tensile strength but improves ductility when austempered at a temperature below 350 °C.
Nickel: Nickel is also effective in increasing the hardenability but at lower austempering temperature below 350 °C. Nickel has a tendency to decrease the tensile strength but increases the ductility and fracture toughness. Nickel content is restricted to 2% in ADIs.

Molybdenum: It is a very potent element to increase the hardenability (**Figure 33**) and is invariably necessary for heavy section castings to prevent pearlite formation. Like Mn it also has a segregating tendency at cell boundaries and forms carbides. As a result, both tensile strength and ductility decrease with increase in Mo content. Therefore, Mo content is restricted to 0.2% in heavy section castings with an objective to improve the hardenability.

Alloy Combination: Combination of the aforesaid alloying elements are often used to overcome the problems of segregation and degradation of mechanical properties. A judicious use of Mn and Mo for improvement of hardenability and the excess use can be supplemented by either Cu or Ni. A typical iron composition which ensures consistent nodule count and pearlite/ferrite ratio with castings free from shrinkage is shown in the **Table 8**.

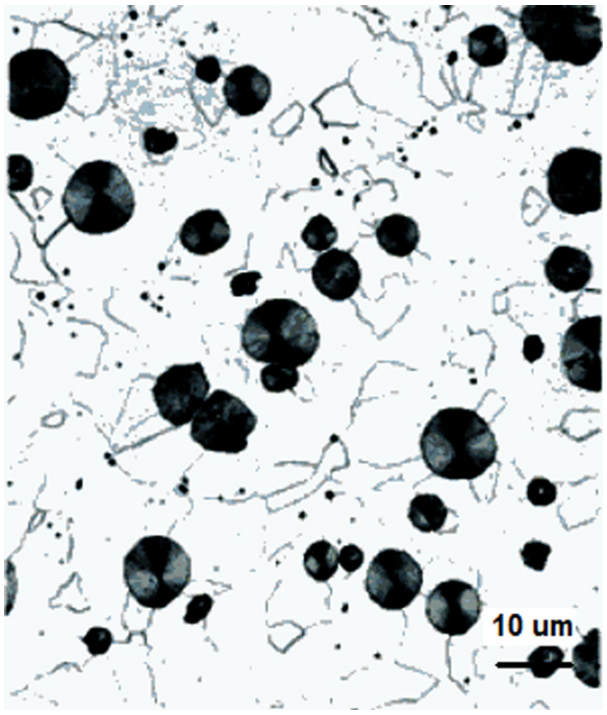

Figure 24 Microstructure of annealed ductile iron featuring a fully annealed ferritic matrix. Davis, J. R. *ASM Specialty Handbook: Cast Iron*; ASM International: Materials Park, OH, 1996; Figure 7, p. 195.

2.10.4.5.1.2 Practical factors affecting successful austempering

In addition to the effect of composition and section thickness of the components, the practical factors like austenitizing temperature and holding time at austempering temperature and time, furnace atmosphere, etc., are of utmost importance.

a. *Austenitization*: As the austempered hardness is high enough, only finish machining is to be carried out after austempering. Care must be taken to avoid surface decarburization and scaling during high-temperature austenitizing. Suitable process includes austenitization in salt bath, controlled atmosphere furnace, fluidized beds, or employing some scale resistant coating on the casting surface. The temperature distribution in the furnace should be homogeneous otherwise failure to austenitization and distortion of the castings are caused. Variation in the temperature can arise from the incorrect stacking of the charge, poor process control, and inadequate furnace design.

   Austenitization is usually carried out within the temperature range of 850–950 °C. As the austenitization temperature is increased the equilibrium carbon content in the austenite will increase and this will ultimately affect the IT characteristics during austempering. With increase in 'C' content the martensite start temperature (Ms) is depressed and the bainite transformation time is delayed particularly at lower austempering temperature. It has been observed that, both tensile strength and yield strength are increased as the austenitization temperature is increased from 850 to 925 °C for 1 h and austempered between 300 and 425 °C. Elongation is not affected by the change in austenitization temperature.[5,6,17,27]

   Austenitizing time should be minimum necessary to homogenize the temperature throughout the cross-section and to saturate the austenite with equilibrium 'C' content. Austenitization time is also affected by the chemical composition, the austenitization temperature, and the nodule count.[5,6,17,27]

b. *Austempering*: The ultimate mechanical properties of austempered iron depends on the microstructural parameters such as the bainite or ausferrite morphology, the volume percentage of retained austenite, and the presence of

Table 7 Details of annealing processes for ductile irons

Annealing processes	*Purpose*	*Temperature of castings*	*Time of soaking*	*Cooling cycle*
Subcritical ferritizing	In absence of carbides to develop a ferritic matrix	700–720 °C	1 h 25 mm^{-1} section thickness	Furnace cooling @ 55 °C h^{-1} to 345 °C, air cooling
Full annealing (for 2–3% Si)	No eutectic carbides. To develop ferritic matrix with maximum low temperature impact toughness	870–900 °C	Same as above	Same as above
Full annealing	With presence of carbides. To develop a ferritic matrix	900–925 °C	2 h minimum; longer time for heavier sections	Furnace cooling @ 110 °C h^{-1} to 700 °C, hold at 700 °C for 2 h, furnace cooling @ 55 °C h^{-1} to 345 °C and air cooled

martensite. The formation of martensite is accentuated by the low austempering temperature with short holding time.

Irons which have lower bainitic structure (**Figure 34**) yields higher strength and lower ductility than those with upper bainite. Lower bainite is typically formed at austempering temperature below about 330 °C and the transformation kinetics are influenced by chemical composition and the 'C' content in the austenite. The 'C' content in its turn is a function of austenitization temperature and time. Upper bainite is formed at isothermal treatment about 330 °C and below the pearlite formation temperature, i.e., 500 °C. Ductility and toughness of upper bainite structure is much higher compared to lower bainite counterpart (**Figure 35**) but the hardness is lower in the former one. Another microconstituent present after austempering is retained austenite when austempering time ranges 0.5–3 h. The amount of retained austenite is much higher (up to 40%) in the upper bainitic irons than that in lower bainitic irons (less than 10%).

Excessive austempering time can cause the decomposition of ausferrite into ferrite and carbide which results in lower strength, ductility, and fracture toughness.

The attainment of maximum ductility at any selected austempering temperature is a function of austempering time (**Figure 36**). Even with its high strength, ADI shows a remarkable resistance to crack propagation. With a 0.2% proof strength of 1100 MPa K_{IC} values exhibited is 50 MPa. $m^{0.5}$ which is three times greater than those of pearlitic S.G. iron with the yield point of only 500 MPa. Because of the presence of high proportion of retained austenite, there is no obvious ductile to brittle transition temperature in impact toughness.[5,6,17,27]

c. *Surface deformation treatments*: Improved fatigue properties can be achieved by the presence of a compressive residual stress at the surface in the components subjected to fatigue loads. The residual compressive stress can be introduced by shot peening or surface rolling. These cold working can cause an additional benefit to transform the retained austenite in ADI to strain-induced martensite. The strain-induced martensite formation is associated with 4% increase in volume which further cause the increment in

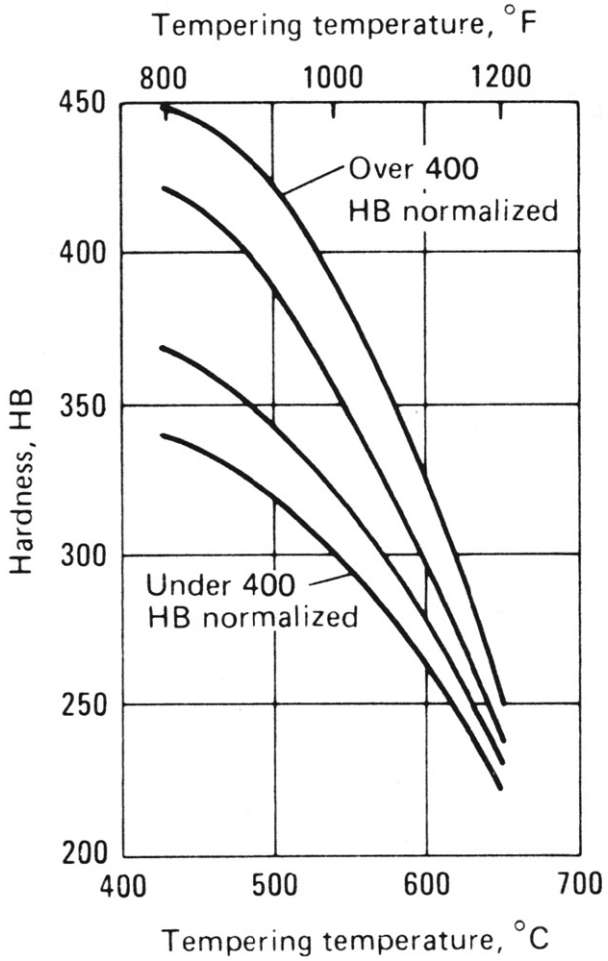

Figure 28 Hardness of normalized and tempered ductile iron at various temperatures. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 14, p. 1500.

compressive residual stress. The strain-induced martensite significantly improve the wear resistance.[6,27]

2.10.4.5.2 Two-step austempering heat treatment

To improve further properties of ADI, another two-step austempering heat treatment cycle has been developed. In two-step austempering, the austenitization process is similar to conventional practice.[34,35]

The component is subsequently quenched to a temperature bath in which temperature is increased just after quenching to a final higher temperature (Figure 37). The reason of using that process is to get higher toughness values in combination with high level of strength. Quenching at low temperatures results in finer grains, and consequently, improves the strength. On the other hand, the heating of the salt bath results in faster diffusion of carbon, and this in turn results in higher austenite carbon content, and consequently, higher toughness.

For further improvement of the properties of ADI, it is alloyed with Ni and Mo. In the as-cast form, proper addition of Ni and Mo can improve the properties of ductile cast iron through increasing the pearlite percentage in the structure. While in the ADI, addition of Ni and Mo results in improvement in the

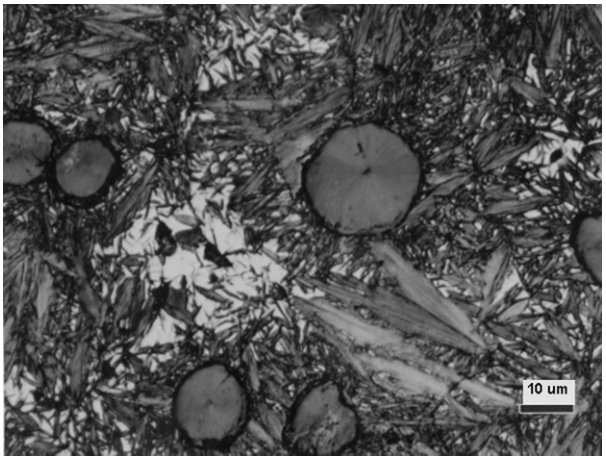

Figure 29 Microstructure of hardened ductile iron. George Vander Voort. *Metallographic Procedures for Cast Irons*; Vac Aero International Inc. Newsletter; Figure 15.

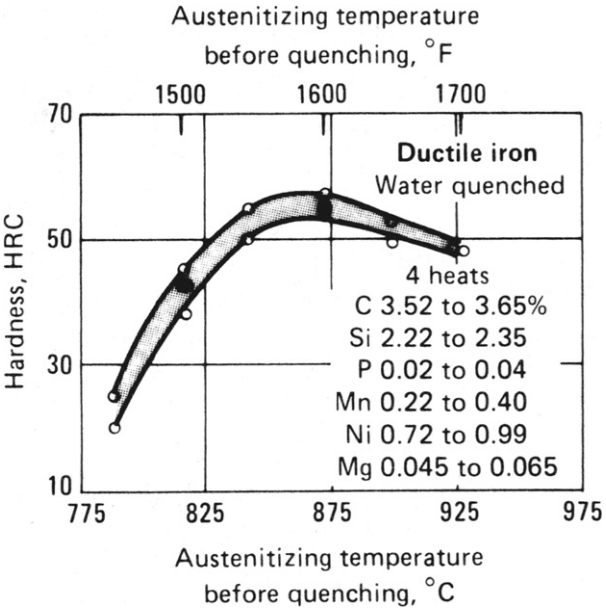

Figure 30 Effect of austenitizing temperature (time 1 h) on as-quenched hardness of ductile iron. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 15, p. 1501.

fracture toughness of ADI through their effect on the volume percentage of retained austenite (Figures 38 and 39).

Case study:[37] ADI gears were produced from continuous cast iron bars, heat treated for Grade 3 of ASTM ADI Standard A897M-06 (UTS > 1200 MPa) and compared the performance to carburized steel of AISI 8620 and to induction hardened steel of AISI 4140. The chemical compositions, heat treatment sequences, nodule characteristics of the ADI material and the mechanical properties of the gear materials are shown in Tables 9–12 respectively. Macroscopic images were taken from the gear teeth flank, showing the condition before running-in and after each step of the fatigue tests, so that the damage evolution in the flanks with the loading cycles could be

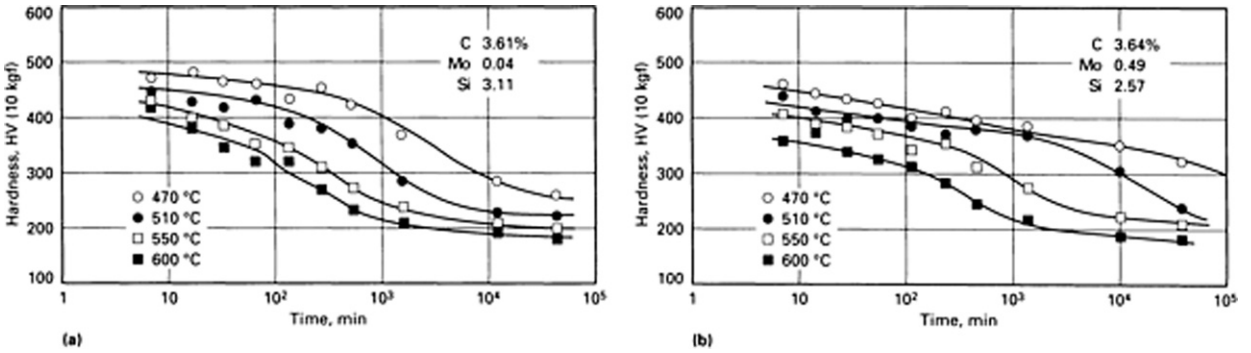

Figure 31 Effect of tempering temperature and time on the tempered hardness of two different ductile irons. Rundman, K. B.; Rouns, T. N. On the Effects of Molybdenum on the Kinetics of Secondary Graphitization in Quenched and Tempered Dutile Irons. *AFS Trans.* **1982**, *90*, 487–497.

observed. These images were used to quantify the pitting area. Tests on gears were made measuring the time for pitting and spalling on the surface of the gears. The results of the total rate of damage (damaged area (*A*%)/number of cycles (*N*)) for all the materials tested are shown in Figure 40.[37]

The ADI with small nodule size showed to be very competitive with wear resistance similar to AISI 4140 induction hardened steel. The nodule size affects the contact fatigue life independently of the ductile iron microstructure. The size and count of nodules affect both the nucleation and propagation of cracks. ADIs with small nodule size has a greater wear resistance.

2.10.4.6 Surface Hardening of Ductile Irons

Ductile irons can be surface hardened by flame, induction, or laser hardening treatments.[17,18,38] As the pearlitic matrix has the less diffusion distances, it can most readily respond to surface hardening treatments. A satisfactory response toward surface hardening is obtained with ferritic matrix. However, a fully ferritic matrix requires higher heating time to be hardened. The hardening temperature is generally ranging from 845 to 900 °C and the surface hardness values range from 35 to 62 HRC depending upon fully ferritic to a mostly pearlitic matrix. The final hardness values depend on various factors such as heating temperature and time, dissolved carbon content in austenite, section size, and rate of quenching. Water quenching develops higher hardness but soluble oil or polymer quenching media are often used to avoid quench cracking.

The response to induction hardening also depends on the amount of pearlite in the matrix and prior condition of the castings. In as-cast condition, the hardening temperature ranges from 955 to 980 °C for 3.5 s depending on the pearlite contents. If the casting contains less than 50% pearlite higher hardening temperature is to be selected and with pearlite content greater than 50%, a lower hardening temperature range 900–925 °C is sufficient. In normalized and tempered condition, the response to hardening is poor with lower pearlite content ($\leq$50%), since during tempering the carbon is diffused from matrix to graphite nodules. The carbon is again absorbed from nodule to matrix during reheating but the extent of migration is not enough due to insufficient time of heating. In this respect the graphite nodule count is also important, higher the nodule count lesser is the diffusion path of carbon resulting in a deeper hardening. Casting having prior quenched and tempered treatment is more responsive even with higher ferrite percentage in the matrix. During tempering the secondary graphite nodules formed are responsible for supplying the adequate carbon to the matrix during induction reheating.

In case of surface hardening by plasma or laser heating a very high local heating is achieved which in turn produce a very small melted area on the surface. This melted area rapidly resolidifies because of self-quenching effect of the casting mass and develop a white iron structure with high hardness and wear resistance. If the source is moved on the surface a sufficient area is possible to be hardened.[17]

2.10.4.7 Stress Relieving of Ductile Irons

Complex-shaped castings which are employed in unheat treated condition should be stress relieved in the subcritical temperature range from 510 to 675 °C. The extent of stress relieving is dependent on factors like severity of initial residual stress, the stress-relieving temperature and time, the heating and cooling rate, and composition and microstructure of the casting.[6,17] The lower temperature of stress relieving is generally used for unalloyed and low-alloyed irons whereas higher ranges are employed for high and austenitic irons. The time of stress relieving depends on the casting shape and the desired extent of stresses relieved (Figure 41). As a common rule, 1 h plus 1 h per 25 mm section thickness is recommended. After soaking, the castings are to be furnace cooled to 290 °C followed by air cooling to room temperature. Austenitic irons are generally uniformly air cooled from stress-relieving temperature.

2.10.5 Heat Treatment of High-Alloy Irons

High-alloy irons are a separate category of irons comprising of alloy content greater than about 4% and intended for use in some specific applications. These specific applications include heat resisting, corrosion resisting, and abrasion resisting. The high-alloy irons can be broadly classified as high-alloy graphitic irons and high-alloy graphite free white irons. The family of these high-alloy irons are shown in Figure 42.

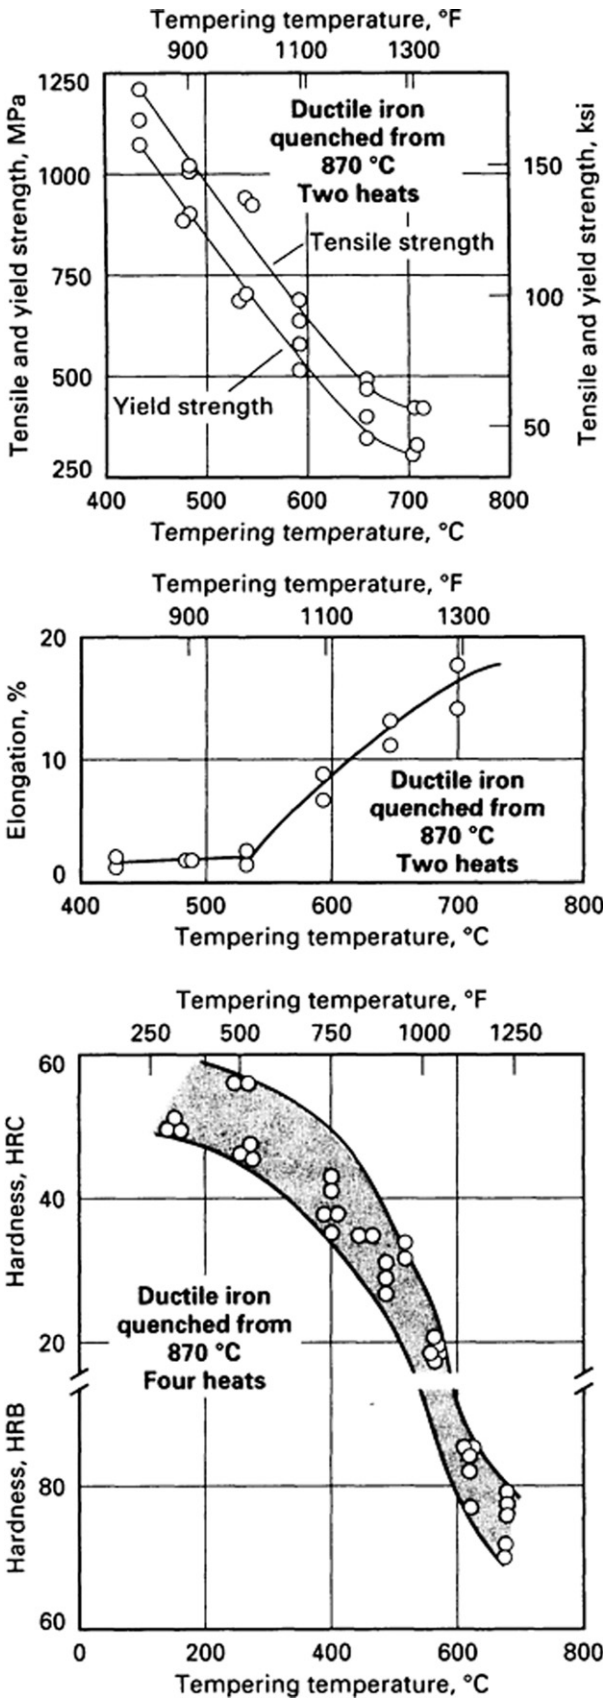

Figure 32 Effect of tempering temperature on the tensile properties and hardness of ductile iron quenched from 870 °C and tempered for 2 h. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 17, p. 1502.

2.10.5.1 Austenitic Graphitic Irons

The nickel alloyed austenitic graphitic irons also known as Ni-resist irons may be of flake type or nodular type in an austenitic matrix (**Figures 43** and **44**). The austenite phase is stabilized at room temperature by alloying with austenite stabilizers such as nickel, copper, etc. The spheroidal grades because of higher strength, ductility, and elevated temperature properties are being widely used. The advantages of flake type Ni-resist include lower cost, fewer foundry problems, better machinability, and thermal conductivity.[6,39,40] The standard ASTM flake graphite and austenitic ductile iron compositions are shown in **Tables 13** and **14** respectively.

General characteristics of Austenitic graphitic irons are as follows[40]:

a. Corrosion resistance: The corrosion resistance of this class of irons is much superior to the normal and low-alloy cast irons. Therefore, these irons are employed for corrosion resistant applications such as handling of salt solutions, sea water, mild acids, alkalis, and oil field liquids. These irons degrade by uniform corrosion rather than by localized deterioration.
b. Heat resistance: All Ni-resist irons are heat resistant and relatively low rates of oxidation in air. The adherent oxide layer formed on the surface reduces further oxidation. Among the two types spheroidal graphite Ni-resist has superior elevated temperature properties and can be used at temperature up to about 1050 °C. The flake graphite Ni-resist irons are mostly employed up to 700 °C.
c. Controlled thermal expansion: The thermal expansion of Ni-resist irons ranges from 5.0×10^{-6} to 18.7×10^{-6} cm per cm per °C and because of this low expansion these irons can be employed for producing precision parts.
d. Wear resistance: Austenitic graphitic irons possess excellent galling resistance and so are the potent material for making cylinder liners, piston wear rings, sleeves, bearings, and other metal-to-metal rubbing parts.
e. Erosion resistance: Ni-resist irons are having outstanding corrosion–erosion resistance and are most suitable material for handling slurries, wet stream, and fluids with entrained solids.
f. Magnetic and electrical properties: Because of the non-magnetic nature and high electrical resistance of some Ni-resist irons they are suitable for resistance grids, electric furnace parts, clutches, etc.
g. Machinability: Machinability is similar to higher strength grades of gray cast iron austenitic stainless steel.
h. Castability: Complex-shaped casting which are difficult to be cast in other materials can be economically cast in Ni-resist irons.

2.10.5.1.1 Effects of composition on the structure and properties

Nickel: In Ni-resist irons Ni is the primary element and is responsible for the stable austenite formation. Addition of nickel imparts corrosion and oxidation resistance and mechanical properties required in the high temperature range. Ni is also controlling the co-efficient of thermal expansion of the iron.

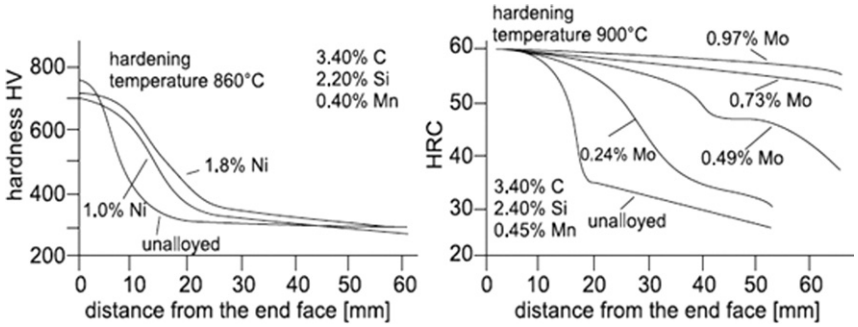

Figure 33 Effect of Ni and Mo on the hardenability of ductile iron. *Duktiles Gusseisen*; Verlag Schiele & Schon: Berlin, 1996; p. 178.

Table 8 Typical iron composition ranges for consistent properties

Carbon*	3.7%	+/−0.2%
Silicon*	2.5%	+/−0.2%
Manganese	0.28%	+/−0.03%
Copper	As required	+/−0.05% up to 0.8% maximum
Nickel	As required	+/−0.10% up to 2.0% maximum
Molybdenum	Only if required	+/−0.03% up to 0.25% maximum

Note: *Carbon and silicon should be controlled to produce the desired carbon equivalent for the section size being produced.
Source: Ductile Iron Data for Design Engineers, Section IV, Alloy Ductile Iron; Ductile Iron Society: Strongsville, OH, 1998.

Chromium: Chromium is responsible for improvement in strength and corrosion resistance at elevated temperature range. The mechanical properties such as hardness, wear, and corrosion–erosion resistance are increased by Cr addition. However, the ductility is deteriorated by the formation of huge amount of hard carbides. High percentage of Cr also tends to form microporosity in the castings.
Copper: It enhances the austenite stabilization effect along with Ni and improves corrosion resistance in mild acidic solution. But it is not suitable in austenitic ductile irons as copper has an adverse effect on Mg treatment.
Carbon: Carbon is the base element for any ferrous alloy. It has the effect to suppress the solidification temperature and improves the melting and pouring behavior. High strength and toughness are developed with lower carbon irons as fewer carbides are formed.
Silicon: Castability of irons especially thin-walled castings is remarkably improved by Si as it enhances the fluidity. The corrosion resistance is also improved by addition of Si. It reduces the extent of chromium carbide formation.
Manganese: Mn is a potent austenite stabilizer and improves low temperature properties of Ni-resist ductile iron D-2M and non-magnetic alloys such as Ni-resist NiMn 13 7. But it has almost no contribution in the improvement of corrosion resistance, high temperature properties, and mechanical properties.
Niobium: It leads to improved weldability of Ni-resist irons. To achieve maximum effect of Nb, the elements like Si, S, and P are to be controlled.
Molybdenum: For improved high temperature strength Mo is sometimes added in a few grades of N-resist irons.[6,39,40]

2.10.5.1.2 Heat treatment of austenitic graphitic irons

The heat treatment processes are similar in both the graphite forms viz. flake graphite and spheroidal graphite.[6,36,39–42] Nominal mechanical properties for flake graphite and spheroidal graphite Ni-resist irons are listed in **Tables 15** and **16** respectively.

2.10.5.1.2.1 Stress relieving

The objective of stress relieving is to remove the residual stresses developed during solidification or machining operation or a combination of both. For heavy thin walled castings mold shake-out is recommended below 315 °C rather than stress-relieving treatment to eliminate the solidification stresses. For other common applications, austenitic cast irons are stress relieved at 620–675 °C for 1 h per 25 mm section thickness followed by furnace cooling. At 675 °C, about 95% of stresses are relieved whereas stress relieving at comparatively lower temperature such as 480 °C with same soaking time will relieve only 60% of the residual stresses.

2.10.5.1.2.2 Spheroidizing annealing

When castings are cooled at fast rates especially thin-walled castings, formation of carbides causes high hardness greater than 200 HB. A spheroidizing annealing in the range of temperature of 980–1040 °C for 0.5 to 5 h softens the casting by either dissolving or spheroidizing the carbides. Only the hardness is lowered without affecting the strength.

2.10.5.1.2.3 High temperature stabilization

Castings intended for high-temperature applications above 480 °C are often subjected to a high-temperature stabilization treatment. The treatment involves heating the casting at 760 °C and soaked for minimum 4 h or alternatively, heated to a higher temperature at 870 °C and soaked for minimum 2 h subsequently furnace cooled to 540 °C and air cooled to room temperature. By this treatment excess carbon from the austenitic matrix and carbides are removed and the microstructure is stabilized which prevents distortion in service. Final machining is to be done after the stabilization treatment.

2.10.5.1.2.4 Dimensional stabilization

Precision castings requiring exact dimensional stability are to be treated for stabilization before employing in service. In this treatment the castings are to be heated to 870 °C and soaked for minimum 2 h and additional 1 h per 25 mm of section thickness followed by furnace cooling to 540 °C at the

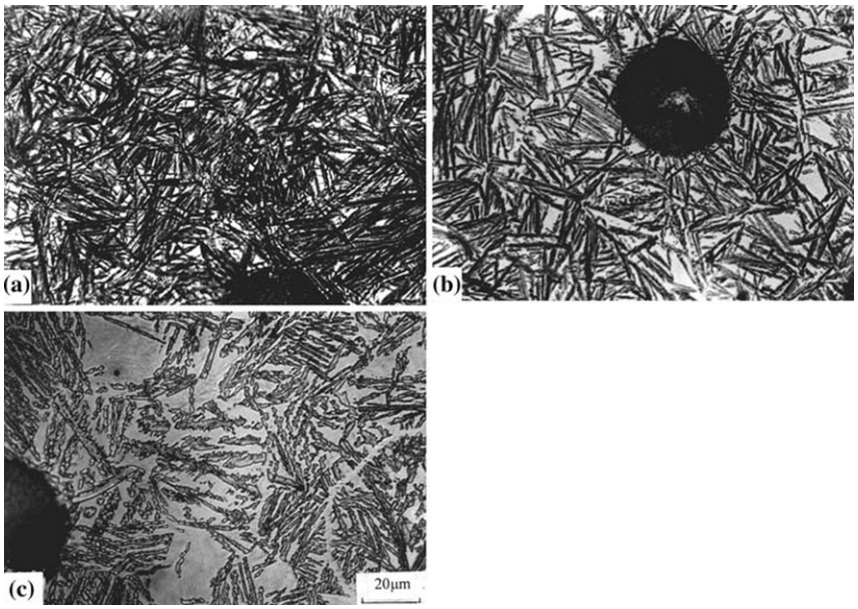

Figure 34 Microstructures of austempered ductile iron (3.5 C, 2.8Si, 0.3Mn, 0.02 S, 0.02 P, 0.04Mg, 0.5Cu, 1.5Ni, 0.3Mo) austempered at (a) 300 °C; (b) 350°; and (c) 400 °C. *J. Mater. Sci.* **2008**, *43*, 359; Figure 2.

maximum rate of 50 °C h^{-1} held at this temperature for 1 h per 25 mm section thickness followed by air cooling to room temperature. Then it is rough machined and reheated to 455–480 °C for a soaking period of 1 h per 25 mm section thickness and cooled to room temperature by air cooling. Finally, finish machining is done and reheated to 260–315 °C followed by uniform air cooling.

2.10.5.1.2.5 Solution treatment

As the name implies, the treatment involves the dissolution of some of the carbons in the austenitic matrix and subsequent rapid quenching suppressing the carbon precipitation. The higher carbon austenite will produce higher strength and hardness than normal conditions. In actual practice, the treatment comprise of heating the casting to 925–1000 °C followed by oil/water quenching. Quench cracking is not likely to take place as no phase transformation occurs.

2.10.5.1.2.6 Refrigeration and reaustenitization

This treatment is given to some specific types of irons viz. type D2 with a purpose to increase the yield strength without affecting magnetic properties and corrosion resistance in sea water or dilute sulfuric acid. Initially, the castings are solution treated at 925 °C followed by cryogenic quenching at − 195 °C. The castings are then reheated to 650–750 °C and air cooled.

2.10.5.1.3 Case studies on austenitic graphite irons

Case 1: Corrosion performance of Ni-resist austenitic irons is excellent in marine environments. Examples are sea-water pumps and valves to combat the corrosion at velocities ranging from no-flow to turbulent conditions. Ni-resist D2 and D2W are preferred. These irons also perform well in aerated and deaerated sea water with increased temperature. The corrosion behavior of pump material at low and high velocities of sea water are shown in **Tables 17** and **18**.[40]

Case 2: The unique combination of corrosion–erosion resistance of Ni-resist irons in sea water as well as petroleum is most suited for applications in oil and gas production.[40] In crude oil and gas containing several gases like hydrogen sulfide, carbon di oxide, and organic acids, the self-protective layer on the surface of these irons causes low corrosion rates. These are shown in **Tables 19** and **20**.

Case 3: The remarkable corrosion resistance of some specific grades of Ni-resist irons such as Ni-resist 3, D3 and D 3A with high nickel content of about 30% makes them suitable for handling of alkalis like sodium hydroxide and other strong caustics (**Tables 21** and **22**). Stress corrosion cracking a common failure observed in other iron-base alloys in such environments can be avoided with stress relieved Ni-resist irons prior to the in-service application.

Case 4: Steam turbine components such as diaphragms, shaft, and control valves are subjected to high steam temperatures where adequate resistance to growth and scaling is required. Ni-resist is potent material to combat these atmospheres.[40] **Table 23** and **Figure 45** show the elevated temperature mechanical properties and short-time tensile properties respectively of some appropriate Ni-resist irons.

Case 5: Cast iron or steel components when subjected to cyclic heating and cooling at elevated temperature range of 675 °C and above the ferrous alloys pass through a critical temperature range. Consequently, cracking and/or distortion results in as the matrix phase alternatively changes between ferrite and austenite. As the Ni-resist iron has a single austenite phase at all temperatures, do not undergo any phase

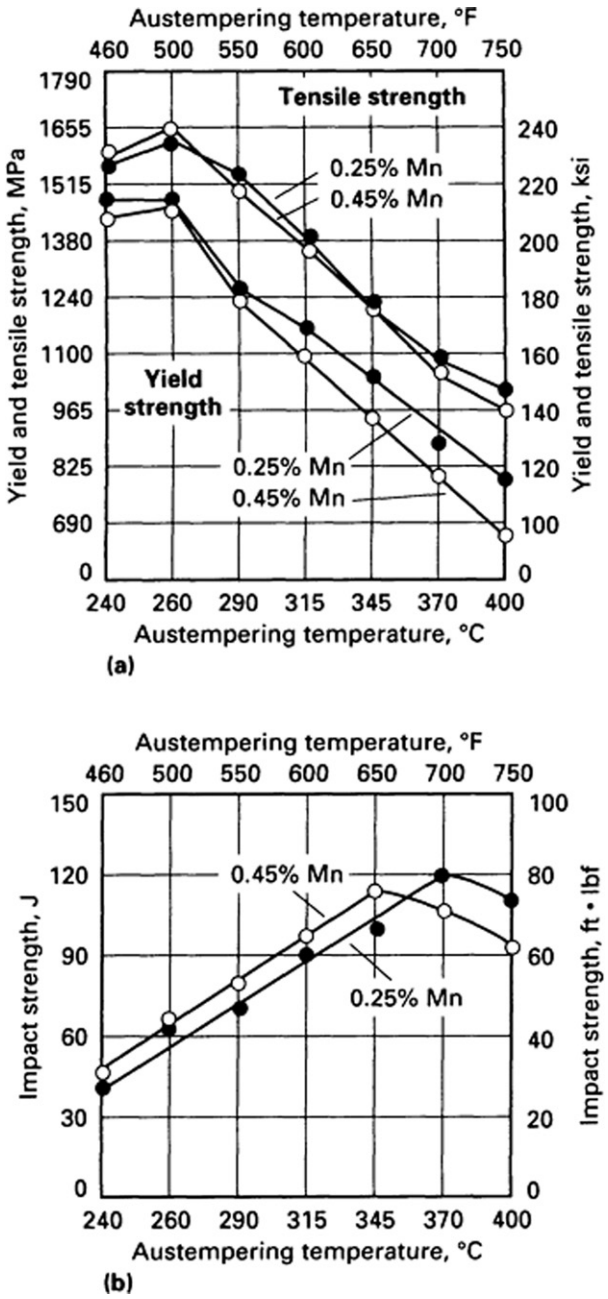

Figure 35 Effect of austempering temperature on the properties of ductile iron; (a) yield and tensile strength versus austempering temperature; (b) impact strength versus austempering temperature. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 19, p. 1505.

transformation and so have no sharp volume changes. Even though a high temperature stability heat treatment further improves the problem of cracking and distortion as the excess carbon is dissolved in the austenite.[40]

Case 6: For high temperature oxidation resistance applications, higher strength ductile Ni-resist irons such as D2, D2B, D3, D4, D5B, and D5S provide excellent resistance to oxidation and maintain their mechanical properties up to a temperature of 760 °C. The presence of high-chromium and high-silicon contents form dense, adherent self-protecting surface oxide layers. Under thermal cycling condition, cracking and flaking of oxide protective scale occurs and in such cases low expansion grades such as D4 grade is employed.[40]

2.10.5.2 Heat Resistant High Silicon Irons

Graphitic high silicon irons with 4–6% Si are low-cost group of irons for elevated temperature applications. High silicon irons may be of two types – (1) high-silicon flake graphite gray iron and (2) high-silicon ductile iron. In both these irons the matrix is stable ferritic and up to a temperature of 900 °C. The ferrite does not undergo any phase change. The presence of Si causes to raise the ferrite to austenite transformation temperature of the cast iron. The rate of oxidation at elevated temperature is drastically reduced due to the formation of a dense, adherent iron silicate layer at the surface. The strong ferritizing tendency of Si stabilizes the matrix against the formation of carbides and pearlite, thus reducing the growth associated with the decomposition.[6,39]

The high-silicon gray irons are commonly known as Silal. In this group of irons the matrix consists of stable ferrite along with fine undercooled type D graphite flakes producing a good oxidation resistance. Further improvement in oxidation resistance is achieved by addition of 2% chromium. At room temperature these irons are brittle but are reasonably tough above 250 °C.

High-silicon ductile irons are more widely used oxidation resistant iron as the graphite flakes are replaced by nodules which causes further improvement in oxidation resistance and growth. Higher strength and ductility in this group are added advantages for stringent applications.

With increase in silicon content from 4 to 6% further improvement in the oxidation resistance can be achieved but the impact transition temperature is raised above the room temperature and causes brittleness. The ductility is again restored above 425 °C (**Figure 46**).

Addition of molybdenum of about 0.5% to ferritic ductile iron improves significantly the creep and stress-rupture strengths which are requisites for high-temperature applications. Further improvement in high-temperature tensile, creep, and stress-rupture strengths are observed with an increment of Mo content to 2% (**Tables 24** and **25**). A typical microstructure of Si Mo51 grade ferritic ductile iron is shown in **Figure 47**.

2.10.5.2.1 Heat treatment of heat resistant high-silicon irons

A graphitizing full annealing in the austenitic range is generally adopted to anneal any pearlite and undesirable amounts of carbides present in high-silicon nodular irons. In practice, the casting containing 4–5% silicon are subjected to the full annealing at a minimum temperature of 900 °C for several hours of soaking followed by slow cooling below 700 °C. Higher silicon content (>5%) nodular irons are generally having carbide-free microstructure and if present these are decomposed easily. A subcritical annealing in the range of 720–790 °C for 4 h is sufficient to ferritize the matrix. These subcritically annealed nodular irons develop higher strength but with lower ductility and toughness compared to fully annealed irons.[6,39]

2.10.5.3 Heat Treatment of Corrosion Resistant High Silicon Irons

The corrosion–resistant ferritic cast iron group contains high silicon of about 15% and are widely used in chemical processing and corrosive liquid handling.[6,39] Chemical compositions of most common high-silicon irons as per ASTM A 518M specification are shown in **Table 26**.

Because of the presence of high silicon content of about 15%, these irons are very brittle in as-cast condition. Common heat treatments have no significant effects on the corrosion resistance behavior of these irons except stress-relieving treatment. Simple shaped castings can be safely shaken out from

the molds after cooling to ambient temperature. However, to avoid hot cracking complex castings are to be shaken out in hot condition from molds and are subjected to immediate stress-relieving treatment at 870–900 °C followed by furnace cooling to ambient temperature.

2.10.5.4 Oxidation Resistant High-Aluminum Irons

Aluminum in cast iron stabilizes the ferrite phase up to a temperature of 980 °C. It remarkably enhances the oxidation resistance of cast iron at elevated temperatures and forms a dense, adherent self-protecting oxide scale on the surface of the casting and prevent further oxidation. There are two groups of aluminum-alloyed irons- (1) low-alloy group containing 1–7% Al and (2) high-alloy group containing 18–25% Al. As aluminum has a strong graphitizing effect it replaces silicon in the iron. In the low-alloy group as the Al content is increased from 1 to 7% the strength and hardness is increased which is maintained even at higher temperatures. However, in the high-alloy range it is solidified as white iron and very much brittle and as such have no commercial importance.

The commercial productions of aluminum alloyed irons are still limited due to their inherent difficulties in the casting production. As aluminum is highly reactive at molten iron temperature, reacting with air it forms dross and comes in the casting as inclusions. Another problem is cold shut or laps formation in the casting due to viscous nature of the iron.[6]

2.10.5.5 Abrasion Resistant High-Alloy White Irons

The high-alloy white irons are basically used for abrasion resistant applications such as in mineral processing industries and abrasive materials handling. Both primary eutectic carbides and the secondary carbides produced by heat treatment provide high hardness and wear resistance. The matrix also has vital role to act as a hard and tough holding base for carbides against the wearing and action. Therefore, a suitable composition and heat treatment are to be chosen to develop the desired structure. High-alloy white irons invariably contain chromium, a strong carbide former to stabilize the carbide phase. Other alloying additions such as nickel, molybdenum, and copper are often made to suppress the pearlite transformation and to increase the hardenability and promote martensitic matrix with a range of hardness of 450–800 HB. However, the low-alloy white irons contain pearlitic matrix and possess lower range of hardness of 350–550 HB.[6,39,43–57]

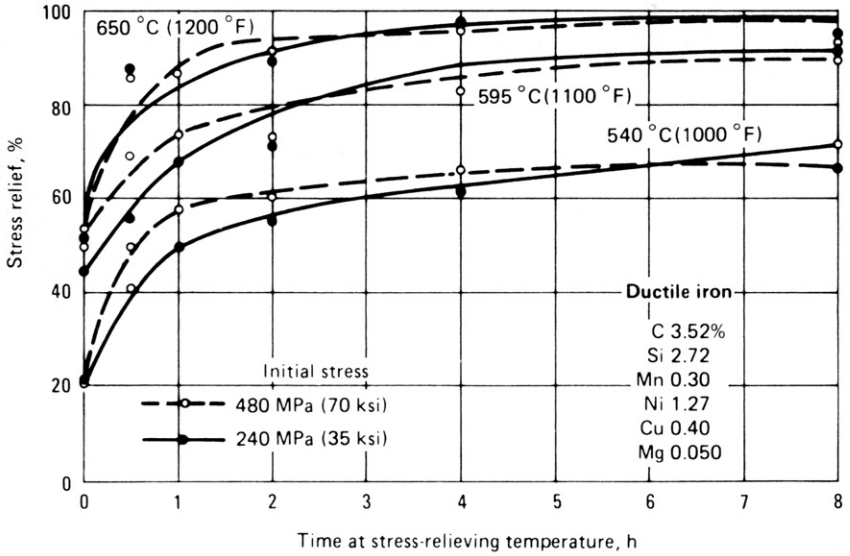

Figure 41 Effect of stress-relieving time on the percent stress relived in ductile iron. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of Ductile Iron; Figure 23, p. 1509.

The high-alloy white cast irons fall into three broad categories:

a. The nickel–chromium white irons commonly known as Ni-hard irons which are low-chromium alloys containing 1–4% Cr and 3–5% Ni except in one grade contains 7–11% Cr.
b. The Chromium– molybdenum irons containing 11–23% Cr and up to 3% Mo and are sometimes additionally alloyed with elements like Ni or Cu.
c. The 25% Cr to 28%Cr white irons occasionally containing alloying elements like Mo and/or Ni up to 1.5%.

The composition of different grades of high-alloy white irons as per ASTM A 532 are shown in **Table 27**.

2.10.5.5.1 Heat treatment of nickel–chromium white irons

High-alloy nickel–chromium white irons also known as Ni-hard irons are cost effective wear resistant material for mining and mineral processing, cement industries, etc. This class of irons contain 3–5% nickel and 1.4–4% chromium. Nickel promotes a hard martensitic matrix suppressing the pearlitic transformation even on slow cooling in the mold. Chromium is added to form hard eutectic carbides in the structure

invariably stress relieved to reduce the transformation stress for austenite to martensite transformation. A low-temperature tempering treatment at 205–260 °C for at least 4 h of holding are often given to the castings to temper the martensite and to transform some retained austenite. The treatment results in an increase in strength and impact toughness by 50–80% without any reduction in hardness and abrasion resistance.

Precautions must be taken to avoid (1) loading the furnace in hot conditions and (2) fast rate of heating and cooling. These will develop thermal shock in the castings and generate cracks which are particularly important in case of complex and heavy section castings.[43,44]

2.10.5.5.1.2 Destabilization treatment

This hardening treatment is carried out to destabilize the austenite and to form martensite embedded with fine carbides. The castings are austenitized in the temperature range of 750–790 °C with a soaking period of around 8 h. Subsequent air cooling or furnace cooling at rate of 30 °C h^{-1} causes conversion of austenite to martensite. Finally the hardened matrix is tempered to eliminate the residual stress.

2.10.5.5.1.3 Cryogenic treatment

The purpose of this treatment is to convert more amount of retained austenite to martensite to achieve a higher hardness and consequent higher abrasion resistance. The treatment involves in quenching the casting in a cryogenic bath at a temperature between −70 and −180 °C for 0.5–1 h. After cryogenic treatment an increase in as-cast hardness by about 100 HB is observed. Final hardness greater than 650 HB may be developed when the martensite content exceeds 80%. Typical microstructure developed by cryogenic treatment of class I type D nickel–chromium white iron is shown in **Figure 49**.

2.10.5.5.1.4 Case study on heat treatment of nickel–chromium iron

Rolls for coal and cement grinding are generally made of Ni-hard 4 grade with a typical composition of 3.11 C, 1.22Si, 0.6Mn, 8.32Cr, and 5.39Ni. As a result of its high-alloy content, as-cast rolls contains more than 50% retained austenite developing a hardness below 550–600 HV. To increase the hardness to the desired level a more complete transformation of retained austenite to martensitic matrix is required. This is achieved by destabilization above 820–860 °C with a soaking

time of 10–12 h followed by still air cooling. Martensitic matrix embedded with fine secondary carbides causes higher hardness. The hardenability of Ni-hard four iron is sufficient to allow cooling rates of $<30\ ^{\circ}C\ h^{-1}$ through the temperature range between 600 and 300 °C without pearlite formation. A final tempering is often carried out at 200 and 270 °C to eliminate the residual stresses.[43]

2.10.5.5.2 Heat treatment of high-chromium white irons

High-chromium white irons provide the best combination of abrasion resistance and toughness in alloyed white cast irons. High-chromium martensitic irons generally contain minimum 12% chromium and are often alloyed with molybdenum, nickel, and copper to suppress the pearlite formation and increase the matrix toughness. The presence of high chromium produces a hard and relatively discontinuous M_7C_3 type of eutectic carbides. The as-cast matrix is either fully martensitic or a combination of martensite and austenite. The retained austenite can be transformed to a predominantly martensitic matrix by a suitable heat treatment to achieve maximum abrasion resistance and toughness. However, castings with a mixture of austenite and martensite structure in as-cast condition are also very often employed to avoid the thermal and transformation stress generated in heat treatment. A suitable alloy combination is to be designed to suppress the pearlite transformation.[6,39,45–57] The effective section sizes

without pearlite formation obtained with minimum alloy additions are shown in **Table 28**. Based on the CCT diagrams, the critical cooling rate to avoid pearlite formation for a minimum alloy content have been calculated. **Table 29** indicates the minimum alloy content for air quenching castings of effective section thickness. Ni and Cu promote retained austenite and should be restricted to combined levels of 1.2% max. Mn behaves similarly and should be restricted to 1.0% max.

2.10.5.5.2.1 Annealing

Sometimes, to improve the machinability of the castings either subcritical annealing or a full annealing is adopted. The subcritical annealing involves heating in the range of temperature of 6900–700 °C with a soaking time of 4–12 h. A pearlitic matrix with a hardness range of 400–450 HB is produced. The full annealing is intended for further softening and the castings are heated to 950–1010 °C and subsequently cooled slowly in furnace to a temperature of 760 °C and held at this temperature for 10–50 h depending upon the composition.

2.10.5.5.2.2 Destabilization treatment

To achieve a maximum hardness, toughness, and abrasion resistance by a martensitic matrix structure embedded with fine alloy carbides, destabilization is most suitable treatment and is widely used. The destabilization involves reaustenitization of the castings at 955–1060 °C and held for 3–6 h followed by air cooling. The reaustenitization at just above the upper critical temperature (A_3) causes excess carbon and alloying elements to be rejected out and form very fine secondary M_7C_3 type carbides. The martensite start temperature (M_s) of this alloy depleted austenite is raised and during subsequent air cooling the austenite is transformed to martensite embedded with fine alloy carbides (**Figure 50**). The alloy must have adequate hardenability to allow air hardening.[45–48]

During heating to the austenitization temperature furnace temperature and the rate of heating should not produce any thermal gradients in the castings. Simple shapes can be loaded at 260 °C with a heating rate of 100 °C h^{-1}. On the other hand, complex castings are recommended to load in the cold furnace with slow heating rate of 30 °C h^{-1}. The heating rate can be accelerated once the castings are red hot.

Austenitization temperature and time are selected on the basis of composition and microstructure. A very high austenitizing temperature cause retention of higher amount of austenite and reduces the hardness and abrasion resistance (**Figure 51**). In contrast, lower austenitizing temperature will cause lower amount of dissolved carbon in austenite and produces low-carbon martensite with lower hardness. The austenitizing time can be 3–6 h, shorter times are adopted with as-cast pearlitic matrix whereas longer times are required for predominantly austenitic matrix.

Air quenching from the austenitization temperature preferably by fan cooling to a temperature below the pearlitic transformation range is recommended to produce desired martensitic structure. Below his temperature the cooling rate must be slow enough to minimize the residual stress. Complex and heavy castings are reinserted in the furnace at 550 °C and kept sufficient time to equalize the temperature in the castings following this castings are either furnace cooled or cooled in still air.

The destabilized castings are very often tempered at a low temperature range of 200–230 °C for 2–4 h to improve toughness to some extent and to relieve the residual stress.

The destabilized castings invariably contain 10–30% of retained austenite which are causing failure from spalling. Subcritical tempering in the range of 450–525 °C for a soaking time of 8–12 h reduces the retained austenite content and increases the hardness. Higher treatment temperature and time will cause decrease in hardness as spheroidized ferrite–carbide structure is developed.

2.10.5.5.2.3 Subcritical heat treatment

It has been reported[58] that during such treatments, the highly alloyed metastable austenitic matrix can be decomposed into various combinations of ferritic and secondary carbide phases with the primary M_7C_3 phase being practically unaffected. Wang[50] studied the behavior of a 16Cr–1Mo–1Cu white cast iron during subcritical treatment at 580 °C for different time intervals of processing. A sharp hardness increase was observed between 2 and 10 h, followed by a smooth drop for the next 6 h. Above 16 h of processing, a slight increase was observed. These hardness fluctuations were associated with the different

microstructural features. Wang *et al.*[51] studied the effects of precipitation and transformation of secondary carbides on the hardness of a 15Cr–1Mo–1.5V white cast iron under a sub-critical treatment. Heating at 560 °C led to two hardness peaks, after 10 and 14 h, respectively. The first peak was attributed to martensitic transformation and $M_{23}C_6$ precipitation. The second peak was associated with the presence of MoC, $(Cr, V)_2C$, and $M_{23}C_6$ carbides.

2.10.5.5.2.4 Case studies on failure of high-chromium iron

Case 1:[47] Failure of grinding media ball is a crucial problem due to improper destabilization treatment. The grinding

media are subjected to repeated severe impact causes spalling prior to the failure. The failures have been investigated and the retained austenite contents have been found to be high around 20–70% in the matrix. One of the possible causes of failure is the formation of strain-induced martensite from the retained austenite transformation producing high-transformation stress. The lowering of retained austenite is possible by a subcritical treatment after the destabilization treatment.

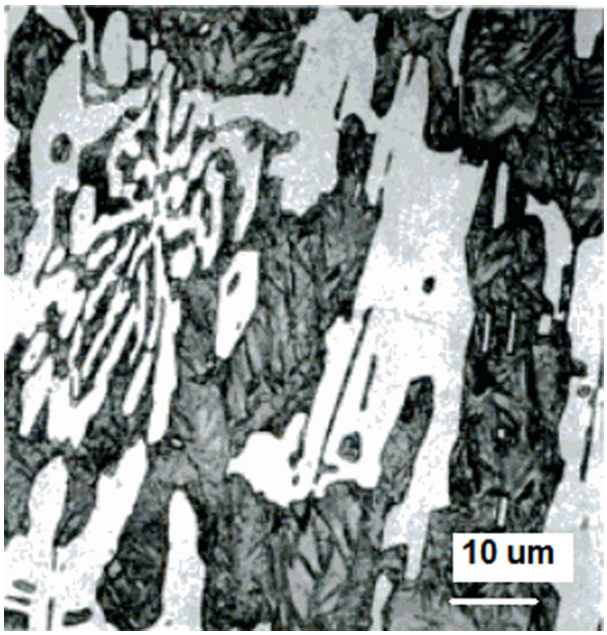

Figure 49 Microstructure of class I type D nickel–chromium white cast iron after cryogenic treatment. *ASM Handbook*, Vol. 4, 1991 ed., Heat Treating of High-Alloy Iron; Figure 6, p. 1530.

The resistance to impact of Fe–Cr–C white irons with high-chromium content is relatively poor, and many researchers have attempted to identify the microstructural features which influence the impact resistance. Some researchers have demonstrated that the austenitic matrix under impact promotes spalling and brittle fracture. Under impact, austenite is thought to transform into martensite in surface regions. The volume expansion associated with martensite formation produces compressive stresses in the surface layers, which, to maintain static equilibrium, are balanced by subsurface tensile stresses. Cracking of the eutectic carbides and carbide matrix interfaces due to these tensile stresses leads to spall formation.[52]

Case 2:[53] High-chromium cast irons (HCCIs) are often used under tribo-corrosive conditions, for example, in slurry transfer pumps. HCCIs possess their appreciable corrosion resistance to the presence of a passive layer that forms on the surface due to a sufficient amount of chromium in solid solution with the iron-based matrix. Hard carbides surrounded by a tough metallic matrix impart a relatively high wear resistance to these alloys. For multiphase alloys like HCCI the galvanic coupling between the matrix and carbides determines the overall corrosion tendency. Therefore, corrosion proceeds

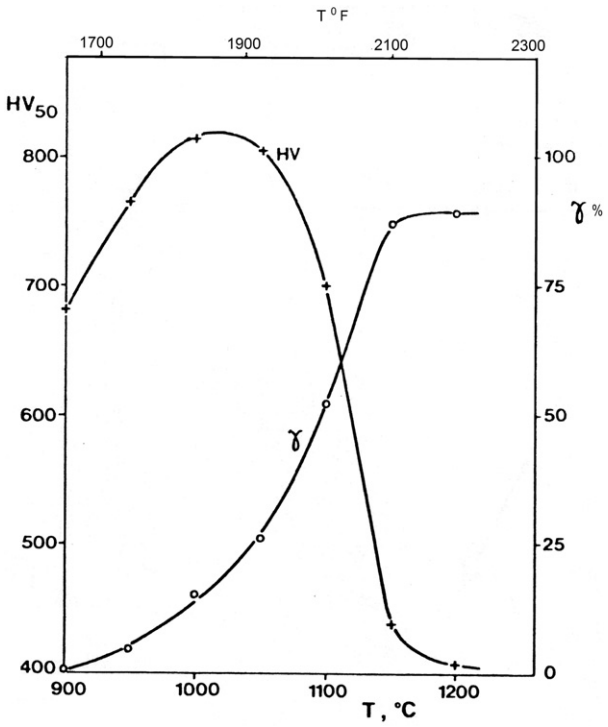

Figure 51 Effect of austenitizing temperature on hardness and retained austenite content in high-chromium white irons. Maratray, F.; Poulalion, A. Austenite Retention in High-Chromium White Irons. *AFS Trans.* **1982**, *90*, 795–804; Figure 1, p. 796.

in a localized manner rather than being uniformly distributed over the surface. Narrow crevices between the carbides and the matrix have been reported as the most susceptible sites where the corrosion process initiates. The electrolyte characteristics (composition, pH, temperature) may significantly alter the severity and mechanism of corrosive attack of HCCIs.

In alkaline media at lower potentials the abrading grits remove both the thin oxidized layer of carbides and the metallic matrix at a similar rate. At noble potentials, the carbide oxidized layer is thicker and the rate of carbide removal is faster than that of the matrix. The matrix is subsequently extruded into the carbide-depleted regions. Presence of aggressive chloride ions in slightly alkaline solution yields localized dissolution of the matrix. In neutral electrolytes, dissolution of the matrix is observed, accelerated by the presence of Cl^- ions. The matrix dissolution that often begins at the matrix/carbide interface leaves behind unsupported carbides. Interaction with abrading grits causes chipping and fracture of carbides.

2.10.5.5.2.5 Cryogenic treatment

Recently, a number of researches have been carried out to establish the effect of cryogenic treatment on the destabilization behavior of HCCIs.[59–63] The purpose is to (1) reduce the retained austenite content after conventional destabilization treatment and (2) increase the volume percentage of secondary ultrafine carbides. Both of these contribute to the increase in hardness and abrasion resistance. For cryogenic treatment the castings are initially austenitized at 900–1150 °C for 0.5 h and quenched in a liquid nitrogen bath at −196 °C and kept immersed for 3 h. The cryogenic treatment causes a reduction in retained austenite to about 10% (with a final hardness of around 62 HRC) compared to 20% in conventional destabilization (Figure 52).

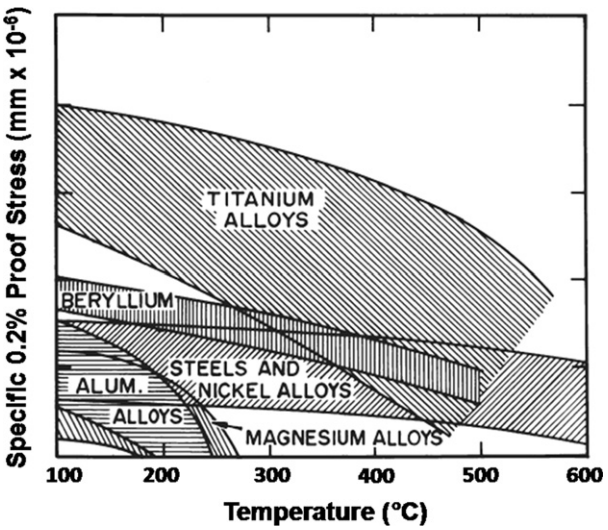
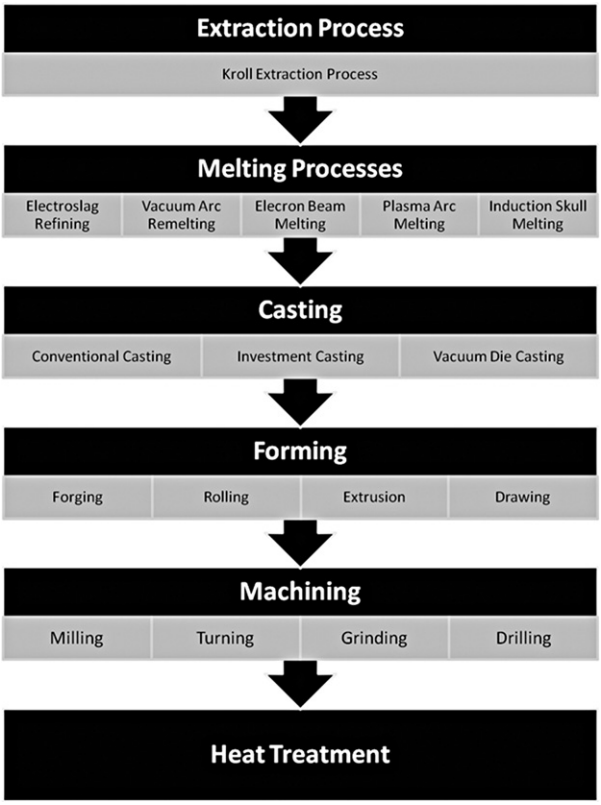
2.11.1 Introduction

Titanium is named after the Titans, the powerful sons of the earth in Greek mythology. Titanium (Ti) is the fourth most abundant metal on Earth's crust (~0.86%) after aluminum (Al), iron (Fe), and magnesium (Mg). It is not found in its free state. The pure metal forms in nature as oxides such as ilmenite ($FeTiO_3$) and rutile (TiO_2). It has almost similar strength as steel, but with a weight nearly half that of steel. Aerospace industries require materials with high strength-to-weight ratios at elevated temperatures. Initially, the stimulus for the development of Ti alloys during the past 40 years came from the critical need for such materials. Ti has a high melting point of approximately 1678 °C, which was taken as an indicator of good creep strength over a wide temperature range. However, thorough investigations revealed that this temperature range was narrower than expected. Nevertheless, Ti alloys are now featured as essential materials in the aerospace industries. Recently, chemical industries have recognized the importance of Ti and its alloys for its excellent corrosion resistivity. This metal is also utilized by medical industries, with Ti and its alloys used for prosthetic and implant materials in the human body.

Ti was produced in the late 1940s, when its relatively low density and high melting point made it uniquely attractive as a potential replacement for Al in the aerospace industries. The high specific strength of Ti alloys when compared with other light alloys, steels, and nickel alloys is presented in Figure 1.[1] The fact that this advantage is maintained to approximately 500 °C has led to the universal acceptance of certain Ti alloys for the components of gas turbine heat exchangers. Ti alloys have also found increasing demand for their use in critical structural components in aircraft as well as in the chemical and power generation industries due to outstanding corrosion resistance.





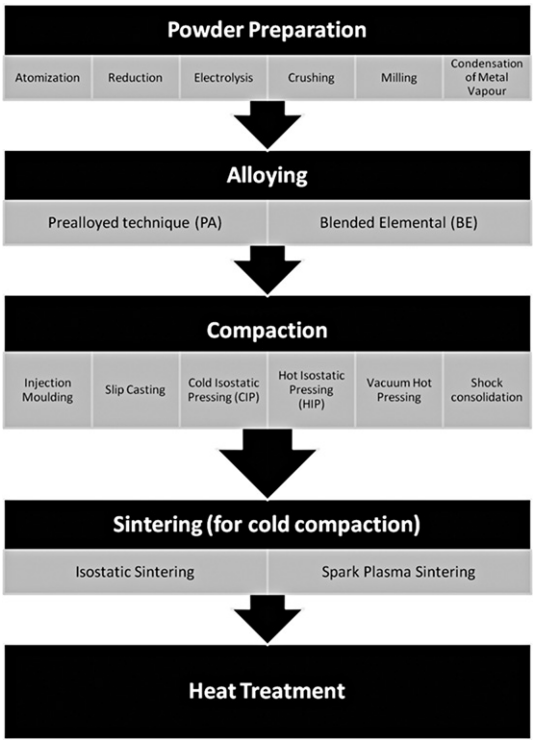


Figure 1 Relationship of specific 0.2% proof stress (ratio of proof stress to relative density) with temperature for light alloys, steels, and nickel alloys.[1]

2.11.2 Production of Ti

2.11.2.1 Casting Route

2.11.2.2 Powder Metallurgy Route

2.11.3 Alloying System of Ti Alloys

Ti is a transition element that has a conversion temperature of 882.3 °C, at which a transformation between the two stable phases of Ti occurs. These two phases are the α phase and the β phase.[2] Apart from these two phases, there is a third phase that is metastable in nature, which is called the ω phase.

2.11.3.1 α Stabilizers

The α phase of Ti has its atoms arranged in a hexagonal close-packed (hcp) structure. The hcp structure results in very high strength and modulus. It is the room temperature phase of Ti. The elements that stabilize the α phase are Al, O, N, C, Ga, Ge, Ce, La, and others. These elements promote the formation of the α phase in Ti, thereby suppressing the formation of other phases. Elements that dissolve preferentially in the α phase expand the α field in the phase diagram, which raise the α/β transus. Among the comparatively few elements that behave in this way, Al and oxygen (O) are the most important.[2]

2.11.3.2 β Stabilizers

The β phase of Ti consists of atoms arranged in a body-centered cubic (bcc) crystal structure. The strength and the modulus are lower than that of the α-Ti alloys. Being the high temperature phase of Ti, this type of alloy requires β-stabilizing elements in adequate amounts to stabilize the phase at room temperature. From a purely β-phase Ti alloy, a combination of α/β phases is noticed by varying amounts of alloying elements. Elements that decrease the α/β transus and stabilize the β phase may be classified in two groups: those that form binary systems of the β-isomorphous type and those that favor formation of a β-eutectoid. It should be noted, however, that the eutectoid reactions, in a number of alloys, are very sluggish and, in practice, the alloys tend to behave as if this reaction did not occur. Examples are the binary systems Ti–Fe and Ti–Mn, and these alloys behave as if they conformed to the β-isomorphous phase diagram. Examples of β-isomorphous stabilizers are V, Mo, Nb, Ta, W, Re, and others. The β-eutectoid stabilizing elements are Cr, Fe, Mn, Cu, Ni, Co, H, Ag, Au, Pb, and others.[2]

2.11.3.2.1 ω Phase

The ω phase is a metastable phase that forms in Ti alloys with elements that tend to stabilize the high-temperature β phase. The formation of this phase can be either during quenching from high temperatures (β phase region) or during aging of the quenched materials, depending on the conditions.[3] This phase provides the alloy strength, but it also increases brittleness. Addition of elements like Al (α stabilizer), zirconium (Zr), or tin (Sn) (neutral, but acts as an α stabilizer in the presence of other α stabilizers) suppress the formation of the ω phase to promote formation of the α phase.[2]

2.11.3.3 Neutral Elements

Neutral elements are those that do not promote any of the α or β phases of Ti. Elements like Zr, Sn, Si, and Hf are neutral to the phases of Ti. They are generally used for purposes other than modification of phases, like strengthening and processing.

2.11.4 Classification of Ti Alloys

Ti alloys are classified according to the constituent phases. The presence of α, β, or their combination dictates the properties and hence, the classification of these alloys. These alloys are mainly classified as:

1. α alloys,
2. α/β alloys, and
3. β alloys.

2.11.4.1 α Alloys

The α stabilizing elements (Al, O, and others) and some of the neutral elements (Sn, Zr, and others) dissolve in the α phase of Ti and help to retain it in low temperatures and also increase its strength by solid solution hardening. O and N (generally present as impurities) promote interstitial hardening. Controlled amounts of O in Ti produce the commercial purity titanium (CP Ti), which may also contain some other alloying elements to produce different grades of CP Ti with different mechanical properties.

The α alloys are further classified into two main categories:

- Fully α-Ti alloys.
- Near α-Ti alloys.

Practically, there is a limit (approximately 9%) to the amount of α-stabilizing elements that may be added to Ti because the alloys tend to embrittle because of an ordering reaction that occurs when the aluminum equivalent exceeds 9%. This quantity of α-stabilizing elements is calculated empirically from by summing the weight percentage as follows:

$$\text{Al Eq} = \text{Al} + 1/3(\text{Sn}) + 1/6(\text{Zr}) + 10(\text{O} + \text{C} + 2\text{N})$$

A finely dispersed, ordered phase (α_2), which is coherent with the lattice of the α phase over a wide temperature range, may form during artificial aging (at elevated temperatures) of alloys with Al content higher than 5–6%. This phase α_2 coarsens gradually when subjected to prolonged aging. In α alloys such as Ti–Sn, and in more complex compositions, there is a larger misfit between α and α_2, which makes the heterogeneous nucleation of α_2 more difficult. This nonuniform dispersion has a less deleterious effect on ductility.[1]

2.11.4.1.1 Fully α-Ti alloys

The several grades of CP Ti (which are, in effect, Ti–O alloys) and the ternary composition Ti–5Al–2.5Sn are the commonly used fully α alloys of Ti. The alloys are of single phase and have tensile strengths that are relatively low, although their high thermal stability leads to reasonable creep strengths in the upper temperature range. Good low-temperature ductility and

weldability are some of the highlighting features of these alloys. Hot working of the alloys at temperatures below α/β transus limits their formability because of their hexagonal crystal structure, causing them to exhibit a high rate of strain hardening. This is the reason why Ti–5Al–2.5Sn has tended to be replaced by the age-hardenable Ti–Cu alloy, which can be more easily fabricated after solution treatment but prior to aging, when it is relatively soft.

CP Ti is the second most used Ti alloy, with applications in the aerospace, architectural, chemical, and process engineering industries. Four commonly available grades, which have increasing levels of oxygen and room temperature tensile strengths ranging from 240 to 740 MPa, are:

- Grade 1 (0.18O–0.2Fe) has the lowest strength and displays excellent cold formability so that it can be deeply drawn.
- Grade 2 has a tensile strength between 390 and 540 MPa and is the most widely used CP Ti alloy. Examples of applications are skin panels and fire walls in aircraft and tubing in heat exchangers.
- Grade 3 (0.40O–0.5Fe) is confined mainly to pressure vessels.
- In addition, a composition containing 0.2% palladium (IMI 260) has been developed that has a particularly high resistance to corrosion.

Use of the alloy Ti–5Al–2.5Sn has declined in recent years because alloys with better forming properties and higher creep resistance have become available. However, there has been one continuing application in cryogenic storage tanks for which the relatively high strength of Ti alloys at low temperatures is attractive. A special grade that is low in interstitial elements (designated extra low interstitials (ELI)) has been developed in the United States of America to increase the toughness of the alloy, and it has been used to store liquid hydrogen ($-253\ ^{\circ}C$). Ti alloy pressure vessels, overtaking the lightweight aluminum and the high-strength stainless steel, have become standard for fuel storage in a number of space vehicles because their specific strengths are approximately double at such temperatures.[1]

2.11.4.1.2 Near α-Ti alloys

Demands for higher operating temperatures in the compressor section of aircraft gas turbine engines, as part of the continuing quest for improved performance and efficiency, made way for development of this class of forging alloys. They possess higher tensile strength at room temperature than do the fully α alloys, and they show the greatest creep resistance of all Ti alloys at temperatures above approximately $400\ ^{\circ}C$. The American composition Ti-8-1-1 and the British alloy IMI 685, which were used for the forged gas turbine compressor disk or wheel, are a few of the early developed near α-Ti alloys. Bomberger has produced an empirical expression to denote those compositions providing maximum creep strength:

$$36 - 2.6(\%\mathrm{Al}) - 1.1(\%\mathrm{Sn}) - 0.7(\%\mathrm{Zr}) - 27(\%\mathrm{Si}) - 3(\%\ \text{Mo equivalent}) \leq 10$$

where

$$\%\ \text{Mo equivalent} = 1.0(\%\mathrm{Mo}) + 0.67(\%\mathrm{V}) + 0.44(\%\mathrm{W}) + 0.28(\%\mathrm{Nb}) + 0.22(\%\mathrm{Ta}) + 2.9(\%\mathrm{Fe}) + 1.6(\%\mathrm{Cr}) + 1.0(\%\mathrm{Al})$$

To introduce small amounts of β phase into the microstructure and improve forgeability, the near α alloys are prepared with up to 2% of β-stabilizing elements. However, normal strengthening through the decomposition of retained β is insignificantly small because these additions of β-stabilizing elements are normally too small. The improvement in mechanical properties in these alloys arises mainly from the formation of martensitic α' and from the manipulation of α/α' microstructures.

Most near α alloys are forged and heat-treated in the $\alpha+\beta$ phase field to ensure presence of primary α grains in the microstructure. More recently, improved creep performance has been achieved in special compositions by performing these operations at higher temperatures, which places the alloys in the β-phase field and results in a change in the microstructure. The two alloys that show the highest creep resistances (maximum operating temperature 590–600 °C) are IMI834 and Ti 1100, and they are forged in the $\alpha+\beta$- and β-phase fields, respectively.[1]

2.11.4.2 α/β Alloys

There are limitations in strength that can be developed in the fully α alloys because of the ordering reaction occurring at higher solute contents. Also, these alloys are difficult to hot-form. These drawbacks led to the early investigation of compositions containing both the α phases and the β phases. Currently, these α/β alloys have the greatest commercial importance with one composition, IMI 318, comprising more than half the sales of Ti alloys both in Europe and the United States of America. IMI 318, also known as Ti64 (i.e., Ti–6Al–4V), offers the prospect of relatively high tensile strength and improved formability with some sacrifice in creep strength (higher than 400 °C) and weldability. The principal use of this alloy is for forged components, such as in the fan blades of jet engines and as bulkheads in the new Lockheed/Boeing F22 military aircraft. This alloy is currently the most popular choice in the case of both bioprosthetic and implant materials because of its excellent corrosion resistance property.

Most α/β alloys contain α-stabilizing elements to stabilize and strengthen the α phase, together with 4–6% of β-stabilizing elements that allow substantial amounts of β phase to be retained on quenching from the β- or $\alpha+\beta$-phase fields. The β phase commonly undergoes solid solution strengthening, although to a relatively small extent. Subsequent tempering or aging treatments can be utilized to improve the strength properties of α/β alloys to achieve as much as 1400 MPa tensile strength at room temperature. However, hardenability effects on quenching, aggravated by the low thermal conductivity of Ti, restrict most of the compositions from sustaining these levels of strength in thick sections.

As mentioned, the most commonly used α/β-Ti alloy is Ti–6Al–4V, which has many applications as a general purpose

alloy used in the annealed condition. For applications such as fasteners that require higher strength, the alloy is solution-treated high in the $\alpha+\beta$-phase field, quenched, and aged or annealed at approximately 700 °C, which results in a structure comprising equiaxed α grains in a matrix of fully transformed β. The alloy combines a minimum tensile strength of approximately 960 MPa with good creep resistance up to 380 °C. It is particularly used in forgings, but it is also available in plate, sheet, rod, or wire forms.

A number of other α/β forging alloys with greater strengths have been developed for applications such as aircraft engine mounting brackets and undercarriage components. The heat treatment potential of the alloys are explored more; in general, the content of stabilizing elements has been increased so that the M_s temperature is decreased well below room temperature, and significant amounts of β are retained, such as the alloys Ti–6Al–6V–2Zr–0.7 (Fe, Cu) (Ti-662), Ti–6Al–2Sn–4Zr–6Mo (Ti-6246), Ti–4Al–4Sn–4Mo–0.5Si (IMI 551), and Ti–4.5Al–5Mo–1.5Cr (Corona-5). Solution treating in the $\alpha+\beta$-phase field, quenching, and aging are performed to transform the retained β to obtain full strengthening. However, fracture toughness is higher if the alloys are first cooled from the β-phase field. For example, the alloy Corona-5 has plane-strain fracture toughness as high as 155 MPa $m^{-1/2}$, with a tensile strength of 950 MPa, if it is first annealed in the β-phase field. This value for fracture toughness is double than that normally obtained with Ti–6Al–4V and is again attributed to the slower rate of crack propagation through the microstructure containing elongated Widmanstätten laths of the α phase.

2.11.4.3 β Alloys

The β-Ti alloys are defined as those containing enough total alloying elements that enable the β phase to be retained in either a metastable or a stable condition after cooling to room temperature during heat treatment (Figure 2).[1] Alloy compositions that place them between the critical minimum level (β_c) of these stabilizing elements (i.e., where the M_s line intersects the room temperature axis) and the similar intersection point of the β-transus line (β_s) are commonly referred to as metastable β-Ti alloys because they will precipitate a second phase (usually α) upon aging. Stable β alloys have more highly alloyed compositions to the right of β_s and could not be hardened by heat treatment.

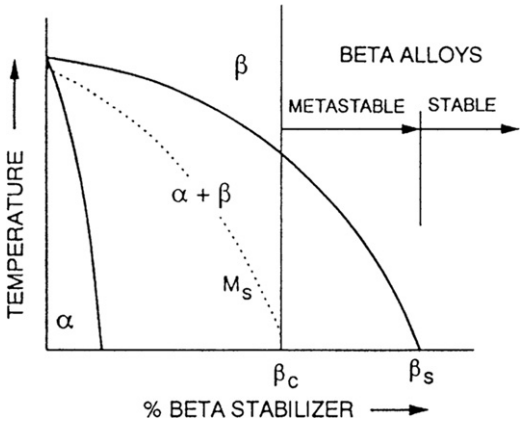

Figure 2 Pseudo-binary β-isomorphous phase diagram showing locations of metastable and stable β-Ti alloys.[1]

Molybdenum (Mo) is a well-known β-stabilizing element. The general class of β alloys has been arbitrarily defined as those having a Mo equivalent content ≥ 10. A formula for calculating the Mo equivalent value was shown in Section 2.11.4.1.2. In its application to β-Ti alloys, the Al content is subtracted to reflect the opposite effect of this element in stabilizing the α-Ti phase. In addition to Mo, those most widely used in β-Ti alloys are V, Cr, and Fe (Figure 3).[4]

The superior forming characteristics anticipated from the bcc structure attracted attention to the β-Ti alloys. Moreover, the prospect of cold-forming in a relatively soft condition and then strengthening by age-hardening is a very useful processing characteristic for any material because a combination of both flowability and strength can be imparted in the alloy. The presence of a high content of solute elements increases hardenability, which may allow the through hardening of thick sections during heat treatment. Such high contents of β stabilizing elements did, however, cause problems with ingot segregation and tend to increase density.

The first commercially used alloy was the composition Ti–13V–11Cr–3Al, which may be solution-treated, quenched, cold-formed, and aged at 480 °C to give a tensile strength as high as 1300 MPa. Strengthening is mainly due to a combination of solid solution hardening of the β phase and precipitation hardening, achieved by precipitation of a fine dispersion of the β phase in the α matrix. Due to formation of the ω phase in the heat-affected zones, the weldability of the alloy is somewhat poor. Moreover, it is proven to be unstable if exposed for long durations at temperatures higher that 200 °C because such treatment causes precipitation of the compound $TiCr_2$, thus reducing the toughness of the alloy. Another relatively early β alloy was the medium-strength British composition Ti–15Mo (IMI 205), which has found applications in the chemical industry.

2.11.5 Heat Treatment of Ti alloys

Heat treatment of any material is dependent entirely on the desired microstructure, properties, and constituents. The heat treatment of Ti alloys is mainly dependent on the desired phases of the alloy: whether α or β or $\alpha+\beta$ or any of these with retained ω phase. Generally, the α alloys are nonheat-treatable. Heat treatment of the α alloy (e.g., CP Ti) from the β-phase region results in a microstructure that contains other phases along with the hcp α phase.

2.11.5.1 Heat Treatment in α-Ti Alloys

2.11.5.1.1 Heat treatment in CP Ti and α-Ti alloys

In CP Ti and α-Ti alloys, which have single-phase microstructures, the tensile strengths are relatively low. However, their high thermal stability leads to reasonable creep resistance and toughness. The α alloys contain stabilizing elements such as Al, Sn, Zr, and O. These alloying elements give rise to substantial solid solution hardening, thereby increasing tensile

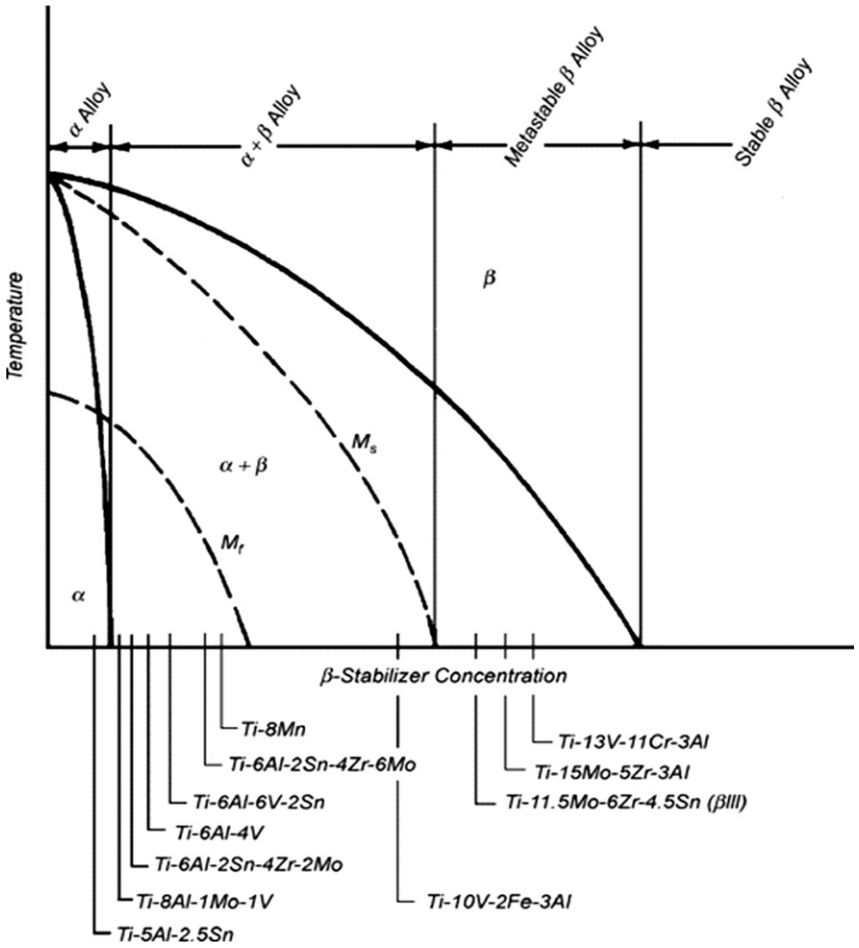

Figure 3 Ti and β-Ti stabilizers phase diagram with positions of some common alloys.[4]

strengths by increments of 35–70 MPa for each percent of the added element.[5] Examples of such alloys are: CP Ti grade 1, Ti–0.5Fe–0.4O–0.05N–0.08C–0.015H; CP Ti grade 2, Ti–0.25Fe–0.08C–0.2O–0.03N–0.015H; CP Ti grade 3, Ti–0.03Fe–0.2O–0.05N–0.08C–0.015H; and CP Ti grade 4, Ti–0.2Fe–0.15O–0.08C–0.015H.[6]

For heat treatment, the alloys are heated to the β-phase field (**Figure 3**) and then cooled by various means as follows:

- Annealing from the β-phase field in CP Ti produces an equiaxed hcp α-phase microstructure.
- Quenching from the same region changes the hcp α phase to martensitic hexagonal α' phase and remaining β grains.
- Air cooling of CP Ti from the β-phase field forms Widmanstätten α plates (**Figure 4**).

2.11.5.1.2 Heat treatment in near α-Ti Alloys

The additions of small amounts of β-stabilizing elements extend the $\alpha + \beta$ temperature range sufficiently to allow both α/β and β hot working.[7] Although these alloys contain some β phase in the microstructure, they behave more like α alloys than α/β alloys. The higher strength of these alloys in comparison to the α alloys arises mainly from the formation of the α' (martensitic) phase or α/α' microstructures during heat treatment. Many near α alloys are thermomechanically processed in the $\alpha + \beta$-phase field, such as those usually found for Ti–2.25Al–11Sn–5Zr–1Mo–0.2Si (IMI 679) and Ti–8Al–1Mo–1V (Ti-8-1-1). To improve creep performance, some alloys such as Ti–6Al–5Zr–0.5Mo–0.25Si (IMI 685), Ti–5.5Al–3.5Sn–3Zr–0.25Mo–1Nb–0.3Si (IMI 829), and Ti–6Al–2.75Sn–4Zr–0.4Mo–0.45Si (Ti-1100) are hot-worked and heat-treated in the β-phase field. Silicon (Si) (an element that dissolves in the α phase and forms silicides as well) is frequently added to increase the strength and creep resistance of these alloys.[8]

Heat treatment of near α-Ti alloys can be classified in two broad categories according to the temperature of heating of the alloy:

- the alloys can be heated to the $\alpha + \beta$-phase field, and
- the alloys can be heated to the β-phase field.

Heat treatment from the $\alpha + \beta$-phase field is possible when the alloys have sufficient amount of α stabilizers without severe loss of ductility. Small amounts of β stabilizers (Mo, V, etc.) are added to promote the response to heat treatment. The alloy is heated to a temperature to obtain an equal amount of α and β phases. Normalizing from this temperature produces equiaxed primary hcp α phase and Widmanstätten α formed by nucleation and growth from the β phase. Quenching from that temperature transforms β into a martensitic hexagonal α'

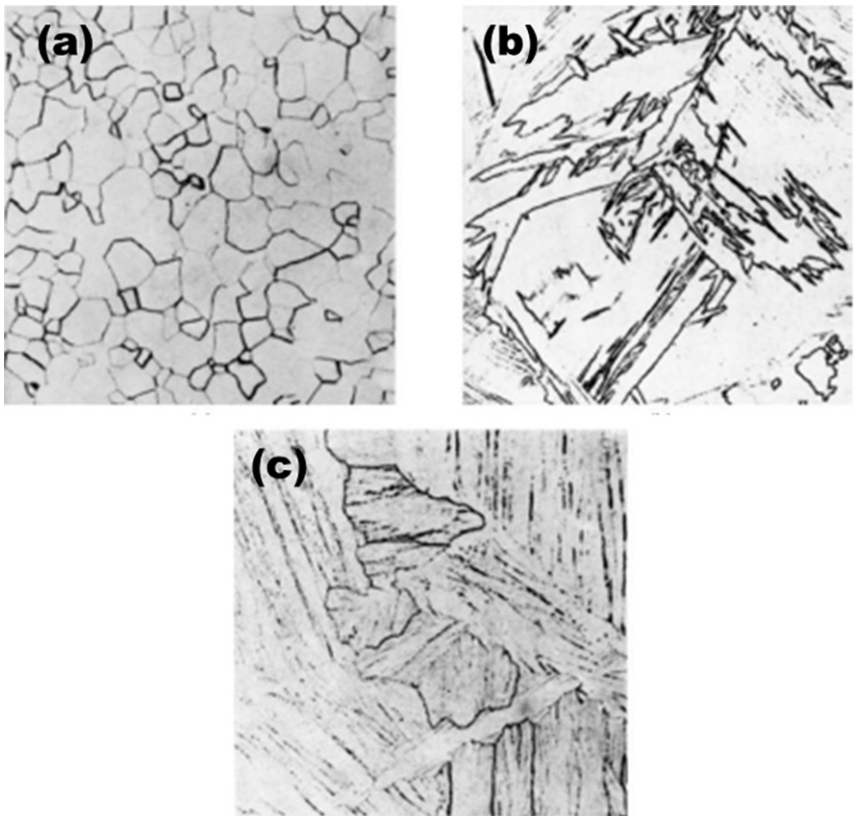

Figure 4 Microstructure of CP Ti: (a) annealed from the β-phase field showing equiaxed hcp α phase, (b) quenched from the β-phase field to obtain martensitic hexagonal α' phase, and (c) air-cooled from the β-phase field forming Widmanstätten α plates.[1]

phase, which gives higher strength. The high-temperature flow curves of CP Ti grade 2,[9] Ti–5Al–2.5Sn,[10] Ti–6Al–5Zr–0.5Mo–0.25Si (IMI 685),[11] and Ti–5.8Al–4Zr–4Sn–1Nb–0.5Mo–0.35Si (IMI 834)[12] are shown in **Figures 5–8**, respectively. It is evident that all the flow curves show an initial work-hardening region followed by a regime of near steady-state flow. Higher peak stresses are observed at higher strain rates and lower temperatures, as shown for CP Ti in **Figure 9**.[13] Comparison of the properties of CP Ti grade 2 and several α alloys (**Figure 10**) reveals that the flow stress at a given temperature increases with the Al equivalent.[14] The increased steady-state stress of α-Ti with Al addition is shown in **Figure 11**.[15] Similar behavior is also observed when the flow stress data are presented in terms of T-T_β, where T is the deformation temperature. For example, Ti–5.8Al–4Zr–4Sn–1Nb–0.5Mo–0.35Si (IMI834) has a total of approximately 15 wt% alloying elements and displays a much higher flow stress than CP Ti grade 2 with only approximately 0.6 wt% additions (**Figure 12**).[14] This increase in flow stress is mainly associated with an increase in substitutional solute strengthening.

Deformation below the β transus is typical of material undergoing dynamic recovery in which the rate of hardening by multiplication of dislocations is balanced by the rate of softening due to dislocations annihilation, thus resulting in the constant flow stress deformation.[16,17] This is very similar to the flow behavior of α-Zr, for which an initial period of hardening followed by steady-state flow is also frequently observed.[18] The apparent activation energy for the deformation of α-Ti alloys has been found to be in the range 200–360 kJ mol^{-1},[18] which is similar to that for creep, as determined over a wide range of strain rates, but is somewhat higher than the activation energy ($\sim$150 kJ mol^{-1}) for self-diffusion in α-Ti.[19] The α-phase flow stress is dependent on strain rate through a power law with an exponent of approximately 4.5 (**Figure 13**).[20] Furthermore, the high-temperature steady-state deformation behavior of α-Ti can be represented by the Dorn equation (eqn [1]),[15] provided that the temperature dependence of the shear modulus is taken into account. The equation gives creep rate as:

$$\dot{\varepsilon} = 8.0 \times 10^4 D \left(\frac{Gb}{kT}\right)\left(\frac{\sigma}{G}\right)^{4.1} \qquad [1]$$

where D is the diffusivity depending on the mechanism of creep, G is the shear modulus, σ is the stress involved, T is the temperature, b is the Burger vector, and k is the Boltzmann constant.

The dependence of the normalized steady-state stress (s) on the normalized strain rate ($\dot{\varepsilon}$) for deformation in the temperature range of 600–850 °C for material with fine α (0.1 mm) or coarse α (1 mm) grains is shown in **Figure 14**.[21] The α-Ti alloys were previously classified as CP Ti, α alloys, and near-α alloys. It is important to emphasize that for CP and α alloys, hot deformation below the β transus occurs in the α-phase field. However, for near α alloys, sub-transus hot deformation takes place in the $\alpha + \beta$-phase field.

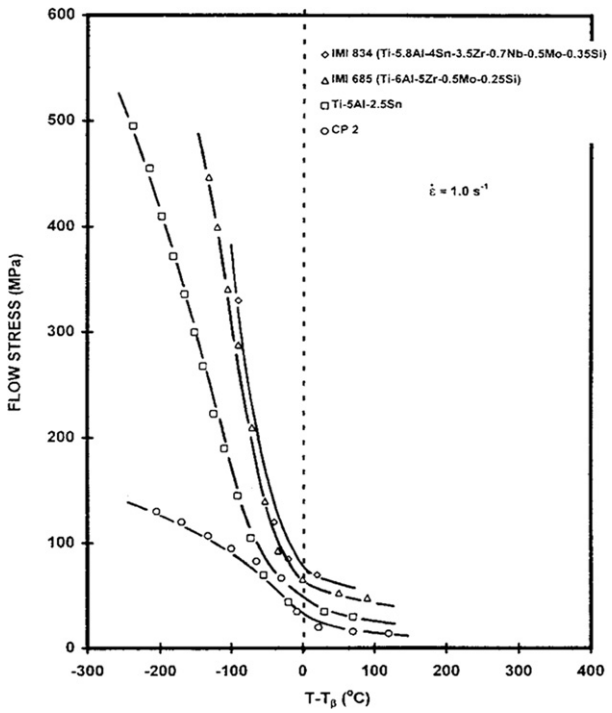

Figure 12 Flow stress of various α and near α-Ti alloys as a function of T–T_β at a strain rate of 1 s^{-1}.[14]

Typical microstructures after hot deformation are shown in Figure 15[11,13] for CP Ti grade 2 and IMI 685 alloys, respectively. The elongated grains observed in Figure 15 are the result of deformation of alloy with an initially equiaxed microstructure at 800 °C and a strain rate of 0.1 s^{-1} to a strain of approximately 0.7.[13] Similarly, the IMI 685 alloy with an initially acicular microstructure deformed at 975 °C, and a strain rate of 10^{-3} s^{-1} to a strain of approximately 0.5 also developed an elongated α grain structure containing the lamellar and equiaxed α phase morphology shown in Figure 16.[11] The α-Ti alloys deformed by slip on basal and prismatic planes give rise to sub-grain structures, which are less recovered than those found in β-Ti alloys.[14] For example, Figures 17 and 18

show the dislocation substructures in CP Ti[13] and IMI 685[11] alloys, respectively. Sub-grain formation is more pronounced in the α phase of IMI 685.

The control of microstructure and deformation uniformity is of great importance in optimizing final mechanical properties. The selection of process parameters such as deformation temperature, strain rate, and deformation rate to avoid

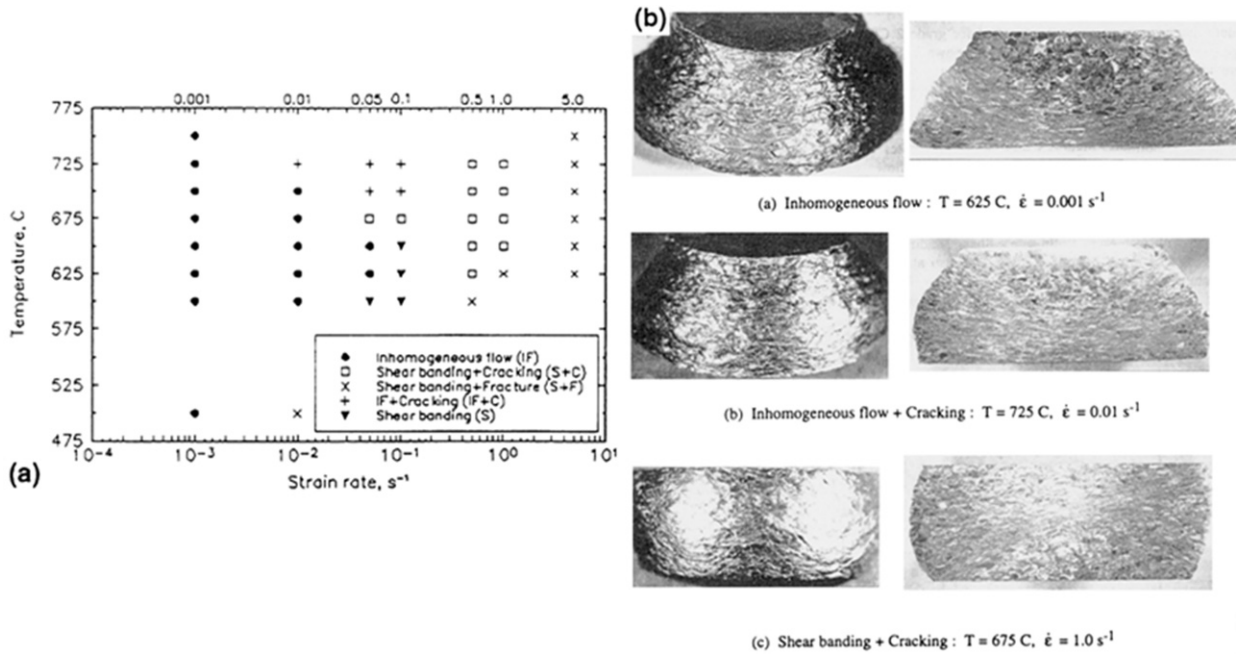

Figure 19 (a) Processing map and (b) corresponding macrographs of the cylindrical surface and the macro-etched longitudinal section of the hot compression samples used to establish the processing map for CP Ti grade 2 magnification of 4.[22]

nonuniform microstructure, strain localization, and failure may be aided by the utilization of processing maps shown in Figure 19.[22] The development of this processing map for α-Ti alloys was based on the appearance of deformed compression samples and the identification of temperature and strain rate conditions that lead to macroscopically uniform deformation. Different deformation modes are identified, including inhomogeneous flow, shear banding, and cracking (Figure 19(b)), which can lead to material failure. The corresponding map for CP Ti grade 2 (Figure 19(a)) delineates these failure modes and identifies those processing parameters that result in uniform deformation. In addition to deformation temperature, strain rate, and total strain, the material starting microstructure can have an important effect on flow stability, workability, and failure.[23] For example, CP Ti grade 2 (0.12 w% O, 0.03 w% Fe) with an acicular starting microstructure exhibits high flow stresses and flow softening during high-temperature deformation (Figure 20).[24] However, CP Ti grade 3 (0.28 w% O, 0.2 w% Fe) with an equiaxed starting microstructure shows lower flow stresses and work hardening during deformation (Figure 20). When CP Ti grade 3 with an equiaxed microstructure is heat-treated to produce a Widmanstätten microstructure, the flow stress increases and slight flow softening is detected (Figure 20).

The near-α alloy IMI 834 was developed to meet the need for a material with a good blend of fatigue and creep properties that could be processed readily.[25–27] This property combination is obtained by α–β processing to produce a microstructure of 7.5–15% equiaxed α in a matrix of transformed β. The small amount of α pins the β-grain boundaries during hot working or heat treatment in the higher region of α + β-phase field. This yields a fine β-grain structure that minimizes the loss of fatigue properties in the presence of a colony of Widmanstätten α microstructures desirable for creep

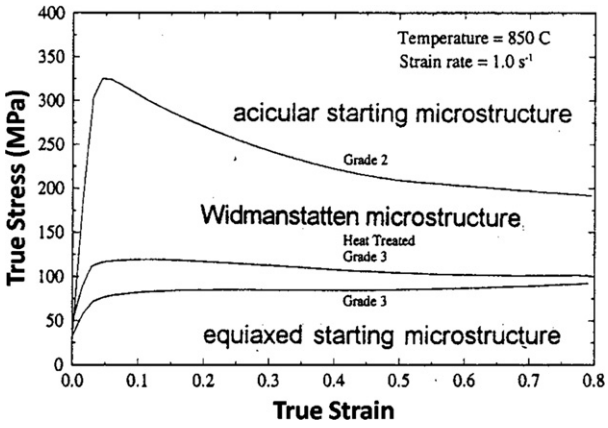

Figure 20 Flow curves of grade 2, grade 3, and heat-treated grade 3 CP Ti at 850 °C and 1 s^{-1}.[24]

performance. Unlike other near-α alloy, IMI 834 has a shallow β-approach curve (Figure 21),[26] an attribute that enhances the ability to control the volume fraction of α near the β transus under typical production conditions. Such a β-approach curve is obtained through an intentional carbon addition to the alloy; the carbon also provides an increase in strength, much like oxygen.

When the alloy is heated to the β-phase field, then different microstructures are obtained depending on the cooling rate. Quenching from the β-phase field produces laths of the martensitic α′ phase, which are delineated by thin films of β phase. Normalizing from the β-phase field gives rise to a 'basket-weave' structure of Widmanstätten α phase delineated by β phase. Aging causes precipitation hardening by precipitation of the α-phase dispersion. Flow curves of CP Ti grade 2,[9] Ti–5Al–2.5Sn,[10] Ti–6Al–5Zr–0.5Mo–0.25Si (IMI 685),[11] and IMI

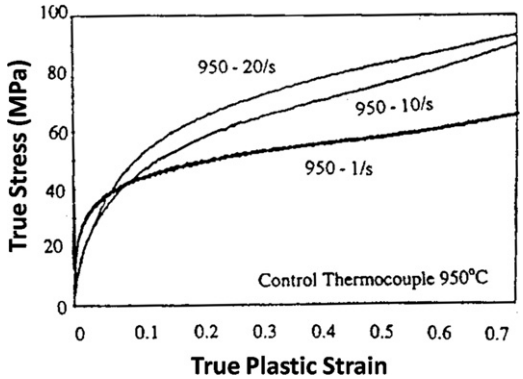

Figure 22 Flow curves for CP Ti grade 2 measured above the β-transus temperature.[9]

834[12] at super-transus temperatures are shown in Figures 22–25, respectively. After yielding, a substantial amount of work hardening is observed, especially for CP Ti. The work-hardening period is followed by steady-state flow at high strains, particularly for high-temperature and low-strain rate conditions. The deformation in the β-phase field is typical of

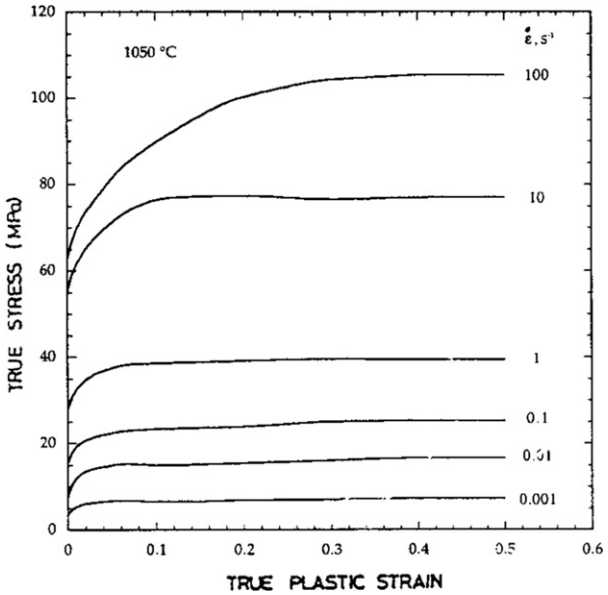

Figure 23 Flow curves for Ti–5Al–2.5Sn measured above the β-transus temperature.[10]

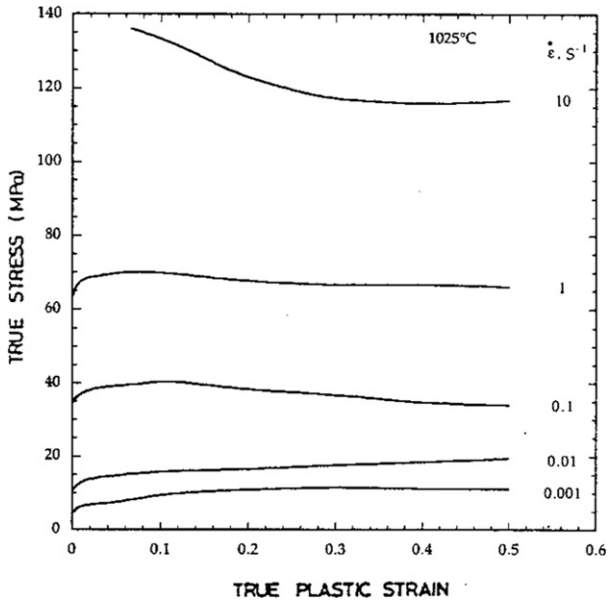

Figure 24 Flow curves for IMI 685 measured above the β-transus temperature.[11]

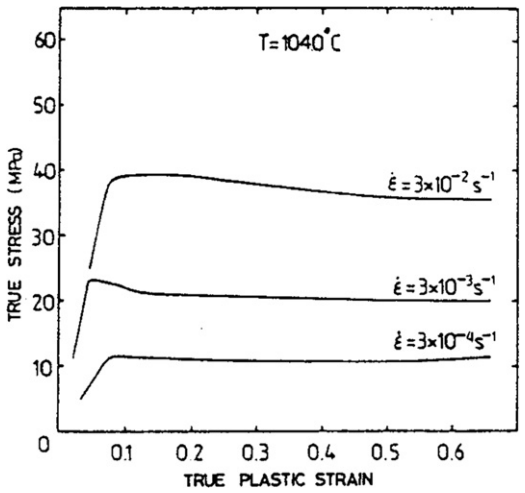

Figure 25 Flow curves for IMI 834 at 1040 °C.[12]

that in material undergoing dynamic recovery, which gives rise to well-developed sub-grains. Under some conditions, flow softening is also observed (**Figures 24** and **25**). Although the bulk of the flow softening observed at high strain rates probably results from deformation heating, some of it may also be ascribed to texture softening of the β phase.

The high-temperature steady-state deformation behavior of CP Ti in the β-phase field can also be represented by the generalized Dorn equation, as given in eqn [1] in Section 2.11.5.1.2,[15] as long as the temperature dependence of the shear modulus is taken into account (**Figure 26**).[21] At high temperatures ($T>0.6T_M$), plastic deformation can be rationalized in a similar way that creep deformation is analyzed, especially in the deformation range where power law creep is operating. At very high temperatures above $0.8T_M$, dynamic recrystallization has also been observed to occur, resulting in

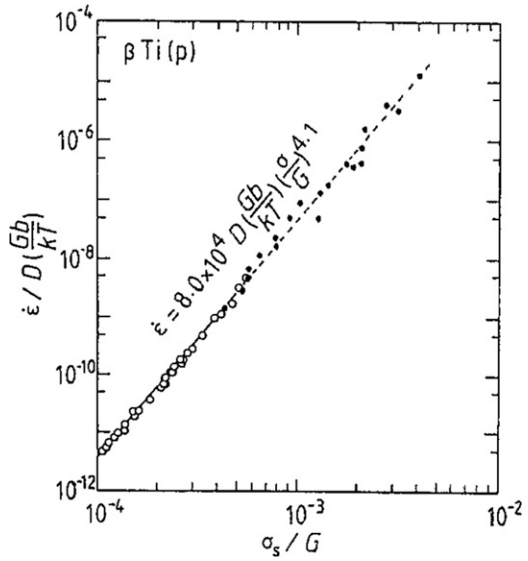

Figure 26 Relationship between the normalized steady-state stress and the normalized strain rate of CP Ti.[21]

the formation of recrystallized grains along the deformed β-grain boundaries (**Figure 27**).[28] Hot deformation in the β-phase field yields apparent activation energy in the range of 180–220 kJ mol^{-1}, which is close to the activation energy for self-diffusion in β Ti (i.e., 153 kJ mol^{-1}).[19,29]

A variation of Ti–6Al–2Sn–4Zr–2Mo–0.1Si, Ti-1100 (Ti–6Al–2.75Sn–4Zr–0.4Mo–0.45Si) is an alloy designed to provide enhanced creep resistance to a temperature of approximately 600 °C. This is accomplished through alloying (increased silicon and thus silicides) and thermomechanical processing in the β-phase field to produce a colony of Widmanstätten α microstructure on cooling. The alloy has a β-transus temperature close to 1015 °C and silicide solvus at 1040 °C. Previous work[30,31] has shown that the creep resistance and post-creep ductility of Ti-1100 were not too sensitive to β-forging temperature and cooling rate following forging, provided that forging was performed above the silicide solvus. In addition, β-forging plus direct stabilization aging provided better post-creep ductility than β-forging plus β-annealing plus aging. Subsequent efforts[32] have shown that fan cooling or oil quenching following β-forging may be required to obtain optimal properties in thick-section forgings. Most recently, it has also been found that sub-transus hot working of Ti-1100 followed by solution heat treatment at temperatures between the β transus and silicide solvus may provide the optimal combination of strength, creep, and fatigue properties.[33] In this processing route, the presence of silicides during β-solution heat treatment restricts β-grain growth and therefore minimizes the concomitant loss of strength, ductility, and high cycle fatigue properties associated with the development of coarse β grains during thermomechanical processing above the silicide solvus.

There are two typical annealing treatments for the near α-Ti alloys: (1) mill annealing and (2) duplex annealing. Mill annealing is a general purpose treatment given to all mill products. It is not a full anneal and can leave traces of cold or warm working in the microstructure of heavily worked

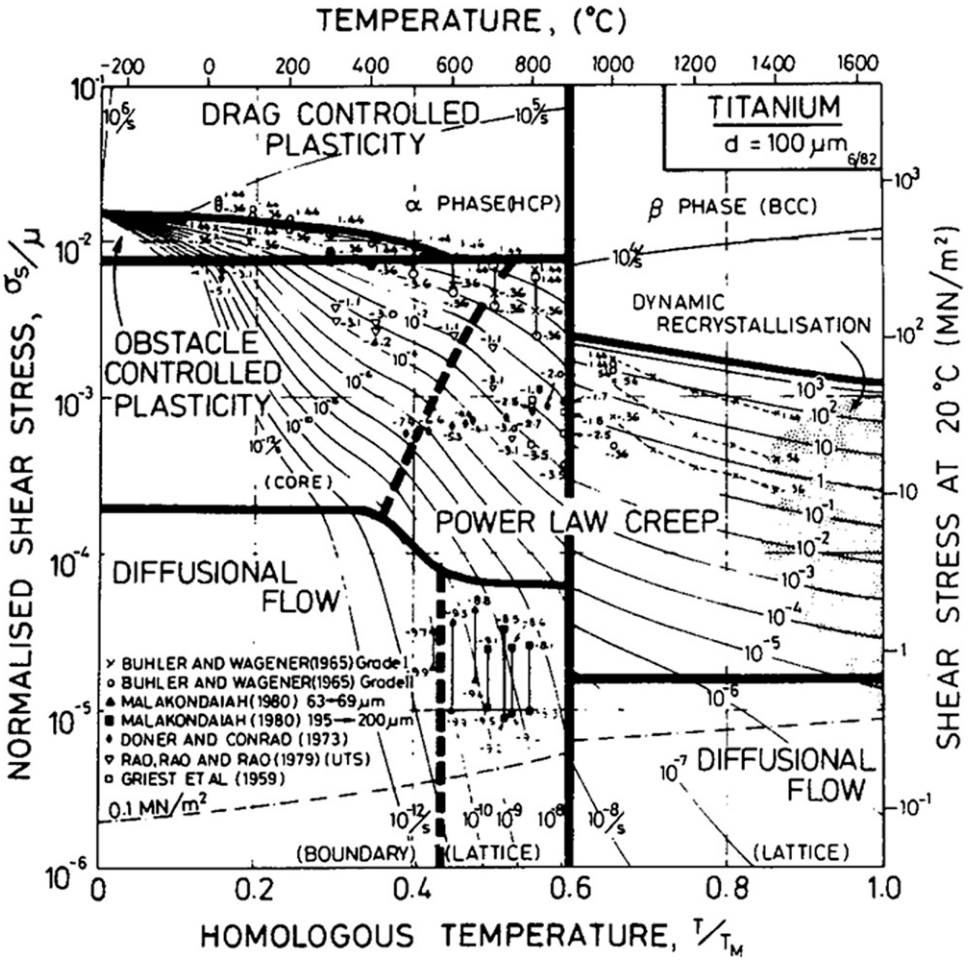

Figure 27 A stress–temperature map for Ti with grain size of 100 mm.[28]

products (particularly sheet). Duplex annealing is an example of the multiple annealing processes that sometimes are specified. This modifies the shapes, sizes, and distributions of phases as required for improved creep resistance and/or fracture toughness. For example, in the duplex annealing of the Corona 5 alloy, the first anneal is near the β transus to globularize the deformed α and to minimize its volume fraction, followed by a second lower-temperature annealing to precipitate new lenticular (acicular) α between the globular α particles. This formation of acicular α is associated with improvements in creep strength and fracture toughness.[6]

2.11.5.2 Heat Treatment in α/β-Ti Alloys

In α/β-Ti alloys, heat treatment can be achieved with incorporation of thermomechanical processes to achieve the desired microstructure and hence, desired properties. These alloys can be strengthened by a series of heat treatment, solution treatment and aging (STA). Ti–6Al–4V, the most popular α/β alloy, is not an exception, and its tensile strength level is raised from 900–1000 MPa in the annealed state to 1100–1200 MPa.[34] Ti–Al–Fe-based α/β alloys such as Ti–5Al–2.5Fe,[35] TIMETAL 62S,[36] and Ti–5.5Al–1Fe,[37] all of which have been developed in the past 15 years, have also been subjected to STA[35,38] in an attempt to increase the strength level. Ti–5.5Al–1Fe has been developed as a low-cost substitute for Ti–6Al–4V[33,34] and has almost the same strength level, β-transus, and M_s temperature as Ti–6Al–4V. The phase transformation of this alloy during STA was examined and compared to that of Ti–6Al–4V.

The STA process is more effective for alloys with an equiaxed microstructure than those with the Widmanstätten structure because strengthening by STA is accompanied by a decrease of ductility, and an equiaxed microstructure exhibits sufficiently higher ductility, unlike Widmanstätten structure. In this respect, near-net shape (NNS) products manufactured by powder metallurgy or casting are not always effectively strengthened by STA because they usually have the Widmanstätten structure. For NNS products, thermochemical processing, in which hydrogen is used as a temporary alloying element, is considered to be effective for the improvement of mechanical properties through microstructural refinement.[39] However, this process generally involves a large amount of hydrogen, and thus hydrogen embrittlement results in the increase of the production cost, which may be one of the reasons hampering its application on an industrial scale. Thus, a new and less costly thermochemical process is introduced based on the previous work[40] on the phase transformation of the hydrogen-added Ti–6Al–4V.

For Ti–6Al–4V, solution treatment at 955 °C followed by water quenching and aging at 538 °C for 4–8 h is used as the standard STA condition.[34] On quenching from the solution treatment temperature, almost all of the β-phase transforms to the α' lath martensite or the fine lath α plates.[34,41] Aging stabilizes those phases to the stable fine acicular α/β structure.[34] For Ti–5.5Al–1Fe, the best relationship between strength and ductility can be obtained by solution treatment at 940 °C, followed by water quenching and aging at 500 °C for 4–8 h.[38]

Tensile properties are shown in Figure 28.[42] The 0.2% proof stress of the as-solution treated alloys was lower than that of the annealed one. However, by following aging at 500 °C for 4–8 h, 0.2% proof stress and tensile strength increased by approximately 100 MPa and 50 MPa, respectively. Aging for 8 h or longer led to overaging, resulting in the decrease of strength level.

The evolution of the phases after different heat treatment schedules is presented in Figure 29.[42] Peaks corresponding to α and β phases appear in the specimen after annealing. In the solution-treated specimen, the diffracted X-ray intensity of the β phase was decreased, whereas the intensity was increased at both sides of the (110) β peak, which corresponds to the (020) and (111) planes of orthorhombic α'' martensite. In fact, the α'' phase was confirmed by transmission electron microscopy (TEM) analyses as shown (Figure 30).[42] Aging at 500 °C for 4 h reduced the intensity of the β phase. Although a clear (110) β peak did not appear, a small amount of the β phase was detected by TEM (Figure 31).[42] The intensity of the β phase was further reduced in the specimen aged at 500 °C for 8 h, whereas there was a strong peak corresponding to FeTi compound in place of the β.

Figure 30 shows the microstructures of the solution-treated specimen. The transformed β phase is composed of the fine acicular α'' martensite (orthorhombic) and the retained β phase (bcc). The microstructures of the aged specimen are shown in Figure 31. It is noticeable that there are two kinds of transformed

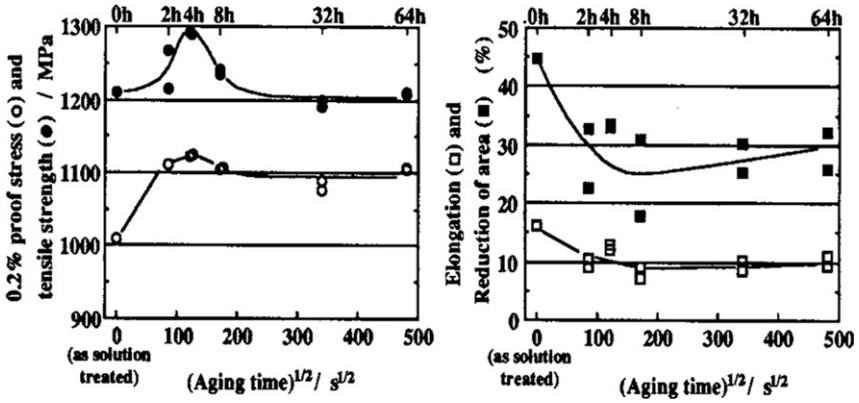

Figure 28 Tensile properties of Ti–5.5Al–1Fe solution treated at 940 °C followed by water quenching and aged at 500 °C for 2–64 h.[42]

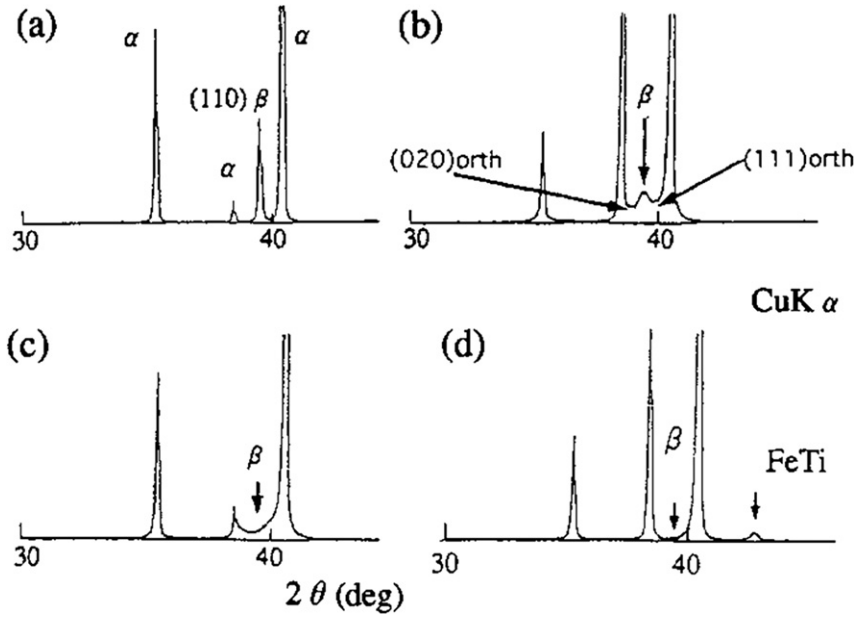

Figure 29 X-ray diffraction analyses for the specimens (a) annealed at 750 °C for 1 h, (b) solution-treated at 940 °C followed by water quenching, plus (c) aged at 500 °C for 4 h, and (d) aged at 500 °C for 8 h.[42]

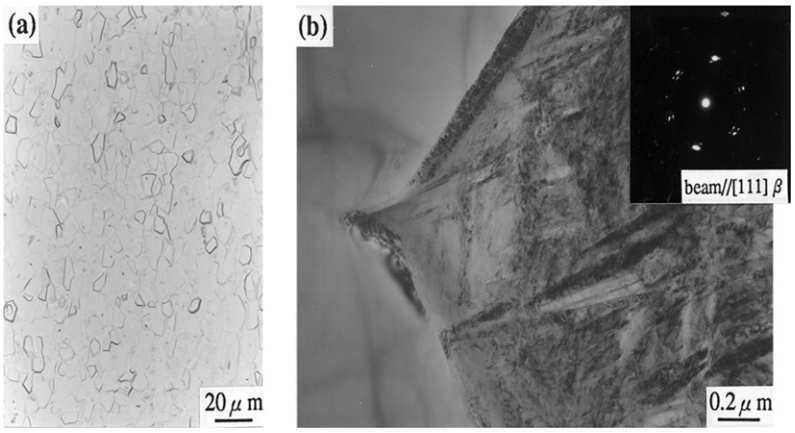

Figure 30 (a) Optical and (b) transmission electron microscopy microstructures of the solution-treated specimen.[42]

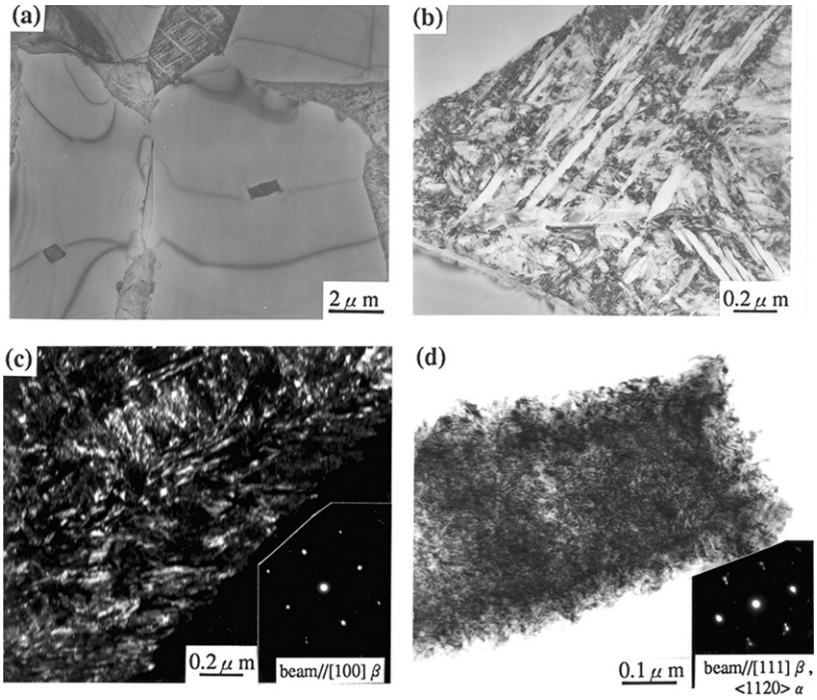

Figure 31 Transmission electron microscopy microstructures of the solution-treated specimen: (a) transformed β phase, which is located between the α grains; (b) transformed β phase, which is located between the fine acicular α phase; (c) the dark field image of the β phase in the transformed β phase in Figure 31(a); and (d) the fine α precipitation in the isolated β phase in the α grain.[42]

β phases. One is the commonly observed transformed β phase, which is located between the α grains (Figure 31(a)), in which a small amount of the β phase is contained as shown in the dark field image (Figure 31(c)) as well as the fine acicular α phase (Figure 31(b)) with similar morphology and size to those of the α'' in the as-solution treated specimen. The other is the isolated β phase existing inside the α grains, in which much finer α particles exist (Figure 31(d)).

The main transformation route that contributes to strengthening is the same in both Ti–6Al–4V and Ti–5.5Al–1Fe, that is, the formation of fine transformation products in the transformed β phase during quenching from the solution treatment temperature and the stabilization of the same, which includes the tempering process. However, there exist few differences between the two alloys.

- First is the morphological difference of the transformation products in the solution-treated alloys; the lath type of the α' or α plates in Ti–6Al–4V and the acicular α'' in Ti–5.5Al–1Fe. The formation of the lath plates is accompanied by the diffusion of the alloying elements and the acicular α'' is formed by complete diffusionless transformation. This indicates that the hardenability of the β phase at the solution treatment temperatures is higher in the Ti–5.5Al–1Fe.

- Second is the larger amount of the retained β phase in the solution-treated Ti–5.5Al–1Fe, which is shown by the relatively strong intensity peak of the diffracted X-ray from (110) β (Figure 29) and a TEM micrograph (Figure 30(b)). This is probably the cause of lower 0.2% proof stress in the solution-treated specimen as a result of the deformation-induced martensite transformation.
- Third is the drastic decrease of the β phase in Ti–5.5Al–1Fe during aging, as shown in Figure 29. The fine martensite is probably converted to the α phase or acts as a nucleation site for the α phase, followed by growth during aging. Although Ti–5.5Al–1Fe is basically an α/β alloy, the aged alloy is liken the α type, which mostly consists of the α phase.
- Fourth is the FeTi formation when the solution-treated alloy is aged at 500 °C for more than 32 h. Although conspicuous deterioration is not detected in tensile properties, unnecessarily longer aging times should be avoided from the viewpoints of fatigue properties and corrosion resistance. The FeTi formation is reportedly very sluggish, and it takes 500–1000 h of exposure at approximately 500 °C in a binary Ti–Fe system.[43] However, the addition of the α stabilizer seems to accelerate it. The faster FeTi formation is also reported in the annealed alloy when exposed at 450 °C for 64 h or longer[37,38] and in Ti–Fe–O–N systems.[43]
- Fifth is the isolated β phase inside the α grains. Such morphology is not seen in Ti–6Al–4V, and it may be a feature of Ti–Fe-based alloys. The fine α particles in this β are probably the trace of the ω phase, which precipitates prior to the α formation at the early stage of aging because they are quite similar to the previously observed ones as a result of the direct transformation from the ω particles.[44] The composition of this Fe-enriched β phase is considered to be in the compositional range in which the ω phase easily forms.

Kerr[45] reported that the addition of more than 0.5 (mass %) hydrogen to Ti–6Al–4V generates the hydride phase below the eutectoid temperature. The author has also confirmed that the three-phase region containing α, β, and hydride does not appear in Ti–6Al–4V with 0.4 (mass %) hydrogen even at temperatures lower than 500 °C.[40] Figure 32[40] is the continuous cooling transformation (CCT) diagram of Ti–6Al–4V + 0.4H (mass %).[40] The β transus is 780 °C and the α'' martensite forms at 480 °C (M_s temperature) when the alloy is cooled at cooling rates higher than 30 °C s^{-1}.[40] The martensite phase is quite large in this case and does not contribute to the microstructural refinement. When the alloys are cooled at cooling rates lower than 0.3 °C s^{-1}, the coarse grain boundary α and the sideplate α phase form.[40] Meanwhile, at the intermediate cooling rates from 0.3 to 30 °C s^{-1}, the extremely fine α precipitation occurs in the β grains and the grain boundary α phase rarely appears.[40]

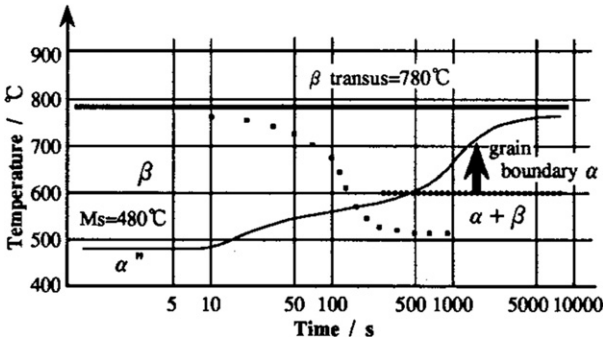

Figure 32 Continuous cooling transformation diagram of Ti–6Al–4V + 0.4 mass % H.[40]

Figure 33[42] shows the microstructural changes that occur during the process. The initial coarse microstructure containing the grain boundary α phase (Figure 33(a)) was converted, by hydrogenation, solution treatment and direct aging, to such a fine microstructure that each α phase could not be distinguished in the optical micrograph (Figure 33(b)) and the fine acicular configuration was made clear by TEM (Figure 33(c)). Another microstructural feature in this specimen is that there is absence of α phase on the grain boundary. No distinct difference was observed between the specimens aged for 1 and 6 h. The microstructure was slightly coarsened and the grain boundary α phase reappeared on a few former β grain boundaries during dehydrogenation at 750 °C for 10 h (Figures 33(d) and 33(e)). However, it is still fine compared with the initial one and no grain boundary α phase was recognized on most of the former β grain boundaries. Mechanical properties of the material aged for 6 h and dehydrogenated are shown in Table 1[46] along with those of the specimens manufactured by the blended elemental powder metallurgy (BE/PM), which generally have a coarse Widmanstätten structure.[46] Tensile strength and fatigue strength were approximately 70 and 90 MPa, respectively, higher in the material processed by the new method, although fatigue strength seems to be lower than that by the conventional process that utilizes hydride.

The α phase is generally coarser in α/β alloys than in β alloys because the precipitation occurs at higher temperature just below the β transus in α/β alloys, whereas the precipitation at lower temperatures is possible in β alloys. In the new process, the α/β alloy is converted to a β alloy temporarily by hydrogen addition and the devised heat treatment pattern to attain the fine α precipitation. The addition of hydrogen lowers the M_s temperature and increases hardenability. However, the amount of hydrogen is not sufficient to lower the M_s temperature below room temperature in Ti–6Al–4V with 0.4 (mass %) hydrogen and to convert the alloy to α/β alloy. Therefore, the heat treatment pattern that consists of solution treatment, relatively rapid cooling to the aging temperature, and direct aging is required in this process. In fact, the aged microstructure shown in Figure 33(c) is quite similar to that of β alloy.[47] Coarsening and reappearance of the grain boundary α phase on a few former β grain boundaries during dehydrogenation may be improved by dehydrogenation at lower temperatures, whereby more improvement of mechanical properties is expected. A few processes that were conducted by Kerr[45] (0.43 and 0.46 mass % hydrogen, solution-treated at 870 °C, followed by air cooling and directly aged at 540 °C for 2 h) are probably the same as the present one, although the exact cooling rate from the solution treatment temperature and the aged microstructure are not shown in their study.

The major advantages of this process are considered to be as follows:

1. The total amount of hydrogen used is low and the time needed for hydrogenation is short compared to the conventional method.

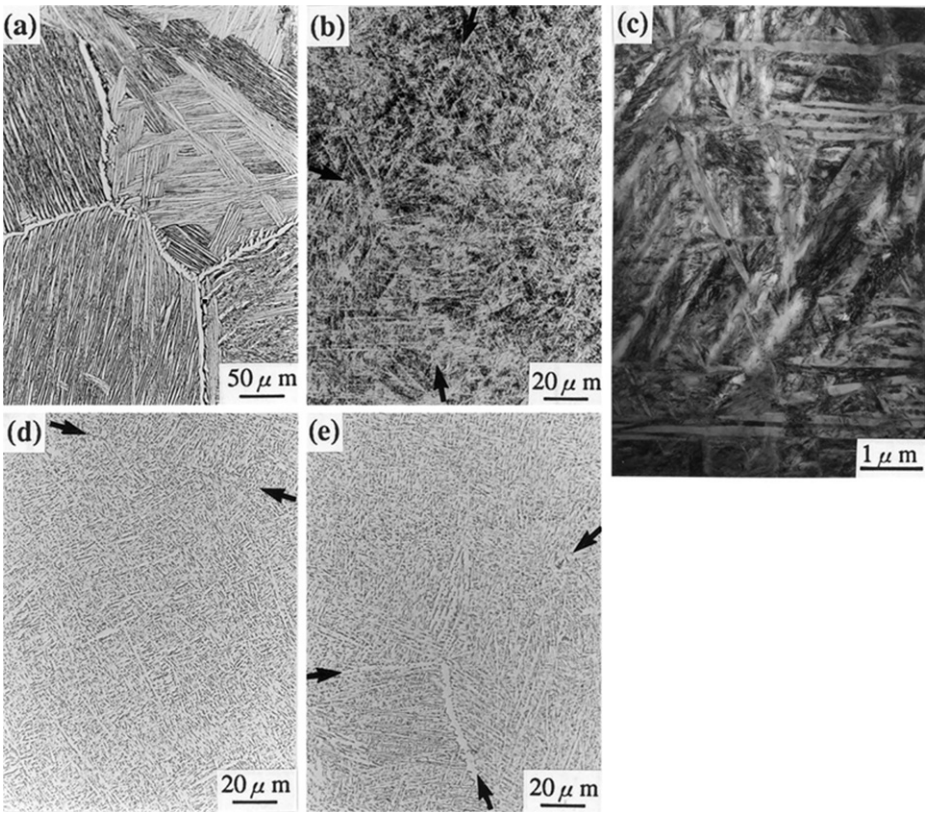

Figure 33 Change of the microstructures during the thermochemical process. (a) Starting microstructure (β-annealed), (b) and (c) 0.4% hydrogenated, solution-treated and directly aged at 500 °C for 1 h, respectively, (d) and (e) plus dehydrogenated at 750 °C for 10 h in vacuum, and (c) is a transmission electron microscopy micrograph. Arrows indicate the former β grain boundaries.[42]

Table 1 Mechanical properties of the materials processed by the new process of the thermochemical process (TCP) and by blended elemental powder metallurgy (BE/PM)[46]

	0.2% Proof stress (MPa)	*Tensile strength (MPa)*	*Elongation (%)*	*Reduction of area (%)*	*Fatigue strength[a] (MPa)*
TCP	952	1042	12.5	21.4	490
BE/PM[b]	862	969	15.1	36.9	392

[a]Rotational bending (R = −1) at 10^7.
[b]Oxygen content is 0.15 mass %, HIPed.

2. Extremely brittle hydride is not needed throughout the process and the handling of intermediate products is much easier.

Both advantages lead to cost reduction. However, fatigue strength is not as high as that by the conventional method at present.

The heat treatment of the α/β-Ti alloys can also be categorized depending on whether it was heated to the $\alpha+\beta$-phase field or to the β-phase field. Depending on the cooling rate, different microstructures can be obtained.

2.11.5.2.1 Annealing

Annealing from the $\alpha+\beta$-phase field produces microstructures approaching equilibrium equiaxed hcp α phase surrounded by the retained β phase.

Annealing from the β-phase field causes a transformation from the β to α microstructure containing the lamellar microstructure of a similar crystal orientation.

2.11.5.2.2 Normalizing

Normalizing from the $\alpha+\beta$-phase field provides equiaxed primary hcp α phase in a matrix of the transformed acicular β phase.

Normalizing from the β-phase field produces fine acicular α, which is transformed from the β phase by nucleation and growth.

2.11.5.2.3 Quenching

When the alloy is quenched from a region, which is below the β transus but above the martensitic start temperature (M_s), the

microstructure obtained consists of the primary α phase embedded in the transformed β phase (α′ martensite).

But when the alloy is quenched from a region that is below the M_s yet above the α transus, then the microstructure obtained consists of the primary α phase and a small amount of retained (untransformed) β phase.

2.11.5.2.4 Tempering

When a quenched alloy is subjected to subsequent elevated temperature treatments, the martensitic microstructure decomposes depending on the martensitic crystal structure and alloy composition. The reactions may be complex and the various types are shown here. These reactions lead to a wide range of microstructures. In the β-isomorphous alloys, α′ decomposes directly to α of equilibrium composition at the tempering temperature and β forms as a fine precipitate, nucleating heterogeneously either at martensite plate boundaries or at internal substructures such as twins. In β-eutectoid alloys, α′ may decompose directly into the α-phase and an intermetallic compound formed in several stages. However, in systems such as Ti–Mn, where the normal eutectoid reaction is sluggish, the martensite tempers first by forming α with precipitates of β, with the intermetallic compound appearing slowly at a later stage.

Tempering of α″ martensite may occur by two mechanisms:

- In alloy compositions in which M_s (α″) occurs at a relatively high temperature, α″ decomposes first by the formation of a fine and uniformly dispersed α-phase in the α″ matrix. Further aging causes both the coarsening of these particles and the nucleation of a cellular reaction at the prior β-grain boundaries, leading to the growth of a lamellar structure of α + β. Growth of these lamellar cells then occurs at the expense of the other regions.
- In alloys with an M_s (α″) temperature near room temperature, the α″ reverts to the β phase, which then decomposes by a mechanism that is characteristic of the particular tempering temperature. Decomposition of the β-phase is discussed in Section 2.11.5.2.5.

α′ Martensite		
β-Isomorphous alloys		$\alpha' \rightarrow \alpha + \beta$
β-Eutectoid alloys	Alloys with slow eutectoid reactions, for example, Ti–Mn	$\alpha' \rightarrow \alpha + \beta \rightarrow \alpha +$ Compound
	Alloys with fast eutectoid reactions, for example, Ti–Cu	$\alpha' \rightarrow \alpha +$ Compound (may form in several stages)
α″ Martensite		
	Alloys with high M_s(α″) temperature	$\alpha'' \rightarrow \alpha'' + \alpha \rightarrow \alpha'' + \alpha + (\alpha + \beta) \rightarrow \alpha + \beta$
	Alloys with low M_s(α″) temperature	$\alpha'' \rightarrow \beta \rightarrow$ Products

2.11.5.2.5 Decomposition of metastable β

The retained β obtained after quenching decomposes when subjected to aging at elevated temperatures, inducing high-tensile strength in the alloy. The metastable β phase is transformed into equilibrium α phase at high aging temperatures due to difficulty in nucleating hcp α phase on the bcc β matrix. Three types of reactions are possible during the decomposition.

2.11.5.2.5.1 Formation of ω phase

The ω phase induces high strength, but it also causes embrittlement. This phase appears as fine dispersion particles after metastable β is isothermally aged at 100–500 °C. This phase can be avoided by controlling the aging conditions, temperature, and composition of the alloy.

2.11.5.2.5.2 Separation of β phase

The β phase may be separated into two bcc phases: $\beta \rightarrow \beta_{(enriched)} + \beta_{1(depleted)}$. This reaction occurs in high-β stabilizer-containing alloy and prevents formation of the ω phase. With time, this β phase slowly transforms into the equilibrium α phase.

2.11.5.2.5.3 Formation of equilibrium α phase

Equilibrium α phase can form directly from the β phase or indirectly from the ω or the β_1 phase.

2.11.5.2.6 A case study on the effect of thermal treatment on an α/β-Ti alloy

A case study of the failure analysis and optimization of thermo-mechanical process parameters of titanium alloy (Ti–6Al–4V) fasteners for aerospace applications is presented here.[48] Ti–6Al–4V is currently the most useful of all the titanium alloys used in aerospace applications because of their high strength-to-weight ratio, good corrosion resistance, excellent fracture toughness, and other attractive mechanical properties. It contains Al as the α-phase stabilizer and V as the β-phase stabilizer at room temperature. Depending on the chemical composition, processing history, and thermal treatment procedures, the alloy shows different microstructures and properties. The objective of the presented study was to perform metallurgical analysis of the failed bolt, fractography study to find out the root cause of the failure, and optimization of processing (i.e., thermal treatment) parameters for fastener manufacturing.

2.11.5.2.6.1 Composition of the alloy

The chemical composition of the alloy studied is given in **Table 2**.

2.11.5.2.6.2 Process of manufacture

The input rod with a 9.0-mm diameter was processed by hot rolling at 955 °C, followed by annealing at 700 °C for 1 h with air cooling. The rods were further reduced to 5.6 mm in diameter by hot swaging. Finally, centerless grinding was applied to achieve a diameter of 4.5 mm.

The rods were head-forged by flame-heating the head portion of feed stock, followed by swagging on the dies. The head-forged feed stock was solution-treated at 940 ± 10 °C

Table 2 Chemical composition of Ti–6Al–4V (by % weight)[48]

Alloy	*C*	*Al*	*V*	*Fe*	*O*	*N*	*H*	*Ti*
Ti–6Al–4V	0.01	6.28	4.03	0.03	0.169	0.008	0.006	Balance

Table 3 Mechanical properties in annealed and solution treatment and aging (STA) condition[48]

Heat treatment condition	*Yield strength (MPa)*	*Ultimate tensile strength (MPa)*	*% Elongation*
Annealed	950	1069	16
STA	1143	1240	15

with a soaking period of 45 min, followed by water quenching. Further, aging was performed at $535 \pm 10\ ^{\circ}C$ for 5 h with air cooling. The socket head was punched by cold working. Threads were processed on the heat-treated head-forged feed stock by thread rolling.

2.11.5.2.6.3 Observations

2.11.5.2.6.3.1 Clearance criteria followed for the fastener material (observations of the input material)

2.11.5.2.6.3.1.1 Mechanical properties

The details of mechanical properties of the input feedstock material in annealed and STA conditions are illustrated in **Table 3**.

2.11.5.2.6.3.1.2 Metallurgical analysis

Metallurgical analysis was performed using light microscopy. The specimens were prepared by grinding with 1000 grit SIC paper and fine polishing with 1 mm diamond paste, followed by etching with kroll (10 ml $HF + 30$ ml HNO_3) reagent in annealed condition.

2.11.5.2.6.3.1.3 Acceptance test on the fasteners

1. Mechanical test on the fasteners was conducted and withstood a specified load of 9.6 kN, further allowing testing up to the breaking load of 10.43 kN.
2. Torque test was conducted at 3.0 N m for five cycles and was found to be satisfactory.
3. Metallurgical analysis was performed on the finished fastener. The β structure in the head portion and $\alpha + \beta$ structure in the shank portion of the fastener in were revealed in the STA condition.
4. Another 100% dimensional inspection was performed as per NFL22-220 with acceptance criteria of 6 g.

2.11.5.2.6.3.2 Observations on failed bolt

To qualify as a bolt for flight assembly, the bolt assembly must have undergone proof pressure testing at 2.4 MPa, vibration testing at a frequency range of 20–100 Hz at ± 3 dB oct^{-1} for 120 s in both lateral and longitudinal directions, and flight acceptance testing. During routine visual inspection before electrical check, it was observed in one of the three fasteners that the head of the bolt had gotten sheared off the shank portion of the bolt. Further, a failure analysis was performed on the failed bolt.

Figure 34 Good fasteners.[48]

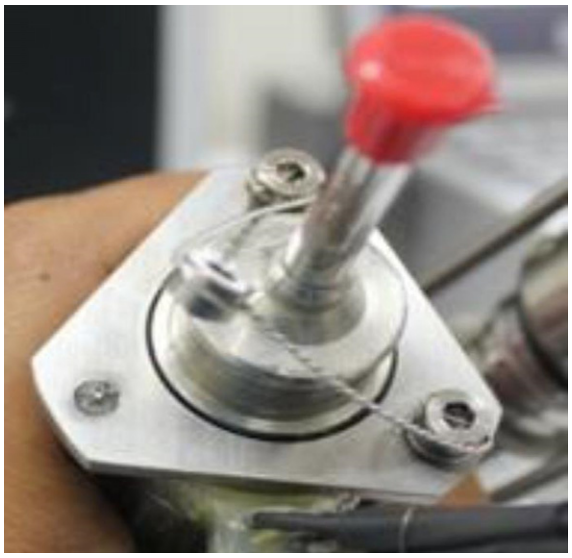

Figure 35 Assembly of the bolt.[48]

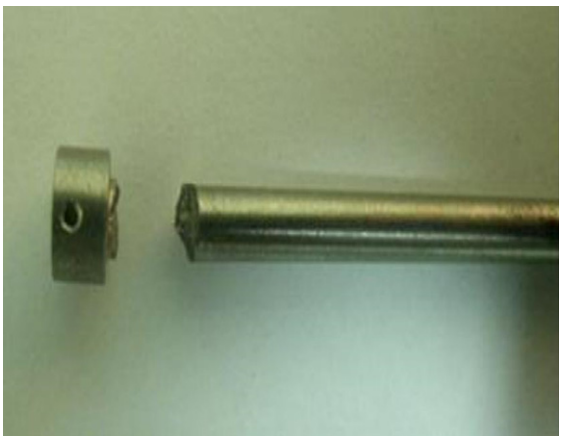

Figure 36 Fracture portion of the bolt.[48]

2.11.5.2.6.3.2.1 Visual inspection

The used bolt had a 25-mm-long thread portion and a 75-mm plain shank portion, as shown in **Figure 34**. It had a bolt assembly with valve housing, as shown in **Figure 35**. Failure occurred at the head–shank junction (**Figures 36** and **37**).

Figure 37 Head region.[48]

Figure 39 Crack at head region.[48]

Figure 38 Hole pierced in the head.[48]

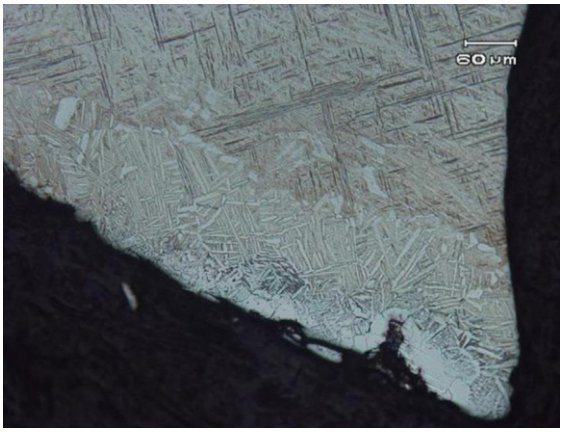

Figure 40 Edge of the failure zone.[48]

Further, stereo zoom microscopic analysis of the crack portion of the head and shank portion was performed. It was observed that a hole was pierced into the shank, as shown in **Figure 38**. Dye penetration test performed on the fresh bolts as per ASTM E165 detected the presence of circumferential cracks at the bottom of the head and some cracks extending to the shank side.

2.11.5.2.6.3.2.2 Metallurgical analysis

The head portion, failure zone, and shank portion of the bolt were subjected to metallurgical analysis. In the head portion, a crack was observed adjacent to one corner of bolt. The micrographs revealed a fine lamellar structure with β grains at the head portion but coarse lamellar with β grains at the portion adjacent to crack region (**Figures 39–42**). It is evident from **Figure 43** that in the shank portion of the failure zone, a crack branched from the cracked region. Microstructure (**Figure 44**) of the same revealed a coarse lamellar structure near the crack region and fine lamellar structure slightly away from the failure zone.

Microstructures of the shank portion of the bolt, as shown in **Figures 45** and **46**, revealed the grain boundary α-phase at prior β-grain boundaries and the martensitic α-structure, respectively. Fractography of the fracture surface of the failed bolt under scanning electron microscope (SCM) indicated a shift in the socket head hole from the center along with machining marks of a pierced hole of the socket head into the shank (**Figures 47** and **48**). At the head location, the nucleation of cracks started at the notch zone and further propagated to the outer periphery, as shown in **Figure 49**. At the shank portion, cracks were confined to a circular hole, as shown in

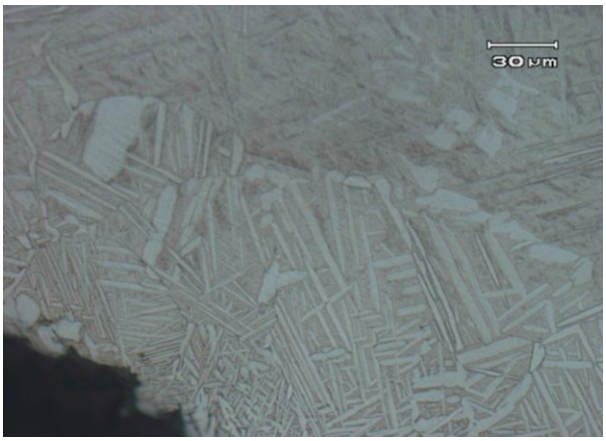

Figure 41 Coarse lamellar structure in β grains.[48]

Figure 50. In addition, fracture surface had fatigue striations, as shown in Figures 51–53, occurred due to vibration loads on the bolts. A dimple type of zone at the periphery of the bolt that was observed is shown in Figure 54.

2.11.5.2.6.4 Results and discussion

Generally, failure in mechanical fasteners occurs due to overload of static loading, such as tension, shear, bending, or

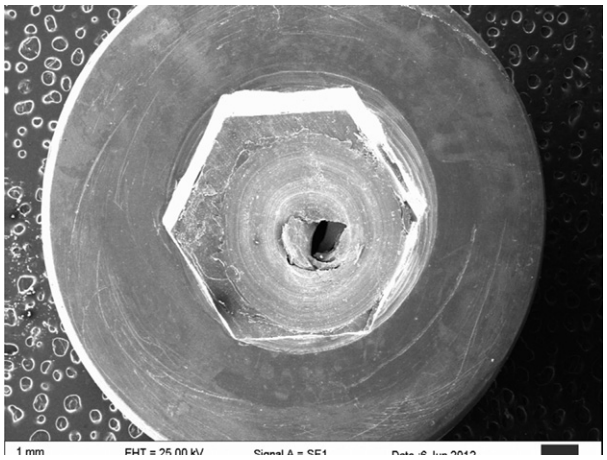

Figure 47 Shift in socket head hole from the center.[48]

Figure 48 Pierced zone of hole in the shank.[48]

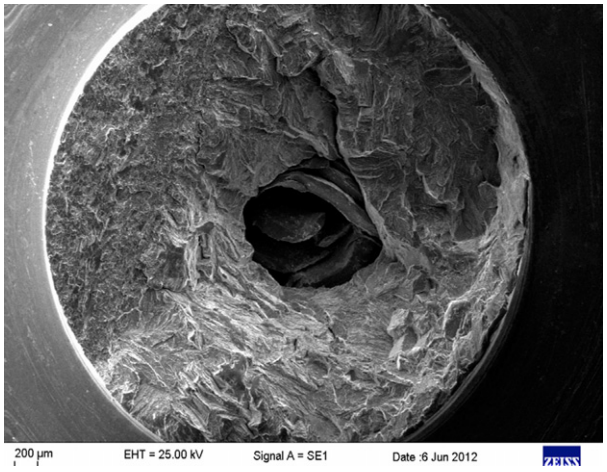

Figure 49 Nucleation crack in head.[48]

torsion and dynamic forces resulting from impact loading and cyclic fatigue loading, including vibration loads. Other common causes of failure include environmental effects, manufacturing discrepancies, improper use, and incorrect installation. However, for the case presented, the primary reason for failure was a socket head hole. The shank portion

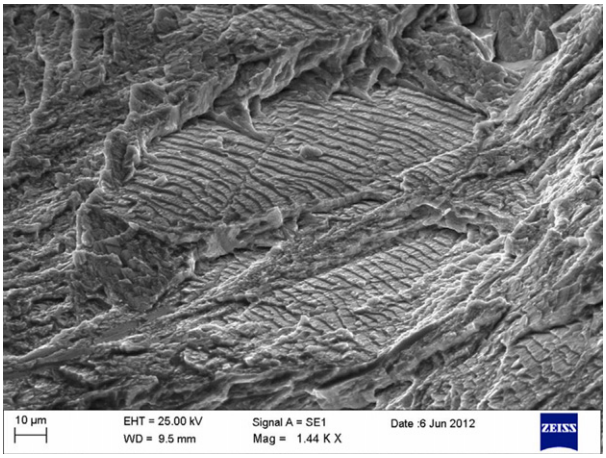

Figure 53 Striations due to fatigue loading at ×1400.[48]

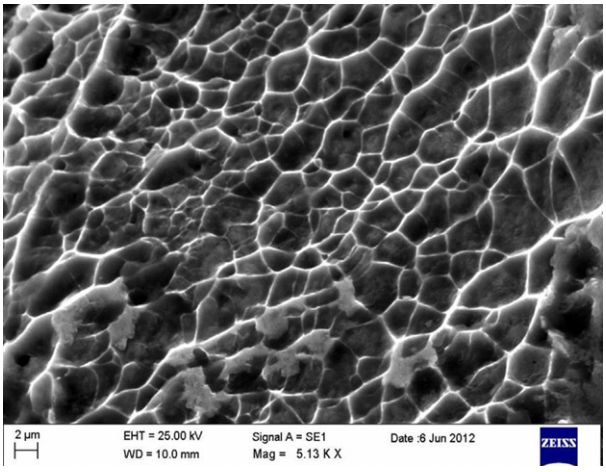

Figure 54 Dimple type of fracture zones observed at ×5000.[48]

became pierced, thus reducing the effective load-bearing area. This allowed more stress concentration zones at the interface zone. The cracks started the interface region as the pierced zone acted as a notch, and this region experienced dynamic loads due to vibration testing. Surface cracks present in the interface region were due to uncontrolled-process parameters that followed head forging and socket head hole punching.

Heterogeneity in microstructures is observed from microstructure analysis of the bolt from the head to shank. A localized increase in temperature during head formation is indicated by absence of primary α in the head portion and coarse lamellar structure in the failed zone. Presence of fine and coarse lamellar structures is also visible in the interface zone. This is credited to transformation decomposition of the high-temperature β phase. Microstructure of the shank portion reveals martensitic α and grain boundary α, with prior grain boundaries occurring because of improper processing after heating to the β field. Improper processing of Ti–6Al–4V after heating to the β field can result in the preferential α phase along the prior β grains. Extensive hot work is required to break up such structures; because cracks tend to propagate in or near interfaces, this type of structure can provide loci for initiation and propagation of cracks, thereby leading to premature failure.

Fatigue performance is greatly influenced by the forging temperature. Forging Ti–6Al–4V just below the phase transition temperature produces a microstructure that has a fatigue limit higher than that of the microstructure obtained by forging above the β_t temperature. It can be finally concluded that the bolt has failed due to fatigue, which transpired due to manufacturing discrepancies of head forging and socket hole. Further, heterogeneity in the microstructure facilitated the propagation of cracks.

The failure analysis was utilized to study the process parameters followed for manufacturing of the fasteners. Possible microstructures during thermo-mechanical processing with different temperatures and cooling mediums are illustrated in **Figure 55**.[48] It was concluded that localized heating (using torch flame) and lack of temperature control during head forging of the bolt caused manufacturing discrepancies. The strain rates followed for head forging are very high (i.e., approximately 10^{-1}–10^{-2} s^{-1}). Finalized process parameters were obtained only after repeated experiments were conducted on head forging. The details of process parameters for manufacturing fasteners are given in **Table 4**.

Head forging was performed by controlled heating below the β-transus temperature (<950 °C) in a furnace. Forging was performed at a strain rate of 10^{-2}–10^{-3} s^{-1} by removing the counter weight of 256 kg.

Dye-penetration test results were obtained and the interface region was found to be free of surface cracks. Radiography suggested no significant discontinuities. Further, metallurgical analysis was performed on the head portion, interface region, and shank area but found no evidence of heterogeneity in the microstructure. Also, the socket hole is removed from the design and the plain hexagonal socket head bolt is recommended for future applications.

2.11.5.2.6.5 Conclusions

The following conclusions can be drawn from the aforementioned case study:

- Failure analysis of Ti–6Al–4V fasteners was performed and the failure was attributed to fatigue damage. This damage occurred due to piercing of the socket head hole into the shank.
- Heterogeneity in the microstructure is confirmed by metallurgical analysis. This is a result of the uncontrolled process parameters that were followed during fastener manufacturing.
- An experimental study was conducted to optimize process parameters. The strain rates during head forging were optimized as 10^{-2}–10^{-3} s^{-1}, and heating was performed in a controlled furnace at 900 °C. Metallurgical analysis of the fasteners produced by optimum process parameters revealed no evidence of heterogeneity in microstructure.

2.11.5.3 Heat Treatment in β-Ti Alloys

The β-Ti alloys form one of the most versatile classes of materials with respect to processing, microstructure, and

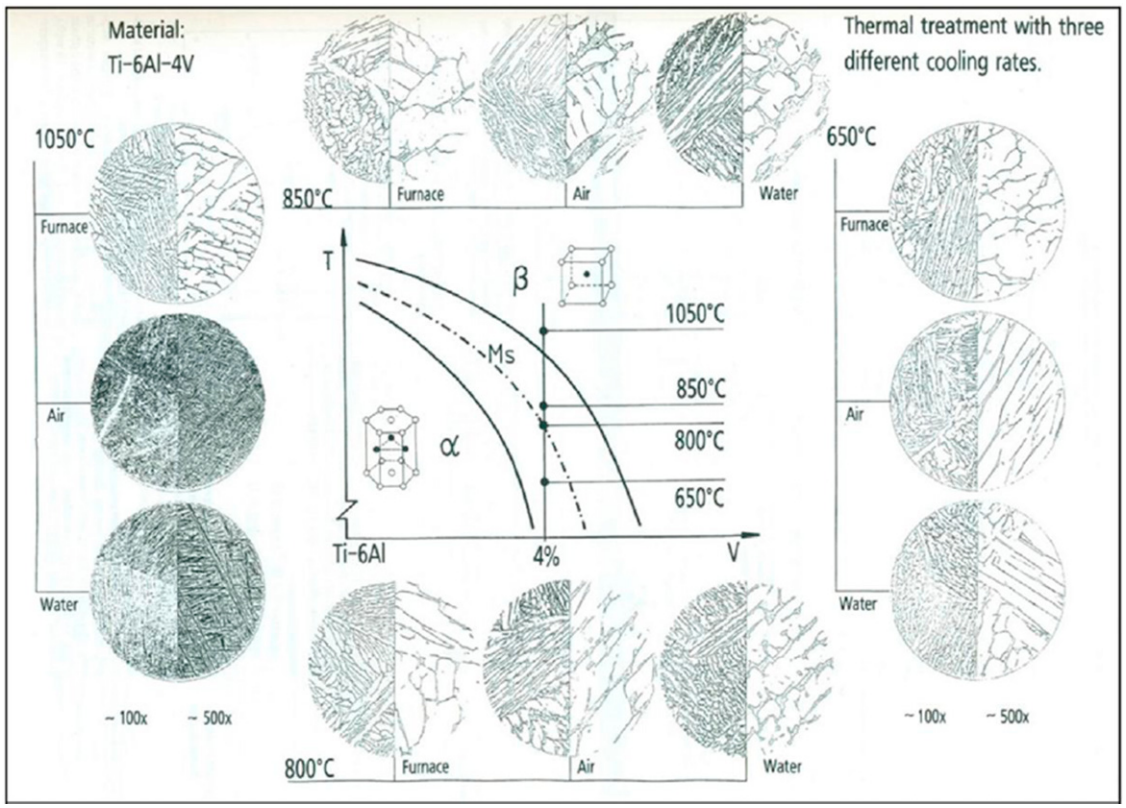

Figure 55 Microstructure of Ti–6Al–4V during thermo-mechanical processing.[48]

Table 4 Process parameters of manufacturing of fastener[48]

Process of manufacture	*Process parameters*
Hot rolling	Hot-rolled to the size F9.0 mm at temperature of 9558 °C
Annealing	700 °C, 1 h, air cooling
Swaging	Reduced to 4.5 mm diameter by hot-swaging
Head forging	Heated to 9008 C, forged at strain rate of 102–103 s^{-1}
Solution treatment and aging	Solution treatment at 895 °C for 1 h, water quenched, aging at 520 °C for 4 h, air cooling
Thread rolling	One single-pass thread-rolling

mechanical properties. These alloys include stable β, metastable β, and β-rich α/β alloys. They offer an attractive alternative to the α/β alloys due to their increased heat treatability, wide and unique range of strength-to-weight ratios, deep hardening potential, and inherent ductility that is the result of their bcc structure. In addition, they possess superior fatigue resistance as compared to α/β alloys. These alloys can be found in aerospace, power plant, sporting good, automotive, orthopedic implant, and down-hole service applications.

Generally, the β-transus temperature (T_β) tends to decrease as the Mo equivalent (Mo eq) (see Section 2.11.4.1.2) increases (**Figure 56**).[49] Higher values of the Mo Eq indicate heavily stabilized alloys, such as Ti–13V–11Cr–3Al (B120VCA) or Ti–35V–15Cr (alloy C). β Alloys were developed in the early 1950s, when the B120VCA alloy was introduced. Later, β alloys such as Ti–1Al–8V–5Fe (Ti-1-8-5), Ti–8V–8Mo–2Fe–3Al (Ti-8-8-2-3), and Ti–11.5Mo–6Zr–4.5Sn (*B* III) were formulated. Three important alloys were commercialized between 1969 and 1978, which are Ti–3Al–8V–4Mo–4Zr (*B* C), Ti–10V–2Fe–3Al (Ti-10-2-3), and Ti–15V–3Cr–3Sn–3Al (Ti-15-3). Newer β alloys such as Timetal® 21S, Timetal® LCB, *B*-CEZ, SP-700, and Ti–13Nb–13Zr were introduced in the 1990s. A more complete description of alloy composition, category, application, source, and year of introduction is provided in **Table 5**[50] for the major β alloys.

The high-temperature flow curves of Ti–10V–2Fe–3Al,[51] Ti–15V–3Cr–3Sn–3Al,[52] and *B* CEZ[53] are shown in **Figures 57–59**, respectively. It is apparent that all the stress–strain curves exhibit a sharp initial peak stress (discontinuous yielding) followed by almost constant stress deformation. Discontinuous yielding has been observed in a large number of β-Ti alloys such as Ti–9.4Mn, Ti–13Mn, Ti–14.8V,[54,55] Ti–8Mn, Ti–15Mo, Ti–13Cr–11V–3Al,[56] Ti–11Mo–6Zr–4.5Sn–0.035Fe, Ti–10V–2Fe–3Al, Ti–3Al–8V–6Cr–4Mo–4Zr,[57] Ti–15V–3Cr–3Sn–3Al,[52,58,59] and Ti–5Al–2Sn–2Cr–4Mo–4Zr–1Fe.[53] Discontinuous yielding has not been observed in CP Ti, Ti–5Al–2.5Sn (α alloy), and Ti–6Al–4V (α/β alloy) hot-deformed above the transus temperature.

This discontinuous yielding phenomenon has been related to the rapid generation of mobile dislocations from grain boundary sources, which leads to hot deformation proceeding from the grain boundary region inward. The magnitude of the peak stress decreases with increasing temperature, decreasing strain rate, and increasing grain size.[60] Following the peak

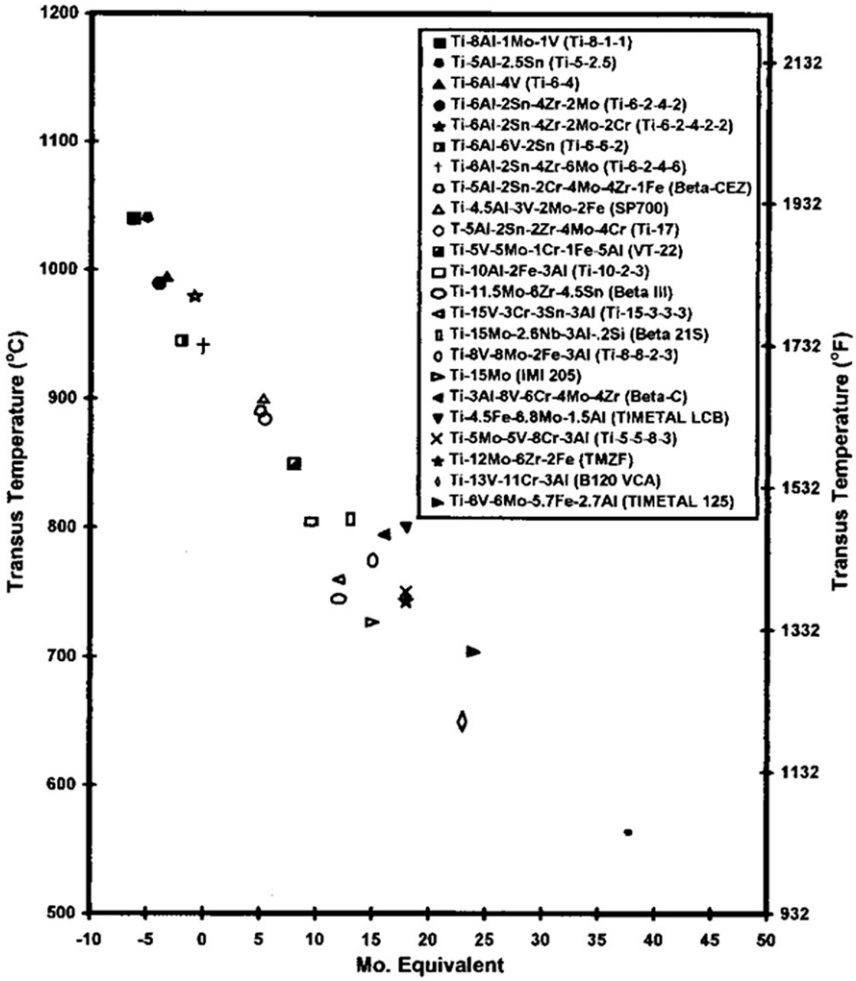

Figure 56 Variation in β-transus temperature with 'moly equivalent.'[49]

stress, a domain of near steady-state flow is usually observed (Figures 57–59). Higher steady-state flow stresses are observed at higher strain rates and lower deformation temperatures, as shown in Figures 60 and 61(a).[61,62] It is evident from the comparison of the flow stresses of several metastable β alloys and Ti–6Al–4V deformed at different temperatures that the flow stress of Ti–6Al–4V is the highest (Figures 60 and 61(a)). However, when the flow stress data are presented in terms of T–T_β (where T is the deformation temperature and T_β is the β-transus temperature), alloys with the highest concentration of alloying elements exhibit the highest flow stresses. For example, Ti–15V–3Cr–3Sn–3Al has a total of 24 wt% alloying elements and displays a much higher flow stress than Ti–6A–4V, with only 10 wt% additions (Figure 61(b)). This increase in flow stress is mainly attributed to an increase in solute strengthening.

2.11.5.3.1 Deformation in the β-phase field

Deformation in the β-phase field is similar to that for alloys undergoing dynamic recovery in which the rate of hardening by generation of dislocations is balanced by the rate of softening due to dislocation annihilation, thus resulting in the constant flow stress deformation noted.[16,17] The apparent activation energy for the deformation of β-Ti alloys has been found to be in the range of 130–175 kJ mol^{-1},[18] which is very close to the activation energy for self-diffusion in β Ti (i.e., 153 kJ mol^{-1}).[53] Table 6[49] contains some deformation parameters for several metastable β and β-rich alloys hot-deformed in the β-phase field. A typical hot deformation microstructure is shown in Figure 62(a)[63] for Ti–10V–2Fe–3Al forged to a 65% reduction at 1230 °C. Deformed β grains with increasingly (during deformation) serrated boundaries are observed. Small recrystallized grains appear in the vicinity of the deformed grain boundaries, when a strain of approximately 1.0 or more is induced. These grains, which are of the size of sub-cells, result from continuous recrystallization.[63] This type of recrystallization can also be considered as a special case of dynamic recrystallization. It is sometimes referred to as necklace recrystallization.[64] Under static annealing of this alloy, nucleation of new recrystallized grains occurs by the bulging mechanism.[65] As shown in Figure 62(b),[63] once nucleated, they grow to consume the recovered regions at a rate controlled by the amount of prior deformation as well as the annealing temperature and time.[17,66]

Details of microstructure and substructure formation, which characterize the dynamic recovery process, can be

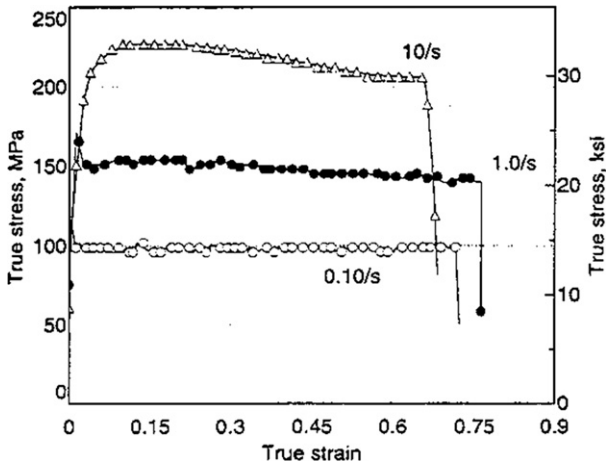

Figure 57 Flow curves of Ti–10V–2Fe–3Al alloy deformed above transus.[51]

obtained from observations for Ti–15V–3Cr–3Sn–3Al[52] and β-CEZ[64] (**Figures 63** and **64**). For some deformation conditions (low temperatures and high strain rates) of coarse grain alloys, such as cast alloys, an inhomogeneous substructure is observed (**Figure 65**).[52] Under these conditions, a finer and denser dislocation structure is developed along deformed grain boundaries. A coarser and less dense substructure is produced in the grain interiors as observed in cast Ti–15V–3Cr–3Sn–3Al deformed at 790 °C to a true strain of 1.05 (**Figures 64(a)** and **64(b)**).

Substructure evolution in the β phase has been quantified by microtexture analysis of β-CEZ samples deformed to strains of 0.25 and 1.0.[64] In this work, substructure misorientations were revealed qualitatively by orientation contrast scanning microscopy, as shown in **Figures 64(a)** and **64(b)**. Quantitative microtexture analysis was also performed on all sub-grains present in two or three adjoining grains (**Figures 66** and **67**).[64] During the initial deformation, it was observed that dynamic recovery produces a large proportion of low-angle sub-boundaries ($\Delta\theta \leq 12^\circ$). At a total strain of 0.25, these sub-boundaries are 97% of the total sub-boundaries measured (**Figure 67(a)**), whereas at a higher strain (approximately 1.0) the proportion of low-angle sub-boundaries is reduced to approximately 54% (even though their density has increased appreciably), and new medium-angle ($13^\circ \leq \Delta\theta \leq 25^\circ$) and high-angle boundaries ($\Delta\theta > 25^\circ$) are formed (**Figure 67(b)**). Measurements of sub-boundary misorientations at intermediate strains indicated that the development of medium-angle and high-angle boundaries is a continuous process that is controlled by dynamic recovery during hot deformation. However, the

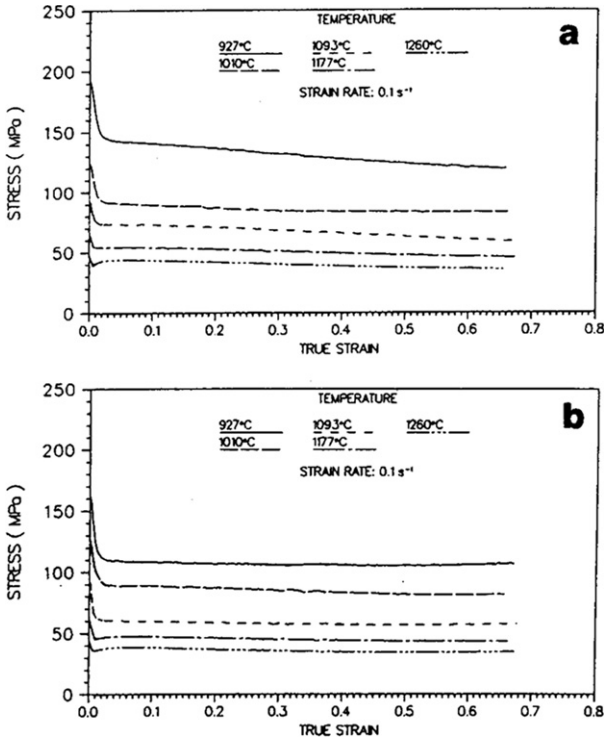

Figure 58 Flow curves of (a) as-cast and (b) recrystallized Ti–15V–3Sn–3Cr–3Al deformed in the range of 927–1260 °C at a strain rate of 0.1 s^{-1}.[52]

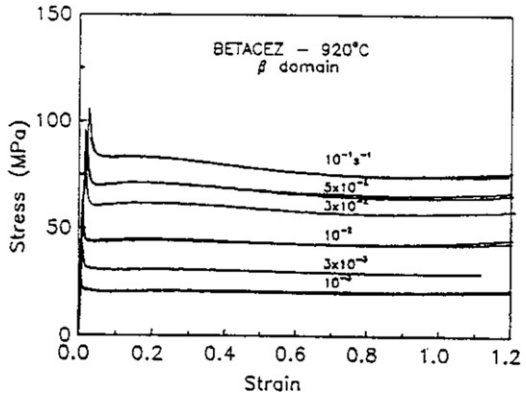

Figure 59 Flow curves of Ti–5Al–2Sn–2Cr–4Mo–4Zr–1Fe (β-CEZ) deformed above transus.[53]

growth process of these high-angle boundaries during or after deformation is similar to meta-dynamic recrystallization; in fact, it is evident that the recrystallization process for the β-Ti phase is not typical dynamic recrystallization whereby nucleation and growth of new recrystallized grains are occurring during hot deformation of low-stacking fault materials.[17]

The control of grain size, shape, and uniformity is very significant for secondary processing and to optimize final mechanical properties. Working in the β-phase region sometimes leads to the formation of a mixed grain structure containing large as well as small grains.[66–68] Such nonuniform microstructures are the result of selective recrystallization in regions of high strain along β-grain boundaries and the

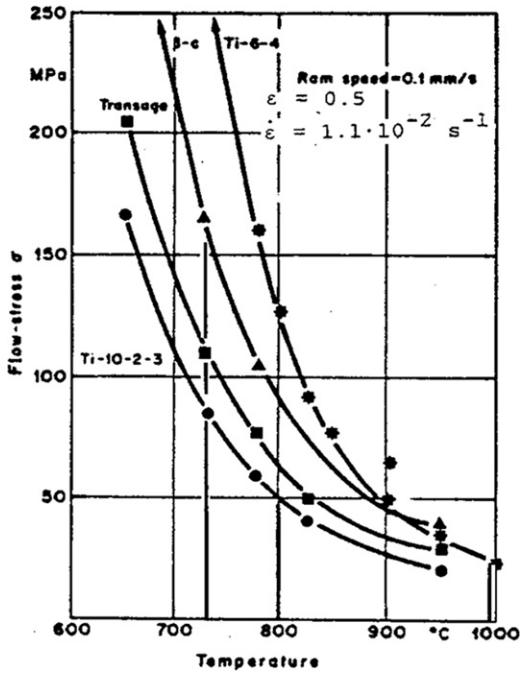

Figure 60 Flow stresses of different titanium alloys at a strain of 0.5.[61]

reduced driving force for recrystallization in the grain interiors, where dynamic recovery dominates. Once introduced, it is impossible to remove the mixed grain structure by heat treatment alone.[67]

Selection of the proper choice of process parameters such as deformation temperature, amount of deformation, and subsequent annealing temperature and time to avoid mixed grain structures may be aided by utilization of processing maps, as shown in **Figures 68** and **69**.[69] The nature of processing maps and the associated 'processing windows' are rationalized in terms of the occurrence of deformation localization at low deformation temperatures, and the formation of coarse and stable substructures are rationalized in terms of the occurrence of deformation localization at high deformation temperatures (**Figure 70**).[68] In addition to deformation and annealing conditions, the chemical composition of the alloy being hot-worked (**Figure 71**)[69] and its initial grain shape and size (**Figure 72**)[69] also affect the extent of the processing window. When processed through the processing window, fine-recrystallized grains can be obtained (**Figure 73**).[69] **Figures 73(a)–73(c)** shows the effects of variation of deformation temperatures prior to annealing treatment at a high temperature, whereas **Figures 73(d)–73(f)** and **Figures 73(g)–73(i)** show the effects of similar variation only for intermediate and low annealing temperatures. However, the effects of variation of the annealing temperature are clear when the microstructures are observed column-wise. **Figure 73(a)** reveals fine grain formed due to low deformation temperatures with a tendency of polygonization at high annealing temperatures. **Figure 73(c)** shows a tendency toward grain coarsening because of both high temperature of deformation and annealing. In **Figure 73(g)**, the grains are fine as well as elongated because of the low deformation temperature and low annealing temperature. **Figure 73(i)** shows distorted

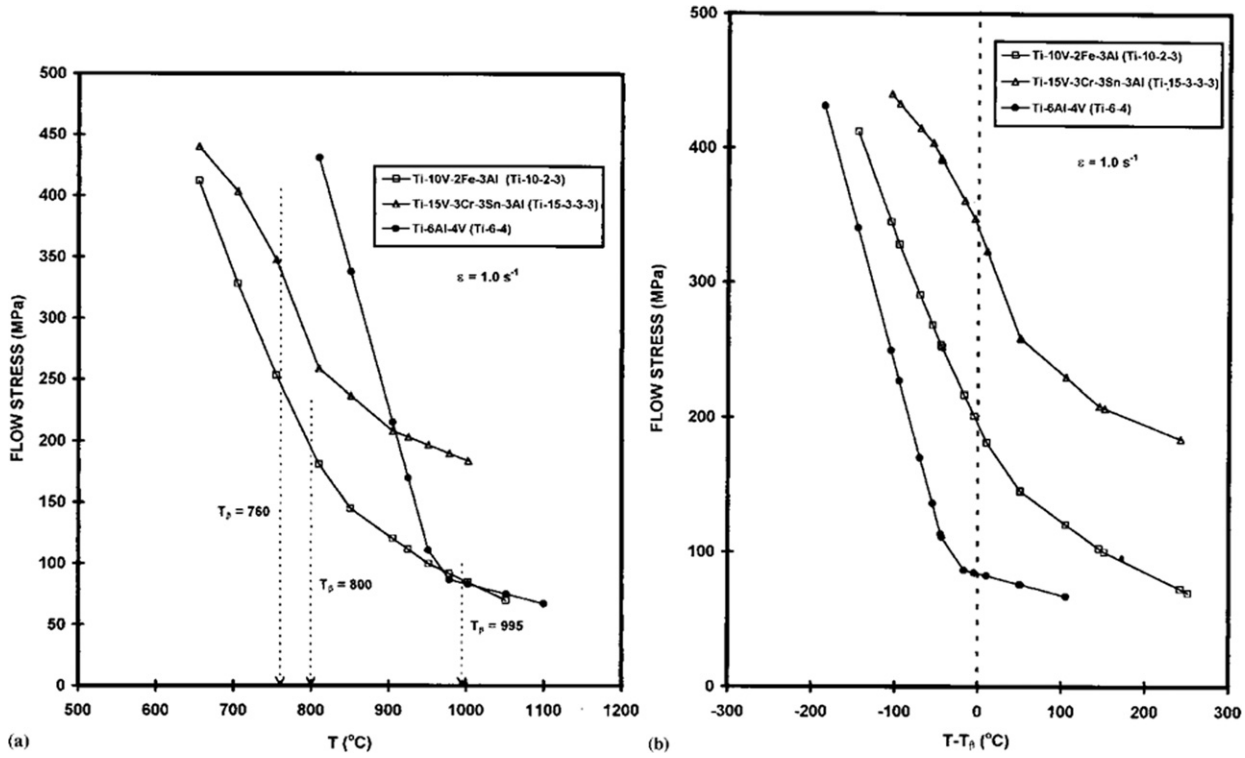

Figure 61 (a) Flow stress as a function of temperature for several titanium alloys deformed at an average strain rate of 1 s^{-1}.[62] (b) Flow stress as a function of $T–T_\beta$ for several titanium alloys deformed at an average strain rate of 1 s^{-1}.[62]

Table 6 Deformation parameters for several metastable β and β-rich alloys hot-deformed in the β-phase field[49]

Alloy	*Temperature range (°C)*	*Strain rate range (s^{-1})*	*Strain rate sensitivity (m)*	*Activation energy for deformation, Q_D (kJ mol^{-1})*
Ti–6Al–4V (Ti-6-4)	1120	5×10^{-3}–5	0.20	300
Ti–10V–2Fe–3Al (Ti-10-2-3)	820	10^{-3}–10^{-1}	0.33	169
Ti–15V–3Cr–3Sn–3Al (Ti-15-3-3-3)	800–900	5×10^{-3}–0.8	0.33	166–174

Ti–5Al–2Sn–2Cr–4Mo–4Zr–1Fe (Beta-CEZ)	890–1000	10^{-2}–10^{-1}	0.33	175

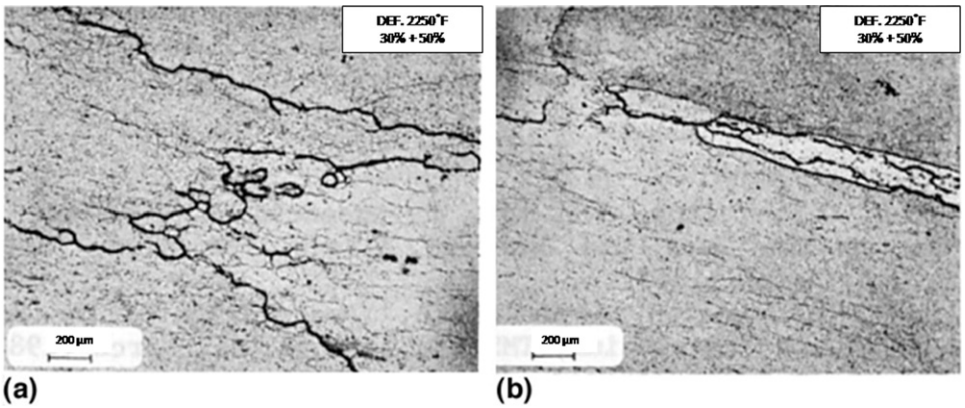

Figure 62 (a) Deformation substructure after forging to a 65% reduction at 1230 °C.[63] (b) Nucleation and growth of recrystallized grains following forging to a 65% reduction and annealing at 1035 °C for a short time.[63]

grain, which is the result of low annealing temperature but is coarser in nature due to high deformation temperature. From these figures it is evident that the grain refinement phenomenon is dominated by the temperature of deformation, whereas distortions of grains are more dependent on annealing temperature. Reheating and annealing times should be controlled and

optimized to eliminate excessive grain growth (Figure 74)[70] to preserve this microstructure.

2.11.5.3.2 Deformation in the $\alpha + \beta$-phase field

The high-temperature flow curves of Ti–10V–2Fe–3Al and Ti–5Al–2Sn–4Mo–4Zr–2Cr–1Fe (β-CEZ)[53] at sub-transus temperatures, as shown in Figures 75 and 76,[49,53] respectively, indicate that after yielding and a very short period of work hardening, a noticeable amount of flow softening takes place, whose magnitude is greatest at low temperatures (Figure 75)[49] and high strain rates (Figure 76).[53] The flow softening is followed by steady-state flow at high strains, particularly for high-temperature and low-strain-rate conditions. Although some of the flow softening observed at high strain rates results from deformation heating, most of it can be credited to dynamic microstructure or texture changes in the α phase. The sub-transus flow stress data also reveal that the β-preform microstructure (produced by β annealing and water quenching) is somewhat stronger than the α/β preform microstructure. However, at large strains, the flow curves for the two microstructures approach each other, and this behavior is similar to the trend observed in α/β alloys. A comparison of the sub-transus flow stresses of different β and α/β alloys with an α/β microstructure indicates that the flow stress of the Ti–6Al–4V alloy is the highest. However, if corrected for the different transus temperatures, the alloy with the highest solute level (Ti-17) exhibits the highest flow stress, as shown in Figure 77.[71]

Hot deformation in the $\alpha + \beta$-phase field yields relatively high apparent activation energy in the range of 400–700 kJ mol^{-1}, which is much higher than the apparent activation energy for self-diffusion in the β phase (153 kJ mol^{-1}).[53] The physical interpretation of the activation energy for sub-transus hot working is complicated by the variation of the α phase volume fraction with deformation temperature (Figure 78).[70] Table 7[49] lists some deformation parameters for several metastable β and β-rich alloys deformed in the

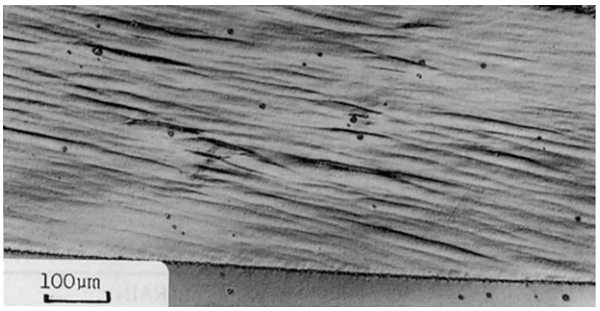

Figure 63 Substructure in as-cast Ti–15V–3Sn–3Cr–3Al deformed at 790 °C to a true strain of 1.05.[52]

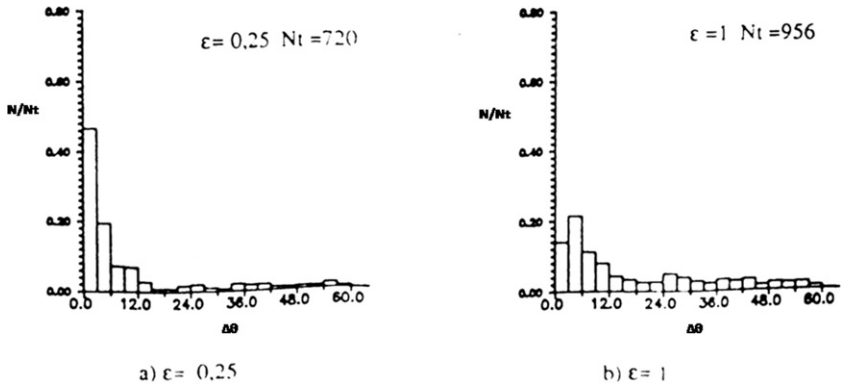

Figure 67 Sub-grain misorientation distribution in β-CEZ deformed to strains of (a) 0.25 and (b) 1.0.[64]

$\alpha+\beta$-phase field. Hot-working temperatures of metastable β and β-rich alloys associated with α/β processing are typically (T_β-100 °C) or higher, at which the volume fraction of the primary α phase is less than 30% (Figure 78).

The effect of microstructure on flow is further explained in Figure 79.[72] Higher flow stresses are displayed by an acicular α morphology microstructure (Figure 79(b)) as compared to those for equiaxed α morphology (Figure 79(a)). It has been observed that the strain rate in the α phase (which is less than the average strain rate) is higher for an acicular or elongated grain morphology and lower for globular grain morphology.[72] Consequently, higher flow stresses are expected for acicular microstructures.

The presence of α grain also affects microstructure and substructure evolution during sub-transus hot working. The α phase is considerably harder than the β phase, and it behaves like a dispersion of hard particles in a soft matrix (Figure 80).[73] Figure 81[53] shows that the strain in the α phase is approximately three-tenths of the nominal strain, thus preventing the α phase from

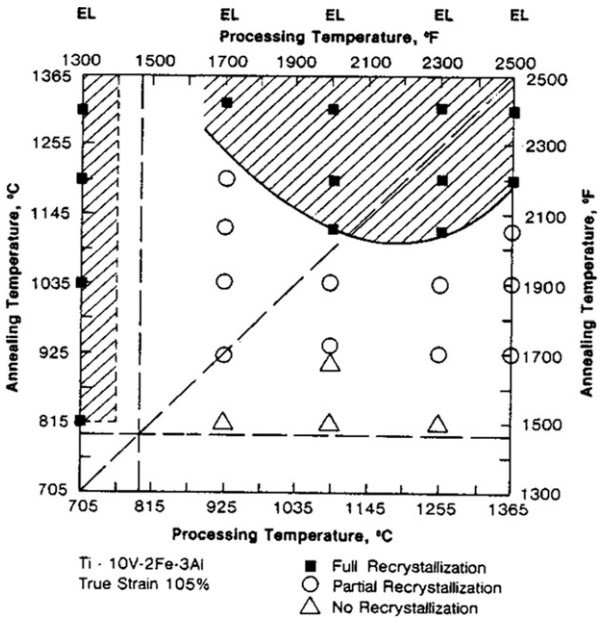

Figure 68 The effect of processing and annealing of Ti–10V–2Fe–3Al alloy forged to 65% reduction.[69]

converting into a more equiaxed morphology. The same effect has been observed in other alloys (Figure 82).[74] Because the α phase deforms less than the β phase, development of strain concentrations in the softer β phase is a necessity in the vicinity of the α phase, leading to the formation of smaller highly misoriented sub-grains in comparison to the sub-grains produced in the remainder of the β matrix (Figure 83).[74] At higher strains, sub-boundaries develop in the α phase, followed by cusp formation and β-phase penetration along the α/α sub-boundaries, resulting in a more equiaxed morphology α phase (Figure 84).[70] Similar features have also been observed in α/β alloys (Figure 85).[75] The softer β matrix also undergoes microstructural changes associated with grain elongation and formation of sub-boundaries, increasing their misorientation continuously, thereby creating small-recrystallized grains surrounded by high-angle boundaries in the vicinity of the highly deformed β grain boundaries.

Control of the size and morphology of the α and β phases can be achieved by selecting the proper hot-working parameters (temperatures and amount of deformation). Along with the volume fraction of the α phase (Figure 86(a)),[73] the size of the α phase can also be modified by changing the deformation temperature, as shown in Figure 86(b).[73] Further control of the α size and morphology can be obtained by fast-cooling β-processed material producing the acicular α morphology (Figure 87)[76]

followed by α/β deformation and sub-transus annealing (Figure 88).[76] To preserve a fine-grain microstructure, excessive grain growth and, consequently, inferior mechanical properties should be eliminated by controlling and optimizing reheating and annealing parameters (Figure 89).[72]

2.11.5.3.3 Shape memory alloys

The unique shape memory effect (SME) in an equiatomic Ti–Ni alloy was first found by Buehler *et al.*[76] in 1963 at a naval ordnance laboratory. The name of the alloy, nitinol, was derived with the objective of incorporating the chemistry of the alloy and the place of invention. Although the SME was found in Au–47.5 at% Cd[77] and In–Tl[78] alloys previously, it attracted limited attention from researchers. In contrast, the TiNi alloy earned its popularity soon after its discovery, mainly due to its good mechanical properties, which were found to be suitable for various applications. Although Ti–Ni-based alloys exhibited many common characteristics with other shape memory alloys (SMAs) like SME, superelasticity (SE), two-way shape memory effect (TWSME), and others, they also exhibited

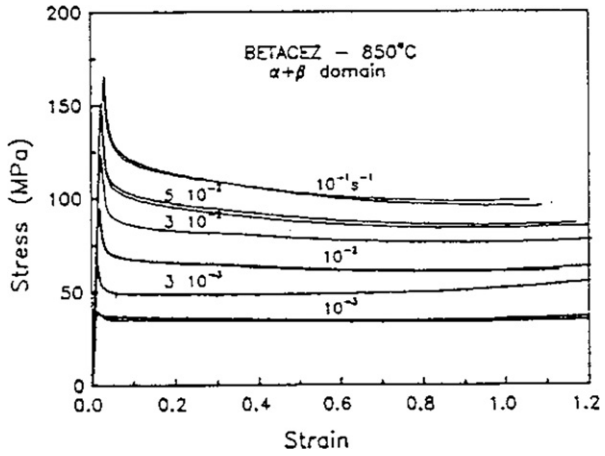

Figure 76 Flow curves of Ti–5Al–2Sn–2Cr–4Mo–4Zr–1Fe (β-CEZ) deformed at 850 °C.[53]

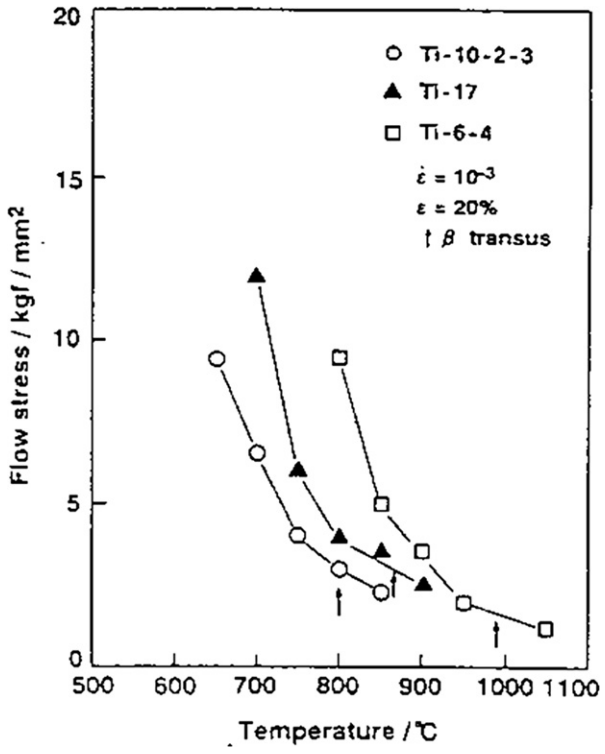

Figure 77 Flow stresses of different titanium alloys at a strain of 0.2.[71]

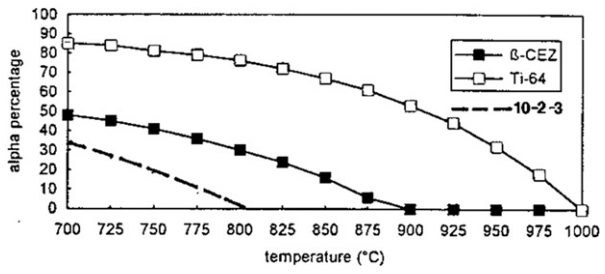

Figure 78 Variation of α-phase percentage with temperature.[70]

some additional characteristics that are quite unique compared to other SMAs. They exhibit low elastic anisotropy, as low as nearly 2, in comparison with other SMAs exhibiting a value of approximately 10 or more.[79]

Although, Ti–Ni is an intermetallics compound, it is quite ductile under certain conditions. The composition of nickel plays a vital role in deciding the transformation temperatures.[2] The austenite start temperature (A_s) for nitinol can vary from −50 to 166 °C through variation in Ni content (wt%) from 53.5 to 56.5%.[80]

2.11.5.3.3.1 Phase diagram

Figure 90 shows the phase diagram of a Ti–Ni alloy system.[81,82] The research interests related to shape memory are focused on the central portion bounded by the $NiTi_2$ and Ni_3Ti phases. The single-phase 'Ti–Ni' appears near the equiatomic composition, which is responsible for the SME. **Figure 90** also shows metastable phase equilibrium between the Ti–Ni and Ti_3Ni_4 phases, which is very useful in adjusting transformation temperatures and in designing the heat treatments schedules.[79]

The Ti–Ni phase has a B2 (CsCl) type of ordered structure with a lattice constant of 0.3015 nm at room temperature.[83] The B2 phase is retained upon quenching or slow cooling to room temperature. This is the phase that plays the essential role in the martensitic transformation (MT) and the associated SME.[79] The boundary of the Ti–Ni phase region is almost vertical on the Ti-rich side, but there is some solubility on the Ni-rich side at high temperatures. The Ti–Ni phase region becomes very narrow at temperatures below 650 °C.

2.11.5.3.3.2 Martensitic transformation in Ti–Ni alloys

The unique behavior of Ti–Ni is based on the temperature-dependent austenite–martensite phase transformation on an atomic scale, which is also called thermo-elastic MT. The thermo-elastic MT causing the shape recovery is driven due to the need of the crystal lattice structure to attain the minimum energy state at a given temperature. In Ti–Ni, the relative symmetries between the two phases lead to a highly ordered transformation in which it is possible to predict the displacements of individual atoms. The transformation eventually leads to a shape change on a macroscopic scale. The crystal structure of martensite is relatively less symmetric compared to that of the parent phase.[79]

Generally, Ti-Ni alloys show a one-stage B2 → B19′ transformation during quenching from high temperatures.[83–87] The vertical boundary in the Ti-rich side of the Ti–Ni phase region makes it difficult to get supersaturated Ti in a Ti–Ni matrix. Therefore, Ti-rich alloys have a relatively consistent matrix because equiatomic alloy and similar transformation behavior are expected. However, on the Ni-rich side, a 1 at% increase in Ni content can change the transformation temperature by more than 100 °C.

Apart from the direct transformation from B2 → B19′, there is a second type of intermediate transformation known as R-phase transformation.[79] There are usually three ways to introduce the R-phase transformation prior to the transformation to B19′ phase,[86] such that the Ti–Ni alloy transforms

Table 7 Deformation parameters for several metastable β and β-rich alloys deformed in the $\alpha + \beta$-phase field[49]

Alloy	*Temperature range (°C)*	*Strain Rate range (s^{-1})*	*Strain rate sensitivity (m)*	*Activation energy for deformation, Q_D (kJ mol^{-1})*
Ti–6Al–4V (Ti-6-4)	850	10^{-3}–10^{-1}	0.18	470–572
Ti–10V–2Fe–3Al (Ti-10-2-3)	650–790	10^{-3}–10^{-1}	0.21	255–480
Ti–5Al–2Sn–2Zr–4Mo–4Cr (Ti-17)	805–845	10^{-3}–10^{0}	0.22	437
Ti–5Al–2Sn–2Cr–4Mo–4Zr–1Fe (Beta-CEZ)	800–850	10^{-2}–10^{1}	0.27	400

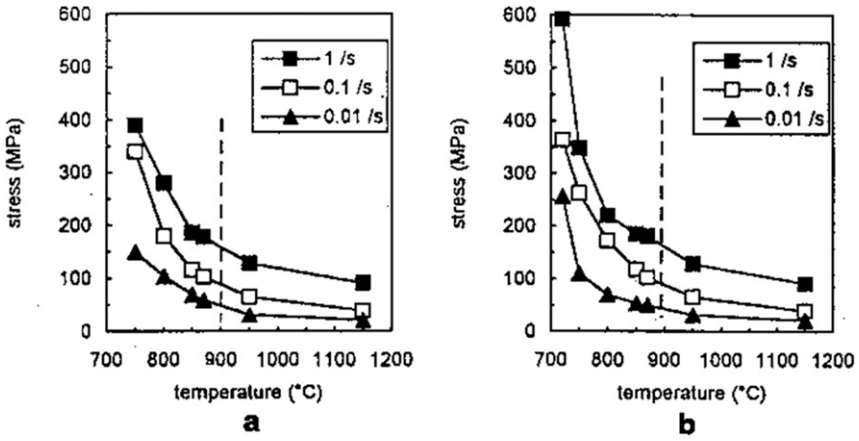

Figure 79 Flow stresses of Ti–5Al–2Sn–2Cr–4Mo–4Zr–1Fe (β-CEZ) with (a) acicular morphology and (b) equiaxed morphology.[72]

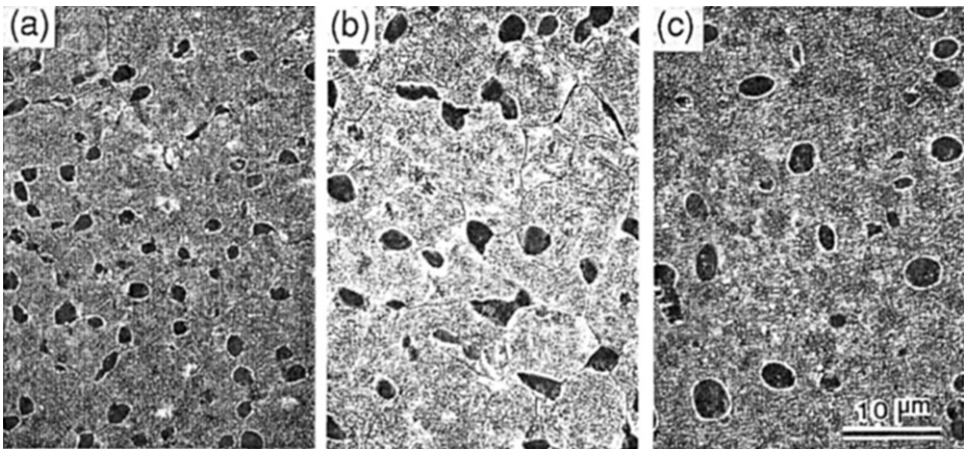

Figure 80 Microstructure of Ti–10V–2Fe–3Al following deformation at 700, 750, and 770 °C.[73]

in two-steps (i.e., B2 → R → B19′): (1) by substitution of a few percent of Ni in Ti–50 at% Ni alloy by Fe or Al; (2) by aging Ni-rich Ti–Ni alloys at proper temperatures (e.g., 400 °C) to cause the precipitation of Ti_3Ni phase; and (3) heat treatment of Ti–Ni alloys after cold-working with the aim of creating rearranged dislocation structures. In these cases, formation of both the R-phase and B19′ phase are affected by: (1) the third element (Fe or Al); (2) stress field of precipitates; and (3) stress field of dislocations. However, the effect for the B19′ phase is larger than that for the R-phase, thus making the transformation temperatures of both phases separable.

The two-step transformation also depends on the applied external stress.[88] For lower stress, the R-phase transformation temperature is higher than the B19′ transformation temperature, but it exhibits smaller stress dependence. Therefore, with increasing stress, the B19′ transformation temperature eventually exceeds the R-phase transformation temperature, and this leads to one-stage transformation.

Figure 91[79] shows the three-different possibilities of transformations in Ni–Ti-based alloys. In the schematic representation it is clearly revealed that all the alloys have a tendency to transform from B2 to B19′ martensite in

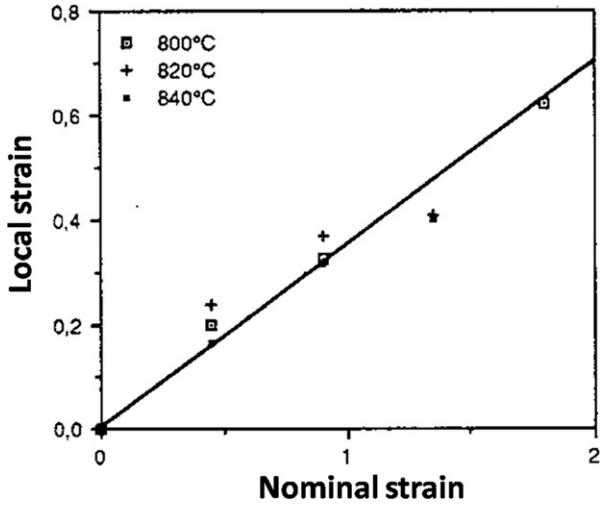

Figure 81 Strain in the α phase for different nominal strains.[53]

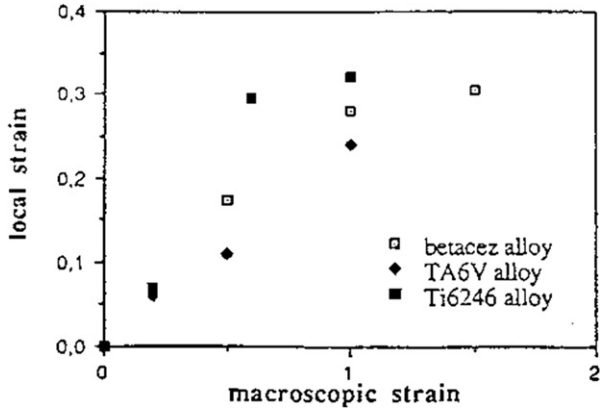

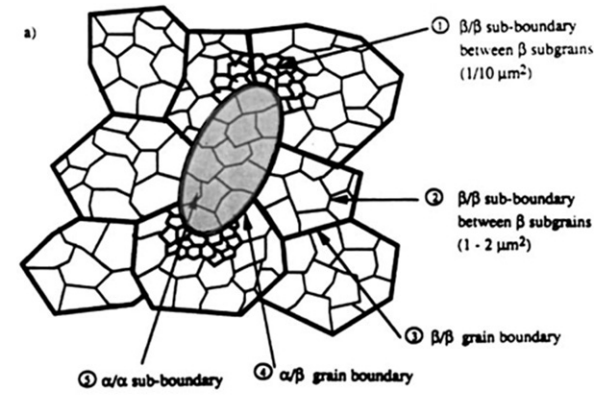

Figure 82 Strain in the α phase as a function of nominal strain for different titanium alloys.[74]

Ni-Ti-based alloys; in fact, for the solution-treated binary Ni–Ti alloys, the transformation occurs from B2 to B19′ directly, whereas for the uppercases and lowercases two successive transformations occur on continuous cooling. However, depending on the composition and heat treatment, only the first transformation may occur and the second one may be lost, because the possible transformation temperatures for the second one become too low (i.e., below 0 K) in that case.[79]

2.11.5.3.3.3 Precipitation in Ti–Ni alloys

Shape memory characteristics of the binary Ti–Ni alloy can be improved by the following treatments:

- specific thermo-mechanical treatments (TMTs), such as annealing following cold working (Ni < 50.5 at% practically),[83,89–91]
- thermal and/or stress cycling,[92–95] and
- aging after solution treatment (Ni > 50.5 at%, practically).[83,86,89,96]

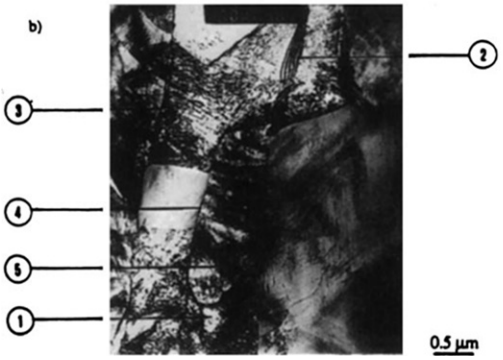

Figure 83 Formation of substructure in the α and β phases during deformation of Ti–5Al–2Sn–2Cr–4Mo–4Zr–1Fe (β-CEZ) at a temperature of 840 °C and strain rate of 0.3 s^{-1}.[74]

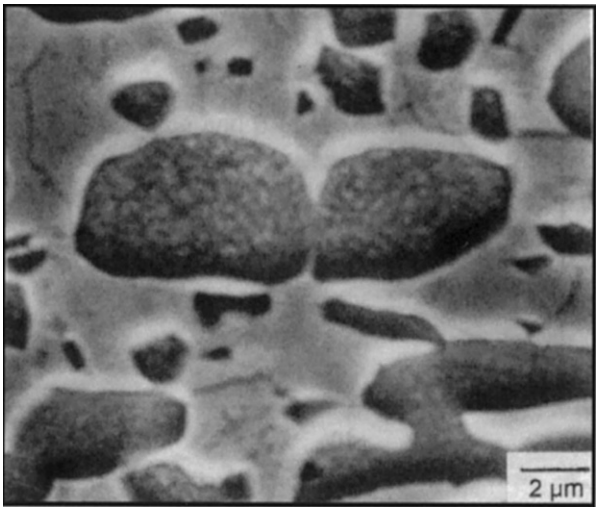

Figure 84 Formation of cusp and β-phase penetration along α/α sub-boundary.[70]

Among these treatments, the aging treatment has been found to be the most effective method for improving the shape recovery and mechanical properties of Ti-Ni-based alloys.

It is important to mention here that studies on the thermomechanical behavior of the Ti-rich Ti–Ni alloys[93,97,98] are

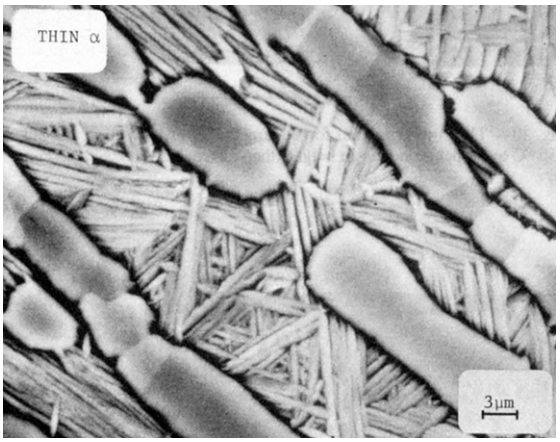

Figure 85 Channeling contrast scanning electron microscope of α-plate material deformed 20%, followed by annealing at 925 °C.[75]

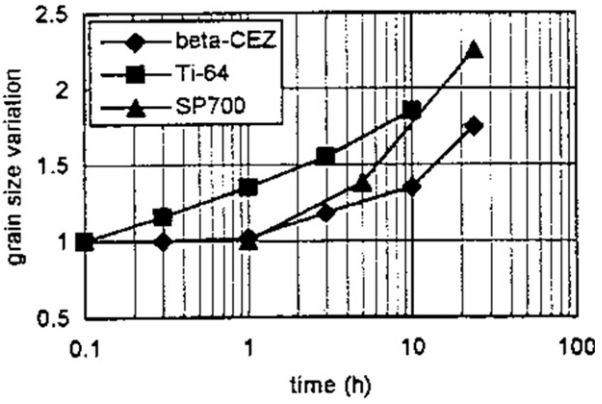

Figure 89 α-phase coarsening at 850 °C for an initial α size ranging from 2 to 5 mm for different alloys.[72]

limited in number, although Pelosin *et al.*[99] reported a detailed investigation on the premartensitic (R-phase) and the MT in the case of Ti–49.6 at% Ni alloy. It has been established that the R phase is formed by annealing of the Ti-rich Ti–Ni thin films.[100,101] Nam *et al.*[102] reported that the R-phase is also induced by rapid solidification of Ni–51Ti alloy ribbons. Both treatments form coherent Ti_2Ni particles that suppress the MT and induce the R phase. Zhang *et al.*[103] reported the effect of the equilibrium Ti_2Ni precipitate phase on the MT and shape memory behavior in the case of Ti–49 at% Ni alloy. The Ti_2Ni phase has been found to be responsible for the possible R-phase formation in this alloy.

2.11.5.3.3.3.1 Effect of thermomechanical treatment

The properties of Ti–Ni alloys are significantly affected by TMTs, which are essential to control the transformation temperatures, mechanical properties, and monotonic and cyclic

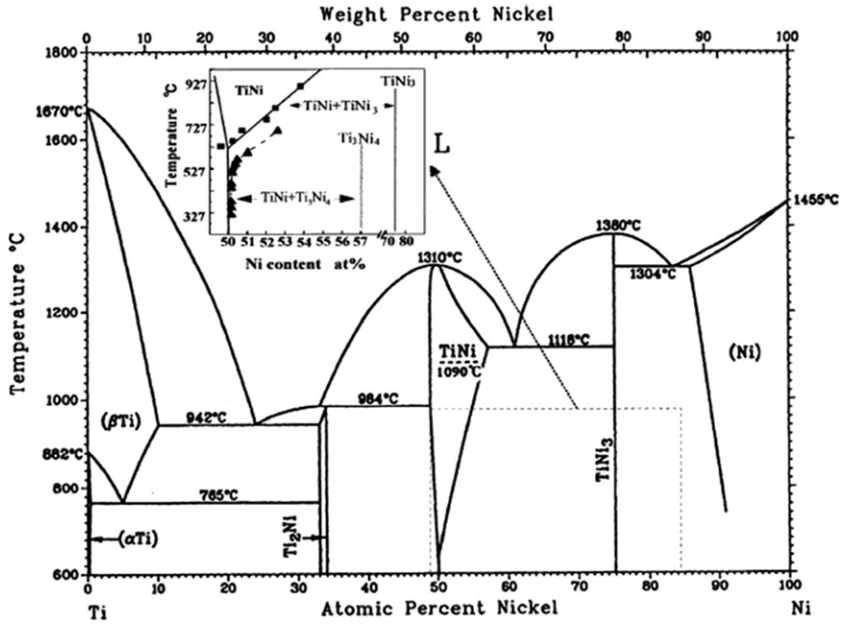

Figure 90 Phase diagram of Ti–Ni,[81] to which the phase equilibrium between the B2 and Ti_3Ni_4 is added (inset).[82]

responses. The common thermomechanical treatments are ausforming[104–106] and marforming,[106,107] in which defects are introduced into the austenitic and martensitic structures, respectively. The purposes of both ausforming and marforming are to improve the characteristic SME and pseudoelasticity (PE) by suppressing the irreversible slip deformation during the martensite reorientation (MR) and stress-induced martensitic transformation (SIMT) by raising the critical shear stress for slip.[89,104,108,109] In particular, the objectives of these thermomechanical processes are: (1) to control transformation temperatures with the aim of achieving the desired transformation path (thermally induced or stress-induced transformation at a given temperature); (2) to increase the transformation stress of the stress-induced parent-to-martensite transformation while the SME and/or PE are expected to be preserved; and (3) to enhance thermomechanical fatigue resistance.[107] Apart from the effects of marforming and ausforming, the thermomechanical treatment of Ti–Ni alloys has been reported in studies related to cold rolling and annealing[110,111] and severe plastic deformation of the SMAs.[105,107,112–114]

2.11.5.3.3.3.2 Effect of cold rolling

The reversible transformation and the concerned microstructural evolution in Ti-rich alloys are critically sensitive to the chemistry of the alloy and thermomechanical treatment to which the alloys are subjected. Phase diagram of Ti–Ni alloy exhibits that at near equiatomic composition, the parent (austenite) phase is a stoichiometric ordered phase with B2 structure. However, on the Ti-rich side, the alloy is amenable to precipitation of the Ti_2Ni phase under favorable conditions. The brittle intermetallic phase acts as the nucleation site of martensite (B19′) that, in turn, alters the composition of the matrix and volume fraction of B2 and B19′ components at room temperature in the microstructure. Such variations are critically manifested in the shape memory behavior.

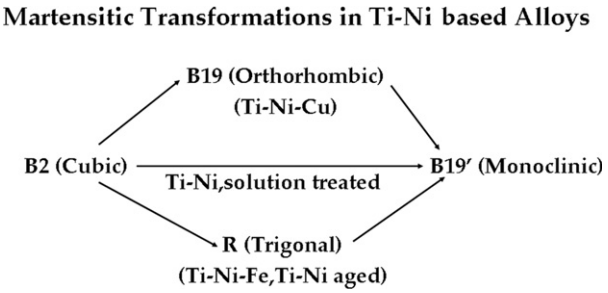

Figure 91 Three-transformation paths of Ti–Ni-based alloys.[79]

The effect of deformation is also significant regarding evolution of the microstructure. Part of the deformation energy may result in the elevation of temperature of the alloy giving rise to transformation of some B19′ back to B2.[115] Simultaneously, some part of the B2 phase may undergo deformation-induced transformation to transform into B19′ phase.[99,116] Plastic deformation of martensite that is present in the matrix also stabilizes the same against reversible transformation on withdrawal of the load. Another issue of concern is the mechanism that governs the deformation of the low-symmetry monoclinic B19′ phase.

- X-ray diffraction: **Figure 92(a)**[117] shows the room temperature X-ray diffraction (XRD) pattern of the homogenized samples quenched in the ice–water mixture. The pattern shows the presence of both austenitic (B2) and martensitic phases (B19′) in the sample. The identity of the phases has been more clearly demonstrated by deconvolution of the relevant portion of the angular (2θ) range (i.e., from 36° to 46°, as appended in the figure). The de-convoluted pattern reveals the sharp intense peak ($2\theta = 42.7°$) corresponding to (110) reflection of the austenite (B2) along with the adjacent peaks corresponding to

(101), (−111), (020), and (111) reflections of the martensite (B19′). Figure 92(b) shows the increase in volume fraction of martensite compared to Figure 92(a). Therefore, an increase in the volume fraction of the martensite in the case of samples deformed at temperatures close to 0 °C substantiates the deformation-induced transformation of the austenite into martensite. It is also apparent that the presence of B2 and B19′ phases, with remarkable differences in the inflow behavior, resulted in the inhomogeneous deformation pattern during rolling. The inhomogeneous deformation pattern is delineated by the formation of bands of martensite.

- TEM: Figure 93(a)[117] shows the finer features of the microstructure in the case of a homogenized and quenched (HQ) sample observed during TEM investigation. Figure 93(a) reveals the presence of internal twins within the martensite plates. Figure 93(b) reveals the deformed microstructure of the cold-rolled or cold-worked (CW) samples quenched in ice water. Figure 93(b) reveals the accommodation variants with evidence of coalescence and detwinning. The microstructure does not reveal any perceptible presence of twinning in the microstructure.[118]
- Tensile property: Figure 94[117] shows the tensile plots obtained from the homogenized samples quenched in ice water and subjected to rolling at temperatures close to 0 °C. In the case of homogenized and quenched samples, the plot exhibits four distinctly different stages identified in accordance with the variation of slopes. Stage I (2% strain), stage II (2–7% strain), stage III (7–15% strain), and stage IV (>15% strain) correspond to the initial elastic deformation, deformation concerning recovery strain, uniform elastic deformation of reoriented martensite, and plastic deformation of martensite, respectively. In contrast to the homogenized and quenched samples, the tensile plots of the deformed samples do not reveal the prominent iso-stress plateau region corresponding to the stage II deformation.

The absence of iso-stress plateau[91,119,120] in the tensile plots of the deformed samples may be attributed to the fact that in the deformed samples, the process related to the recoverable strain like martensite reorientation, variants coalescence, and detwinning have partially occurred prior to cold deformation. After the initial elastic yielding, plastic deformation of the oriented martensite sets in and overlaps with the mechanisms related to the recoverable strain associated with the remaining misaligned martensite. This results in plastic deformation with steeper slopes of work hardening, as evident from the stress–strain plots (Figure 94).

The increasing slope observed in the case of deformed samples in stage II of the tensile curves implies the necessity of the increase in stress with the increase in strain for martensite reorientation and variant coalescence in stage II of tensile deformation. The necessity of increasing stress may be explained in terms of the varying size of the martensite plates present in the microstructure, which lead to

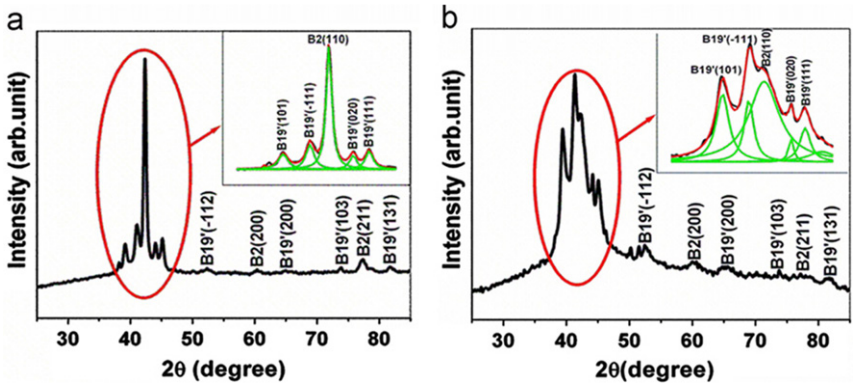

Figure 92 Room temperature X-ray diffraction patterns of the (a) homogenized and quenched (HQ) and (b) cold-rolled (CW) samples (the angular range (2θ) from 36° to 46° in the patterns is de-convoluted and shown as insets).[117]

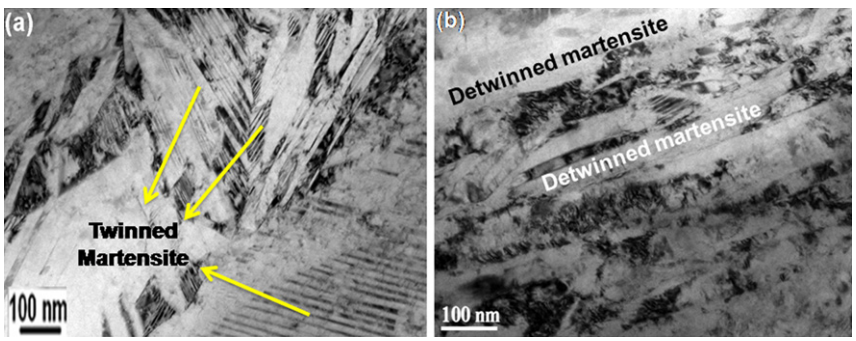

Figure 93 TEM images of (a) homogenized and quenched (HQ) and (b) cold-rolled (CW) samples without aging treatment.[117]

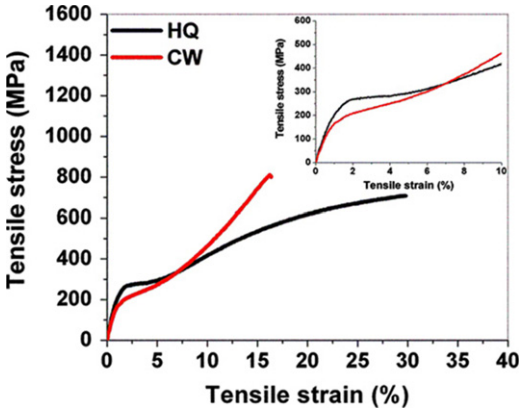

Figure 94 Tensile plots of homogenized and quenched (HQ) samples and cold-rolled (CW) samples.[117]

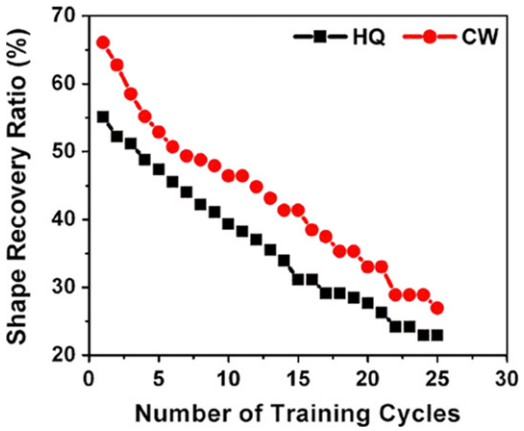

Figure 95 Recovery ratio (%) vs. number of training cycles of the homogenized and quenched (HQ) and cold-rolled (CW) samples.[117]

the microscopic heterogeneity in the process of microstructural transformation. In fact, plates of different sizes necessitate different levels of strain for undergoing the microstructural transformation associated with stage II straining. During the course of subsequent plastic straining, dislocation multiplication, slip, and dislocation pile-ups at twin interfaces are the dominant mode of plastic deformation.[115] However, as the martensite structure becomes heavily deformed, localization of the plastic deformation is expected to give rise to plastic incompatibilities, limiting the further deformation.

In the case of Ti-rich or equiatomic Ti–Ni alloy, the improvement in SME for the cold-deformed samples can be explained in terms of additional strengthening effects, as evident from the tensile plots shown in **Figure 94**.[117] Strengthening by cold working essentially increases the critical resolved shear stress (CRSS) for slip deformation in martensite. With the increase in CRSS, the onset of permanent plastic strain is delayed, favoring the extension of the region of recoverable strain. However, continuous thermal cycling of the martensite under bending strain greater than the recoverable strain introduces more and more permanent strain in martensite and results in the reduced SME.

- Shape recovery: **Figure 95**[117] shows the variation of the shape recovery ratio as the function of the number of training cycles. It is seen that shape recovery is perceptibly higher in the case of the deformed sample as compared to the homogenized and quenched sample. The difference in shape recovery is maintained over the chosen range of the training cycle. The shape recovery experiment indicated improved shape recovery ratio in the case of the deformed samples. Moreover, in the case of the present samples, the thermally activated slip-controlled mode is not the favored mode under the low-temperature deformation condition. The low-temperature strain accommodation like twinning is not as effective as slip to exert hindrance for the martensite reorientation and reversible transformation during thermal cycling. Therefore, the improvement may be attributed to the increase in CRSS due to the formation of finer martensite plates and the consequent delay in the onset of plastic straining during the shape deformation, resulting in improved recovery behavior.

2.11.5.3.3.3.3 Effect of aging treatment

It is well established that the shape memory characteristics of the binary Ti–Ni alloys can be improved by the following treatments: (1) cold working followed by annealing[83,89–91]; (2) aging treatment in Ni-rich alloys[83,85,86,90,92]; (3) thermal and/or stress cycling[92,94,95]; and (4) the addition of third elements.[121] In the case of treatment (1), the binary Ti–Ni alloys were first deformed below the recrystallization temperature and then subjected to annealing heat treatment. In the second type of treatment (2), the Ni-rich Ni–Ti alloys were first solutionized and then aged at different time–temperature combinations. The third treatment (3) involves heating and subsequent rapid cooling cyclically over a range of temperatures and/or implementation of the loading–unloading cycle in the austenitic state of the alloy. Regarding the last case (4), the addition of a third element in the Ti–Ni binary system influences the martensitic transition temperature and results in the formation of 'premartensitic' R phase, which affects the SME and PE. These treatments have focused mainly on the equiatomic Ti–Ni[122,123] or Ni-rich alloys.[88] Very few studies are concerned with similar attempts in the case of Ti-rich Ti-Ni alloys.[97,98,103] Among the aforementioned treatments, the aging treatment has been found to be the most effective method to improve the shape memory characteristics and mechanical properties of the binary Ti–Ni alloys. The potential of the aging treatment is attributed to the formation of fine precipitates, which act as effective obstacles for the movement of dislocations, thereby increasing the CRSS for slip.[104,108,109] In the case of Ti-rich Ti–Ni alloy, the Ti_2Ni precipitate phase formed under the favorable process schedules acts as the nucleation site of the martensite (B19′).[115] As the precipitation reaction proceeds, formation of Ti-rich precipitate is accompanied by the lowering of the Ti content in the Ti–Ni matrix. Therefore, the transformation temperature tends to decrease upon aging.[103] The size and coherency of the precipitates affect the transformation and the mechanical strength of the alloy. The CRSS for slip also increases due to the precipitation hardening. Further, continuation of the aging treatment results

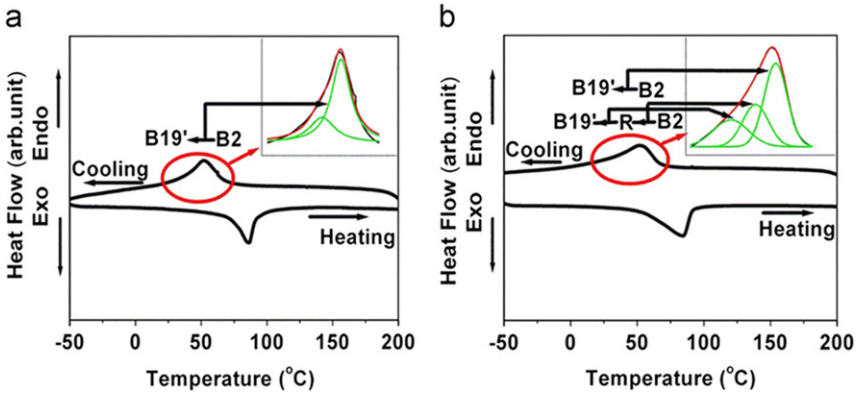

Figure 96 Differential scanning calorimetry thermograms of (a) homogenized and quenched (HQ) and cold-rolled (CW) samples at a heating/cooling rate of 10 °C min^{-1} (the one-stage and two-stage transformations are demonstrated by de-convolution of the appropriate temperature range in the cooling curve).[126]

in an increase in the size of the precipitates and consequent deterioration of mechanical strength. It is well accepted that the interaction of the coherent Ti_2Ni precipitate phase formed during aging with the dislocation substructures formed during thermomechanical processing (i.e., combination of aging treatment and deformation below recrystallization temperature) evolves into a microstructure that favors the formation of the R phase prior to the formation of the B19′ phase.[124] The stress field around the coherent precipitates exerts strong resistance to the formation of B19′[125] because it is associated with a large lattice deformation. On the contrary, the premartensitic R-phase transformation involving smaller lattice deformation is less affected by the presence of precipitate. Thus, the aged Ti-rich Ti–Ni alloys usually undergo a two-stage B2→R→B19′ transformation on cooling from the B2 regime, which is related to the interaction of the Ti_2Ni phase and the dislocation substructures formed during thermomechanical treatments with moving martensite/austenite boundaries.[114,115]

- Differential scanning calorimetry: The reversible transformation behavior of the homogenized sample with and without the subsequent deformation (HQ and CW samples) has been investigated by conducting the differential scanning calorimetric measurements. **Figures 96(a)** and **96(b)**[126] shows the differential scanning calorimetry (DSC) thermograms of the samples at a heating/cooling rate of 10 °C min^{-1}. In the case of HQ samples, one-stage transformation (B2→B19′) takes place during cooling and is depicted by the de-convoluted heat flow profiles of the concerned temperature range in the cooling curve, as appended in the inset of **Figure 96(a)**. Similarly conducted de-convolution in the case of the CW (**Figure 96(b)**) samples exhibits one-stage (B2→B19′) and two-stage (B2→R→B19′) transformations during cooling.

  Table 8[126] presents the enthalpy changes (heat of transformation) related to the one-stage transformations for HQ samples and the multiple stages (both one and two stages) of transformation in the case of CW sample. The heat of transformations decreases because of the prior deformation in the case of the CW sample as compared to the HQ samples.[127]

Table 8 Heat of transformation ΔH (J g^{-1}) of homogenized and quenched (HQ) and cold-rolled (CW) samples at a cooling rate of 10 °C min^{-1}[126]

Sample	*Transformation*	*Heat of transformation ΔH (J g^{-1})*	*Heat of transformation ΔH (J g^{-1}) (from literature)*
HQ	B2→B19′	42.33	33.8±2
	B2→B19′	21.49	25.22
CW	B2→R	7.39	6.36
	R→B19′	8.99	18.18

- High-temperature XRD: The XRD patterns of the HQ and CW samples recorded at different temperatures as shown in **Figures 97(a)** and **97(b)**[126] depict the reversion behavior of B19′ to B2 during heating. The diffraction patterns for the HQ samples recorded at 100 °C reveal the presence of both the B2 and B19′ phases. With increasing temperature, the amount of B19′ is gradually reduced and only the peaks corresponding to (110) and (211) reflections of the B2 phase appear in the pattern recorded at 200 °C. During cooling from 200 °C to room temperature at a rate of 10 °C min^{-1}, the B19′ appears along with the B2 phase. In the case of the CW sample, the diffraction patterns obtained at 100 °C reveal the dominant presence of the B19 phase along with nominal intensity of the B2 phase. With increase in temperature to 200 °C, the intense and sharp B2 peak corresponding to (110) reflection appears in the pattern more prominently. However, in contrast to the HQ sample, presence of the B19′ phase is evident in the XRD pattern of the CW sample recorded at 200 °C. Complete transformation of the B19′ phase to the B2 phase is evidenced in the XRD pattern recorded at 300 °C. After cooling from 300 °C to room temperature at a rate of 10 °C min^{-1}, the peak corresponding to (020) reflection of the B19′ phase and that of the B2 phase appear in the XRD pattern.

  Therefore, the XRD analysis conducted at different temperatures indicates that the plastic strain accumulated in the CW sample effectively stabilizes B19′ and B2 phases during heating and cooling experiments, respectively. The results

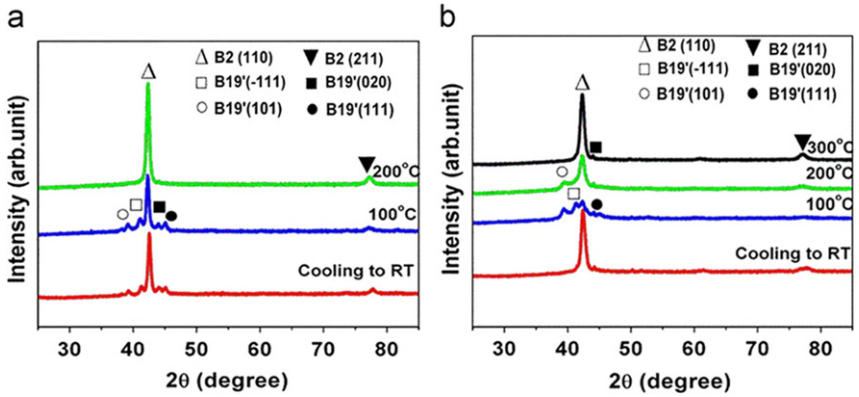

Figure 97 Temperature-dependent X-ray diffraction patterns of the (a) homogenized and quenched (HQ) and (b) cold-rolled (CW) samples.[126]

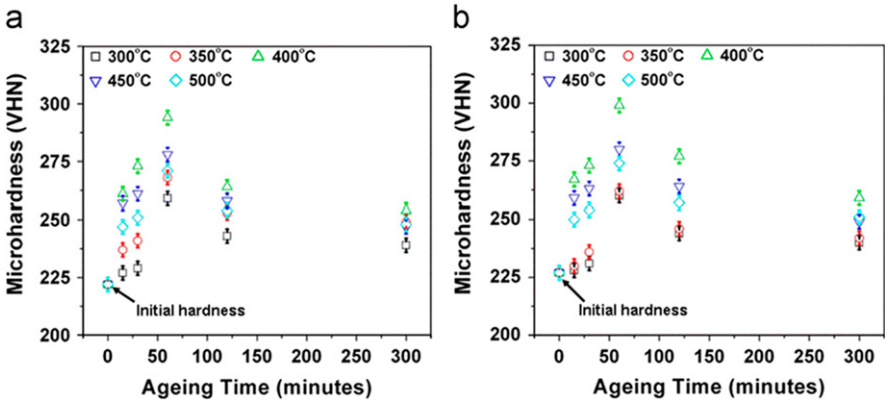

Figure 98 Variation in microhardness (VHN) with aging time at different aging temperatures in the case of (a) homogenized and quenched (HQ) and (b) cold-rolled (CW) samples.[126]

also indicate the effective aging response of the samples, particularly for the deformed ones, at temperature higher than 300 °C.

In view of the results presented in **Figures 96** and **97**, age-hardening behavior of the present samples was studied at selected temperatures in the range of 300–500 °C for different isothermal holding times.

- Microhardness: **Figures 98(a)** and **98(b)**[126] show the variation of hardness (VHN) with aging time at different aging temperatures for HQ and CW samples at a load of 300 gf. Comparison of the hardness results indicates that for all the samples, the maximum hardness values have been achieved for aging treatment conducted at 400 °C for 60 min. Moreover, **Figure 98** shows that the maximum hardness has been achieved after increasing the aging time from 30 to 60 min, beyond which the variation is marginal. Therefore, the results presented in **Figure 98** suggest the combination of 400 °C temperature and 60 min duration as the favorable aging conditions for the present alloy.
- Room temperature XRD: **Figures 99(a)** and **99(b)** shows the room temperature XRD patterns of the HQ and CW samples after aging at 400 °C for 60 min followed by quenching in ice-water solution. The XRD patterns reveal the presence of austenite (B2) and martensite (B19′) phases in all the samples. The angular range (2θ) from 36° to 46° in the patterns is de-convoluted and appended as the insets in **Figures 99(a)** and **99(b)**. In the case of aged HQ samples, the presence of the Ti-rich Ti_2Ni precipitate phase is evident, as well as the presence of B2 and B19′ phases. The deformed samples after aging treatment have yielded a higher volume fraction of martensite in the quenched microstructure as demonstrated by the XRD pattern shown in **Figure 99(b)**. This may be attributed to the role of the plastic strain in refinement of the B2 microstructure during the aging treatment, which, in turn, facilitates the MT. Moreover, the XRD patterns of the deformed samples prior to the aging treatment also show the presence of perceptible amounts of premartensite in the R phase.[128] The Ti_2Ni phase along with the B2 and B19′ phases are also evident.
- SEM: **Figures 100(a)** and **100(b)**[126] shows the SEM images of the homogenized (900 °C) and quenched (in ice water) samples that were aged at 400 °C for 60 min followed by ice-water quenching. It is apparent that the microstructures mainly constitute martensite plates, as revealed in **Figure 100(a)**. It is apparent from **Figure 100(b)** that in several locations, the plates have formed around the coarser precipitates, giving rise to a star-like feature, and such plates have grown to larger sizes relative to the martensitic plates formed elsewhere. Therefore, the coarser precipitates act as the preferential site for martensite

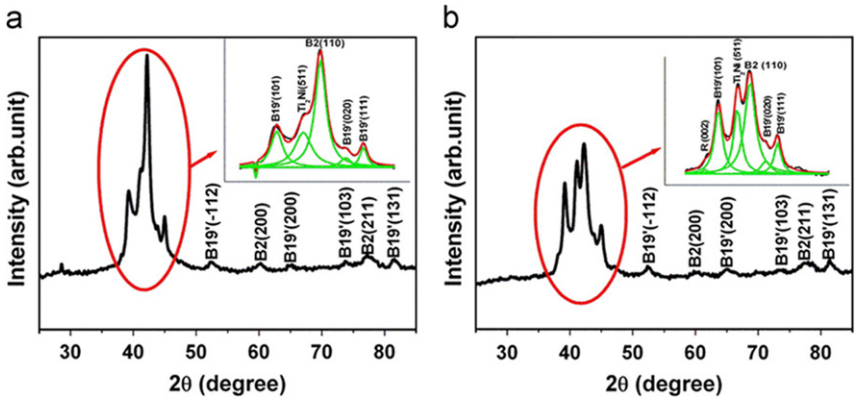

Figure 99 Room temperature X-ray diffraction patterns of the (a) homogenized and quenched (HQ) and (b) cold-rolled (CW) samples followed by aging treatment at 400 °C for 60 min (the angular range (2θ) from 36° to 46° in the patterns is de-convoluted and shown as insets).[126]

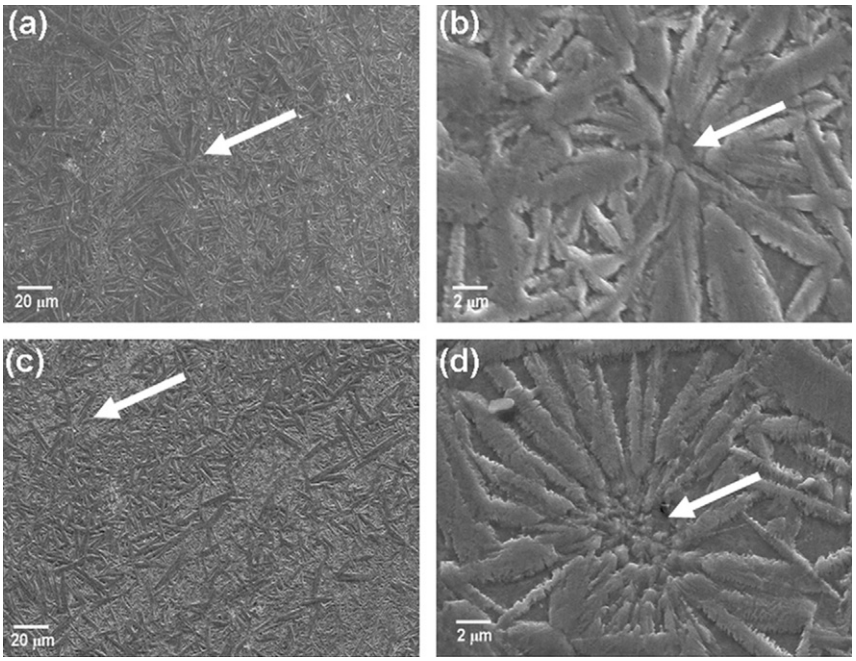

Figure 100 Scanning electron microscope (SEM) images of homogenized and quenched (HQ) sample aged at 400 °C for 60 min showing (a) distribution and (b) morphology of the martensite plates. SEM images of cold-rolled (CW) sample aged at 400 °C for 60 min showing (c) distribution and (d) morphology of the martensite plates (preferential sites for the martensite nucleation are suitably marked by arrows).[126]

nucleation, which has also been reported in previous studies.[115] **Figures 100(c)** and **100(d)** shows the SEM images of the CW (30%) samples aged at 400 °C for 60 min followed by quenching in ice water. The microstructures reveal the random distribution of martensites plates with finer and coarser size scales. The micrographs also reveal significant reduction in the tendency for banding, as observed in the deformed samples, prior to aging treatment.[129] Therefore, it is apparent that the aging treatment has significantly reduced the effect of strain concentration along the shear direction and results in the formation of favorable volume fraction of uniformly distributed martensite. Occasionally, martensites are nucleated from the preferred sites, as revealed in **Figure 100(d)**.

- TEM: **Figure 101(a)**[126] shows the microstructural features observed during TEM studies of the HQ samples subjected to the aging treatment followed by ice-water quenching. **Figure 101(a)** shows the presence of Ti-rich precipitate phase (Ti_2Ni) formed during the aging treatment. **Figure 101(b)** shows the precipitate distribution in the case of CW samples subjected to the aging treatment followed by ice-water quenching. It is evident from the microstructure that the maximum size of the precipitate is less than 50 nm.
- Tensile property: **Figures 102(a)** and **102(b)**[126] presents the tensile plots obtained at different strain rates (4×10^{-2}, 4×10^{-3}, 4×10^{-4} s^{-1}) for HQ and CW samples subjected to the aging treatment. It is evident that with the increase in the strain rate, the plateau region concerning stage II of

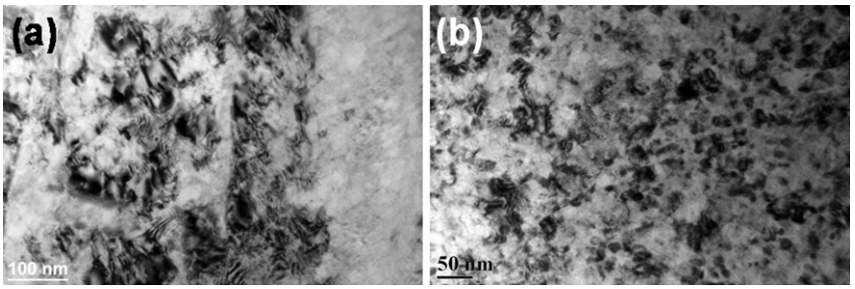

Figure 101 (a) Transmission electron microscopy (TEM) images of homogenized and quenched (HQ) sample after aging at 400 °C for 60 min show the presence of the Ti_2Ni precipitate phase and the B19′ phase. (b) TEM images of cold-rolled (CW) sample after aging at 400 °C for 60 min show the presence of the Ti_2Ni precipitate phase.[126]

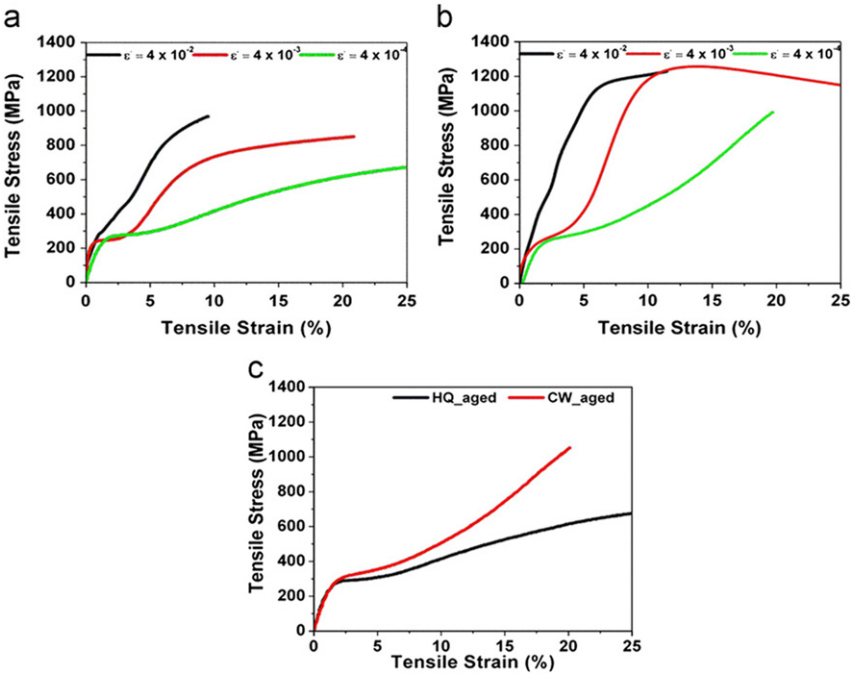

Figure 102 Tensile stress vs. strain plots of (a) homogenized and quenched (HQ) and (b) cold-rolled (CW) samples followed by aging treatment at 400 °C for 60 min at strain rates of 4×10^{-2}, 4×10^{-3}, and 4×10^{-4} s^{-1}. (c) Tensile stress vs. strain plots of HQ and CW samples followed by aging treatment at 400 °C for 60 min at a strain rate of 4×10^{-4} s^{-1}.[126]

deformation is gradually diminished and almost completely disappears at a strain rate of 4×10^{-2} s^{-1} for all the tensile plots. The strain hardening has remarkably increased with the increase in the strain rate in stage III of deformation. It is also interesting to note that the tendency of necking is evident in the case of deformed samples at the intermediate strain rate value of 4×10^{-3} s^{-1}. The results clearly establish the strain rate sensitivity of the samples not only in stages III and IV but also in stage II. The response is most prominent in the case of deformed samples. Figure 102(c)[126] compares the tensile plots of the samples subjected to different processing routes at the strain rate of 4×10^{-4} s^{-1}. It is evident that the CW samples exhibit more pronounced work hardening than the HQ samples.

- Shape recovery: Figure 103(a)[126] shows the variation in the shape recovery ratio with aging time and the aging temperature of 400 °C for HQ and CW samples. It is evident that with increases in aging time, the shape recovery ratio increases up to 60 min and then decreases. Continuation of aging up to 120 min results in a sharp decrease in the shape recovery ratio value. After prolonged aging beyond 120 min, the shape recovery ratio reaches a plateau. Comparisons of the variations in microhardness (Figures 98(a) and 98(b)) and shape recovery ratio (Figure 103(a)) values as functions of aging time reveal a unique agreement, corroborating that the shape recovery behavior of the present alloy critically depends on the aging condition and is maximized at the peak aging condition.

  Figures 103(b) and 103(d)[126] shows the variation of shape recovery ratio as a function of the number of training cycles for HQ and CW samples for durations of 15, 60, and 300 min. It is seen that with all aging conditions, shape recovery is higher in the case of CW samples compared to

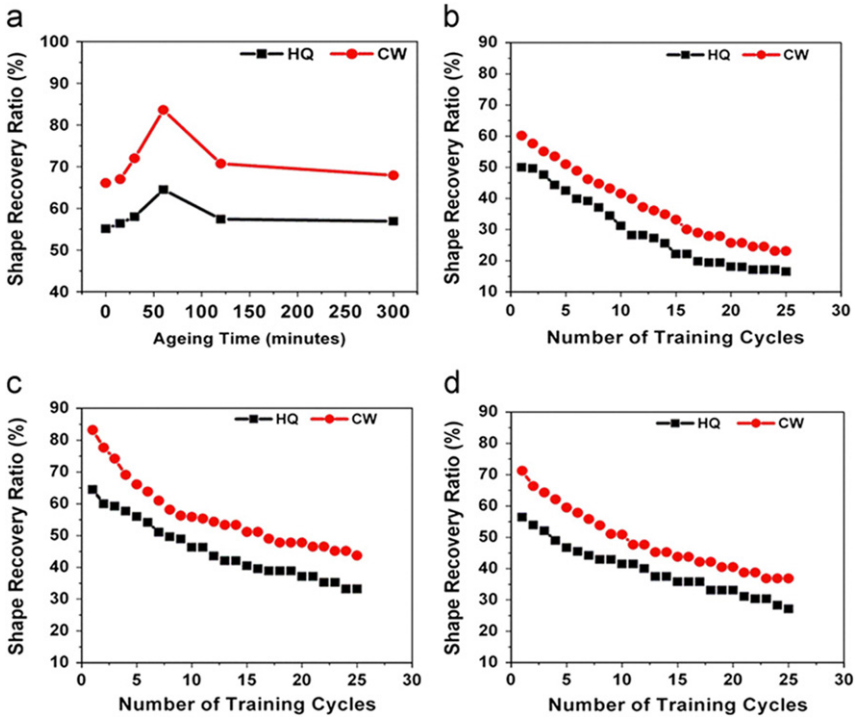

Figure 103 (a) Variation of the shape recovery ratio (%) with aging time at 400 °C for homogenized and quenched (HQ) and cold-rolled (CW) samples and plots of the shape recovery ratio (%) vs. number of training cycles of HQ and CW samples aged at 400 °C for durations of (b) 15 min, (c) 60 min, and (d) 300 min.[126]

the HQ samples. Such a difference in shape recovery is maintained over the range of the training cycles. The maximum shape recovery ratio for different samples has been obtained at 60 min of holding time (**Figure 103(c)**).[126] It is also evident that the degradation in the shape recovery ratio is less pronounced in the case of CW samples, as depicted in **Figures 103(b)** and **103(d)**.

2.12.1 Introduction

Aluminum is the third-most abundant element (behind oxygen and silicon), comprising 8.1% of the Earth's crust. Alumina is the second-most plentiful compound (behind silica), comprising 15.9% of the Earth's crust. In its pure form, aluminum is a lighter and softer metal with limited strength. It has only one-third the density of ordinary steel. Electrolytic pure commercial aluminum contains much less than 1.0 % impurity. For applications requiring greater mechanical strength, aluminum is alloyed with elements such as copper, magnesium, manganese, and zinc, usually in combinations of two or more of these elements together with silicon and iron.[1]

The properties of aluminum alloys depend on a complex interaction of chemical composition and the microstructural features developed during solidification and then modified by thermal treatment and/or deformation processing. Heat treatment plays a significant role in developing the desired properties of commercial aluminum alloys. In this chapter, some of the most practical aspects of heat treatment of aluminum alloys are discussed.

2.12.1.1 Designation System of Aluminum Alloys

The specifications and designations of widely varied wrought aluminum alloys have differed from country to country. This is why it is important for the secondary fabricators and users of aluminum to have a working knowledge of the aluminum alloys and their temper designation system.

The selection of aluminum alloys for engineering applications is difficult because an impressive number of commercially available aluminum alloys have been developed to meet specific requirements. Aluminum alloys are divided into two major categories, namely those to be fabricated into wrought form and those used for castings. A further division of each category is made based on the primary mechanism of property enhancement. The chemical composition and mechanical properties of the principal alloys are covered in different national and international standards.

The most commonly used alloy designation system is covered by American National Standards Institute (ANSI) standard H35.1 and is registered by the Aluminum Association (AA) of the United States.[2] This system is also adopted by the

International Alloy Development System (IADS) and by most of the countries in the world.

ANSI 35.1 standard uses a four-digit number for each wrought aluminum alloy, and the first of the four digits is assigned for the major alloying element of the alloy within the group (Table 1). Therefore, we have the 1xxx series alloys, which are unalloyed and contain a minimum of 99% aluminum. For the 2xxx through 7xxx series, the alloy group is determined by the alloying element present in the greatest mean percentage. Series 6xxx is an exception in which the proportions of magnesium and silicon to form Mg_2Si are predominant. Another exception is considered for modified alloy of a previously registered alloy. If the greatest mean percentage is the same for more than one element, then the following sequence will be used to determine the group: copper, manganese, silicon, magnesium, magnesium silicide, zinc, or others.

The second digit indicates impurity level or alloy modifications. A zero second-digit indicates unalloyed varieties. Integers 1 through 9 (assigned consecutively if needed) indicate special control of one or more individual impurities in the 1xxx series and specific alloy modification in all other aluminum alloys.

The third and fourth digits are significant in the 1xxx series, but not in other alloys. In the 1xxx series, the last two digits indicate the minimum purity level of aluminum. Thus, alloy 1100 has a minimum purity of 99.00%, whereas alloys 1150 and 1199 have minimum purity levels of 99.45 and 99.99%, respectively. For all other aluminum alloys, the third and fourth digits have no special significance and serve only to identify the different alloys in the series. Thus, alloys 3003, 3004, and 3005 are distinctly different Al–Mn alloys, just as alloys 6061 and 6063 denote two different types of Al–Mg–Si alloys.

A prefix X is often used to denote that the alloy is at an experimental state of its development.

No internationally accepted system of nomenclature similar to wrought aluminum alloys is available for identifying aluminum and aluminum alloys in the form of castings and foundry ingots. However, the AA of the United States has introduced a revised four-digit system of its previous three-digit system, and this has some similarity to that adopted for wrought alloys.

The first digit in this four-digit system indicates the alloy group, determined by the alloying element present in the greatest mean percentage (Table 1). For modified alloy of a previously registered alloy, if the greatest mean percentage is the same for more than one element, then the alloy group is determined by the element that comes first in the sequence.

For the 1xx.x group, the second and third digits indicate the minimum percentage of aluminum in the alloy. Thus, alloy 150.x indicates a composition containing a minimum of 99.50% aluminum. The last digit after the decimal point indicates the product form: 0 indicates castings and 1 indicates ingots.

For the 2xx.x to 9xx.x alloys groups, the second and third digits have no special significance and serve only to identify the different alloys in the series. The last digit after the decimal point again indicates the product form.

A serial letter is included before the numerical designation when there is a modification to the original alloy or to the normal impurity limits. These serial letters are assigned in alphabetical sequence starting with A, but omitting I, O, Q, and X. Like wrought alloys designations, the letter X is reserved for experimental alloys.

2.12.1.2 Temper Designations

A system of temper nomenclature has been adopted for all forms of wrought and cast aluminum alloys (with the exception of ingots) to specify the mechanical properties of an alloy and the treatments, either thermal or chemical or both, used to achieve these properties. This takes the form of letters and digits and is added as suffixes to the alloy number, with the two being separated by a hyphen. Basic temper designations consist of letters, whereas the subdivision of basic tempers

Table 1 Wrought alloys and cast alloys nomenclatures

Four-digit system for wrought alloys		*Three-digit system followed by a decimal value for cast alloys*	
Aluminum of 99.0% minimum purity	1xxx	Aluminum of 99.0% minimum purity	1xx.x
Aluminum alloys, grouped by major alloying element(s):		Aluminum alloys, grouped by major alloying element(s):	
Copper	2xxx	Copper	2xx.x
Manganese	3xxx	Silicon with copper and/or magnesium	3xx.x
Silicon	4xxx	Silicon	4xx.x
Magnesium	5xxx	Magnesium	5xx.x
Magnesium and silicon	6xxx	Zinc	7xx.x
Zinc	7xxx	Tin	8xx.x
Other elements (e.g., tin, lithium)	8xxx	Unused series	6xx.x
Unused series	9xxx	Unused series	9xx.x
• In the 1xxx group, series 10xx is used for unalloyed compositions, with natural impurities. The last two digits indicate the minimum aluminum percentage		• In the 1xx.x group, the second two digits indicate aluminum purity. In the 2xx.x–8xx.x groups, the second two digits indicate alloy content. The last digit separated by decimal indicates product form (0, castings; 1 and 2, ingots)	
• In the 2xxx–8xxx groups, the second digit indicates alloy modification (0, unmodified; 1–9, modified)		• An alphabetic number in front of the numerical designation indicates alloy modification or impurity limits in unalloyed aluminum	

based on strain-hardening or heat treatment are indicated by one or more digits following the letter used for the basic temper. The system deals separately with the nonheat-treatable and heat-treatable alloys. The temper designation system for aluminum alloys indicated in the ANSI 35.1 standard is briefly discussed in the following sections and given in summarized form in Figure 1. Following Figure 1, alloy 5456-H39 refers to commercial aluminum–magnesium alloy heavily worked and hardened. It is noteworthy that yield strength of this alloy is approximately 500 MPa. Also, 7079-T6 would refer to an aluminum–zinc–magnesium–copper alloy, which is solution-treated and quenched, followed by age hardening.

2.12.1.2.1 Basic temper designations

F *As-fabricated*. Applied to the products shaped by cold/hot working or casting, with no special control over thermal conditions or strain hardening.

O *Annealed*. Applied to wrought products, which are annealed to obtain lowest strength and to cast products that are

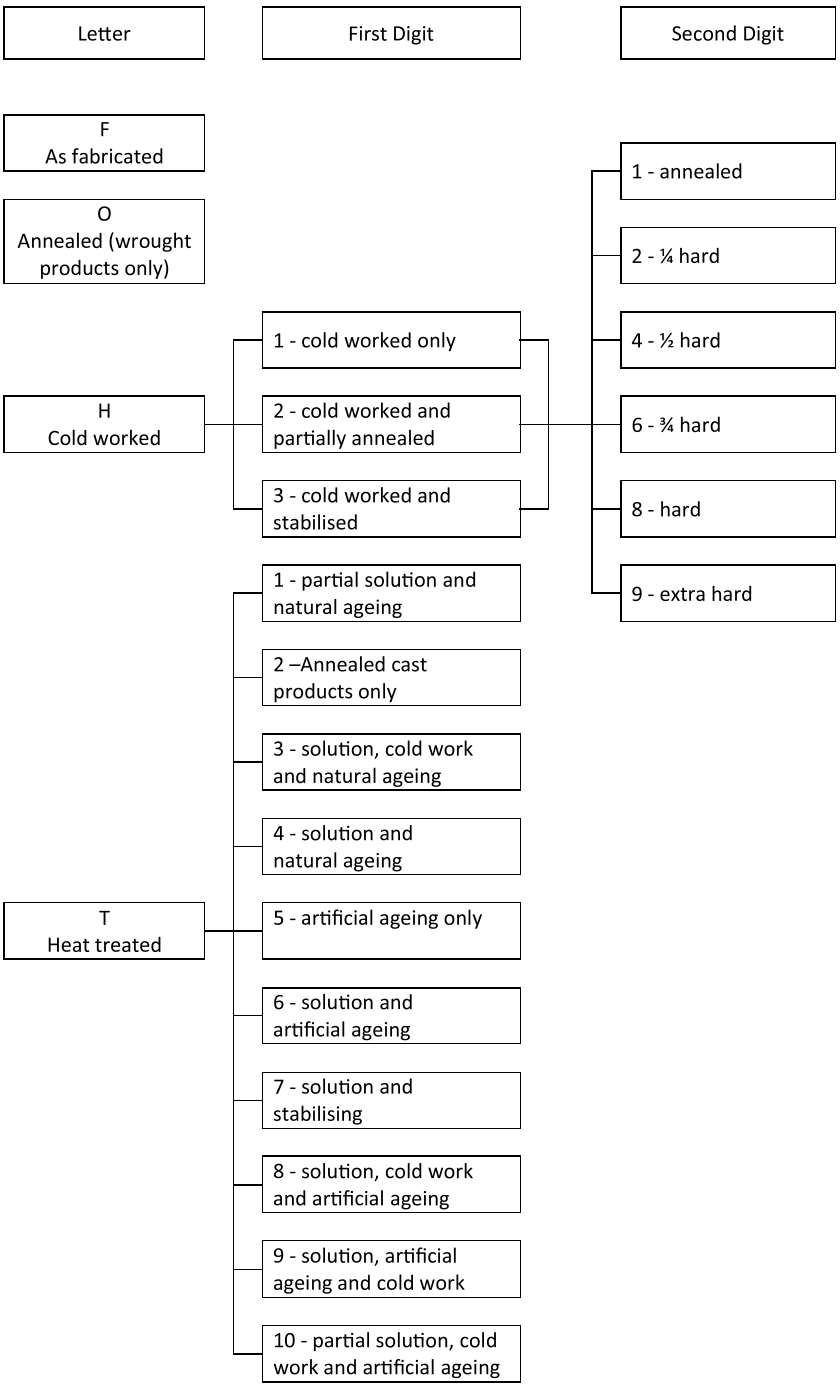

Figure 1 Temper designation system for aluminum alloys.

annealed to improve ductility and dimensional stability; may be followed by a digit other than zero.

H *Strained hardened (for wrought product only)*. Applied to products that have strengthened by strain hardening, with or without thermal treatment; usually followed by two or more digits.

W *Solution heat-treated*. This is applicable to alloys whose strength is unstable and naturally changes at room temperature (RT) over a duration of months or years after solution treatment.

T *Solution heat-treated*. This is applicable to alloys whose strength is stable within a few weeks of solution treatment; always followed by one or more digits.

2.12.1.2.2 Subdivisions of basic tempers

2.12.1.2.2.1 Subdivision of H temper: Strain-hardened

H1 *Strain-hardened only*. Applies to products that are strengthened by strain hardening; digits following H1 indicate the degree of strain hardening.

H2 *Strain-hardened and partially annealed*. Strain-hardened more than the desired final amount and then reduced in strength to the desired level by partial annealing; digits following H2 indicate the degree of strain hardening remaining after annealing.

H3 *Strained-hardened and stabilized*. Products that are strained-hardened and the mechanical properties are stabilized (to improve ductility) by a low-temperature thermal treatment or heat introduced during fabrication; digits following H3 indicate the degree of strain hardening remaining after annealing.

2.12.1.2.2.2 Subdivision of T temper: Thermally treated

T1 *Cooled from high-temperature (HT) shaping process and naturally aged*. Products are not cold-worked after HT shaping process (e.g., casting, extrusion) and mechanical properties are stabilized by natural aging.

T2 *Cooled from HT shaping process, cold-worked, and naturally aged*. Products are cold-worked to improve strength after HT shaping process (e.g., rolling, extrusion) and mechanical properties are stabilized by natural aging.

T3 *Solution-treated, cold-worked, and naturally aged*. Products are cold-worked to improve strength after solution heat treatment (SHT) and mechanical properties are stabilized by natural aging.

T4 *Solution-treated and naturally aged*. Products are not cold-worked after SHT and mechanical properties are stabilized by natural aging.

T5 *Cooled from HT shaping process and artificially aged*. Products are not cold-worked after HT shaping process (e.g., casting, extrusion) and mechanical properties are substantially improved by precipitation heat treatment.

T6 *Solution-treated and artificially aged*. Products are not cold-worked after SHT and mechanical properties and/or dimensional stability are substantially improved by precipitation heat treatment.

T7 *Solution-treated and overaged or stabilized*. Applied to wrought products that are precipitation heat-treated beyond the point of maximum strength to provide special characteristics, such as enhanced resistance to stress-corrosion cracking (SCC).

T8 *Solution-treated, cold-worked, and artificially aged*. Products are cold-worked to improve strength after SHT and mechanical properties and/or dimensional stability are substantially improved by precipitation heat treatment.

T9 *Solution-treated, artificially aged, and cold-worked*. Products are cold-worked specifically to improve strength after SHT and precipitation heat treatment.

T10 *Cooled from HT shaping process, cold-worked, and artificially aged*. Products are not cold-worked specifically to improve strength after HT shaping process (e.g., rolling, extrusion) and mechanical properties are substantially improved by precipitation heat treatment.

2.12.1.2.2.3 Variation of O temper: Annealed

A digit following the O is often used to indicate a product in annealed conditions with special characteristics. For example, O1 indicates a wrought product that has been heat treated at approximately the same time and temperature required for SHT and then slow-cooled to RT, whereas O2 indicates a wrought product laboratory test material that has been furnace-annealed from F temper to determine the minimum limits to which H temper designations are assigned.

2.12.1.2.2.4 Variation of H temper

There are a few H tempers consisting of three digits.[3]

H111 Temper. This is used when alloy is less hardened compared to H11.
H121 Temper. This is used when alloy is less hardened compared to H12.
H311 Temper. This is used when alloy is less hardened compared to H31.
H321 Temper. This is used when alloy is less hardened compared to H32.

2.12.1.2.2.5 Variation of T temper

There are a few T tempers consisting of three to four digits.[3]

T42 Temper. This indicates solution treated from O or F temper, quenched, and naturally aged.
T62 Temper. This indicates solution treated from O or F temper, quenched, and artificially aged.
Tx51 Temper. This indicates stress is relieved by stretching. Permanent deformation can vary from 0.5 to 3%. X denotes 3, 4, 6, or 8.
Tx52 Temper. This indicates stress is relieved by compression. X denotes 3, 4, 6, or 8.
Tx53 Temper. This indicates stress is relieved by thermal treatment. X denotes 3, 4, 6, or 8.
Tx54 Temper. This indicates stress is relieved by both stretching and compression. X denotes 3, 4, 6, or 8.

2.12.1.3 Classification of Aluminum Alloys

2.12.1.3.1 Wrought and cast alloys

In general, the lion share of wrought aluminum products is used in the form of plates (more than 6 mm thickness), sheets (0.15–6 mm), foils (<0.15 mm), extrusions, tubes, rods, bars, and wires. These are produced from cast ingots and the final

structure is developed after various working and thermal treatments.

Aluminum foundry alloys are one of the most versatile and commonly used foundry alloys because of their low melting points and negligible solubility for all gases (except hydrogen), and usually result in good surface finish in the final products. Most alloys also show high fluidity, and a wide variety of compositions can be selected with solidification ranges suitable for particular applications. The most commonly used processes are sand casting, permanent mold (gravity die) casting, and high-pressure die casting.

The heat-treatable and nonheat-treatable wrought and casting aluminum alloys series are reported in **Table 2**. The designation and the chemical composition of commonly used wrought and casting alloys are given in **Tables 3–6**, whereas those of commercial lithium-containing aluminum alloys are given in **Table 7**.

2.12.1.3.2 Heat-treatable and nonheat-treatable alloys

Aluminum alloys with limited solid solubility in the solid state are heat-treatable and normally recognized as the precipitation hardenable alloys. In addition, the other requirements include the possibility of retaining single-phase supersaturated solid solution by quenching and precipitation of coherent or partially coherent solid phase by decomposition of the supersaturated solid solution with time. Alloys containing copper (2xxx and 2xx.x series), silicon and magnesium (6xxx and 3xx.x series), zinc and magnesium (7xxx and 7xx.x series), and lithium (8xxx series) are the most important heat-treatable aluminum alloys.

Binary aluminum alloys of Mg, Si, Zn, Cr, and Mn show little change from thermal treatment whether the solute is completely in solution, partially precipitated, or substantially precipitated. Although these alloys show a decrease in solid solubility in the phase diagrams that is necessary for precipitation hardening, they rarely show any change in the mechanical properties after heat treatment because of their inability to form coherent or partially coherent clusters of solute atoms, either by natural aging or artificial aging.

Alloy compositions that cannot be strengthened by heat treatment are commonly regarded as the nonheat-treatable alloys. They consist of a homogeneous solid solution with or without noncoherent precipitate(s) and show low strength and high ductility. Strength in these alloys is developed by *strain hardening* by cold rolling, drawing, or stretching during manufacturing, *solid solution hardening*, strengthening from *second-phase microstructural constituents* (due to the presence of predominantly second-phase constituents such as iron, nickel, titanium, manganese, and chromium), and *grain refinement* with dispersed precipitates.

Nonheat-treatable wrought alloys mainly comprise the various grades of pure aluminum (1xxx series) and aluminum alloys with manganese or magnesium as the major additions, either singly or in combination (3xxx and 5xxx series). Binary aluminum alloys with silicon (4xx.x series) or magnesium (5xx.x series), however, are the most important nonheat-treatable cast alloys. Further discussions on nonheat-treatable alloys are beyond the scope of this chapter and are not discussed further.

2.12.2 Heat Treatment of Aluminum Alloys

Heat treatment typically indicates an event of thermal practices that invokes microstructural changes leading to desired mechanical properties. In practice, heat treatment can increase hardness, improve wear resistance, modify strength and other mechanical properties, and relieve residual stresses. In ferrous material, heat treatment covers a vast field. However, in aluminum alloys, heat treatment, in particular, refers to strengthening of parts by precipitation hardening. Other strengthening mechanisms of aluminum alloys include hardened by working for a few nonheat-treatable alloys, softening (annealing), solution treatment, and/or quenching processes for a few alloys under specific conditions.

2.12.2.1 Heat Treatment Furnaces

The choice of heating medium depends on the procedure of heat treatment for a particular alloy and parts complexity. To induce thermal environment, molten baths or furnaces are used. Molten baths are usually salts baths, and furnaces are simple air-chamber furnace. Oil or gas-fired furnaces are rarely used for this purpose because the work surface comes in contact with combustion products, leading to severe HT oxidation. Salt baths are not involved with this HT oxidation

Table 2 Heat-treatable and nonheat-treatable wrought alloys and cast aluminum alloys

problem. Induction heating appears to be a good choice in terms of possibility of high heating rates; however, such a high rate may cause nonequilibrium melting followed by a microstructure containing a small portion of eutectics.

Among the choices of heating medium, salt baths appear to be more suitable in terms of soaking time required, dimensional stability during treatment, and interrupted supply of parts. In this medium, parts are heated by conduction of heat from the molten bath. Heat is transferred quickly from the surface to the interior of the parts and uniform heating is thus achieved. Any dimensional distortion is apparently avoided because heating is gradual and uniform, and buoyancy support is obtained from the bath. A suitable salt must be chosen depending on heat treatment schedule and its affinity toward moisture. Instead of molten salt baths, lead baths, oil baths, or fluidized beds can also be used for heat treatment. It should be remembered that exposure to molten baths may possess health hazards, and there may be a small chance of explosion. Therefore, bath concentration generally varies depending on alloy composition, and surface cleaning of parts prior to dipping into baths may be required.

In contrast, air-chamber furnaces perform better because these risks are not encountered and use of different temperatures in regular intervals is possible; therefore, they are more economical than salt baths, especially for complex-shaped parts. Atmosphere of the furnace must be controlled to prevent any blistering of the surface. High-strength 2xxx and 7xxx series alloys are prone to such adverse effects. However, it should be borne in mind that surface discoloration is a common phenomenon during heat treatment (especially SHT) of aluminum alloys, and this should not be considered as damage during heat treatment.

2.12.2.2 Strengthening by Heat Treatment

2.12.2.2.1 SHT

The first stage of heat treatment is to dissolve the maximum possible alloying elements into the solid solution before trapping them by quenching prior to aging to allow them to precipitate as particles to improve hardening. This first stage is known as SHT.

SHT for aluminum alloys is performed in the single-phase region, above the solvus line of the equilibrium phase diagram, to keep all the alloying elements in the solid solution.[6] Before the start of SHT, the solutes are concentrated in different phases or in solution, as shown in **Figure 2(a)**.[7] During heating, these phases/particles start to dissolve into the matrix by diffusion throughout the microstructure (**Figures 2(b)** and **2(c)**). Consequently, dislocation motion is less restricted during deformation and ductility is somewhat improved.[8]

SHT temperature has pronounced effects on expected mechanical properties and microstructure. For example, in **Figure 3(a)**, an aluminum–zinc phase diagram is shown. Prior to any precipitation hardening by aging treatment, the alloy needs to be heated at a suitable temperature in the α-region (here, a single-phase region) so that foreign elements can come back into the solution of the aluminum matrix. In **Figure 3(b)**, an aluminum–magnesium phase diagram is shown. As expected, the SHT temperature range here is in the single-phase field, (Mg) phase. For example, for an Al–10Mg alloy (LM-10 alloy), the temperature range is 425–435 °C. This is clearly depicted in the phase diagram. Typically, the temperature is selected as close as possible to the solidus line.[9] However, utmost care should be taken so that the chosen

temperature does not result in overheating or underheating. If overheating occurs, especially by exceeding the solidus temperature line of the phase diagram, then local melting or liquation of solids at grain boundary regions may occur. This, in turn, will result in loss of tensile properties and fracture toughness. Such incipient melting can effectively be detected by X-ray microtomography methods. In Figure 4, incipient melting, characterized by small irregular regions with smooth surfaces, is seen at 551 °C (824 K) immediately after the start of SHT for an Al–Si–Cu alloy.[10]

In addition, if induction heating is used or if high heating rate is considered, then nonequilibrium heating conditions

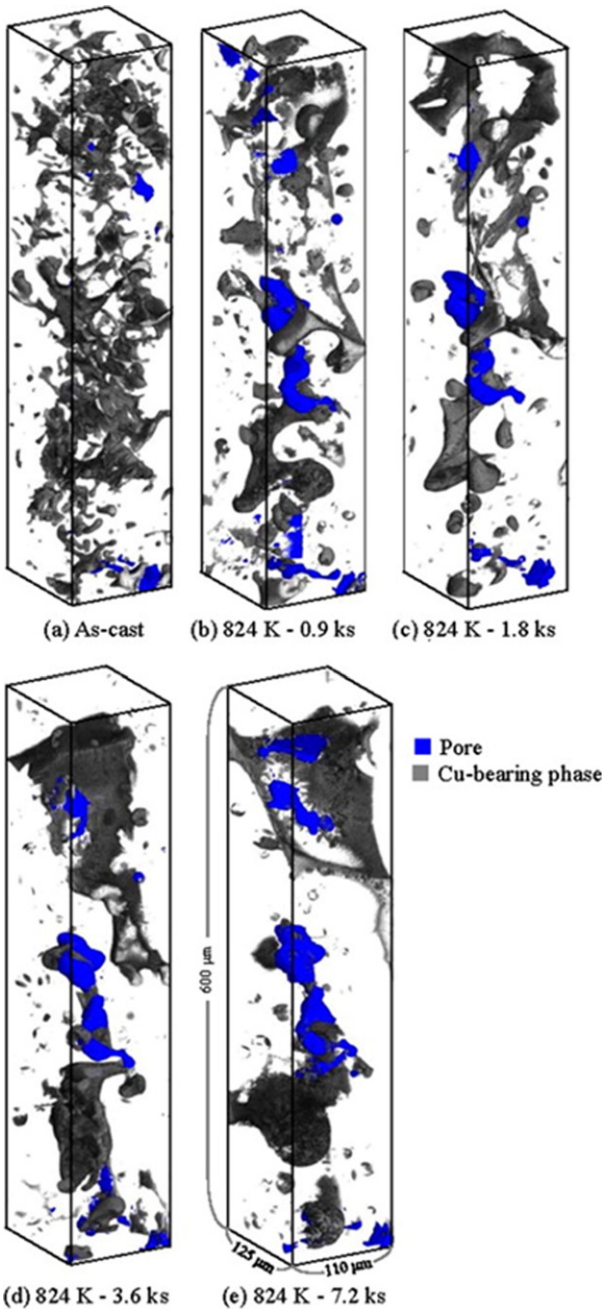

Figure 4 3D perspective views of pores and copper-bearing phase. Solution treatment temperature was 824 K. Incipient melting is clearly seen immediately after the commencement of heating. Large, irregularly shaped regions with smooth surfaces and small spherical regions are the proof of this local melting. These spherical regions disappeared over time, whereas irregular regions were coalesced together with time. Adapted from Ref. [10], used with permission.

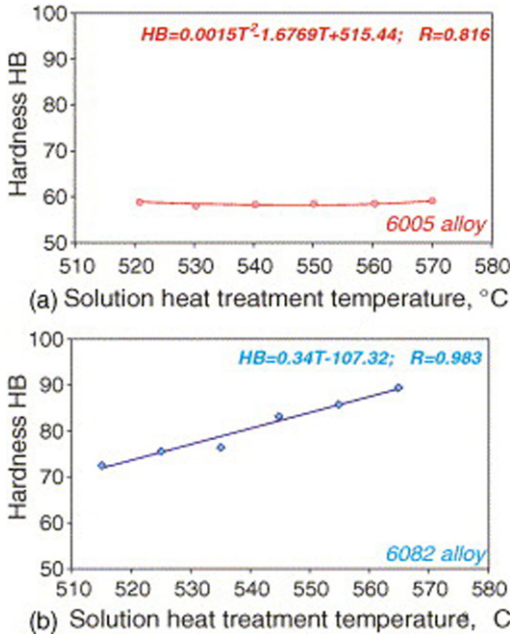

Figure 5 Influence of the solution heat treatment temperature on hardness of: (a) 6005 alloy and (b) 6082 alloy. The mechanical properties of 6005 alloy is not dependent on solution treatment temperature. In contrast, in 6082 alloy a strong dependency is observed. This is due to the difference in magnesium, silicon, and manganese amount in both alloys. More Mg_2Si (β) phase was nucleated when the solution temperature was increased. This explained the improvement of hardness. Adapted from Ref. [12], used with permission.

would prevail, indicating vertical movement of the solidus line, and leading to further liquation. When underheating occurs, expected mechanical properties may not be achieved. In aluminum alloys, solvus lines are typically shallow, and a small decrease in temperature may affect the desired level of trapped solutes by attaining unexpected strengths after aging. For a 6082 alloy, hardness values were observed to increase with SHT temperature.[12] It was experimentally found that the amount of trapped magnesium and silicon in the solid solution required for the formation of Mg_2Si particles (responsible for strengthening) increased when the SHT temperature was moved upward, following corresponding phase diagram. However, it should be kept in mind that increasing SHT temperature only cannot always result in improvement of properties (**Figure 5(a)**); the amount of alloying elements present in the alloy is also of prime concern. In **Figure 5(b)**, the same SHT treatment applied for a 6082 alloy had significantly improved hardness compared to a 6005 alloy, which had a lower concentration of magnesium and silicon. It is noteworthy that in commercial aluminum alloys, obtaining a well-distributed solute atom concentration is a rare event due to nonequilibrium solidification, and formation of eutectic phases with a low melting point from these segregations is unavoidable. Therefore, a very high SHT temperature beyond which these eutectics were solidified can lead to local melting, as mentioned. Unfortunately, such low melting can even occur without any segregation, as seen in Al–Mg–Si[13] and Al–Zn–Mg[14] alloys. Therefore, a slightly lower SHT temperature is industrially preferred.

The time for SHT (soaking time) must be adequate to allow dissolution of phases present and homogenous distribution of solutes,[15] and hence a more formable material. A properly selected soaking time helps to reduce irregular precipitates and residual stresses. A longer time generally helps coarsening of hard particles, which may not dissolve at low SHT temperature.

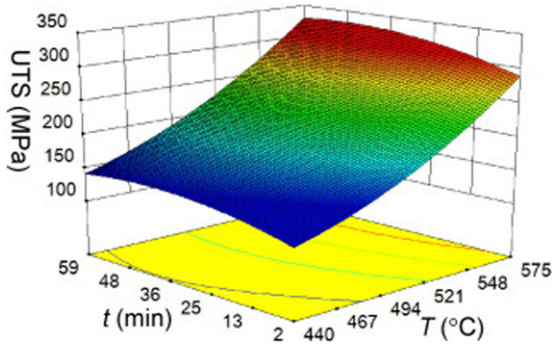

Figure 6 Effect of solution heat treatment temperature (T) and time (t) on ultimate tensile test for an AA6082 alloy sheet with thickness of 1.50 mm. Adapted from Ref. [18], used with permission.

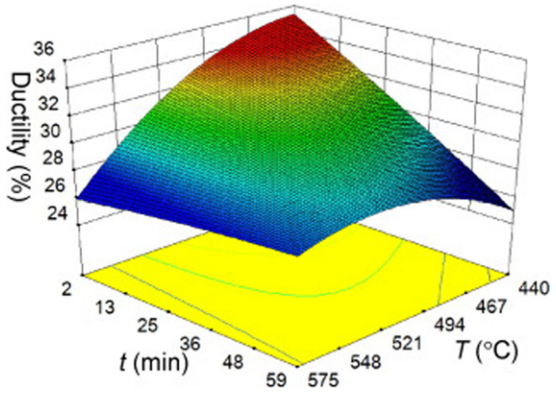

Figure 7 Effects of solution heat treatment temperature (T) and time (t) on ductility for an AA6082 alloy sheet with thickness of 1.50 mm. Adapted from Ref. [18], used with permission.

This spheroidizing ultimately contributes to ductility during flow of materials.[16] The soaking time is generally shorter for investment, sand, and permanent mold castings, in progressive order.[17] The time can vary from a few seconds for very thin sheets to approximately a day for large and complex castings. Soaking time is calculated differently for different heating mediums. In molten salt baths, soaking time is estimated as soon as the parts are immersed and the temperature is still on its way to the scheduled temperature. In contrast, in air-chamber furnaces, soaking time is calculated after the chamber reaches its scheduled temperature on machine readings.

The effects of SHT temperature and soaking time are clearly demonstrated in the surface model, as shown in **Figure 6**. Ma *et al.*[18] showed that for an AA6082 aluminum alloy sheet with a thickness of 1.5 mm, ultimate tensile strength (UTS) was increased with SHT temperature and soaking time. For any particular soaking time, increasing SHT temperature raised UTS significantly, consistent with previous observation with hardness data. Low SHT temperature (above solvus line) may not be sufficient to dissolve a large number of solute atoms, even if the soaking time is reasonably longest. Similarly, the effects of SHT temperature and soaking time on ductility are shown in **Figure 7**. Ductility was enhanced at both shorter soaking time and SHT temperature. Interestingly, the effect of soaking time on ductility was more pronounced at lower SHT temperatures compared to higher SHT temperatures. In a different approach, the strength effects can be considered based on particle coarsening. Strengthening by precipitated particles occur either by shearing of particles or by Orowan loop formation. For large particles, yield strength can be increased by the first method or decreased by the second method. Longer soaking time eventually increases the particle size, because the diameter of $Al_3(Sc,Zr)$ particles of an SSA108 alloy was found to increase significantly during longer soaking time.[19] With an increase in particle diameter, the yield strength was decreased and it was claimed that the Orowan loop mechanism was responsible for this decrease in strength.

It is now obvious that it is possible to depict a limiting range of temperature for solution treatment. As shown in **Figure 8**, for the binary aluminum–copper system, the solution treatment temperature range is carefully chosen slightly below the eutectic temperature for that alloy system.

2.12.2.2.2 Quenching

Quenching is considered one of the most critical thermal processes. It involves heating of the workpiece to a certain temperature and then rapid cooling, usually to RT. The aim of this treatment is to trap maximum possible solute atoms in the solid solution, keeping the minimum residual stresses. Large thermal gradients can cause inhomogeneous plastic deformation, leading to the development of large residual stresses. If the quenching is accomplished in cold water, then forged AA7449 alloy induces biaxial compressive stress of a magnitude of 250–300 MPa at the surface and 350 MPa tensile stress in the core.[20] Quenching also helps to keep a sufficient number of vacancies in solid state to permit diffusion at lower temperatures. Quenching eventually produces a supersaturated solid solution, which is a favorable condition for aging. However, maintaining dimensional stability is a challenge that deals with appropriate quenching medium and quenching duration.

It is believed that quenching heat treatment alters properties, and that tensile properties including ductility are generally improved compared to the as-cast (F) condition. This quenching treatment is designated as T4 (see Section 2.12.1.2.2.2), which denotes SHT followed by quenching and natural aging. However, commercially, this condition is not attractive because artificial aging can improve mechanical properties significantly.

As a quenching medium, water is most commonly used for aluminum alloys. Generally, boiling water, warm water (65 °C), or RT water is used as a quenchant. When selecting a quenchant, factors affecting the cooling rate such as formation of a vapor blanket, heat of vaporization, specific heat, and conductivity become vital,[21] and different alloys require different choices. Further changes in cooling rate can be obtained by coating the part or by adding polymers in the quenchant.

Total quenching duration should be kept as short as possible. Otherwise, there is a possibility of random precipitation, which eventually does not contribute to strengthening and protection from corrosion. To reduce susceptibility of such precipitation, quench delay, such as time to transfer parts from the furnace area to the quenching area of the plant, should be kept as short as possible because such interruption can lead to

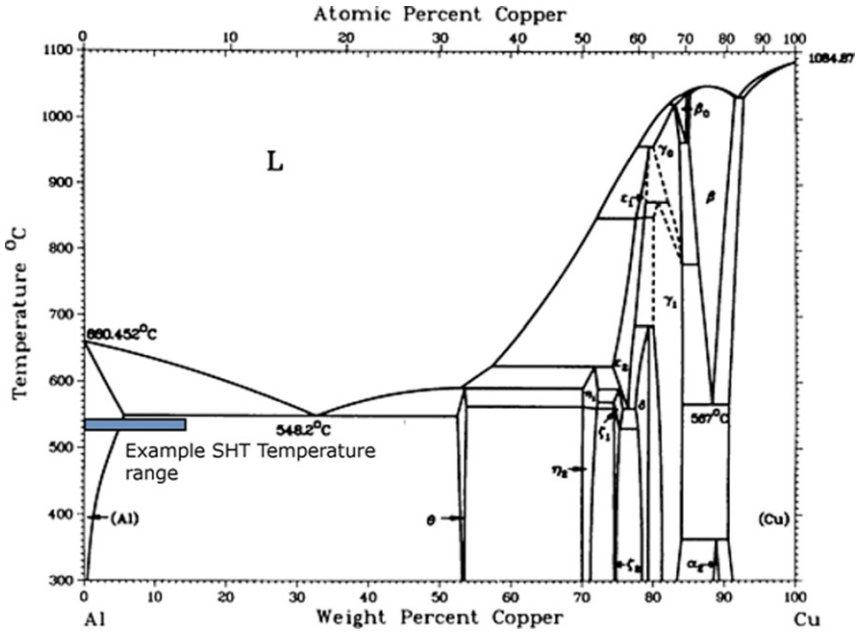

Figure 8 Aluminum–copper binary equilibrium phase diagram. Temperature range for solution heat treatment is shown by highlighting just below the eutectic temperature line. Adapted from Ref. [11], used with permission.

a certain degree of precooling. Also, to prevent any extent of reheating or disruption of cooling during quenching (which can also promote precipitation), the flow of the quench medium should be closely monitored.

Cooling rate affects total strengthening obtainable from quenching and is a crucial factor for microstructural distribution.[22] For example, for a nonstrontium-modified Al–Si–Cu–Mg alloy, a rapid cooling rate was found to improve hardness values.[23] It partly controls aluminum dendrite size, eutectic silicon size (if present), and the size, shape, and distribution of phases and porosity. As mentioned, it is essential to retain all soluble elements in the solid solution of aluminum. Therefore, the rate must be high enough (without any interruption) to ensure greater initial soaking temperature for the estimated duration of quenching to dissolve everything into solution, and at the same time to prevent formation of particles in the grain boundary. Any interruptions (known as quench delay) during quick transfer of job parts from the furnace to the quenching medium would lead to rapid precooling and formation of particles depending on alloy composition and soaking temperature.

If particles are precipitated during quenching, then the total number of formable particles during aging is reduced, and corrosion resistance and mechanical properties are somewhat compromised. A rapid cooling rate also increases total number of excess vacancies in the lattice structure to create an environment favorable for diffusion and ultimately promoting precipitation during aging. Nevertheless, increasing the cooling rate causes greater thermal gradients, resulting in higher internal thermal stresses and instability in dimensions of job parts. To minimize thermal stresses, the quenching medium plays an important role. Warm baths are sometimes suggested to prevent development of residual stresses. Otherwise, job parts are treated by immersion in cold water or by spraying with high-velocity cold water.

It is well established that cooling rate depends on alloy composition and can be denoted by quench sensitivity – minimum cooling rate applicable without substantial precipitation during cooling. Quench sensitivity is defined as a relative measure of removal of solute atoms from solid solution in the form of precipitation.[24] Commercial alloys containing a variety of micro-alloying elements for specific applications and fine precipitates are considered more quench sensitive because they can promote heterogeneous nucleation during the cooling schedule. However, there are disputes about the large impact of alloy composition on residual stresses. Also, quenching response of cast and wrought alloys are different. Robinson *et al.*[25] insisted that both AA7010 and AA1075 alloys had shown a closely similar pattern of residual stresses despite the differences in quench sensitivity due to wide variation in alloy chemistry. Alloys from the 2xxx, 6xxx, and 7xxx series are cooled at higher quench rates because they are more susceptible to precipitate during cooling. For example, alloy AA7050 is an aerospace alloy combining strength, SCC resistance, and toughness, and it is less quench-sensitive compared to most competitors. This alloy is heavily used as plate in fuselage frames and bulkheads within a thickness range of 75–150 mm. Recently, modifications in major alloying elements, in the form of the Zn/Mg/Cu ratio, of these alloys have led to the development of AA7085 – used in Airbus A380. For a 413-type Al–Si cast alloy, it was observed that a warm water bath (60 °C) was preferable to ambient air to improve alloy strength.[26] Also, according to Gauthier and co-workers,[27] for an as-cast 319.2 alloy, the best combination of strength and elongation to failure was found by quenching in warm water at 60 °C prior to artificial aging. In an AA7055 alloy, more grain boundary particles containing greater amounts of zinc and magnesium were precipitated at a slow quench rate. Consequently, these electrochemically active

particles and precipitate-free zones (PFZs) near grain boundaries that accelerate corrosion are more electrochemically active and tend to accelerate corrosion. It is noteworthy that PFZs become wider in slowly quenched alloys. It is obvious from **Figure 9** that the greater the cooling rate, the smaller the PFZ and grain boundary particles.[28] Also, slow quench rate increases volume fraction and spacing of particles.

For a commercial AA7108 alloy, different quenching rates were used to understand the effects of cooling velocity on microstructures.[29] It was found that precipitation of the η-phase was promoted during cooling below the solvus line. At a rapid cooling rate, such a phase was small and needle-shaped compared to the microstructure of a similar alloy quenched at a much slower rate (**Figure 10**). The large and largely spaced needles are distinguishably visible in the microstructure. Also, PFZs around particles are readily identifiable after a slow cooling rate.

For an AA6063 alloy, it was experimentally found that quench holding time had a pronounced effect on age treatment and mechanical properties.[15] The alloy was solution-treated at 535 °C for 1 h, quenched in a salt bath, and held there isothermally for a predetermined time prior to aging at 180 °C for 4 h. It is certain that with the increase of holding time in the quench bath, there was a marked decrease in hardness after aging (**Figure 11**). Also, the number density of particles decreased after coarser particle formation. Guinier–Preston (GP) zones (see Section 2.12.2.2.3) and needle-shaped β' phase, in the Al–Mg–Si alloy system, are responsible for strengthening during aging. With the increase of holding time, the needle-shaped β' phase becomes coarser, which means the number density of this phase is reduced. Consequently, the equilibrium β phase formed at the latter stage is coarser and incoherent but is not an effective barrier for dislocation motion. As more magnesium and silicon atoms are taken by this equilibrium phase, fewer atoms remain for strengthening by β'' particles. Therefore, the contribution of this microstructure to strengthening is negligible.

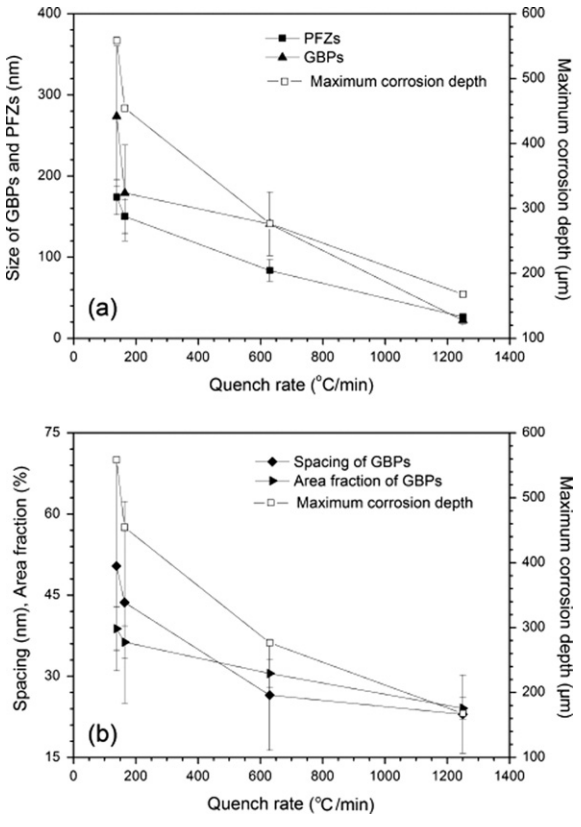

Figure 9 For an AA7055 alloy, the effect of the quench rate on grain boundary microstructures (a) size of precipitate-free zones (PFZs), grain boundary particles (GBPs), and (b) spacing and area fraction of GBPs. The maximum corrosion depth is also given. It is clear that as the quench rate is decreased, the size, spacing, and area fraction of GBPs increase. Also, it is interesting to note that the widths of PFZs near grain boundaries become larger. Adapted from Ref. [28], used with permission.

2.12.2.2.2.1 Quenched-in vacancies

Quenched-in vacancies in the supersaturated solid solution play an important role in further strengthening processes, such as aging.[30] The number of vacancies in equilibrium increases with temperature exponentially. It is therefore expected that at the SHT temperature, the total number of vacancies will be very high. Now, quenching is performed very rapidly, leaving no room for reaching equilibrium conditions, so that equilibrium concentration of vacancies can be rearranged. Consequently, there are many vacancies from the high SHT temperature that become trapped-in – or quenched-in – at RT (quenching temperature). With time, excess vacancies will be annealed out. Vacancies will coalesce to form clusters. Some of these clusters can interact with dislocation loops and grow further, either by adding more vacancies to the cluster or by increase of dislocations. Consequently, these vacancies act as heterogeneous nucleation sites. In addition, vacancies play another vital role. These excess quenched-in vacancies help to accelerate the rate of diffusion of atoms during aging. It is claimed to be the only way the GP zones are formed initially at the very low aging temperature (or RT).[31] As discussed later (see Section 2.12.2.2.3.1), natural aging is accomplished at RT without any stimulation from the outside. Therefore, formation of GP zones by diffusion of atoms can only be explained with the guidance from quenched-in vacancies. If an alloy is solution-treated at different temperatures and then aged after quenching, the rate of GP zone formation is highest for the alloy soaked at the highest temperature. This is proof that quenched-in vacancies increase the rate of diffusion because higher solution temperature means higher concentration of vacancies awaiting being trapped-in. Interestingly, it was found that larger solute atoms would exert stronger affinity for binding with vacancies.[32]

These vacancies are also responsible for formation of PFZ adjacent to grain boundaries. Generally, grain boundaries themselves and the interior of grains contain abundant particles. However, there are some regions very close to boundaries that hardly have any particles. Such a difference in chemical potential can invoke intergranular corrosion. Vacancies with high diffusivity migrate quickly toward grain boundaries as boundaries act as a sink for vacancies. Far-off boundaries and the concentration of vacancies are reduced. As a consequence, precipitation becomes limited due to lack of nucleation sites, because a critical value of supersaturation of vacancies must be

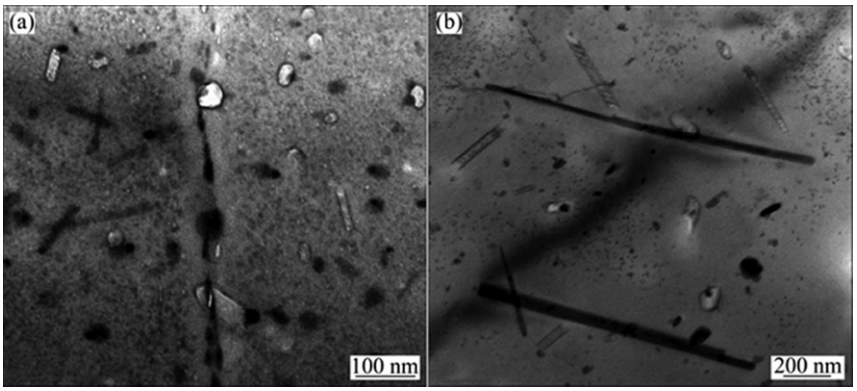

Figure 10 For an AA7108 alloy, TEM bright field micrographs of samples after aging showing microstructure of material continuously cooled from 480 to 200 °C within (a) 10 and (b) 120 min. The microstructure in (a) contains a mixture of η', η, and notable precipitate-free zone (PFZ). Some of the precipitates are needle-shaped. After a longer time, as in (b), η formation is unavoidable in the earlier state, leaving only a subtle amount of solutes for the nucleating η' phase. PFZs are also seen around particles. Adapted from Ref. [29], used with permission.

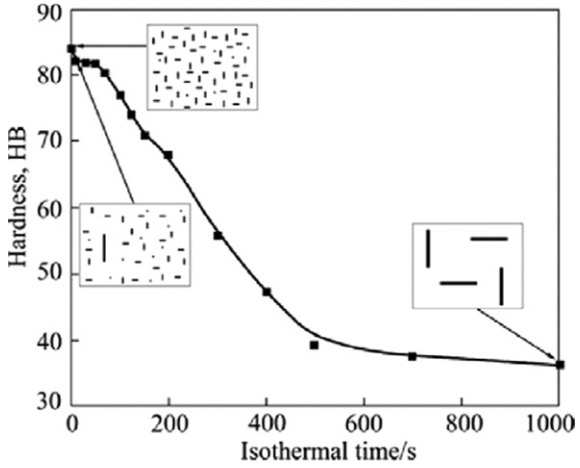

Figure 11 Relationship between precipitate distribution and hardness of aged specimens held at 370 °C for different times for AA6063 alloy. As more magnesium and silicon atoms are taken by the equilibrium β phase, fewer atoms remain for strengthening by needle-shaped β'' particles. Also, the β'' phase becomes coarsened over time. Therefore, the contribution of this microstructure to strengthening is negligible. Adapted from Ref. [15], used with permission.

exceeded for nucleation to occur. It is important to note that solute content in the aluminum matrix in these zones is not affected by this zone formation. Using 3D atom probe tomography techniques, PFZ formation can be visualized.[33] After quenching, excess quenched-in vacancies and different types of solutes are distributed randomly in the aluminum matrix. Now, at the beginning of aging, nanocrystals are formed (**Figure 12(a)**). However, as boundaries act as a sink for vacancies, the number of nanocrystals is comparatively less near the boundaries. As aging continues, these nanocrystals transform into GP zones or intermediate precipitates at grain boundaries and grain interiors, with a limited number of small nanocrystals remaining in areas close to boundaries. These are PFZs. To prevent PFZs from forming, silver may be added as a micro-alloying element. Silver atoms take the nanocrystals as prisoners, and depletion of vacancies in adjacent areas of boundaries is prevented (**Figure 12(b)**). Therefore, a PFZ with a very narrow width is formed. PFZ was reported to form in many aluminum alloys, including Al–Li aerospace alloys,[34] Al–Si cast alloys,[35] and Al–Zn–Mg alloys.[36] There is another mechanical formation of PFZs. At the high-energy grain boundaries, precipitates are formed and grown during quenching from the SHT temperature. This causes a flux of solutes from areas adjacent to grain boundaries. PFZ can deteriorate mechanical properties of alloys.[37] However, it was claimed to have some beneficial effect in damage tolerance by desensitizing the material to the breaking of particles.[38] To prevent formation of PFZs, a higher solution temperature and faster quenching rate are sometimes suggested.

2.12.2.2.3 Aging

Age hardening or precipitation hardening is the final step of three steps of strengthening by the heat treatment process for aluminum alloys. Hardening by aging can be accomplished either at RT (nature aging) or at elevated temperature for a predetermined period of time (artificial aging). Aging involves decomposition of metastable supersaturated solid solution formed during the second step of heat treatment. This decomposition leads to precipitation of a new phase. Interactions between these decomposition products and dislocations play the key role of strengthening by aging. As mentioned, SHT is accomplished at a temperature in the single-phase region and quenching is ended at a temperature in the two-phase region. During aging, precipitation starts with the formation of coherent gathering of solute-rich atoms into the matrix aluminum. These gatherings are called GP zones. The GP zone is the first step of formation of equilibrium precipitates during aging. The next step is semi-coherent intermediate precipitates, which are larger than GP zones. These precipitates can be nucleated at GP zones or at crystalline defects such as dislocations. The final precipitate is incoherent and largest in size. This final phase rarely contributes to strengthening. Maximum strength is obtained from fine dispersion of GP zones and intermediate precipitates. It is important to note that solute clusters and co-clusters of different solute atoms are also observed prior to GP zone

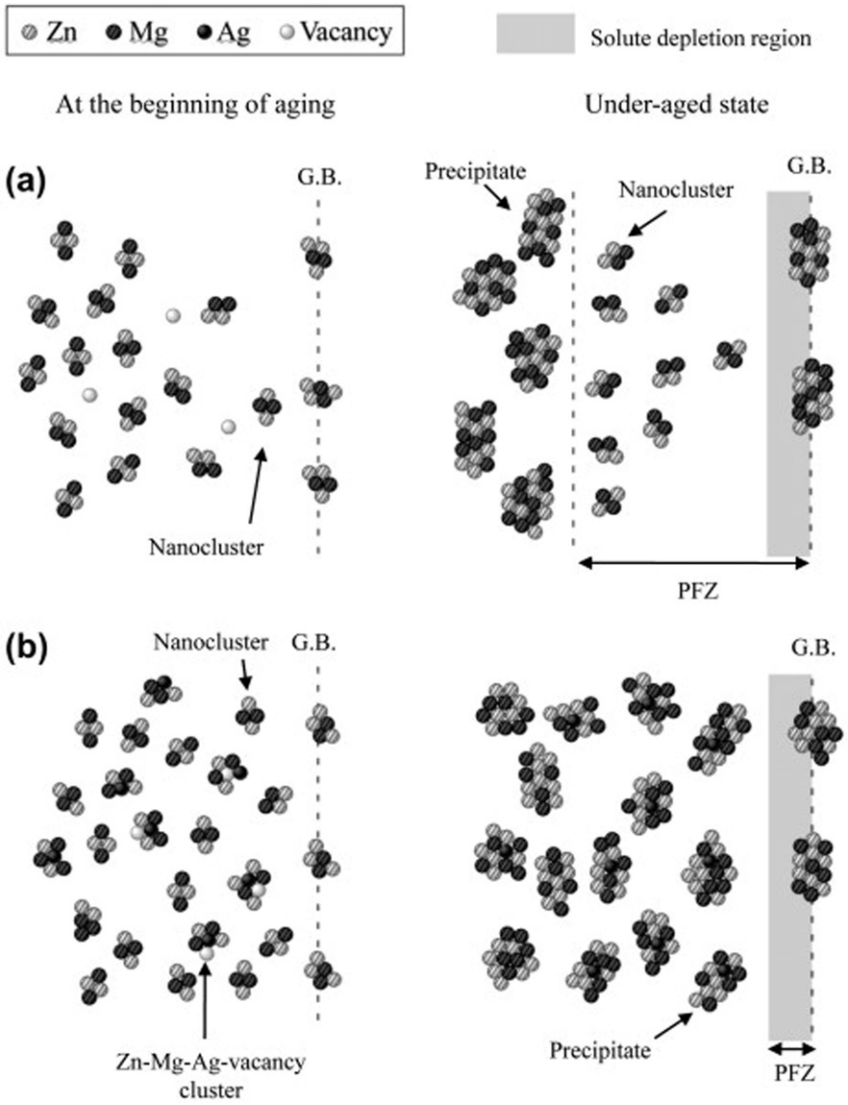

Figure 12 Schematic diagrams of the proposed precipitation processes in the vicinity of grain boundaries during aging in the (a) Al–Zn–Mg ternary and (b) Ag-containing alloys. Left figures are at the beginning of aging, whereas right figures are in an underage state. Adapted from Ref. [33], used with permission.

formation for many aluminum alloys. These clusters are merely regions of concentrated solute atoms. The formation of these clusters was studied using Monte Carlo step (MCS) simulation by Sato and co-workers.[39] **Figure 13(a)** shows that vacancies can be entrapped by solute atoms (here, magnesium). This phenomenon eventually reduces the number of mobile vacancies and restricted diffusion of solute atoms (here, copper). These copper atoms intend to form clusters with magnesium–vacancy complexes, ultimately forming magnesium–vacancy–copper complex co-clusters (**Figure 13 (b)**). These co-clusters act as heterogeneous nucleation sites for GP zones.[40]

For some alloys, especially 2xxx alloys, cold working is performed prior to aging to increase the number of dislocations by dislocation interactions. These forest dislocations provide nucleation sites of the intermediate precipitate to assist in hardening.

2.12.2.2.3.1 Natural aging

Heat-treatable aluminum alloys generally experience at least a small degree of aging at RT. This is termed natural aging. The 2xxx alloys generally reach maximum attainable strength values by 5 days in T3 or T4 temper conditions. On the contrary, a few 6xxx and 7xxx alloys appear to be unstable at ambient temperatures, and precipitation may continue over the course of a year, for example, AA6016 alloy.[41] However, as an exception, AA6014 alloy was observed to attain peak hardness after a few hours of natural aging following T4 treatment, and hardness values were found to decrease after 1 day.[42] Among cast alloys, A356.0 and C355.0 alloys are aged within 48 h, and further changes after this time are negligible. However, T4 tempered 520.0 alloy age hardens over the course of a year.

Composition plays an important role in natural aging. A small addition of gold as an alloying element can restrict the

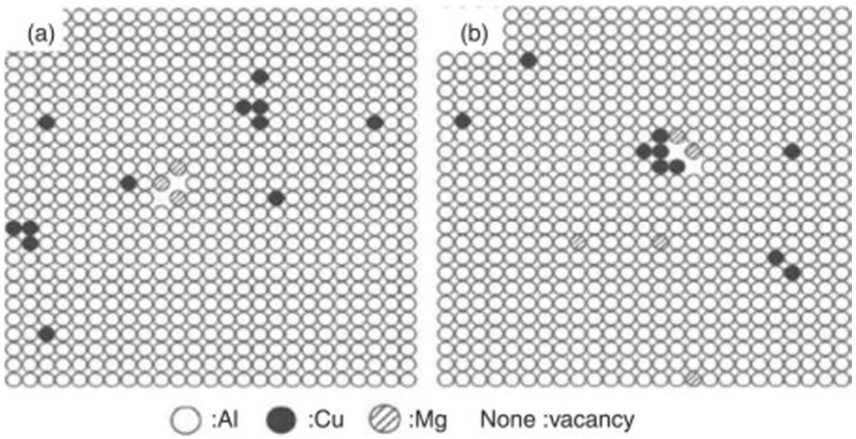

Figure 13 Examples of atom arrangements on the (001) plane simulated for 5X106 Monte Carlo step at 273 K: (a) vacancy trapping and (b) Cu–Mg–vacancy complex clusters. Adapted from Ref. [40], used with permission.

natural aging of Al–Cu alloys due to interaction of quenched-in vacancies with gold atoms.[43] Without the presence of micro-alloying gold, this role is played by copper. The role of quenched-in vacancies is important. They can form complexes with solutes during quenching. These complexes can transport solutes to the solute clusters.[44] Effects similar to the addition of gold are obtained if magnesium is added as a micro-alloying element in Al–Cu systems; the natural aging response is accelerated.[40] However, the formation of solute clusters, which do not interact well in the precipitation reaction sequence, hinder formation of GP zones.[45] In Al–Li–Cu alloys, lithium is generally considered to bind with vacancies and restrict the natural aging response.[46] This is inevitable as the increasing lithium content accelerates formation of intermediate precipitates, sacrificing GP zones due to changes in misfit strain energy by trapping of quenched-in vacancies. However, in the presence of magnesium, lithium–vacancy complexes favor the precipitation sequence (i.e., formation of GP zones).[47]

Cuniberti and co-workers[48] conducted a tensile test on AA6082 alloy sheets in four conditions: SHT and quenched conditions (SS), natural aged conditions (NA), natural aging followed by artificial aging conditions (AA/NA), and artificial aged conditions (AA). It was found that natural aging improved tensile strength, but with loss of ductility. Interestingly the stress–strain curves were serrated for the samples tested in SHT and quenched conditions, and the serration effect was diminished with time during natural aging. It was claimed that solute atoms, in as-quenched conditions, were randomly distributed in the matrix, and their repeated interactions with dislocations occurred during deformation (a well-known Cottrell atmosphere phenomenon), leading to serrated conditions, with profound support from quenched-in vacancies. During natural aging (**Figure 14(a)**), clusters containing solute atoms of Mg/Si in this Al–Mg–Si alloy and quenched-in vacancies were formed, resulting in reduced solutes from the solution and less pronounced serration. In contrast, in AA conditions (**Figure 14(b)**), strength was largest and was found to decrease with samples with a history of AA/NA. This can be understood by observing the microstructural features at different conditions. A few samples were aged at 180 °C for

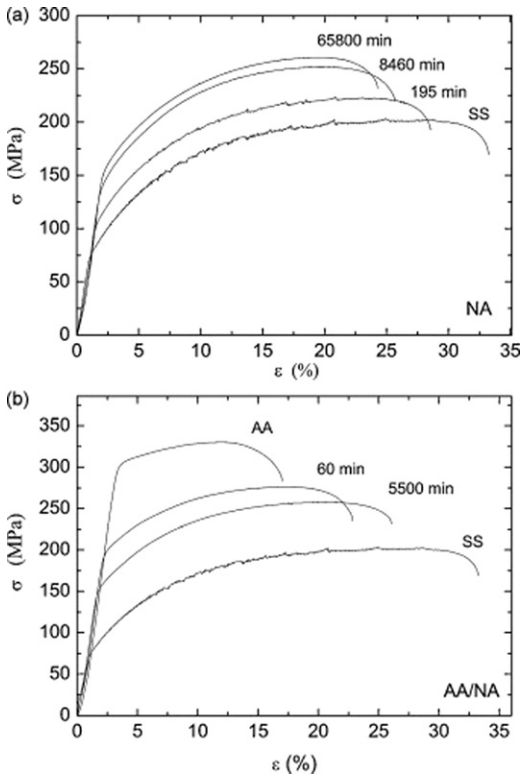

Figure 14 An AW6082 alloy was tensile-tested after aging in different conditions. (a) Stress–strain curves obtained for samples naturally aged (NA) for different durations. (b) Stress–strain curves obtained for samples artificially aged 30 min at 180 °C, with previous natural aging for the duration mentioned (AA/NA). Here, SS denotes as-quenched conditions and AA indicates 180 °C for 30 min of aging with no room temperature pre-aging. Adapted from Ref. [48], used with permission.

30 min (**Figure 15**). If the sample had no history of natural aging, then coherent β'' (Mg_5Si_6) precipitates were formed. However, the lack of these precipitates in naturally aged samples indicates that solute clusters might not be the ideal candidate for heterogeneous nucleation of this phase for this

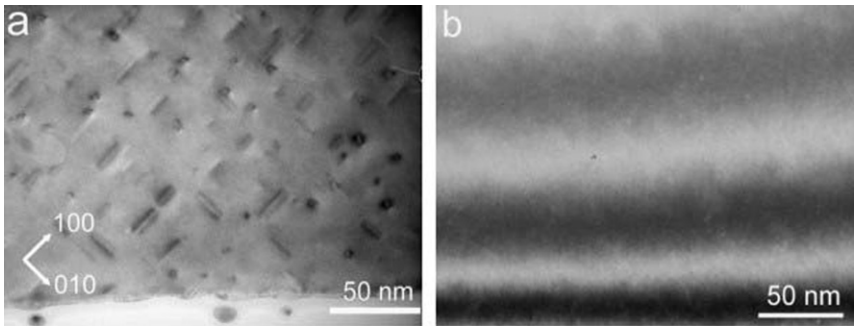

Figure 15 For an AW6082 alloy, TEM images corresponding to 30 min of artificial aging at 180 °C, (a) with no natural aging and (b) with 7 previous days of natural aging. It is clear that after artificial aging for 30 min, immediately after quenching, high number density of needle-shaped β'' precipitates is observed. However, no such precipitates are found if the alloys are naturally aged for 7 days. Adapted from Ref. [48], used with permission.

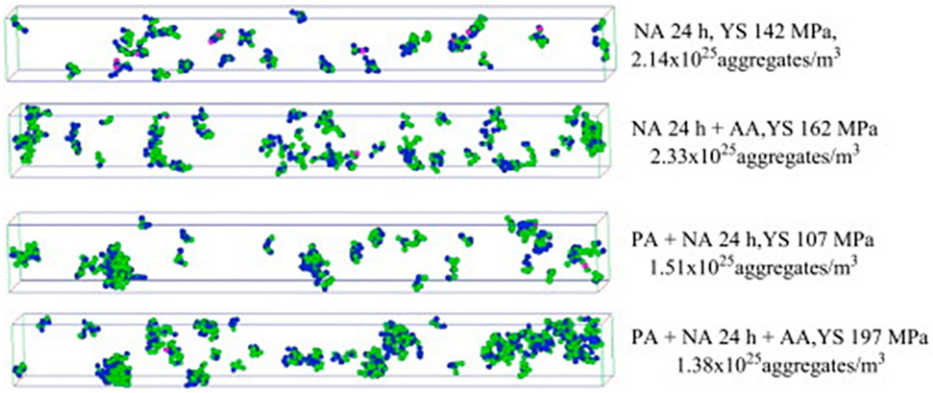

Figure 16 For a 6181A alloy, atom maps were constructed by 3DAP atom probe analysis in different heat treatment conditions. Green, blue, and pink dots represent Mg, Si, and Cu atoms, respectively. To compare visually, the sizes of the boxes were kept the same. The yield strength and overall number density of solute aggregates for each condition are given. AA, artificial aging conditions; NA, natural aging; PA, pre-aging; YS, yield strength. Adapted from Ref. [50], used with permission.

alloy. For an AA6111 alloy undergoing treatment of (1) natural aging for a long time and then artificially aged, and for one undergoing (2) artificial aging immediately after quenching, similar results were found.[49] Flow stress was studied to gradually increase for type (1) – treated specimens. This was attributed to the formation of GP zones, providing effective hardening. It is noteworthy that natural aging prior to artificial aging is typically effective for short aging time.[42]

From a different point of view, pre-aged (PA) AA6181A alloy at 200 °C for 20 s in a salt bath immediately after quenching was found to impede clustering of solutes (atoms of magnesium, silicon, and copper) during subsequent natural aging due to formation of large solute aggregates prior to formation of GP zones.[50] As shown by 3DAP atom probe analysis in **Figure 16**, naturally aged (NA) samples showed small solute aggregates and moderately high yield strength. If this sample is artificially aged (AA), then an expected number of aggregates as well as yield strength will increase. Now, if this alloy is pre-aged in this condition and naturally aged, then the aggregate density is reduced and larger aggregates are observed with a significant decrease in yield strength. Now, if this sample is artificially aged, then a distinct increase in strength is obtained due to the contribution of much larger aggregates – the known β'' phase. Also, solute clusters formed during natural aging can become spherical or elongated, and contribute to strengthening.[51]

2.12.2.2.3.2 Artificial aging

Most of the heat-treatable commercial aluminum alloys are artificially aged at an elevated temperature for a predefined period of time to obtain desired mechanical properties. For the reasons discussed, natural aging is typically avoided prior to artificial aging to minimize any deteriorating effects on properties. For example, Al–Mg–Si alloys containing lower amounts of magnesium and silicon show positive responses toward natural aging prior to artificial aging.[52] However, most commercial alloys of the 6xxx series yield an adverse effect if natural aging occurs. Several explanations are provided in the literature for explaining this behavior. The increase of critical nucleus size for the precipitation of β'' particles by a decrease in vacancy concentration during natural aging or small co-clusters formed may not be efficient enough for nucleation of β'' particles.[53] However, natural aging is sometime unavoidable due to the variety of logistic supports, such as transportation or shifting of parts for aging, present in heat treatment plants. Temperature range for artificial aging generally varies between 100 and 190 °C, and time can be 5 to 48 h, depending on alloy composition and application of the corresponding

alloy. Effects of time and temperature on aging are comparatively less critical than SHT and quenching treatments. However, these two parameters are of paramount importance. Longer time and/or unnecessary higher temperature can lead to low numbers of large lumps of precipitates, ineffective for hardening. T5 to T10 tempers include artificial aging.

Precipitation sequence of artificially aged Al–Mg–Si alloy AA6061 was examined and described by Edwards *et al.*[54] as follows:

Al supersaturated solid solution → Clusters of Si atoms; Clusters of Mg atoms → Dissolution of Mg clusters → Formation of Si/Mg co-clusters → Small precipitates of unknown clusters (GP-I Zone) → β'' Mg_5Si_6 (GP-II Zone) precipitates → β'' and β' precipitates → β Mg_2Si precipitates.

The sequences were observed experimentally using atom probe tomography (**Figure 17**).

Aging of this type of alloy is governed by the number density of mobile vacancies.[56] Number of vacancies present in the quenched condition is controls the rate of advancing the precipitation sequence, irrespective of aging temperature. Aging temperature varies depending on requirement. For example, in the T6 condition, ultimate strength is obtained with negligible hampering of other properties. The same alloy can be aged under T7 conditions, where the temperature is slightly higher and the alloy becomes overaged. Strength is reduced but dimensional stability may be improved or residual stress can be reduced. This AA6061 alloy shows negative responses if naturally aged prior to artificially aging. This phenomenon for this alloy can be explained by the trapping of vacancies by co-clusters of magnesium and silicon.[57] As a consequence, naturally aged AA6061 alloy yields a negative response during artificial aging in standard 170 °C T6 conditions.[55] However, there exists some debate about the efficiency of silicon-rich clusters in aging behavior because it was recently claimed that these clusters might not react to intermediate β'' phases effectively and might remain small during artificial aging.[58] These clusters might be the reason for hardness drop during subsequent artificial aging. Nevertheless, vacancies are again released from the trapping-in co-clusters at higher temperatures; therefore, aging at temperatures above 210 °C results in a marked increase in hardness. To avoid detrimental effects of natural aging, tin can be added as a micro-alloying element. The high affinity of tin for vacancies can avoid formation of clustering to some extent by forming tin–vacancy pairs,[59] and thus the adverse effect of natural aging is minimized. For example, AA6061 alloy was aged between 210 and 250 °C after micro-alloying with 100 ppm tin.[60] An excellent improvement in hardness was noticed immediately. It was assumed that tin might act as heterogeneous nucleation sites and provide guided diffusion of solute atoms, in addition to the trapping effect.

In a few aluminum alloys experiencing T3, T8, and T9 tempers, hardening is improved due to deformation. Cold working results in nucleation of more precipitate particles from increased numbers of dislocations. Alloys such as AA2014 and AA2124 undergoing T8 treatment achieve excellent strength due to cold working after SHT. S phase in AA2139 alloy was reported to nucleate heterogeneously at dislocations.[61]

2.12.2.3 Heat Treatment Scheme for Wrought Alloys

As discussed, wrought alloys can be heat-treatable or nonheat-treatable. Heat-treatable wrought alloys belong to the 2xxx (Al–Cu; Al–Cu–Mg), 6xxx (Al–Mg–Si), and 7xxx (Al–Zn–Mg; Al–Zn–Mg–Cu; Al–Zn–Mg–Cu–Zr) classes. Precipitation hardening type heat treatment is generally used for these alloys for strengthening purposes. Precipitation hardening involves solution treatment, quenching, and aging. Other classes of wrought aluminum alloys show little response toward strengthening by precipitation hardening. These alloys are known as nonheat-treatable wrought alloys. Commonly alloys from the 1xxx (controlled pure aluminum), 3xxx (Al–Mn; Al–Mn–Mg), and 5xxx (Al–Mg) classes are considered nonheat-treatable alloys. Nonheat-treatable alloys are hardened by strain hardening during working (See Section 2.12.1.3.2).

2xxx series alloys (Al–Cu and Al–Cu–Mg systems). These alloys have found their usage in airframes.[62] These alloys experience hardening by precipitation of the Al_2Cu phase. Addition of other micro-alloying elements can modify the precipitation

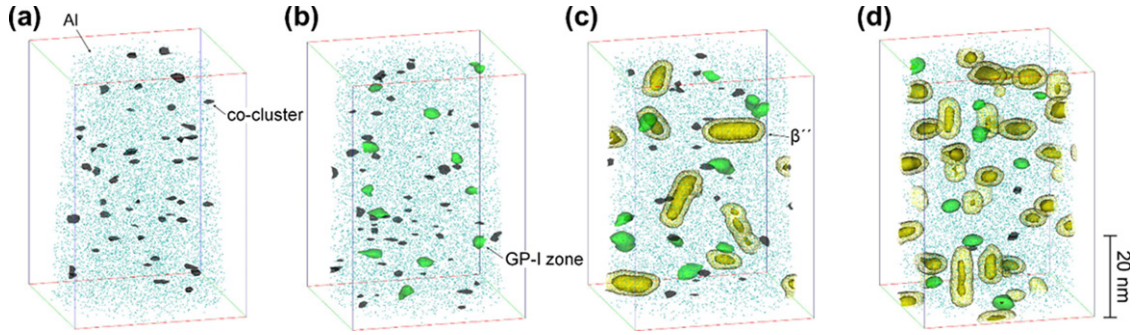

Figure 17 For an AA6061 alloy, atom probe analysis (3DAP) reconstructed for an aluminum matrix for (a) long-term natural aging, (b) 3.6 ks aging, and (c) 28.8 ks aging after quenching and a certain period of storage, and (d) 28.8 ks aging at 170 °C immediately after quenching. Magnesium-rich regions are clearly seen in (a). Due to the tendency to form co-clusters with silicon, black regions (voxels) indicate these co-cluster. The green regions in (b) show the Guinier–Preston (GP) zone (I). These zones are more spherical and rich in solute than co-clusters from natural aging conditions. After longer aging, needle-shaped β'' precipitates are evident in (c). In (d), the microstructure is completely different because it was aged right after quenching. More β'' phase, GP zone (I), and a few co-clusters are observed. Adapted from Ref. [55], used with permission.

reaction, and new precipitates can also be formed. In AA2014 and AA2044, magnesium is added and the Al_2CuMg phase is precipitated simultaneously with Al_2Cu phase. At temperature higher than 100 °C during aging, GP zones are transformed into θ'' (GP zone II), followed by θ' (tetragonal Al_2Cu). Finally, the incoherent equilibrium θ (BCC Al_2Cu) phase is formed. If the alloy contains magnesium, then individual clusters of copper and magnesium are first to nucleate; they can significantly contribute to hardening. Rod-shaped GP zones (magnesium/copper containing GPB zones, i.e., Guinier–Preston–Bagariastkij zones) are then formed,[63] probably heterogeneously on the clusters. Then, the lath-shaped semi-coherent orthorhombic S′ (Al_2CuMg) phase is nucleated at dislocations. Finally, the orthorhombic S phase, equilibrium and incoherent, is developed. Also, the Al_2Cu phase is nucleated and grown depending on Cu:Mg ratio.

6xxx series alloys (Al–Mg–Si system). These alloys are generally aged at 170 °C. From the supersaturated solid solution, individual clusters and co-clusters of magnesium and silicon atoms are formed. These clusters have negligible effects on hardening. Then, spherical GP zones are formed. From the GP zones, needle-shaped coherent monoclinic β'' (approximately MgSi) are nucleated. These precipitates are responsible for hardening in these alloys. As aging continues, the hexagonal β' (Mg1.7Si) phase is formed, which is semi-coherent. At the same time, the semi-coherent hexagonal B′ (MgSi) phase is also precipitated. Finally, the coherent equilibrium FCC β (Mg_2Si) phase is formed from β'.

7xxx series alloys (Al–Zn–Mg systems). These are the most potential alloys. They are high-strength alloys extensively used in aerospace industries. During aging in these alloy systems, at first two types of GP zones (spherical GP I and disc-shaped GP II) are formed. From these GP zones, a disc-shaped hexagonal semi-coherent η' (MgZn) phase is developed. From this η' phase, hexagonal η phase ($MgZn_2$) is formed. It should be noted that if the Mg:Zn ratio is very high, then instead of the η phase, the T′ phase can be formed. This is also a hexagonal semi-coherent phase with a chemical formula of $Mg_{32}(Al, Zn)_{49}$. Ultimately, equilibrium and cubic T phase is nucleated from either η phase or T′ phase. Its chemical formula is $Mg_{32}(Al, Zn)_{49}$. To improve the aging response, copper is added to this alloy system. However, care must be taken to ensure precipitation of large Al_2CuMg phase limiting to a certain amount. For recent alloys, such as 7075, a combined heat treatment procedure is used. It involves T6 treatment and reheating for a short time at a temperature slightly above the aging temperature, followed by cold-water quenching. Then, the alloy is re-aged. The advantages of this are mechanical properties up to the satisfactory level are obtained from T6 temper and resistance to SCC obtainable from T73 temper. This heat treatment is known as retrogression and re-aging (RRA).[3]

Al–Li alloy system. This alloy system belongs to several groups, including 2xxx and 8xxx. Strengthening of these alloys comes from solid solution hardening by lithium and precipitation hardening. During aging, meta-stable spherical cubic and coherent δ' (Al_3Li) phases are precipitated and are responsible for hardening. Note that δ' is an ordered structure of the Cu_3Au ($L1_2$) superlattice type. Finally, the equilibrium noncoherent cubic δ (AlLi) phase is formed. If copper and/or magnesium is added, then the precipitation sequence is altered. Copper promotes θ' and T_1 phase (Al_2CuLi) formation. The crystal structure of the T_1 phase is still a matter of debate.[34] Firm evidence regarding its structure has yet to be obtained. In the presence of magnesium, the rod-shaped Al_2LiMg phase is formed in addition to the δ' phase. The Θ' phase is observed when Cu:Li ratio is greater than 1:3. Also, S′ and S phases can be nucleated if copper and magnesium are present in large amounts. In this alloy system, no direct evidence of presence of GP zones has been reported. Also, presence of the T_1 phase is important for strengthening at an acceptable range. Formation of this phase is facilitated by the presence of copper, magnesium, and silver. T8 temper provides favorable conditions for the nucleation of this phase.

Table 8 shows the heat treatment schedule for common commercial wrought aluminum alloys. After solution treatment, parts should be quenched rapidly without further delay from logistics. Quenching in water in general should be performed with water at RT.

Maximum soaking time and quench delay for solution treatment of wrought aluminum alloys can be related with part thickness. **Table 9** shows the thickness of parts and corresponding required soaking time for both air furnace and molten salt bath and maximum quenched delay.

2.12.2.4 Heat Treatment Scheme for Cast Alloys

Heat treatments for foundry-grade alloys are slightly different from those for wrought alloys. Both types undergo similar procedures of heat treatment but with different limits of parameters. A major difference lies in SHT. Temperature and soaking (holding) time are generally higher in cast alloys due to the presence of larger microconstituents, which take longer to go back into solution. Quenching time is also another parameter that needs proper attention. Casting parts are generally more complex in shape and the quenching process has to be performed carefully to keep residual stresses at a minimum state. For this reason, quenching is often performed in boiling water or similar medium. T6 temper is the most common treatment applied to cast alloys. In addition, T5 and T7 tempers are used in industry. In T5, a slight improvement may occur in hardness. For example, materials of pistons and other machine parts are tempered in T5 conditions to obtain better dimensional stability and strength at elevated temperatures.[64] Sometimes, a combination of toughness and strength is required by sacrificing extra hardness, which can be achieved by using T7 temper. Achievable hardness is not very impressive but toughness is improved.

In high-pressure die casting parts, trapped gases in pores cannot be solution-treated at temperatures (e.g., 540 °C for 8 h) like other alloys. Swelling and/or surface blistering may occur.[65] A360 alloy was solution-treated at different temperatures and time and compared with as-cast conditions (**Figure 18**). The experiment was designed in the following way to compare different specimens: as-cast specimen was indicated by 'a'; sample 'b' was solution-treated for 16 h at 545 °C; in sample 'c,' the time was reduced to 0.25 h (15 min); and SHT temperature was further reduced by 10 °C for samples d, e, f, and g, successively, and soaking time was kept at 15 min. It can be seen that the highest SHT temperature and time

(sample b) resulted in extreme surface blistering and discoloration. Swelling was also evident to some extent, thus questioning its ability regarding dimensional stability. However, soaking time is shortened at the same SHT temperature (sample c), and the detrimental effects on surface and microstructure are eliminated slightly. These effects were almost diminished when temperature was reduced widely (compare sample c with sample g). Therefore, it can be concluded that to minimize porosity and blistering effects, shorter soaking time and lower SHT temperature are required.

Composition, in addition to SHT parameters, plays an important role in mechanical property determination. Lumley and co-workers[67] investigated nine Al–Si–Cu die cast alloys (see **Table 10** for composition) in different temper conditions. Samples that were only solution-treated and quenched showed an increase in percent elongation values, yielding lower strength. T4 temper increased hardness after natural aging, as expected. T6 temper containing official aging improved strength to a very satisfactory level, with a sharp decline in percent elongation values. By adding more copper and magnesium into the alloy (alloy 1 and alloy 5), the 0.2% proof stress was significantly improved. Adding more copper or magnesium (beyond alloy 5) showed no significant increase in strength properties (see **Figure 19**).

It is noteworthy that if Al–Si–Cu alloys contain magnesium, then SHT temperature needs to be modified.[68] However, higher SHT temperature may result in local melting of copper-containing phases and less spheroidization of silicon phases.[69] To resolve this, a two-stage SHT can be a good choice. A319 alloy was heat-treated with a two-stage SHT (495 °C for 8 h and 520 °C for 2 h) and good mechanical properties were achieved.[70] The first stage of SHT allowed all copper to dissolve in solution; during HTs of the second stage, most elements were diffused into the solution.

Spheroidization of silicon phases is achieved during SHT. This is important because a good number of commercial cast alloys contain silicon, and sharp edges of silicon reduce toughness and fatigue properties. SHT temperature and time need to be chosen carefully. The parameters can be varied from 540 °C for 3 min for Sr-modified A356 alloy[71] to 40 °C for 30 min for Al–7Si–0.3Mg alloy.[72] In general, therefore, soaking time changes depending on alloy composition and casting condition. If the microconstituents are smaller, as expected progressively in investment, sand, and permanent mold casting, then short time is desirable. Moreover, if silicon modifiers are used, as shown, then soaking time can be shortened significantly because less time is required to spheroidize.

Table 11 shows the heat treatment schedule for common commercial cast aluminum alloys. After solution treatment, parts should be quenched rapidly without further delay due to logistics. Quenching in water in general should be performed with water temperature at 65–100 °C.

2.12.2.5 Stress Relief

Quenching is inevitable for hardening in most commercial aluminum alloys. Fast cooling is preferred in most cases for better mechanical properties. Unfortunately, rapid cooling can introduce residual stresses in parts by inhomogeneous plastic flow (inelastic strains) due to severe thermal gradients.[73] These residual stresses can lead to warping during quenching, degradation of dimensional stability during machining, and reduced fatigue life during service.[74] The aftermath of residual stress is distortion. For example, during machining, in a part with residual stress, the equilibrium state of stress is distorted and a new equilibrium results; local plastic deformation is then unavoidable.

The level of residual stress depends on properties such as elastic modules and the thermal expansion coefficient of the materials involved. Also, the thermal gradient between the surface and the interior of the part is important because the surface is cooled much faster than the interior, inducing tensile stresses at the surface; obviously, compressive stress would develop in the interior (**Figure 20(a)**).[75] Because the surface temperature is still high enough, it remains plastic and can accommodate any stresses that develop. As a result, no residual stress develops. In the second stage, the outer layer is cooler

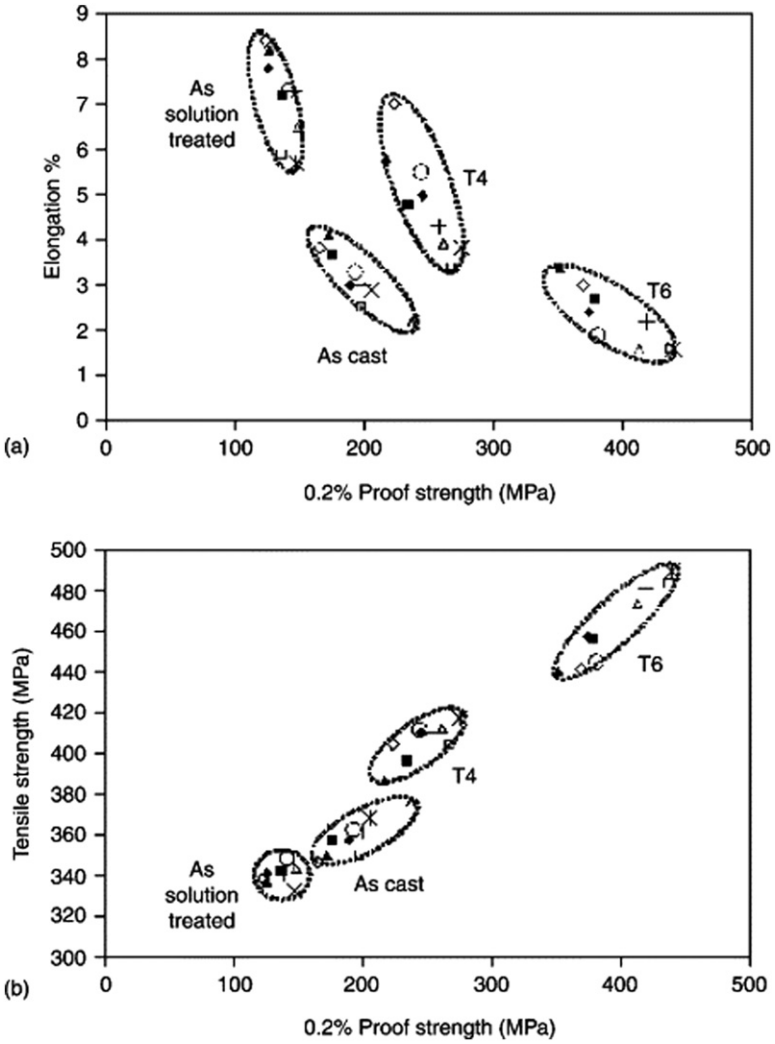

Figure 19 The mechanical properties of HPDC alloys based on Al–Si–Cu showing: (a) elongation as a function of the average 0.2% proof strength and (b) tensile strength as a function of the average 0.2% proof strength for the as-cast solution-treated T4 and T6 tempers. Five samples per condition were tested. Alloy specimens for tensile testing were cylindrical and had a total length of 100 mm, with a central parallel gauge length of 33 mm and a diameter of 5.55 ± 0.1 mm. Adapted from Ref. [66], used with permission.

than the interior and regains strength. Accordingly, the elastic surface can resist any plastic deformation in the interior (**Figure 20(b)**). No residual stress is developed. As the temperature gradient further increases, the cooling rate of the core becomes greater than at the surface; consequently, the elastic interior would try to change its dimension. However, this will be constrained by the elastic surface. As a result, the interior would try to pull the surface inward. That is, tensile stress develops at the core and compressive stress forms at the surface (**Figure 20(c)**). This balanced stress is residual stress.

Residual stresses can be relieved by thermal methods or mechanical methods.

Thermal methods include modifications in the heat treatment schedule by changing temperature, and cooling times are used to reduce stresses. For example, using T7 temper (overaging) for casting causes loss of properties compared to T6 temper, but such a sacrifice is vital compared to the gain in mechanical properties. Also, to reduce the magnitude of residual stress, a less severe quenching method can be applied. For example, as a quenchant, boiling water or organic quenchant can be applied. However, because these quenchants slow the cooling rate, the final mechanical properties may not be to a desired level[76] because microstructural development would be disturbed. This intuitively suggests interrupted quenching by different quenchants. However, there has been some work on it that reduces stresses.[77]

The mechanical method involves stretching or compression of heat-treated parts, which allows a small and controlled amount of plastic deformation at RT or elevated temperature. It is noteworthy that temper designation is slightly different for alloys, diminishing residual stresses by plastic deformation. For example, if residual stress is removed by applying stretching, then temper designation becomes Tx51 (x refers to standard temper digit). Similarly, Tx52 is used when residual stress is removed by compression. For AA7010 aerospace alloy, it was observed that 1% cold compression could relieve most of the residual stress developed during quenching.[78] However, this could not diminish tensile stresses from the core, and

susceptibility of SSC remains. Another 2% of cold compression ultimately removed most of the residual stresses, and compressive stress was developed in the interior of the part. However, the mechanical method is not suitable for most cast products because cast products are generally complex in shape. Therefore, relaxation of residual stress by compression would require special dies. Stretching may not be suitable at all for cast products.

Residual stress can also be reduced by sub-zero treatment and stabilization. This merely involves experiencing the parts to temperatures below and above RT after solution treatment. To reach temperatures below RT, dry ice mixed with alcohol can be used to reach up to $-70\,^{\circ}C$. Also, several cycles of quenching the parts at sub-zero temperatures and then heating in boiling water are engaged. One such technique is known as the uphill quenching method.[79] This process involves first quenching the part in boiling water quenchant for a predefined period of time and then in liquid nitrogen for a certain period of time. After removing from liquid nitrogen tank, the part is sprayed by either boiling water or water vapor, or it is dipped into the boiling water tank again. After, the natural aging or artificial aging process is applied. It has been used for several 6xxx and 7xxx alloys. The uphill quenching process is schematically shown in **Figure 21**. The figure shows its differences compared to the conventional quenching processes. The temperature gradient is eventually small in the uphill quenching process. For example, for an Al–Si–Mg alloy, the temperature difference between solution treatment temperature and quenching is $472.50\,^{\circ}C$ (SHT $538\,^{\circ}C$ to warm water $65.50\,^{\circ}C$).[75] On the contrary, in uphill quenching the temperature difference is $295.50\,^{\circ}C$ ($100\,^{\circ}C$ boiling water to $-195.50\,^{\circ}C$ liquid nitrogen). It should be noted that the residual stress pattern as obtained in the conventional

quenching process is reversed in the uphill quenching method. Therefore, careful assessment must be performed before usage.

2.12.2.6 Annealing

The annealing state generally depicts a soft, tougher, dimensionally stable, and low residual stress condition in aluminum alloy parts. However, this also resembles lower strength and poor machinability. Different types of annealing treatments are used for aluminum alloys.

Partial annealing is applied for nonheat-treatable wrought aluminum alloys to soften cold-worked structure. The temperature for this type of annealing is chosen carefully and is below recrystallization temperature so that partial recovery is accomplished by removal of dislocation tangles. The goal is to obtain a sub-cell structure.

Wrought aluminum alloys, to relieve strain hardening effects, are subjected to stress-relief annealing. Any cold-working effect can be diminished by recovering and recrystallization of structures containing dislocation tangles and minimizing store energy of the material. For an AA3003 alloy, up to 400 °C can be used.[64]

A full annealing process is used when soft and workable aluminum alloy parts are required. Unlike partial annealing, the structure involves dislocation-free recrystallized grains. However, the hot-worked structure may not change during full annealing. For heat-treatable and nonheat-treatable alloys, the outcome of full annealing is slightly different. Nonheat-treatable alloys are worked to achieve strength, and softening can be acquired by full recrystallization of the structure. For heat-treatable alloys, the chance of precipitation is low because the alloy has already undergone aging treatment. A temperature chosen from the range of 260–440 °C is generally used for full annealing.[64] To obtain the advantages of full annealing, a long soaking time is preferred to ensure homogeneous temperature distribution throughout the part.

Cast alloys are soaked for a short time (2–4 h) and temperature involved is a minimum of 340 °C.[17] Because cast parts are more complex, special care should be taken so that new residual stresses are not developed during cooling after the annealing temperature.

Table 12 gives a list of annealing temperature for a few alloys.[11]

2.12.2.7 Dimensional Changes during Heat Treatment

There exists a fine line between dimensional changes and dimensional stability. Dimension changes are dealt with by the manufacturers, and stability is of major concern for the end users. During heat treatment, dimensional changes are sometimes unavoidable. Dimensional changes evolve from thermal contraction and expansion, or they may have mechanical or metallurgical origins. Changes obtained by thermal contraction and expansion are reversible and depend on the thermal coefficient of the alloys. Changes due to mechanical origin arise due to plastic deformation or different states of residual stresses. Similarly, dimensional changes may occur by microstructural alternation. To maintain dimensional stability, overaging is used for some aluminum alloys used for engines in transportation industries.[80] However, strength is fairly compromised, but better dimensional stability is obtained by precipitation of more particles at higher temperatures. If better accuracy is required, then an additional heat treatment can be suggested. This treatment includes repeated heating for a few hours at generally 177–204 °C during machining or cycling sub-zero cooling and heating. It is typically claimed that the most stable condition is obtained in the order of: annealing, overaging, aging, and as-cast condition.[17] During heating at HTs and quenching at an appreciably high rate, plastic deformation may occur, leading to residual stresses. This will have adverse effect on properties by changing the balance of the stress state. As a consequence, dimensional stability can be disturbed.

2.12.3 Inspection and Quality Assurance

After heat treatment, proper testing has to be conducted to ensure the quality of products, and these inspections yield

evidence for conformity of quality. Mechanical tests including tensile and hardness tests should be performed in regular intervals. These properties will determine acceptability of the material in the first instance. However, hardness tests are important in ferrous materials. For aluminum alloys, the tensile test is a more convincing method for comparing results and modification of the heat treatment schedule. Because aluminum alloys are strengthened principally by precipitation hardening, an intergranular corrosion test should be performed. For 7xxx series alloys, a fracture toughness test might be required.

Sometimes it is not surprising to achieve results far below the satisfactory level. This can happen because of several factors. The first thing to consider is examination of the composition of the material. Although there are ranges of composition for any alloy, such a variation in range might result in different precipitation kinetics and microstructure, resulting in degraded mechanical properties. Also, segregation, refinement of grains, and shapes of eutectic phases can be responsible for unacceptable properties. For assessment of root causes, proper maintenance of records is essential. After solution treatment, local eutectic incipient melting and development of porosity may occur. Microscopic observation should be performed to find any possible porosity and partial melting. Eutectic melting can be evidenced by rosettes or eutectic structures at three grain boundary points. Morphology of eutectic phases, such as silicon, should be checked for alloys containing silicon. Morphology should match the heat treatment. After solution treatment, if the silicon morphology appears to be like F temper, then there are some problems with the heat treatment procedure.

2.12.4 Concluding Remarks

Aluminum alloys play an important role in the transportation industry because they contribute to fuel economy, and thus to the environment. Although magnesium is considered the lightest structural material, the use of magnesium has yet reach to the level of aluminum. The extraction, casting, forming, and recycling science of aluminum is much more well established. The heat treatment schedules are well written for commercially important alloys. Similar to working with plain carbon steel, industries and foundries confidently work with aluminum. Introduction of the advanced polymer matrix composites in vehicles and aircrafts has resulted in the threat of a decline in aluminum usage over the past few decades, even though aluminum has high specific strength, good formability, excellent crashworthiness, and impressive corrosion resistance. However, use of large amounts of aluminum in recent aircrafts, such as Airbus 380, and the continuous development of advanced aluminum alloys ensures that aluminum technology will dominate in these sectors in the long term.

2.13.1 Classification of Heat Treatment of Al Alloys

2.13.1.1 General Classification

Al alloys are used in various industrial fabrication fields from digital camera frames and legs to the skin and trusses of aeroplane, and from cast automobile parts to welded high speed train car body, so that the category of heat treatment of Al alloys are also numerous for different alloy systems and different applications. In discussing situation in this chapter the Al alloy is in solid solution (SS) state. Generally, the heat treatment of Al alloy could be classified into three types (refer to Table 5):

- Free status. In this state the parts or ingots are not required to have specific property or other special quality. So it need not any heat treatment.
- Annealed status. This is a state that the parts or products of Al alloy are subjected to heating, heat preservation, slow cooling processes. Usually it is applied to some high precision of size and shape, high corrosion resistance as well, high uniformity of chemical composition and even homogeneous grain structure, and low internal residual stress as well, but not requiring high mechanical property.
- Solutionizing and aging treatment. This is a state that the parts or products need specified mechanical property, or particular physical property. For example, for an application that the parts need very high hardness, a solutionizing plus peak aging process (this is called T6 temper, refer to Table 8) should be applied to the parts. If the application needs not only high hardness and strength, but also good ductility, and high corrosion resistance, a T72 temper (refer to Table 1).

2.13.1.2 Sub-Classification of Solutionizing and Aging

In this chapter, the third type of heat treatment of Al alloys, as mentioned above, will describe in details. Solutionizing and aging treatment as on the word phase is composed by two procedures in general.

First procedure: solutionizing is a heat treatment process that is off course built up by three inseparable steps.

Step 1: heat the parts or products from ambient temperature to specified temperature, which is determined from the solidus of the alloy and the requirement of the application.
Step 2: heat preservation. After the first step the temperature of the furnace gas as well as the parts or products approaches the specified one with some acceptable scatter, then keep the temperature to a given time. The general objective of the heat preservation is to dissolve the secondary phases and alloy elements into the α-Al matrix to get uniform SS.

Step 3: cooling the parts or products to lower temperature, usually room temperature (RT). This is a key procedure for solutionizing process. The cooling rate in general should be high enough to avoid precipitating process during the cooling period. In such a way the parts or products of the Al alloy can be ensured to get a supersaturated solid solution (SSS) at lower temperature.

Second procedure: aging is necessary process for most of parts or products with high mechanical property that is built up by various steps. The sub-classification mainly is due to this procedure. There are four sub-categories of aging process.

(1) One step aging: usually it is called natural aging, that means the parts or products are put on some substrate and kept for specified time, and then get used in service. Before natural aging (one step aging) the parts or products of Al alloys might be cast, cold machined, heat treated somehow, the subsequent aging could ensure the parts or products moderate mechanical property, stable size and shape, low residual stress, etc.
(2) Three step aging: ordinarily also called as artificial aging. This is a normally full aging process including three basic steps: heating the parts or products to specified

Table 1 TXX and TXXX state code and instructions

Code	*Instructions and application*
T42	Apply to O or F state after solution heat treatment, natural aging to steady state, can also be applied to any state of processed products after heat treatment, to achieve good mechanical properties
T62	Apply to O or F state after solution heat treatment, artificial aging products, can also be applied to any state of processed products after heat treatment, to achieve good mechanical performance
T73	Suitable for the products after solution heat treatment, and it can achieve the required mechanical properties and resistance to stress corrosion after aging
T74	The same as the T73's definition but at the state the tensile strength is greater than T73 condition and less than T76 state
T76	The same as the T73's definition, but at the state the tensile strength is higher than T73 and T74 state, stress corrosion cracking resistance lower than T73 and T74 state, respectively. But the exfoliation corrosion resistance is better than them
T7X2	Suitable for O or F state. After solutionizing, carry out artificial aging for good balance between mechanical property and corrosion resistance, make sure they are comparative with T7 state
T81	After solutionizing, subject 1% cold deformation, then artificial, or natural aging

temperature, heat preservation for a specified time, and cooling to (RT). Two key parameters in the second step are very important: aging temperature and keeping time.

(3) Four step aging/grading aging: this aging procedure is constituted by heating the parts or products to a first temperature and keeping a specified time, and then putting them in another temperature (lower or higher than the first temperature), and keeping a time (longer or shorter than the first temperature). This type of aging is usually used in exceptive application, for example, very high mechanical strength.

Complex aging/multi-step aging: this is the variety process and full of alteration. These processes include following variety:

- Cold plastic deformation or forming in some degree, and then artificial/natural aging without previously solutionizing treatment and any other heat treatment.
- Cold plastic deformation in some degree after solutionizing, and then artificial/natural aging. The cold plastic deformation can be compressing or stretching, but the degree is specified.
- Artificial/natural aging just after thermal deformation and cooled down. The thermal deformation could be hot extrusion, forging, rolling, etc.

It must be emphasized that the solutionizing usually is applied for a pre-process of aging, it is an inseparable steps for a full heat treatment of parts or products of Al alloys. Occasionally solutionizing process is used alone, without subsequent aging. In solutionizing state the materials have relatively low mechanical strength, whereas aging processes can endow high mechanical strength.

2.13.2 Purpose and Principles of Aluminum Alloy Heat Treatment

Aluminum alloys are so widely used in industry of nearly all fields from machinery bed to the skin and trusses of aircrafts, and also in articles for daily use from aluminum foil of barbecue to clothes hanger. Both the utilization and processing of aluminum alloys require some regulation of property and status. The most efficient regulating method is heat treatment.

2.13.2.1 Purpose of Heat Treatment of All-Purpose Aluminum Alloys

Heat treatment means that a thermodynamic approach is applied to the products of aluminum alloys to obtain desired property and/or structure. The components or parts can be aluminum alloy ingot, cast machine parts, worked machine parts, even infrastructures, i.e., heat the products in an appropriate rate in a furnace, hold for some time to the solutionizing temperature, and then cool at a designated cooling rate. Through such a process the microstructure of the products will be changed to improve the service performance in the aspect of mechanical properties, corrosion resistance, workability, dimensional stability, and so on. Figure 1 shows the concerning fields of the technologies.

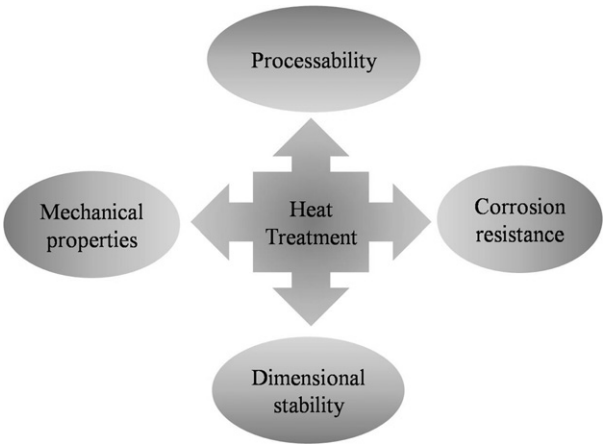

Figure 1 The influence of heat treatment in service performance of aluminum alloys.[1]

In Figure 1 there lists four application fields of heat treatment of Al alloys. The processability is so important that the Al alloys as a type of metallic materials, which must be processed into machine parts (industrial or domestic products) so that the materials get their value. Heat treatment can change or improve processability of Al alloys. For example, by annealing treatment one can improve the punching property of Al alloy: one uses less pressure, less time, and get better products. By T6 (a useful temper code, refer to Table 8) treatment one can make AA2024 (a typical type of Al–Cu–Mg–Mn alloy) very good mechanical property, such as high hardness and high strength, to be used in aeroplane structures. By regression and re-aging (RRA) treatment (another heat treatment code, refer to Table 10) one can get both excellent mechanical property and corrosion resistance. If someone carries out an artificial aging process to a cold worked Al alloy part with proper parameters he will obtain a dimensional stable part in his precise machine.

So you can see, improving processability, improving mechanical property, enhancing corrosion resistance, and increasing the dimensional stability, all need heat treatment.

2.13.2.2 Principles of Heat Treatment of Aluminum Alloys

2.13.2.2.1 SS and equilibrium precipitation

Heat the parts or products of a specific Al alloys to a temperature between the solvus and solidus temperatures and holding for some time to make the intermetallic compounds composed of base aluminum and alloying elements dissolve into base aluminum matrix, and then cool them in an appropriate rate to a lower temperature to get SSS.

The solutionizing involves heating of an alloy to a particular temperature for sufficient time so that the alloying elements go into SS from intermetallic compounds and form a single-phase SS. On quenching (fast cooling) the alloy forms an SSS.

If this SSS is heated at an elevated temperature then precipitation of particle of the secondary phase occurs. In a dispersion state this secondary phase increases the hardness of the alloy and it is called precipitation hardening. The heat treatment which produces the secondary phase is also called aging

treatment. The hardness after solutionizing is comparatively low. The maximum hardness and strength develop by precipitation of very fine dispersed secondary phase particles during aging at a suitable temperature and sufficient time.

2.13.2.2.2 Case study 1: The equilibrium precipitation process of liquid solution and SS[2]

Figure 2 demonstrate the principle why such a process of dissolution-precipitation can happen. Figure 2(a) is an equilibrium phase diagram of ordinary brine (salt water, i.e., you put 60 g solid NaCl powder into 100 ml water and stir and heat the mixture for a while, then you get brine without any solid salt particles), in which the solid line is the solidus, also called as solubility curve, over the line (the space at left side of the curve) the salt is in dissolved state, i.e., in this moment the solid salt NaCl changed into separate Na^+ (basic ion) and Cl^- (negative ion), swimming freely in the water, so you cannot see them. This solution is called unsaturated liquid solution. Under the line (the space right side of the solubility curve, that means decreasing temperature, or increasing the salt content) the solution is called saturated liquid solution. There is solid salt precipitating zone. In the figure the state point moves from X to S point. And the brine's concentration is changed from X to S%. S% is called solubility and the solution at S point is called saturated liquid solution. The precipitating is a nucleation and growth process. Nucleation happens by the accumulation of sufficient number of NaCl molecules which are composed from the basic and negative ions:

$$Na_L^+ + Cl_L^- = NaCl_s \qquad [1]$$

Then you can see the salt particles. As the temperature is low than S point, for example, at T, the concentration of the solution is Q%, and some amount of salt (Na^+ and Cl^- ions) precipitate out of solution, deposited as solid salt particle at the cup bottom. With the temperature decreasing further more and more salt particles precipitate and pile up on the cup bottom. The more salt dissolved out from the salt water because the solubility is decreased with the decreasing temperature. At temperature R the solubility of the salt water is changed into Y%, so in the same cup more solid salt particles precipitated. The concentration now does be the solubility Y%. You now get undissolved salt. Nevertheless the total amount of salt is still the original one, keeping constant.

Figure 2(b) shows a situation of metal alloy. Element A is the solvent (in the above example, water) and element B is the solute (in the above example, salt). The solid line is the solubility curve, here it has a new name: solvus. X_1 is the concentration of the SS, X_2 (in the upper insertion) is the segregated concentration at grain boundary, usually $X_2 > X_1$. S_1 is the solubility at S_1 temperature. At T_1 the SS is located under the solvus and for thermodynamic equilibrium there a number of precipitates occurred from the solution. The concentration of the matrix (α phase) reached to Q_1. The

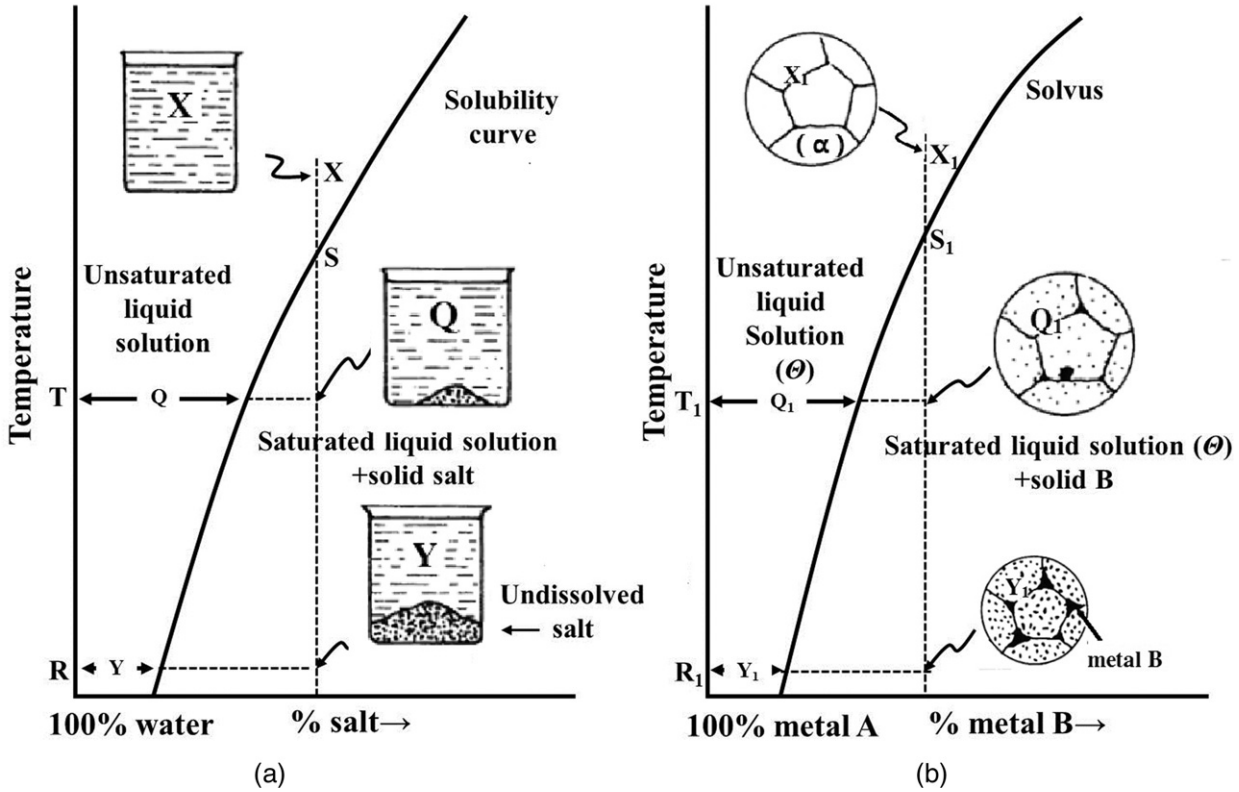

Figure 2 An analogy between the liquid solubility of salt in water and the partial solid solubility of one metal in another. (a) Example of liquid solution and (b) example of solid solution of metal alloy.

precipitated secondary phase is B. B metal exists in two patterns: dispersed particles, located within the grain, and the segregated concentrated at the grain boundary in a continuous net-like deposits. At T_1 the matrix solution is a saturated one. At temperature R_1 there is more B phase precipitated from the matrix, and the concentration of the matrix is Y_1. At this temperature the secondary phase B exists still in two patterns: dispersed particles but much coarse, thicker net-like deposits in grain boundary.

Heat treatable aluminum alloys contain one or more other elements, such as silicon, copper, zinc, and magnesium, etc. The content of these elements can be more than the solubility at low or intermediate temperature, even the maximum solid solubility at eutectic temperature. **Figure 3** is the typical binary phase diagram in aluminum alloys.

The equilibrium microstructure consists of $\alpha+\beta$ phases when the $\omega(B)=C_0$ in which the α phase is the matrix SS based Al, and the β phase is the secondary phase dispersed in α phase. Once the alloy is heated to T_2, the β phase will be dissolved in the matrix and a single α SS phase remained,

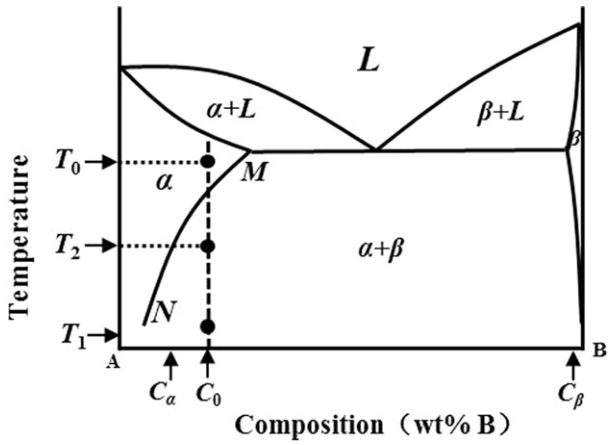

Figure 3 The solubility at different temperature. T_0, T_1, and T_2 should be the specified ones for particular purpose.[2]

which we called solutionizing. If the C_0 alloy is cooled down at a considerable rate from T_2 point, the diffusion and redistribution of solute atom do not have time to take place, leading to little nucleation and growth of β phase in α SS matrix. Moreover, the polytypism shift will not happen in SS matrix in cooling process, the ambient structure is the supersaturated single α SS in which the composition is C_0. This is the solutionizing process, consisting of heat preservation in a given time at specified temperature, and then cooled in an appropriate rate, for example, quenching in water or oil, or air blow.

It should be noted that the SSS mentioned above is not only to the solute atoms, but also to the vacancy, another point crystal defect, that is also supersaturated state. The aging treatment after solutionizing is a diffusion and precipitating process (that will be described in Section 2.13.2.2.2). The existence of vacancies provides an essential condition for atom diffusion in which the interaction between the solute atoms and vacancy concentration can obviously influence the aging precipitation dynamics.

In a binary phase alloy system, the equilibrium phase diagram coupled with the microstructure morphology is presented in **Figure 4**. The upper side of the diagram there is the liquid phase zone, the metal alloy with a B element concentration of X must suffer from full liquid, liquid + α solid phase zone, and then single α phase zone. At lower temperature the alloy goes into another two phase zone: $\alpha+\beta$ two phase zone. The solid curve PQ is the solvus, and under temperature of T_P, but over T_S, the alloy is located in single α phase zone. A little bit lower than T_P, the T_U is specified by the ensuring the alloy not to be remelted, because liquid would occur firstly at grain boundary, that will make some microstructure damage, such as grain boundary cracks or getting oxidized by the oxygen fast diffusion along liquefied grain crevices.

At the interval of T_S and T_U the microstructure of the alloy (parts or products) is single α phase. The solute element atoms are located particular sites separately and uniformly. The SS is unsaturated SS. At the temperature lower than T_S with cooling

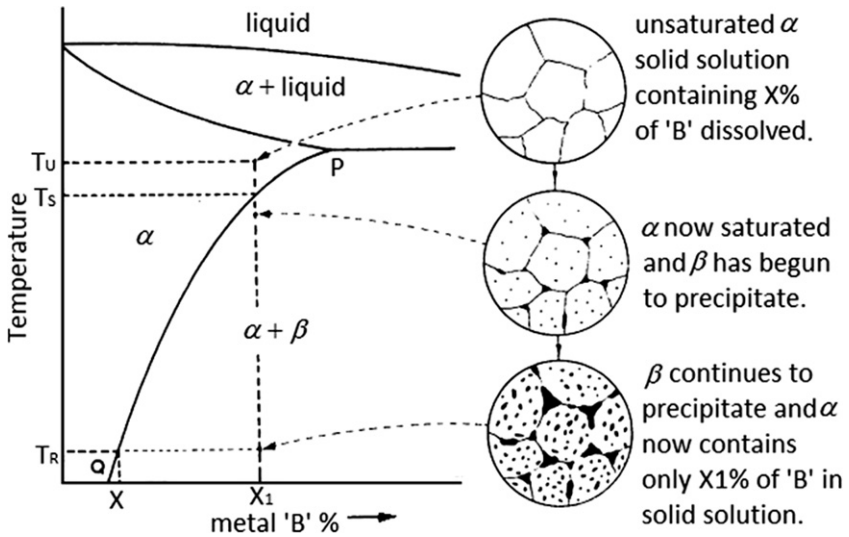

Figure 4 Changes in partial solid solubility with temperature.[2]

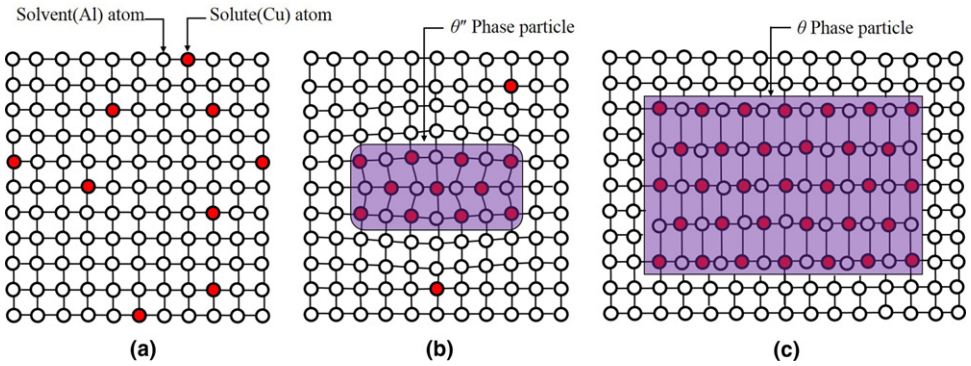

Figure 5 Schematic depiction of several stages in the formation of the equilibrium precipitate (θ) phase. (a) A supersaturated α solid solution. (b) A transition, θ'', precipitate phase. (c) The equilibrium θ phase, within the α matrix phase. Actual phase particle sizes are much larger than shown here.[1]

process, because of the solubility decreased and lower than X %, the solution now changed into SSS, and driven by thermodynamic force the overfull solute B element atoms tend to collect together and changed new β phase.

The solution treatment and precipitation treatment is carried out in those alloys where the solubility of an alloying element increases with increasing temperature. The phase diagram given in **Figure 4** shows that solubility of B element in A increases with increase of temperature and it is maximum at point P. Take an alloy of composition X, which is a two phase structure at RT. On heating at a temperature T_1 the alloy transform to a saturated single-phase SS (α) and on heating at temperature T it becomes unsaturated SS of α-phase. This treatment is solution treatment. Rapid cooling of this SS to RT will maintain single-phase SS, but it is now SSS. Now if this SSS is heated at temperature T_2, the secondary β phase will precipitate out of the SS solution and these particles are extremely fine and precipitate in coherence with the α phase. These particles are responsible for hardening action. However, the aging treatment that produces these hard precipitates is called precipitation treatment.

2.13.2.2.3 Precipitation sequence and aging process

Decomposition of the SSS usually needs to experience at least four distinct stages during aging process, which can be expressed by the following sequence, and the schematic crystal structure evolution is shown in **Figure 5**.

$$\text{SSS} \rightarrow \text{GP 1 zones} \rightarrow \text{GP 2 zones } (\theta'') \rightarrow \theta' \rightarrow \theta \qquad [2]$$

where GP 1 zones are such type of zones that the solute atoms are distributed in clusters, among the clusters the concentration of solute atoms is nearly the equilibrium one. The size of the clusters is very small. In the clusters the solute atoms are short-range ordered. The GP zones are named by the names of two discoverers of such metallurgical phenomenon.[3] GP 2 zones are also solute atom clusters but larger than GP 1 zones, and not so densely distributed. In the GP 2 zones the solute atoms are longer-range ordered, and close to somehow regular crystal lattice, so that they are also designated as θ'' phase. Because they are not regular crystal lattice and much closer to clusters of solute atoms. The transformation from GP 1 zones to GP 2 zones are considered not by merging the GP 1 zones

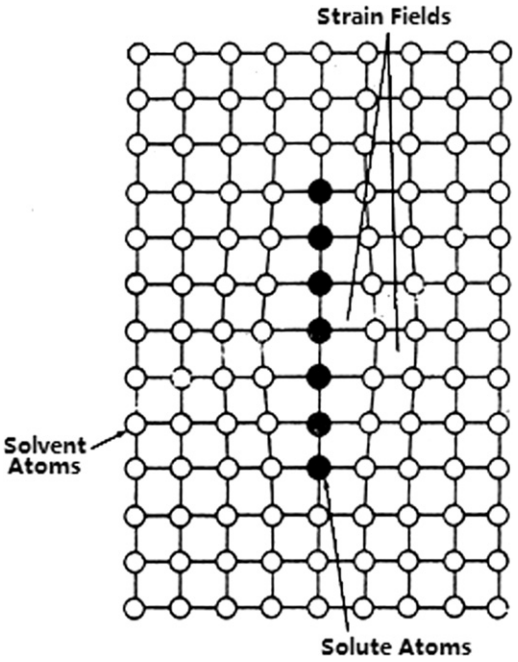

Figure 6 Coherency strains associated with presence of solute atoms having larger radial than solvent atoms.[1]

but by nucleation new cores with GP 2 zones' structure and GP 1 zones dissolving. **Figure 6** shows a schematic of GP 1 zones. θ'' (GP 2 zones) can also be seen as a sub phase and the boundary with the α-phase is coherent. Afterwards with the aging progressing the new phase θ' nucleates, and the GP 2 zones dissolved at the same time. θ' phase is a metastable phase with particular crystal lattice, and the interface between the surrounding matrix (α-phase) is much clearer, not like that between GP zones and α-phase which is blurry even there is not a real interface. The morphology of θ' phase may be particle in shape of dot, needle, sphere, and platelet. Their size (diameter, thickness, or length) is much larger than θ'' clusters. The interface of θ' and α-phase is semi-coherent, i.e., the lattice parameters of θ' in the boundary are very close to that of the matrix (α-phase). So the constraint of coordinate plastic deformation is strong that the hardness and strength of this alloy in this state is higher (refer to **Figures 7** and **8**).

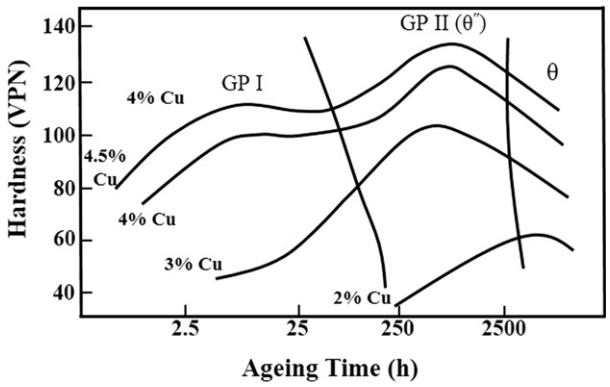

Figure 7 Aging curves for a set of aluminum–copper alloys aged at 130 °C.[1,3]

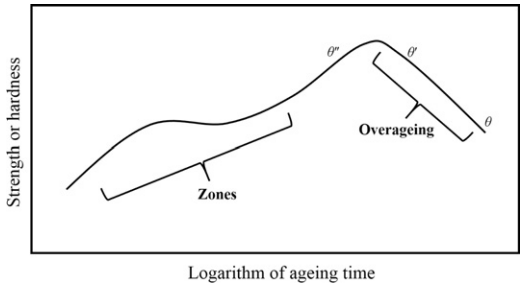

Figure 8 Schematic of full aging dynamic curve.[1]

Late on the equilibrium secondary phase θ nucleates, and the θ' phase dissolved at the same time, too. Usually the new phase θ occurs in the new sites which are not the same as θ'. The morphology of θ phase may also be particulate, in shape of needle, platelet, or sphere. Their size (diameter, thickness, or length) is larger than that of θ' phase. The interface of θ phase and the matrix (α-phase) is incoherent. Thus the constraint of plastic deformation is weaker than that of θ' phase and the alloy demonstrates lower hardness. The atom order of these clusters and metastable phases can be shown in **Figure 5**.

2.13.2.2.4 Case study 2: Al–4Cu alloy and its solutionizing and aging process

Al–4Cu alloy is a typical heat treatable alloy in which the content of copper is about 4 wt.%.[2] The equilibrium phase diagram is presented in **Figure 9**. The eutectic temperature is 548 °C and the maximum solubility is 5.65 wt.% in α phase. The β phase actually is an intermetallic compound $CuAl_2$, Cu content is 54 wt.%. At RT (about 25 °C, 298 K) the solubility of Cu in α phase is about 0.05 wt.%. So if you heat a part or product of the alloy to 540 °C and holding enough time (that would be specified with the size and shape, the heating method as well. For example, you have a piece of Al–4Cu alloy, 10 mm in thickness, 20 mm in width, and 100 mm in length, and you use an electric resistance furnace with gas circulation, and the temperature of the furnace gas is 540°C at the beginning you put you sample, now you can estimate the holding time is 30 min.

Usually experiential method can be used here: the heating through time is about 3 mm (thickness)/minute, namely, the required holding time $= 10\ \text{mm} \times 3\ \text{min mm}^{-1} = 30\ \text{min}$. If your sample shape is complex and with thicker wall somewhere and somewhere else with thinner wall, you can calculate with an average thickness, all Cu atoms should dissolved into the matrix α phase, then you get a single phase.

Solutionizing and aging are the basic heat treatment and then various microstructure and mechanical property can be obtained. At first you heat the parts or products of Al–4Cu alloy into a furnace with gas circulation to a temperature of about 540 ± 5 °C and holding specified time as calculated. Afterwards you take the part out of the furnace and put it into water or carbon dioxide ice to cool it down, i.e., quench the part. The time you transfer the part from the solutionizing furnace to immersing cooling agency is called transferring time. This time should be controlled the shorter the better. For Al–4Cu alloy part, transferring time should not over 15 s, otherwise the part will go through enough time at higher temperature, therefore unexpected precipitation will happen that would use up some solute atoms, and the precipitates at high temperature are not fine enough to bring good hardening effect. Quenching is so important that the fast cooling can ensure to keep the state of the single-phase SS to RT or lower, avoiding unexpected precipitation, then you get SSS, thus the next aging process can produce better fine precipitates. If you cool the parts or products of Al–4Cu alloy slowly, for example, cooled in open air in laboratory, the tensile strength (TS) is 150 MPa, and the microstructure is mainly composed by $\alpha + \beta$, and the morphology of β phase looks as dot-like in grain and net-like in grain boundary. After quenching the alloy has a higher strength of 200 MPa. The part or product with single-phase SSS would be then transferred to another furnace for aging at different temperature. This transferring process here is called parking. Parking effect is fundamental for aging and it is the shorter the better. The greater the supersaturation, the shorter the parking should be. For Al–4Cu alloy of SSS, parking must not exceed 30 min.

In the first stage of aging is the formation of solute-rich (Cu in case of Al–Cu alloy) clusters of atoms within the parent lattice of the SSS. The clusters fit in the crystal structure of the parent (Al) lattice and are completely coherent with it. The clusters are GP (Guinier–Preston) zones and are of 100 Å diameter and three atoms thick (GP 1 zone). These clusters grow to 1500 Å diameter and 150 A thick (GP 2 zone). Another metastable precipitate θ'' forms before the stable θ is observed. When stable θ' forms, the alloy is said to be over-aged and the strength decreases. These precipitation stages are summarized below in sequence (refer to eqn [2]): $\alpha_{sss} \rightarrow \alpha + \text{GP}\ 1 \rightarrow \alpha + \theta''(\text{GP}\ \ 2) \rightarrow \alpha + \theta' \rightarrow \alpha + \theta$. The fine transition precipitates so formed within matrix lead to local distortions and strain fields which restrict dislocation motion. In **Figure 6** the solute atoms distribute into clusters, beside the clusters the internal micro strain fields formed, these strain fields react with dislocations to hinder dislocation movements, and then the plastic deformation force is increased, thus the hardness and strength of the alloy are improved.

With the precipitation from GP 1 zones to GP 2 zones, the internal strain beside them affects larger area, hindering more dislocations to move, therefore the hardness increased. Further

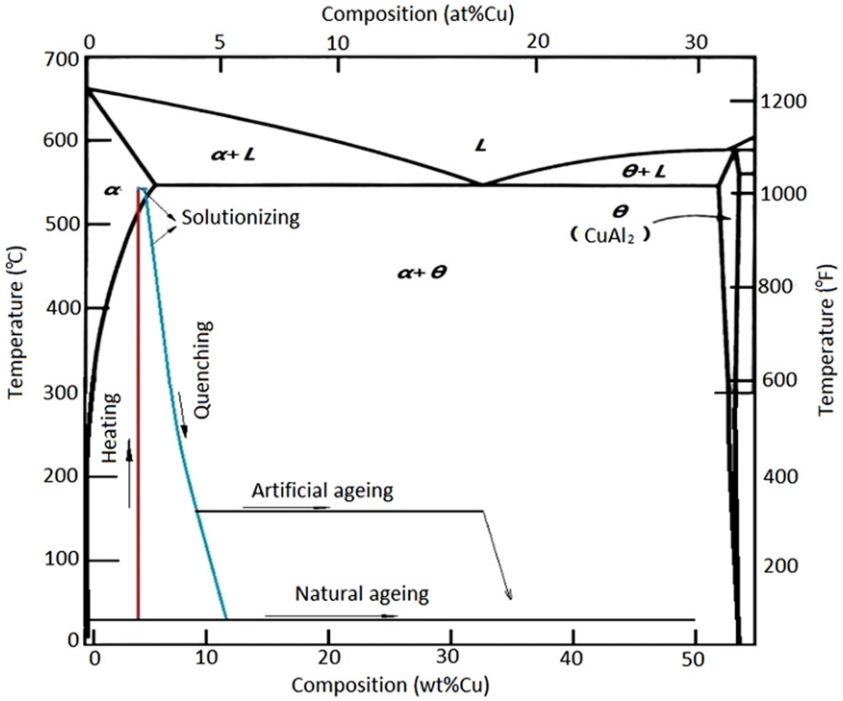

Figure 9 Al–Cu phase diagram and schematic of solutionizing, aging process.[2]

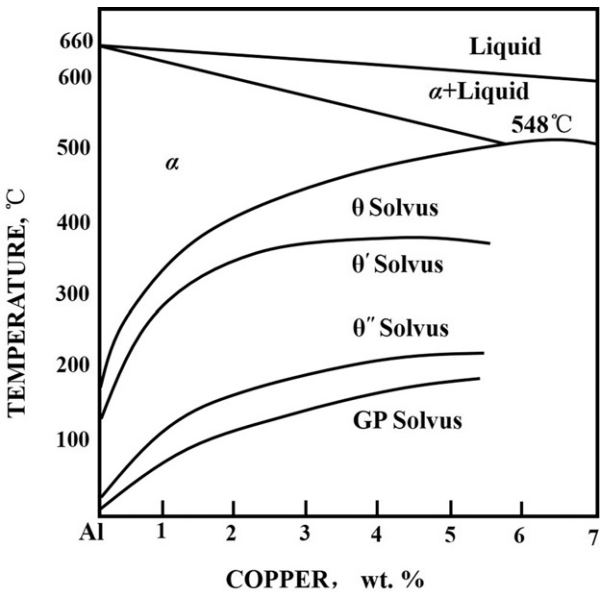

Figure 10 Aluminum–copper phase diagram along with metastable phase boundaries at aluminum end.[4]

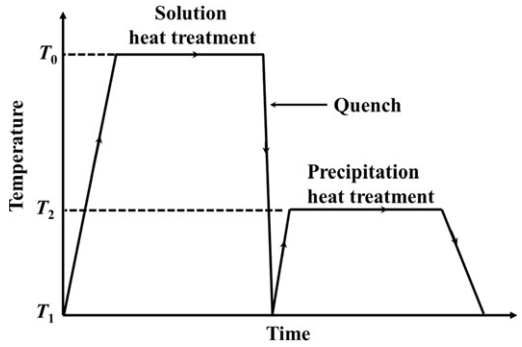

Figure 11 Schematic of solutionizing and aging process.[1]

on the θ' precipitates make much larger internal strain fields, that leads to higher hardness, refer to **Figure 7**.

In **Figure 10** the precipitating temperature of GP zones, θ'', θ', and θ phase are different and depends on the concentration of Cu in the matrix phase. With the increasing in Cu content in matrix, the precipitating temperature increases.

Compare three pictures in **Figure 5**, one can find that in the saturated solid solution (**Figure 5(a)**) the solute atoms (Cu) are randomly distributed in the matrix lattice, and in the metastable phase the solute atoms are located in some specific positions. These positions in θ' (**Figure 5(b)**) and θ (**Figure 5(c)**) phase are different, too. In θ phase the positions in a long-range order.

Figure 11 shows the full solutionizing and aging processes. Where in the figure the solution heat treatment + quenching is solutionizing, and precipitation heat treatment is aging. Temperature T_0, is the solutionizing temperature, T_2 the artificial aging temperature, and T_1 the RT, namely, natural aging temperature.

In **Figure 8** it is illustrated the dependence of aging time at specified temperature on strength or hardness. One can see clearly in different aging period there is corresponding hardness or strength. This is foundation of materials and process design in industry.

The corresponding microstructure of the alloy in different aging period are shown in **Figure 12** analyzed by transmission

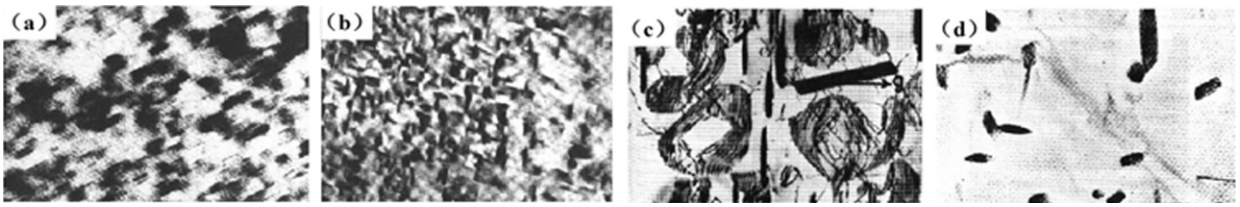

Figure 12 Microstructure evolution during aging by transmission electronics microscope. (a) GP zone; (b) θ''; (c) θ'; (d) θ.[4]

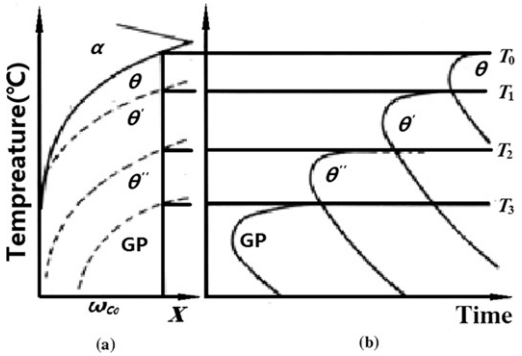

Figure 13 The effect of aging temperature on the sequence of precipitates.[4]

electronics microscope. It is clearly seen that the microstructure is very different for GP zone, θ'', θ', and θ states.

Aging temperature and aging time are the important factors that affect the aging process. The effect of aging temperature on the sequence of precipitates is illustrated by a schematic diagram in **Figure 13**:

(1) When $T<T_3$ the main precipitate is GP zone with the prolonging of aging time, the consequence of precipitates is GP zone $\rightarrow\theta''\rightarrow\theta'\rightarrow\theta$.
(2) When $T_3<T<T_2$ GP zone disappears entirely with the prolonging of aging time, the consequence of precipitates is $\theta''\rightarrow\theta'\rightarrow\theta$.
(3) When $T_2<T<T_1$ both of GP zone and θ'' disappear entirely, with the prolonging of aging time, the consequence of precipitates is $\theta'\rightarrow\theta$.
(4) When $T_1<T<T_0$ the only precipitate that is possible is θ.

So, the full sequence of GP zones and transition precipitates is only possible when the alloy is aged at a temperature below the solvus of GP zones.

Table 2 shows the precipitation sequence in several aluminum alloys series, usually the general precipitation sequence is as follows:

$$\text{Supersaturated solid solutions}\rightarrow\text{GP1 zones}\rightarrow\text{GP2 zones }(\vartheta'')\rightarrow\vartheta'\rightarrow\vartheta$$

In Al–Cu alloys, for example, when the alloys are aged at 130 °C, the formation of GP zone causes the hardness to increase as shown in **Figure 14**. With the prolonging of aging time, GP zone dissolves and θ'' the semi-equilibrium phase forms, leading to further increase of the hardness. And then the hardness begins to decrease with the further increase of aging time, due to dissolution of θ'' which is totally translated into θ', and the overaged phenomenon occurs. But there is no GP zone even at the beginning of the aging process, when the aging temperature is increased to 190 °C.

Table 2 The precipitation sequence in some aluminum alloys[1]

Alloy series	*Precipitation sequence*	*Equilibrium precipitate phase*
Al–Cu	GP zone (Disk)→ϑ'' (Disk)→ϑ'→	ϑ ($CuAl_2$)
Al–Ag	GP zone (Sphere)→γ' (plate)→	γ (Ag_2Al)
Al–Zn–Mg	GP zone (Disk)→ η (plate)→ T'→	η ($MgZn_2$), T ($Mg_3Zn_3Al_2$)
Al–Mg–Si	GP zone (Bar)→β'→	β (Mg_2Si)
Al–Cu–Mg	GP zone (Bar or sphere) → S' →	S (Al_2CuMg)

The aging can be divided into two types according to different aging temperatures, namely cold aging and warm aging. In Al–Ag alloys,[5] for example, as shown in **Figure 15** when the alloy is aged by cold aging (aging at low temperature), the main precipitate is GP zone, and the hardness increases rapidly at the beginning of the aging process, then reach a certain value and keep constant with the prolonging of aging time. And the higher the aging temperature, the faster the increasing in hardness, and the higher the peak hardness as well. So the aging time can be shortened by increasing the aging temperature.

2.13.2.2.5 Over-aging

However, the warm aging is conducted at higher temperature, and the main precipitates are transition phase and equilibrium phase. There is an incubation period at the beginning, and then the hardness increases rapidly up to a maximum value, after that the hardness decreases with time, which is called over-aging. And the higher the aging temperature, the higher the increasing speed of the hardness. But increasing the aging temperature will decrease the maximum hardness value and increase the probability of over-aging.

The essential feature in age hardening of aluminum alloys is the change of solubility with the temperature, i.e., the solubility increases with the increase in temperature. Most of the heat treatable aluminum alloys abide by this condition. The purpose of aging treatment is to create a dense and fine dispersion of precipitated particles in the matrix. The precipitated particles act as obstacles to dislocation movement and thereby strengthen the alloys, and also as a distorted area in crystal structure by the coherent and/or semi-coherent connection with lattice of the matrix.

Table 3 shows the shape of the GP zone in several aluminum alloys series.

The aging hardening of aluminum alloys is quite a complicated process, It not only depends on the composition and

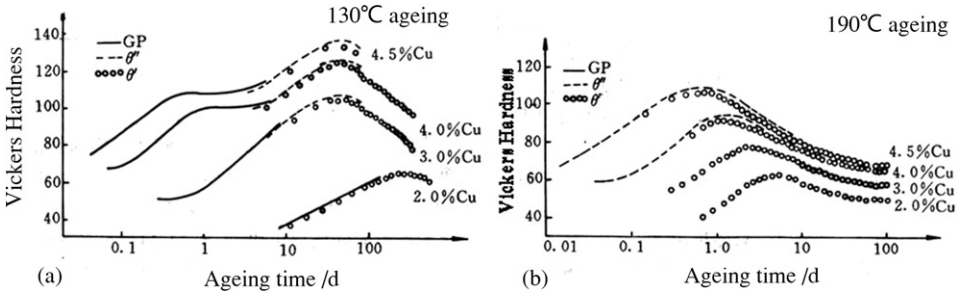

Figure 14 The aging kinetics in Al–Cu alloys at the temperature of 130 and 190 °C.[1]

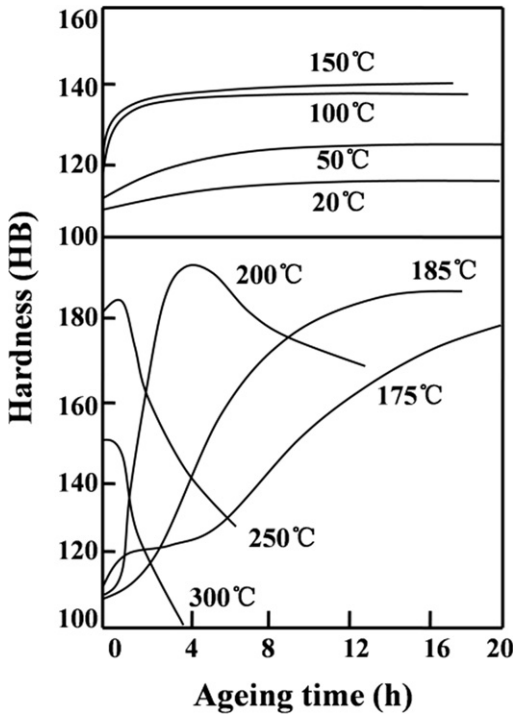

Figure 15 The cold aging and warm aging in Al–Ag alloys.[1]

Table 3 The shape of GP zone in aluminum alloys[1]

Shape of GP zone	*Alloys series*	*Ratio[a] of the majority atom diameters (%)*
Sphere	Al–Ag	+0.7
	Al–Zn	−1.9
	Al–Zn–Mg	+2.6
Disk	Al–Cu	−11.8
Needle	Al–Mg–Si	+2.5
	Al–Cu–Si	−6.5

[a]Ratio of the majority atom diameters is defined as a ratio of atom diameter of the alloying element and that of the base element (Al).

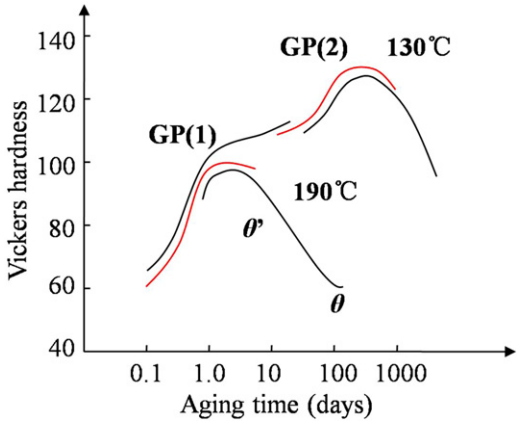

Figure 16 Correlation of structures and hardness of Al–4% Cu alloy aged at 130 and 190 °C.[6]

the aging process, but also the crystal defects, like the amount and/or the distribution of vacancy, the dislocation density, etc. Generally, the aging hardening is a result of the aged zone formation induced by segregation of solute atoms and precipitation. Figure 16 shows hardness change in Al–4% Cu alloy aged at different temperatures.

The vacancies are formed during the solutionizing process, then quench the aluminum at very short time, the cooling rate is so fast that the vacancies will not have enough time to diffuse and vanish. These vacancies remained in the SSS combining with the solute atoms. This is a metastable state in thermodynamics. The metastable thermodynamic state of the SSS must change itself into an equilibrium state at a proper condition. The existence of vacancies accelerates the diffusion rate of solute atoms and also promotes the segregation at the same time and then, the precipitation process emerges.

The size and the number of the precipitates mostly depend on the solutionizing temperature and cooling rate. Higher quenching temperature will give rise to the higher vacancy concentration and afterwards more hardened zone, as well as more precipitation, meanwhile, the decrease in size of hardened zone.

2.13.2.2.6 Dispersion hardening and dislocation mechanisms

Because the clusters are embedded in the crystal structure of the parent metal and because of the atomic size difference between solute and solvent atoms, the coherent structure induces a lot of strain on the lattice. This is referred to as coherency strains and is reflected in an increase in hardness and strength. The strengthening comes from the particles acting as obstacles to dislocation motion.

Dislocation theory explains the actual hardening mechanism. The precipitated particles or zones interact with dislocations. The strain fields associated with the dislocations interact with the strain fields created around the precipitates or zones. Fine particles which are closely spaced hinder the movement of dislocations in the matrix. Moving dislocations can overcome the obstacle either by cutting through the precipitated particles or by bending and by-passing them.

The cutting mechanism is operative when the precipitate particles are small (less than 50 A in size) and are coherent with respect to the matrix. Figure 17 shows the cutting steps. Coupled with this, other surface imperfections such as stacking faults are also created within the particles by cutting mechanism. Both these factors result in increased resistance to dislocation motion.

With larger particles (100–150 Å), the second mechanism, namely, bending of dislocation around the particles and their subsequent by-passing becomes operative. This is explained in Figure 18. The mechanism of by-passing resembles the Frank-read source. The stress needed for bending at dislocation is inversely proportional to average inter particle spacing. Hence when the particles are fine and are closely spaced, there is considerable increase in the level of stress required for bending and by-passing of dislocations. This condition is satisfied when the precipitation hardenable alloy has been aged to optimum level. When the alloy is overaged, particles become coarse (>1000 A); correspondingly, the dislocations are able to bypass them with ease at low stress levels.

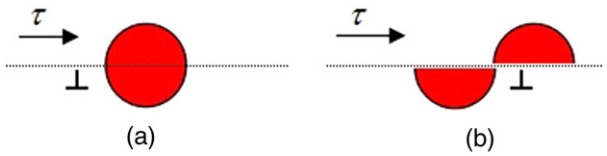

Figure 17 Dislocation cut through the precipitate particles. (a) A dislocation encountering a spherical particle. (b) The dislocation has cut the particle and separated the particle into two parts.

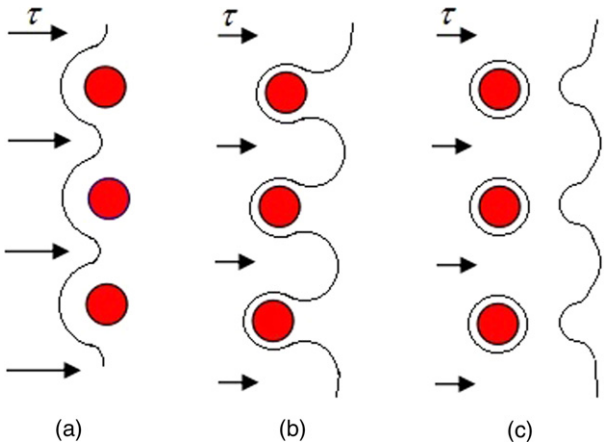

Figure 18 Dislocation bows around the particles. (a) A dislocation encounters a row particles and bent. (b) The dislocation halflings wound the particles and the rest between particles moved forwards. (c) The wound piece of the dislocation surrounded the particles, and the passed-by pieces came across and relinked to a crooked line and went forwards again.[7]

2.13.2.2.7 Regression treatment

For some unexpected mechanical property or microstructure after heat treatment, such as solutionizing and aging process, the property and microstructure can be recovered by another heat treatment, that is regression. Regression is one of the annealing process referring to some changes in the aspects of mechanical properties, physical properties, and intragranular substructure in wrought metals. Usually for higher hardness or better mechanical property, the regression temperature is somehow higher than the normal aging temperature, and then aging in a proper set of aging parameters.[8] For better corrosion resistance and better toughness the regression temperature should even higher. At these higher temperature the regression process is mainly the resolution of partially dissolved precipitates, which makes an unexpected property. In low temperature, regression is dominated by the motion of point defects, while the microscopic structure (i.e., cellular structure) remains steady. In a little higher temperature regime, the main mechanism of regression changes to the movement and interaction of dislocations, as well as the polygonization of subgrain or cellular substructure transformation.

The regression would also happen in cold deformed metals when the annealing temperature is lower and the holding time is shorter. The activation energy for different defects motion is also different. There are various regression mechanisms during the annealing process at different temperatures as show in Table 4.

Schematic diagram of regression annealing dynamics is shown in Figure 19 and the dynamics features of regression is summarized as follows:

1. When annealing at a certain temperature, there are no incubation period in regression, the process is fast at the beginning and then decreases gradually. The properties will tend to steady state after treated for a long time.
2. In a certain temperature, there exist a limit value for a specific properties.
3. The higher the annealing temperature, the closer the properties approach to natural properties P_0, that means the faster the annealing process, the shorter time will be need for arriving the limit value.

2.13.3 Tempers Nomenclature of Aluminum Alloy Heat Treatment

The heat treatment of aluminum alloys has an appointed standard nomination system for all the heat treated conditions. From free machining status to solutionizing and aging, the tempers are listed in Table 5.

2.13.3.1 Tempers for Hot Forged/Extruded Profiles

The eliminating stress heat treatment is often used for forged or extruded aluminum alloys. Add '51,' '510,' '511,' or '54,' etc., after the essential state code 'TX,' 'TXX,' or 'TXXX' to express the status of products which have been treated by eliminating stress heat treatment. The general tempers are listed in Table 6.

Table 4 Three typical regression annealing[1]

Regression process	T_r/T_m	*Mechanism*	*Characteristic*
Low temperature regression	0.1–0.3	Point defects motion	Vacancies or interstitial atoms disappear at grain boundaries or dislocations, together to vacancies couples/group. The point defects concentration decrease while the mechanical properties have almost no change
Mediate temperature regression	0.3–0.5	Dislocation slip, the growth and regulation in subgrain/grain boundary; precipitation resolving and/or growth	The activity of atoms increase with the increasing temperature, dislocation slip or cross slip on slip plane, opposite sign dislocation counteract each other, and the tangle dislocation will redistribute and group with the growth and regulation in subgrain
High temperature regression	>0.5	Grain/subgrain boundary movement, precipitation resolution	With the temperature further increase, the activity of atoms also increase and the grain/subgrain boundary movement

Note: T_r/T_m: T_r regression temperature and T_m melting temperature of the alloys.

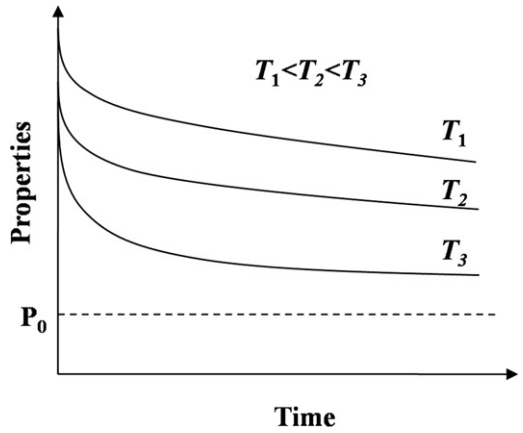

Figure 19 Schematic diagram of regression annealing dynamic.[1]

2.13.3.2 Tempers for Hot and Cold Rolled Sheets/Plates

Hot and cold rolling is a fundamental process of aluminum alloys sheet and plates. The thermodynamic status is designated to H (work hardening). The letter H plus two Arabic numerals (called HXX status), or three digits (called HXXX state), called H subdivision state, listed in Table 7.

2.13.3.3 Tempers for Cast and Forged Aluminum Alloy Parts

The final temper state of heat treated aluminum alloys is divided into 11 categories, coded with T0–T10. Different temper number designates particular tempering technology. Table 8 lists the code, designation, and the instructions of the 11 codes.

For detailed designation of the tempers in sub-steps, the sub-code number of the temper is used. To add a new number after the first category state code TX, becomes TXX and TXXX state (except for eliminating residual stress), namely behind the TX state code to add a one-dimensional Arabic numerals (called a TXX status), or add two Arabic numerals (called TXXX state), said after the obvious change product features (such as mechanical properties, corrosion resistance, etc.) of the specific process condition.

Table 5 Heat treatment status code and instructions

	Code Instructions and application	*Name*
F	Free machining status	Apply to the forming process, no special requirements of work hardening and heat treatment and no requirements for mechanical property in this state
O	Annealed status	Apply to the fully annealed products to obtain the minimum hardness and best corrosion resistance
H	Work hardened status	Apply to the products improving the strength and hardness by work hardening, the softening must be carried out by post-heat treatment
W	Natural aging status	An unsteady status, only apply to the ambient temperature natural aged alloys after hot forging and/or solutionizing treatment
T	Solutionizing and aging status	The alloys achieve to steady status via or not via work hardening after heat treatment

2.13.4 Technological Characteristics of Solution Treatment

2.13.4.1 Criterion and Standard

The solutionizing and quenching process is the most important and rigorous step in the heat treatment. The object of this step is to prepare a SSS for further aging hardening process. There are at least four key factors, like the proper heating temperature, holding time, heating facility, and the cooling method in the design of solutionizing process.

To develop the aging hardening potential of the alloys, heat treated aluminum alloys must be solutionizing treated before the final aging strengthening treatment. The purpose of the solutionizing is to make elements in the SS dissolved well into the matrix to obtain supersaturated alloys, and some good property as well. At the same time, the grains size and shape

Table 6 The state code and instructions for eliminate stress

Code	*Instructions and application*
TX51 TXX51 TXXX51	Apply to the specified amount of tensile plate, cold finishing bars or die forgings and rolling rings after solutionizing or cold formed at the high temperature. The permanent strain for thick plate is 1.5–3%. Rolling or cold finishing rod is 1–3%. The permanent strain of die forgings, rolling rings is 1–5%
TX510 TXX510 TXXX510	Apply to the specified amount of stretched pipes, extruded rods, profiles, and drawn pipes after solutionizing or cooling from the high temperature in high temperature of forming. These products need no longer straightening. The permanent strain of extruded bar, pipe is 1–3% and 1.5–3% for drawn pipe
TX511 TXX511 TXXX511	Apply to the specified amount of stretched pipes, extruded rods, profiles, and drawn pipes after solutionizing or cooling from the high temperature of forming. The permanent strain of extruded bar, pipe is 1–3%, and 1.5–3% for drawn pipe
TX52 TXX52 TXXX52	Eliminate the stress by compression the product to a strain of 1–5% after solutionizing or cooling from the high temperature of forming
TX54 TXX54 TXXX54	Apply to final die forging process, eliminate stress in forged products by cold plastic forming

must be controlled. The factors that influence the solutionizing are heating speed, holding time, quenching transfer time, cooling speed of the quenching, and parking effect (time between quenching and aging). On the other hand, the size of the workpiece, deformation degree, grain size, aluminum clad, quenching stress are also considering factors. When establishing the temperature of solutionizing, firstly, the lowest melting temperature of intermetallic compound phase and the relation between heat treatment parameters and mechanical properties must be measured/calculated, and then the solutionizing system can be decided based on the technical index.

2.13.4.2 Heating Rate and Circulation of Furnace Gas

2.13.4.2.1 Heating temperature

The basic principles to choose solutionizing temperature is to make sure that the SS elements can dissolve fully at as high temperature as possible. However, the precondition is to prevent over burning, inner oxidation in grain boundaries, grain coarsening, and aluminum clad polluted as well. The heating temperature of aluminum alloys is mainly based on the lowest melting point of the eutectic phase in the alloy. When heating, the more the dissolution of the secondary phase, the better the mechanical properties of the alloys are after aging. In general, the process completes faster in higher heating temperature.

But if the temperature is too high, the grains will be coarsened, even the workpiece will melt to be scarped. Therefore the solutionizing temperature range of aluminum alloys is narrow, i.e., the heating temperature deviation must be as small as possible, generally within $\pm 5\ ^{\circ}C$. In such condition, the mechanical properties and microstructure can be ensured.

Table 7 Work hardening state code and instructions

Code	*Instructions and application*
H1	Pure state of strain hardening
H2	Work hardening and incomplete annealing condition
H3	State of work hardening and stabilizing treatment
H4	Work hardening and protuberant processing status
HX1	Tensile strength is limited between O and HX2 state
HX2	Tensile strength is limited between O and HX4 state
HX3	Tensile strength is limited between HX2 and HX4 state
HX4	Tensile strength is limited between O and HX8 state
HX5	Tensile strength is limited between HX4 and HX6 state
H111	Moderate amount of work hardening after final annealing process, work hardening degree not as good as H11 state
H112	Suitable for hot formed products. Require the mechanical properties of products in this state
H116	Apply especially five XXX series alloy when $\omega(Mg) \geq 4.0\%$. These products require mechanical properties and exfoliation corrosion resistance

Figure 20 is a simple binary phase diagram. Firstly, heating temperature should be higher than that of solid solubility temperature to make sure SS elements can dissolve fully in the matrix. Secondly, the heating temperature must be lower than the melting temperature of eutectic phase in the condition of equilibrium and non-equilibrium, or the metal will melt locally, which is called over burning.

2.13.4.2.2 Heating rate and circulation of furnace gas

To determine the heating temperature, following aspects should be considered:

1. Heating rate can influence the recrystallized grain size. The secondary phase dissolution is advantageous to the nucleation of recrystallization. Recrystallization process begins before the secondary phase dissolves at higher temperature, which leads to fine grains after recrystallization.
2. Improving the production efficiency. Speeding up the heating rate can shorten solutionizing time, which is to save energy and improve production efficiency.
3. Controlling the heating rate. When the workpiece is in such condition, such as large size, complex shape or different wall thickness, if the heating rate is too high, because of the big thermal difference between the surface and center, the workpiece would be unevenly heated.
4. In the process of single SS (high temperature solutionizing) of super-high strength aluminum alloy, heating temperature should be controlled. Generally, the process is to heat to 460–470 $^{\circ}C$ within the rate of 60 $^{\circ}C\,h^{-1}$, then increase the temperature to 480 $^{\circ}C$ The aim is particularly to make sure secondary phases in Al–Zn–Mg–Cu alloys dissolved completely first, at the same time, S-phase can be dissolved well. The process can protect the alloy from over burning as well.
5. The installation of furnace air circulation is effective to avoid local overheating and instability of the microstructure after heat treatment.

Table 8 TX state code and instructions

Code	*Designation*	*Instructions and application*
T0	Solutionizing treatment and natural aging	Apply to the product that the strength is improved by cold working
T1	Artificial aging	In metal or green sand mold casting alloy, due to the cooling speed, has been a certain degree of supersaturated solid solution, which is part of the solutionizing effect. Further artificial aging, de-solution strengthening, can increase the hardness and mechanical strength, improve machinability. It is effective to improve the strength quality of ZL104($AlSi_9Mg$), ZL105($AlSi_5Cu_1Mg$) alloys
T2	Annealing	The main aim of T2 is to eliminate internal stress by casting, and size stability of casts, Si and Al–Si-based alloy, to improve its ductility. For Al–Si-based alloy the T2 effect is more obvious, the temperature is 280–300 °C, heat preservation 2–4 h
T3	Solutionizing treatment	Apply to the products after cold working or straightening. Solutionizing at 350–450 °C and holding 2–4 h
T4	Solutionizing treatment and natural aging	By heat insulation, make the soluble phase resolved, and then quenching, to make a large amount of solutionizing strengthening, get the supersaturated solid solution, in order to improve the hardness and strength and the corrosion resistance of the alloy. For Al–Mg alloy as the final heat treatment, an artificial aging is usually employed
T5	Solutionizing treatment and incomplete artificial aging	Used to get higher strength and plasticity, but will decrease the resistance to corrosion, especially the intergranular corrosion sensitivity would be increased. Low aging temperature with shorter holding time is a better way. The aging temperature is about 150–170 °C, heat preservation for 3–5 h
T6	Solutionizing treatment and completely artificial aging	Used to get the highest strength, but the corrosion resistance and plasticity would be reduce. At higher temperature and longer time. It is suitable for the requirement of high load parts, aging temperature is about 175–175 °C, holding time more than 5 h
T7	Solutionizing treatment and stabilizing tempering	Used to stabilize the size and the microstructure of the casts and improve the ability to corrosion resistance (especially the resistance to stress corrosion cracking), and keep high mechanical properties. Suitable for high temperature worked parts below 300 °C, tempering temperature is 190–230 °C, holding time 4–9 h
T8	Solutionizing treatment and soften the tempering	Make solid solution sufficiently decomposed, the precipitates transfer to glomerate, to stabilize the size of casts, improve plasticity, but the tensile strength decreased. Suitable for high the plastic casts, tempering temperature is about 230–250 °C, holding time of 3–6 h
T9	Circulation processing	To further stabilize the size of the casts shape. The repeated heating and cooling, temperature and cycle times are designed according to the parts work conditions, and the required properties. Suitable for size and shape of the parts are required very precise and stable
T10	Cooling after hot forming, cold working, and artificial aging	Suitable for the product that the strength improved by cold working or straightening and leveling

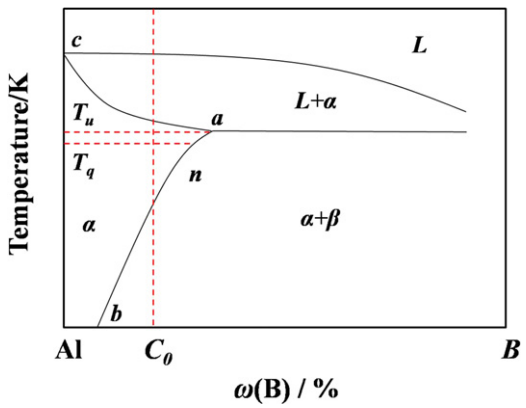

Figure 20 The relationship between solutionizing temperature and composition (T_e – eutectic temperature, T_q – solutionizing temperature).[1]

2.13.4.3 Heat Preservation: Time and Protection

When the temperature of the burden is increased to solutionizing temperature, and then holding for some time to make sure the alloy elements dissolved well. In a continuous production furnace, the speed of the production coming through the work zone should be appropriately deigned, to make sure the holding time meet the requirement of the applicable standard. In industry, the recommended holding time of the wrought aluminum alloy is shown in **Figure 21**. When the burden contains products which has different thickness cross section, the recommended holding time is confirmed according to the cross section of largest thickness.

Choose quenching transfer time is a technological process, too. Quenching transfer time is defined to be the time from the moment metal is out of solutionizing furnace or salt bath to that the work piece is immersed into the quenching medium to be cooled. Quenching transfer time has important effects on the metal properties. When the metal is taken out of the furnace and come into contact with cold air, the temperature at the edges and surface area of the parts falls rapidly, if this fore cooling in air is over too long time, some supersaturated effect would diminishes and the final quenching cooling afterwards will not get the desired effect because of the lower supersaturation. That is why the effect of quenching transfer time and reducing the average cooling rate is alike. In order to prevent the fore local decomposition and precipitation of SSS, which would reduce the effect of solutionizing and aging,

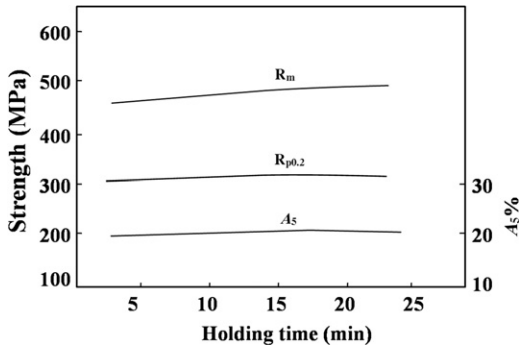

Figure 21 The influence of solutionizing holding time on the mechanical properties for 2A12 alloys (thickness: 1.0 mm, salt bath heating, solutionizing temperature: 500 °C, natural aging).[1]

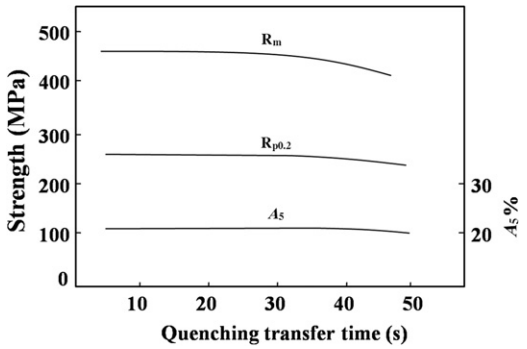

Figure 22 The influence of quenching transfer time on the tensile strength for 2A12 alloy (thickness: 1.0 mm, salt bath heating, solutionizing temperature: 500 °C , natural aging).[1]

quenching transfer time should be as short as possible. The length of quenching transfer time affects the mechanical properties, corrosion resistance, and fracture toughness of high and super-high strength aluminum alloys which are sensitive to quenching speed. To such alloys more strict measure should be taken to control the quenching transfer time. Figure 22 shows a test results for 2A12 alloy.

As for Al–Mg–Si alloys as 6A01, there is a little influence of quenching transfer time on the mechanical properties and corrosion resistance.

2.13.4.4 Cooling Process: Medium, Cooling Rate, and Temperature Range

2.13.4.4.1 Medium

The quenching medium is an important factor to ensure the achievement of the purpose or effect for various heat treatments. The higher the cooling capacity of the quenching medium is, the faster the cooling rate will be got in cast ingot which leading to a higher supersaturation of α SS and reach a good mechanical performance, because many of the alloying elements has been dissolved in the matrix attributing to a strong solutionizing strengthening. The quenching cooling rate in different quenching medium is ranked as follows:

Mixture of dry ice and acetone (−68 °C) > ice water > ambient water > warm water (80–90 °C) > hot water (100 °C) > water spray > vegetable oil > mineral oil (heated to 200–220 °C) > air.

Because the water has some capacity like high heat of vaporization, viscosity, heat capacity, strong cooling ability, and less cost. It is often used as a common quenching medium in industrial production. While its shortcomings are also very distinct: the cooling capacity decrease rapidly once it is heated to boiling. Generally, the cooling process in water can be divided into three stages:

1. Film boiling stage.
   When the hot product contact the cold water, the heterogeneous superheated steam film can be formed and grew upon the surface, it is tightly clinging to the surface and make the cooling rate decrease rapidly because of its poor thermal conductivity of the vapor coat.
2. Bubbling stage.
   Once the steam film is broken, strong heat exchange will happen near the region of surface combing with the boiling and bubbling.
3. Thermal exchange stage.
   Forced cold water circulation or the product motion in the water to break the steam film, accelerate the heat exchange at the interface of ingots and water so increasing the cooling rate.

When the ingots is cooled at boiling water, the cooling process can be divided into two stages:

1. Once put the ingot into water, severe thermal exchange happen at the beginning with a larger cooling rate.
2. The cooling rate turn down accompanying by the formation of lot of bubbles.

2.13.4.4.2 Cooling rate

The object of quenching is to make the alloy cool rapidly to a low temperature to achieve SSS, which contains most both solute elements and vacancies. Preparing the SSS plays a decisive role in the aging aluminum alloys. Faster cooling rate can generally provide a good comprehensive performance of higher strength, toughness, and fine corrosion resistance. That means the improvement of cooling rate is the key factor to ensure the good mechanical property or corrosion resistance.

The cooling rate in the quenching process mainly depends on stability of the SSS. There exist a critical cooling rate v_c, which is tangent to the 'C' curves when the alloy quenching at different cooling rate, shows in Figure 23, v_c is the minimum cooling rate to ensure to obtain the SSS. When the cooling rate in the center of product is higher than the critical v_c, the high temperature microstructure state can be fixed at each part of the product, that is called through hardening.

The cooling rate of quenching influences on the residual stress in the products; the increase in product thickness will turn the cooling rate down.

The lower limit of cooling rate is depended on the corrosion resistance of alloys for most aluminum alloys. For example, 2A11, 2A12, and 7A04 aluminum alloys is most sensitive to slow cooling. To get a higher strength and good corrosion resistance, in 7A04 alloys, the cooling rate in 2A11

and 2A12 needs be over 170 °C s^{-1}, while the cooling rate sensitivity of Al–Mg–Si series is lower.

2.13.4.4.3 Temperature range

The precipitation kinetics often is analyzed using TTT (temperature, time, transformation diagram) curves. In aluminum alloys, the isothermal precipitation kinetics curves is 'C' type which is similar to other solid state phase transformation in cool-down segment. The 'C' type curves is drawn based on the critical time point where the strength decreases to a certain level or the corrosion behavior turns from the pitting corrosion to intergranular corrosion with the precipitation process.

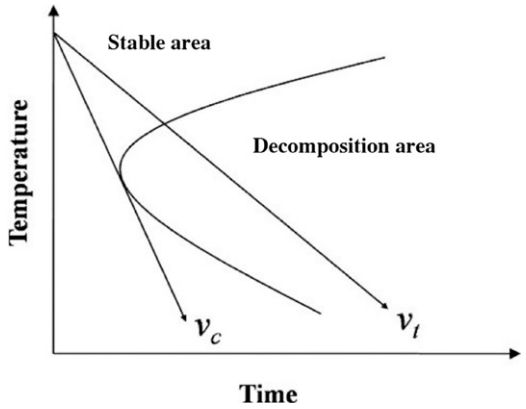

Figure 23 The critical cooling rate, the supersaturation stable area and the supersaturation decomposition area.[1]

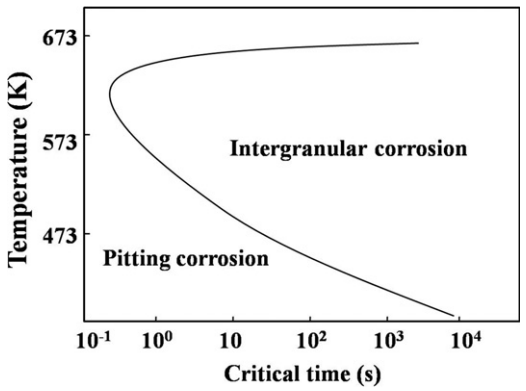

Figure 24 'C' curve of corrosion characteristics of 2A12 alloys after natural aging.[1]

Figure 24 shows the 'C' curve of 2A12 alloys characterized by pitting and intergranular corrosion after natural aging treatment. The fastest precipitate rate happens in the area near the tip region, the corresponding temperature region is called critical temperature region.

2.13.4.5 Cooling Technology: Graded Cooling, Alternative Rate Cooling

The two typical cooling techniques of quenching are shown in Figure 25. Figure 25(a) shows 'isothermal quenching,' namely cooling the products directly to a natural aging temperature. Figure 25(b) shows 'step-quenching' method, i.e., firstly cooling the products to an intermediate temperature of 160–200 °C (the medium may be salt bath or oil), and then after specific time cooling the products again to lower temperature for aging.

Decrease the temperature gradient by designing the temperature of quenching medium can obviously reduce the residual stress after quenching. For the forged product, the water temperature is 10–30 °C, not more than 40 °C, if the product have complex shape and a great differences in thickness, the solutionizing temperature should be a little higher: 40–50 °C, even more than 60–80 °C. The water temperature would be used for more complex small forgings. The isothermal quenching and step quenching can obviously reduce the residual stress and deformation/distortion at the cost of strength, toughness, and the intergranular corrosion resistance.

2.13.4.6 Quenching Faults

Because of the high thermal expansion coefficient of Al alloys and the actual size and shape of the products, the cooling process of the quenching has great effect on the quality of the products. Too faster cooling always makes severe defects, for example, deformation, distortion, warped, twist, etc., even cracks. Table 9 enumerates the main faults and analysis.

2.13.5 Processes of Aging Treatment

Aging treatment, also known as low temperature tempering, is a process in which the solutionized aluminum alloy castings/forgings are heated to a certain lower temperature, held a certain time and then cooled to RT, with the decomposition of SSS and the microstructure more stable.

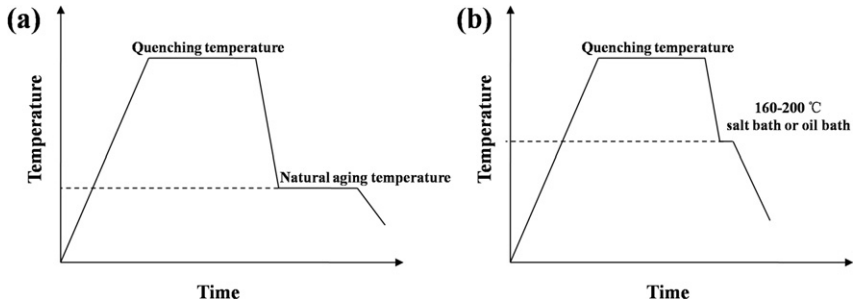

Figure 25 Isothermal quenching and step quenching process in aluminum alloys. (a) Isothermal quenching and (b) step quenching.[1,4,5]

Table 9 The common quenching faults and precautions

Name	*Characteristics*	*Analysis*	*Elimination and precautions*
Deformed, warped	The dimension or shape is changed during the heat treatment	• The heat rate or the cool rate is too fast • Quenching temperature is too high • A complex design of the ingot/forging • Incorrect placing direction in quenching	• Slow down the heating rate and increase the temperature of quenching medium • Thicken the insulation coatings or paint on the quenching sensitive position on the product • Use anti-deformation fixture • Correct the little deformation position directly after quenching
Crack	Macroscopic cracks on ingot/forging surface; the crack is winding and dark gray	• The heating rate or the cooling rate is too fast • Solutionizing temperature is too high • Inhomogeneous temperature distribution in the parts	• Slow down the heating rate or use the isothermal quenching process • Use anti-crack fixture • Thicken the insulation coatings or paint on the quenching sensitive position in the product
Surface corrosion	The casting surface is marked or blocked with spot different color to surface of the aluminum alloy castings	• Not completely cleaning before and after nitrate bath • Nitrate liquid chlorine content is overweight ($>0.5\%$)	• Shorten the transfer time from furnace to quenching bath • Test the chloride content in the nitrate; if it is extensive, make it reduce • Cleaning the ingots using warm water or cold water completely once upon taking it form the nitrate bath
Non-uniform quenching	The hardness and ductility is low in the thick parts and high in the thin positions	• Exist heterogeneity in heating and quenching process • The cooling rate is a little slow in the thick positions, diathermancy of the parts/burden in the furnace is poor	• Do heat treatment again, reduce the heating rate and extend the time of heat preservation • Thicken the insulation coatings or paint on the quenching sensitive position in the product • Make each part of the product quench at the same time, put thick position firstly • Change the quenching medium to organic solvent to reduce the cooling rate

Aging process can be divided into two basic types: natural aging treatment and artificial aging treatment. Natural aging treatment refers to aging strengthening under RT. Artificial aging process is conducted at a higher temperature than room one, which can again be divided into three kinds: incomplete artificial aging (under-aging), full artificial aging (peak aging), and over-aging.

1. Incomplete artificial aging: the casting/forging is heated to 150–170 °C for 3–5 h, so that a better combination of TS, ductility, and toughness can be obtained, but corrosion resistance is lower.
2. Full artificial aging: the casting/forging is heated to 175–185 °C for 5–24 h, so that the highest hardness and TS but lower ductility can be obtained.
3. Over-aging: the casting/forging is heated to 190–230 °C for 4–9 h to lower the strength and improve the ductility, especially to get better anti-stress corrosion cracking and anti-corrosion property can be obtained. It is also known as the stabilization tempering.

The aluminum alloy casting/forging is cooled to a temperature below zero (such as −50, −70, −195 °C) and held for a certain time. Then the casting/forging is heated to a temperature below 350 °C, and the crystal lattice of the SS repeatedly expands and contracts with some little displacement of the grain of each phase, so that the particles in both the alloying atom clustering area and the intermetallic compound area are in a more stable state. In this way, the products size and volume can be more stable. This repeated heating and cooling heat treatment process is called cyclic process. This process is suitable for the products with very sophisticated requirements and stable size (such as some parts on the electronic detecting instrument). Normal casting/forging does not need such treatment.

2.13.5.1 Pre-Conditions and Property Requirements

2.13.5.1.1 Material condition before aging

To realize the potential of age hardening effects, strengthening solution treatment must be carried out before aging for heat treatable alloys, so that the alloying elements could dissolve in the matrix adequately under the non-over burning condition. After the solutionizing treatment, the alloy should be solutionized to make the matrix supersaturated and avoid the second phase precipitation, providing the microstructure basis for the following aging precipitation strengthening. Meanwhile, the grain size and morphology should be controlled in the solution process to ensure the performance of the alloy.

2.13.5.1.2 Determination of aging process

The parameters of aging process are determined on the constituent of alloy, the service performance, such as strength, hardness, toughness and corrosion resistance, and the dimensional stability. If the alloys need high strength and

hardness but moderate ductility, the complete artificial aging (peak aging) would be used. If the alloys require high ductility and toughness and do not require so high strength and hardness, the incomplete artificial aging (under-aging) would be chosen. If the corrosion resistant performance and dimensional stability play more important roles, the aging process with longer aging time and/or higher temperature would be carried out, i.e., over-aging would be conducted. If the alloys need high integrated performance, the multi-stage aging would be used. If the alloy need both high strength and corrosion resistance, the RRA would be chosen.

2.13.5.2 Aging Processes

2.13.5.2.1 Aging parameters

Aging temperature. Aging temperature is one of the most important aging parameters in aging processes. Aluminum alloys with different compositions have different aging temperatures at which they can obtain best aging effect. Statistic results of best aging temperature of all kinds of aluminum alloys show that their best aging temperature is closely related to their melting point, which can be expressed by the following equation:

$$T_a = 0.5 \sim 0.6T_m \quad [3]$$

where T_a and T_m play with degree Kelvin ($T(\mathrm{K}) = T(^\circ\mathrm{C})) + 273.15$ K).

Aging time. For a certain aluminum alloy, **Figure 26** shows the relationship between the hardness and aging time. At lower temperature, the hardening effect increases with the increase in temperature, but the hardness cannot reach the highest value. When the aging temperature reaches a certain value, there is a maximum hardness in the curve, and the alloy can obtain the best hardening effect. Further increasing the aging temperature, the softening (over-aging process) will occur earlier, and the hardening effect decreases with the increase of the aging temperature. Besides, the best hardening effect cannot be obtained.

2.13.5.2.2 Aging process

According to the properties of aluminum alloys and application requirements, different aging process can be adopted, mainly including single-stage aging, step aging, RRA, and deformed aging.

A. Single-stage aging: only aging treatment once after quenching, either natural aging or artificial aging is suitable, and the purpose of single-stage is to obtain aging hardness peak in most cases. Sometimes, over-aging can be used to eliminate residual stress, stabilize microstructure, maintain dimensional stability, or improve the corrosion resistance.

B. Step aging: as-quenched workpieces are heated in two or more times at different temperatures. According to the functions, step aging can be divided into two stages: the pre-aging (also known as nucleation aging) and final aging. The temperature of pre-aging is much lower compared with final aging, due to their different purposes. The purpose of the former is to form high density of GP zone and nuclei of intermetallic compound phase in alloys, but the latter is to promote the continuous growth of the nuclei formed in the pre-aging stage, which can obtain higher density of intermetallic compound and transition phases, and achieve expected performance by adjusting the structure and the dispersion degree of the intermetallic compound phases.

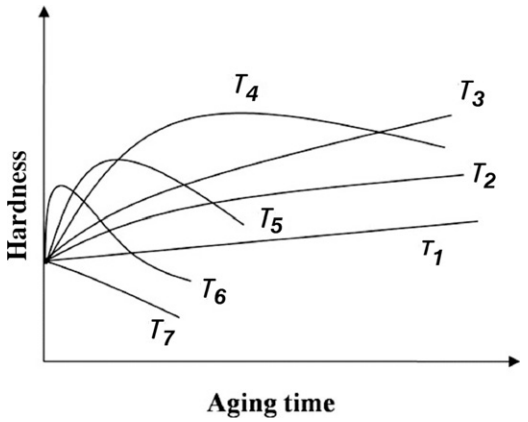

Figure 26 The relationship between the hardness and aging time of aluminum alloys at different aging temperatures ($T_7 > T_6 > T_5 > T_4 > T_3 > T_2 > T_1$).[1]

C. RRA: aluminum alloys after aging are held at higher temperature, leading to decreasing the hardness and strength to a level close to solutionized state, and then aging treatment will be carried out again to achieve required strength of the artificial aging and stress corrosion resistance by step aging. The basic steps include: (1) normal state of solutionizing; (2) peak aging as T6 state; (3) regression process (heated at the temperature that is between T6 aging and solutionizing for a few minutes, then cooled down immediately; (4) T6 aging again.

D. Deformation aging: it is also called thermo-mechanical treatment, which is a new heat treatment method combined aging hardening with work hardening. The purpose is to improve distribution of transition phase and refining the structure in the alloy, in order to obtain high strength, toughness, and corrosion resistance. This method can be applied to plates, thick plates, forged, or extruded components with simple shapes. The deformation degree is usually between 1.5 and 3.5%, a little bit over the general yield strain.

2.13.5.2.3 Stress aging

Stress aging means that the stress lower than the yield stress (YS) is introduced into the casting/forging during the aging, to change the precipitation process of reinforcing phases with coupling effect of stress and temperature, so as to achieve fine, regularly distributed precipitation phases of the type, quantity, morphology, size, and orientation. In 1970s, Hosford and Agrawal[9] studied the effect of stress aging on aluminum alloy, they revealed that the alloys precipitate obvious preferred orientation. Zhu and Starke[10,11] carry out a series of experiments and simulation to study Al–xCu binary alloys in detail, it shows that the factors, such as alloy composition, aging temperature, applied stress amplitude and direction, aging time, have influence on precipitates' orientation. Wang *et al.* find that, in 2E12 alloy, stress aging can prevent continuous precipitation at grain boundary.[12]

2.13.5.3 Aging Quality Control

2.13.5.3.1 Factors that impact aging process and the properties of aluminum alloys

2.13.5.3.1.1 The composition of the alloy

In binary alloys, the major composition of the alloy has a critical concentration and a limited concentration. If the concentration of the major composition is below the critical concentration, aging process is not likely to occur; if the concentration is between these two limits, the growth of hardness of the alloy after aging process increases with the concentration; if the concentration is above the limited concentration, the development of hardness after aging process decreases while the concentration increases (the influence of the composition in ternary alloys is similar to that in binary alloys). The minor composition and the impurity of the alloy, although the contents of which are few, sometimes have an acute impact on the decomposition dynamics of the SSS and the structure and property of the alloys.

2.13.5.3.1.2 Solutionizing treatment system

Higher supersaturated vacancy concentration and degree of supersaturation can be obtained after quenching, so that the diffusion process and dissolution process can be accelerated and higher strength and hardness can be gained. Also the cooling rate of the solutionizing process has a huge impact on the aging. The stability of different SSS differs, so the critical cooling rate, which is meant to restrain the decomposition of the solution in the cooling process, differs too.

The time of the aging. Usually, with the increase in aging time, the tensile stress, YS and hardness of the alloy increase consistently. If the temperature is high enough, these properties will decrease after reaching the maximum, which means the alloy is on the over-aging stage.

2.13.5.3.1.3 The temperature of the aging

When the temperature of the aging increases, the strength of the alloy will decrease after reaching the maximum. If the temperature is high enough, the strength of some alloy is less than as-solutionized state.

2.13.5.3.1.4 Plastic deformation

Usually, aluminum alloys are deformed on some level before aging and after solutionized. The cold deformation before aging of the alloys depending on GP zone and sub-equilibrium precipitating strengthening, can increase the dislocation density, and the vacancies are more likely to enter the dislocation and disappear, which will slow down the generation of GP zone and is against the aging strengthening. On the contrary, the cold deformation, before aging the alloys mainly depending on the disperse and transition phase strengthening, will contribute to the nucleation of the transition phase and the equilibrium phase, thus increasing the strengthening effect.

2.13.5.3.1.5 Others

Ultrasonic can accelerate the dissolution of the SSS and also increase the degree of the disperse of the dissolution, which contributes to the high hardness of the alloy. In addition, irradiation can increase the excessive vacancies, accelerate the dissolution speed and increase the peak value of the hardness.

2.13.5.3.2 Key points of the operation of aging

1. Check if the heat treatment, instruments are functioning properly and the furnace temperature is uniform within the prescribed range ($\pm 5\ ^{\circ}C$).
2. The products are supposed to take grit blasting or get washed, in order to remove oils, dirt, and mud. Do not mix up the alloys with different trademarks.
3. Products whose shapes can be easily changed should be placed on specific plates or brackets, and no parts of the products are supposed to be impending.
4. During the process of heat preserving, the temperatures of everywhere in the furnace should be checked and adjusted at all time, in order to prevent the alloys from being over burnt or even melting.
5. If the furnace is powered off for a long time, the heat preserving state products should be quenched immediately and when later the furnace is working properly, repeat the steps above and continue the heat treatment.
6. Products should be washed and dried to eliminate the rest of the nitrate immediately after have been quenched in nitrate bath.
7. If the products deform after being quenched, the products should be adjusted in time.
8. The products should take aging treatments within half an hour (parking time) after being quenched if they are required to.
9. If the properties of the products after heat treatment are found to be unqualified, repeated heat treatment can be experimented on the same products but no more than twice.
10. The parameters of the heat treatment should be determined by the shapes, sizes, and features of the alloys.

2.13.6 Progress in Heat Treatment of Aluminum Alloys

2.13.6.1 Novel Techniques in Aluminum Heat Treatment

2.13.6.1.1 New short T6 heat treatment for semi-solid forming

The solutionizing treatment is an important part of the heat treatment of aluminum alloys. In this stage, the SSS or the metastable transition microstructure at RT can be obtained, which offers alloying element distribution and microstructure basis for subsequent aging strengthening. For traditional casting aluminum alloys, solutionizing treatment should held for a long time, which limits the efficiency of aluminum alloy heat treatment. However, if the solution time is too short, the secondary phase cannot dissolve in the matrix completely, which is hard to provide ideal microstructure for subsequent aging hardening. Compared with the conventional casting methods, semi-solid forming process has higher cooling rate, which can obtain more homogeneous microstructure and finer intermetallic compounds, which are located next to the eutectic constituent, surrounded by α-phase globules with smaller size. In such a circumstance the diffusion distance of alloying element atoms is quite small and the composition homogeneous time must be shorter. These homogeneous and

finer microstructure existing in components manufactured in semi-solid state can significantly reduce the solution time of T6 heat treatment, leading to a significant increase in productivity and decrease of manufacturing cost. Researches show that the optimal parameters of conventional cast aluminum alloys heat treatment are not applicable to semi-solid processing components, due to their different microstructure and solidification history.[13,14] Menargues *et al.* studied heat treatment characteristics of semi-solid processed A356 and A357 casting alloys, and found that heat treatment, conducted at the solutionizing temperature 540 °C for 30 min, enabled the complete magnesium dissolution, while inhibiting the grain growth of the α-phase and the eutectic silicon.[15]

2.13.6.1.2 Water–air spray cooling

In the heat treatment processes of aluminum alloys, quenching might be the most strict and difficult process to be controlled . Its purpose is to obtain the SSS of solute and vacancies. Therefore, cooling rate of quenching should be fast enough to guarantee the SSS fixed. In general, the highest quenching cooling rate can lead to highest hardness and the best combination of strength and toughness, and obtain the good corrosion resistance, so in order to get good mechanical properties and corrosion resistance, high cooling rate might be adopted. However, with the increase of cooling rate, warping and distortion of the products and the value of residual stress will also increase, thus it is hard to straight and maintain dimension stability when the cooling rate is too high. A novel cooling method which can realize high cooling rate and resist warping and distortion of products should be developed. Water–air spray cooling is such a way (as shown in **Figure 27**). Nowak *et al.* contributed a cooling characteristic of EN AW-6082 aluminum alloy using water–air spray cooling method during extrusion.[16] Their research showed that this method can achieve a high cooling rate, and it can also adjust the final temperature over a wide range and minimize the temperature gradients in the cross section of complex profiles, which can make the products obtain good mechanical properties and deduce profile distortions.

2.13.6.1.3 Digital modeling

With the development of computer technology, digital modeling based on finite element method (FEM), artificial neural network method, etc., is becoming more and more widely applied in materials science and engineering. Digital modeling and simulation can reduce time and costs of laboratory, and greatly improve the efficiency because it does not need to undertake the actual experiments, which makes it a promising material preparation and processing method, even can make some more precise and elaborate work for designing and planning of heat treatment preparation. In the field of heat treatment, digital modeling can be used for preliminary exploration and optimization of technical parameters, which can reduce the costs of production and improve the quality and productivity. However, in order to realistically model different stages of a heat treatment process, it is necessary to prepare sufficient materials data and understand the physical laws that describe the thermal, mechanical behavior of a material during different stage. A commercialized example is Visual Heat Treatment program developed by the company ESI Group. It is based on the interaction of five modules (namely thermal and metallurgical analysis, electromagnetism, diffusion, the formation of secondary phases, analysis of mechanical properties), and then designed to solve problems concerning the heat treatment of materials, such as steels and aluminum alloys. Molotov *et al.* simulated the heat treatment of Al–Mg–Si alloy using the Visual Heat Treatment program, and found that simulation based on FEM could accurately predict mechanical properties of alloy after heat treatment when comparing with the actual experimental results.[17]

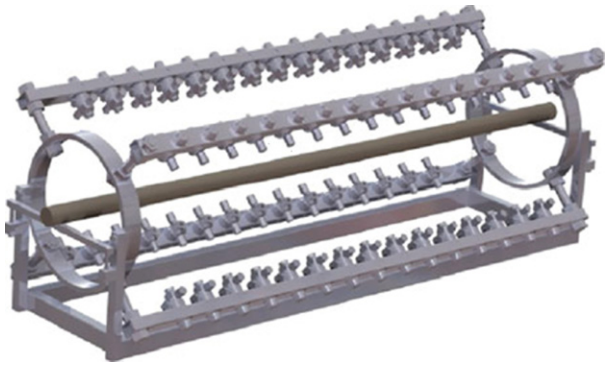

Figure 27 Schematic configuration of the spray cooling device and applied nozzle position.[16]

2.13.6.1.4 Thermo-mechanical treatment

Thermal-mechanical treatment is deforming the metals or alloys at first, and then take heat treatment, usually aging, subsequently. The deformation here is to increase the density and change the distribution of the crystal defects such as dislocation and vacancy, which could increase the driving force for the precipitation and improve the distribution of precipitates. The precipitated phase could pin the dislocation, grain boundary and other defects, and block their motion. After the following treatment, the defects in the metal materials could be stable and refine the microstructure to increase the strength and ductility. The thermal-mechanical treatment on aluminum alloy could be classified into two types by Di Russo *et al.*,[18] and they are intermediate thermal-mechanical treatment (ITMT) and final thermal-mechanical treatment (FTMT). The criterion for dividing categories is that the aging of aluminum alloy under different temperature leads to diverse precipitations. If the precipitation acts as auxiliary particles to induce or hinder the recrystallization, the corresponding process is defined as ITMT. If the precipitation does not effect as auxiliary particles, but a strengthening secondary phase under the aging strengthening process, this kind of thermal-mechanical treatment is FTMT. In the ITMT, the large precipitates impede the dislocation and refine the grains, and they are dissolved in the matrix by solutionizing and quenching in the following recrystallization process. The mechanical property of the aluminum alloys is improved by subsequently aging treatment. The purpose of FTMT is to promote the precipitation of the nano-scale secondary phase to accelerate the aging process. The amount of deformation is always 50% at most. The ITMT has an advantage in improving the ductility on short transverse direction and refining the grains to increase the high-temperature superplasticity.

The FTMT plays a role in increasing the strength of aluminum alloys, accelerating precipitation in the aging process and improving the fatigue performance, corrosion resistance, and toughness.

2.13.6.1.5 Thermo-mechanical treatment for non-ferrous alloy

Used for age-hardenable alloys. Deformation followed by aging treatment. Al, Cu, and Ni-base precipitation hardenable alloys are subjected to TMT. TS increases many times that of conventional quenching and aging treatment.

Two groups:

LT TMT (low temperature thermo-mechanical treatment).

HT TMT (high temperature thermo-mechanical treatment).

In LT TMT heat to single-phase quench (SSS) – deform cold – age at RT or increased temperature (Figure 28(b)). Increased deformation will increase TS, YS, and hardness (after solution treatment and aging).

Mechanism of increased properties: strain hardening and interaction between crystal defects and precipitation of particles. Certain work hardening remains after aging (low temperature). Deformation below recrystallization temperature is cold working. Cold deformation increases defect sites which will increase the rate of precipitated particles transformation from SSS and also increase volume fraction of precipitated particles.

HT TMT (deform – quench) (Figure 28(c)) will increase dislocation and other crystal defects. Increased strength is due to uniform precipitated particles and fine grain size.

In age hardening treatment, the secondary precipitation of fine intermetallic particles develops greater strength and hardness. Because of plastic deformation a large number of defect sites are created. During aging treatment, the supersaturated solute will precipitate out as a secondary phase in the form of a large number of smaller particles at the defect sites, enhanced by deformation. This larger number of smaller particles is responsible for the better mechanical properties achieved by TMT than by conventional aging treatment, which produces less dispersed particles.

In TMT the age hardening alloy is heated to a temperature range where a single SS is formed (Figure 28), the alloy is then plastically deformed at this temperature to a finished shape. And by this deformation a large number of defects are induced in the grain structure. After that it is quenched from this temperature to get a SSS. The deformation may also be carried out after solutionizing and quenching operation. However, the deformed component is then aged at a lower temperature where solute atoms will precipitate out as a secondary phase in a larger number of smaller particles at the defect sites.

2.13.6.1.6 A novel multi-stage solutionizing

Solution strengthening can allow the final solution temperature higher than T_{im} (T_{im} is the onset temperature of incipient melting during solution heat treatment) without producing burnt or coarsened microstructure, leading to improvement of solution degree of solute alloying atoms and final mechanical properties. The solution process includes two stages: in the first stage, low conventional solutionizing temperature (below T_{im})

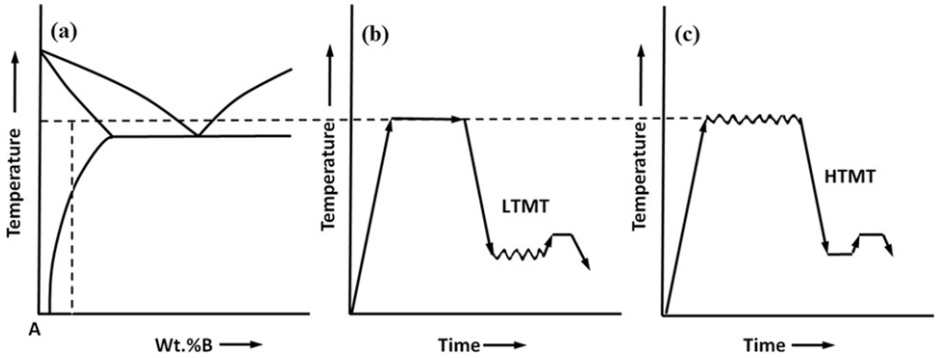

Figure 28 Low temperature thermo-mechanical treatment and high temperature thermo-mechanical treatment cycle for an age hardening alloy.[4]

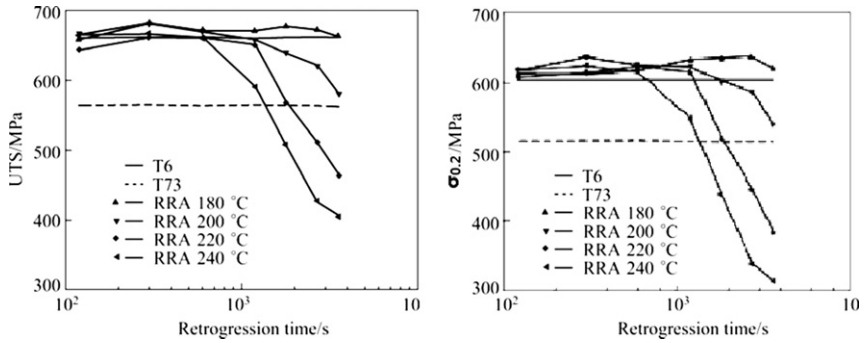

Figure 29 The influence of regression time on the ultimate tensile strength and yield strength in AA7094.[20]

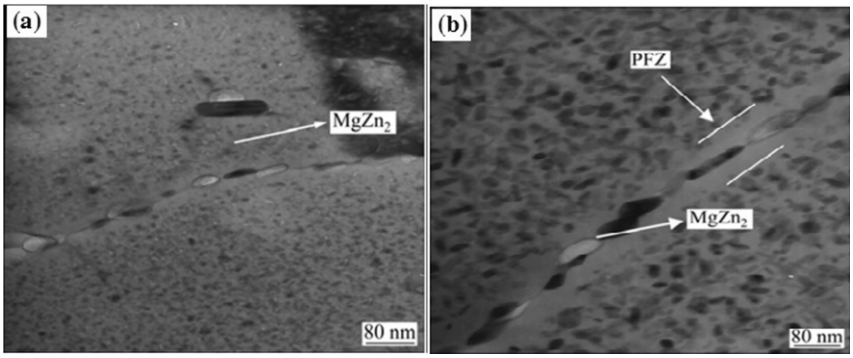

Figure 30 (a) Transmission electronics microscope (TEM) image of alloy in overaged T73 temper; (b) TEM image of alloy after regression and re-aging at 240 °C for 60 min.[20]

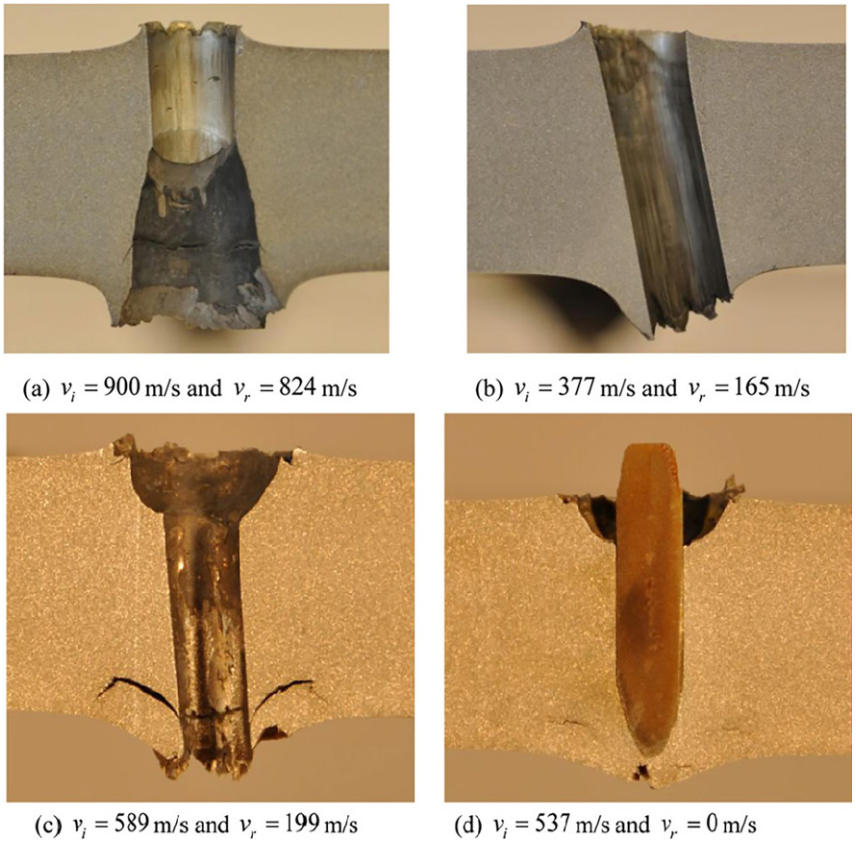

Figure 31 Cross-sectioned morphology of shot targets of 20 mm thick target plates of AA6070 in different tempers. (a) and (b) temper O, (c) and (d) temper T6. The targets were perforated by APM2 bullets at various impact velocities. v_i and v_r are the initial and rear speed of the bullet, respectively.[21]

is used, while in the second stage a much higher temperature is set, and the heating rate should be low from the first stage to the second stage so that the low melting eutectics can dissolve and improve the solid solubility of solute atoms without over burning. By doing this, a more sufficient precipitation strengthening effect can be obtained.

However, Aguilera Luna and colleagues improved the tensile properties of an Al–Si–Cu–Mg aluminum industrial alloy by using multi-stage solution heat treatments.[19] An inverse sequence compared with the sequence used in strengthening solution process is used in their contribution. Namely, the hold temperature of the first stage was always above T_{im}, while the isothermal treatment of the second stage was conducted at a temperature below T_{im}. The results showed that similar or better tensile properties with shorter treatment time than the conventional one can be obtained with the proposed solution treatment.

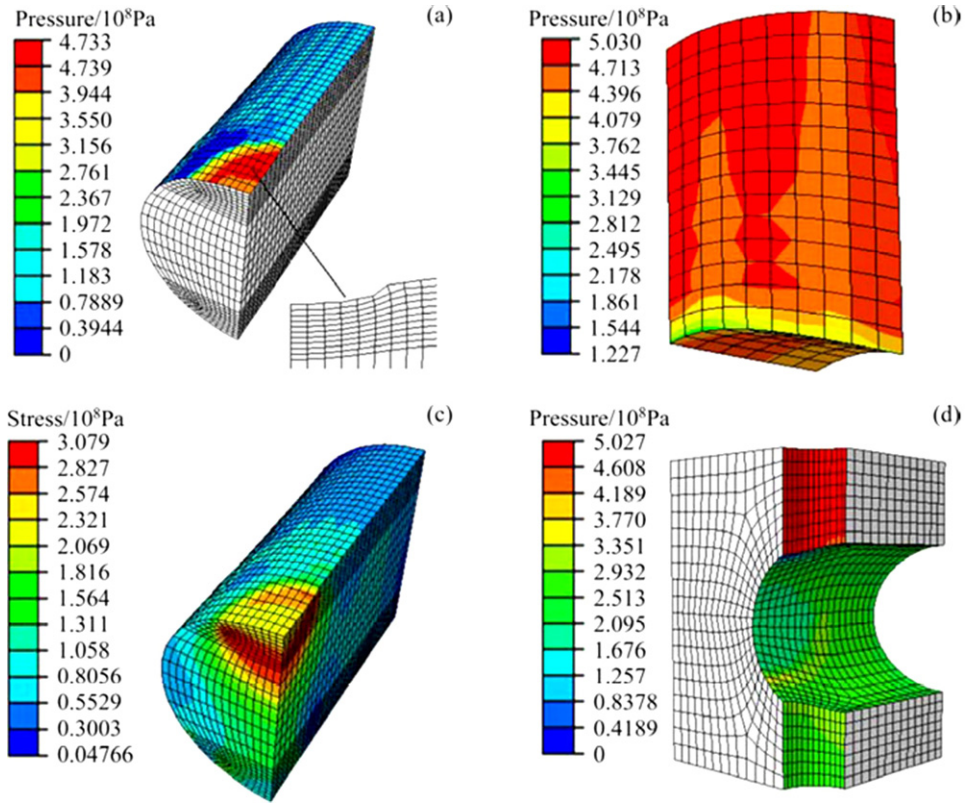

Figure 32 Distribution of heat-induced pressure and stress: (a) heat-induced pressure of cylindrical pin; (b) heat-induced pressure of 2024 alloy; (c) Mises stress of cylindrical pin; (d) heat-induced pressure of mold.[22]

2.13.6.2 The Influence of Multi-Heat Treatment on the Performance of Aluminum

The RRA treat has been proposed in AA7049 alloys.[20] As a multi-stage heat treatment, the RRA is a trade-off between strength in T6 temper and corrosion resistance in T73 temper. This process consists of double aging with an intermediate regression step. The first aging corresponds to the T6 temper, and the regression consists of partial annealing at temperature usually between 180 and 240 °C for a short time ranging from 2 to 60 min, followed by water quenching. Finally, the alloy is re-aged similar to T6 temper. **Figure 29** shows the influence of regression time on the ultimate tensile strength and YS.

Both of T73 temper and RRA can produce a fine distribution of η' precipitates, but the precipitates in RRA is more coarse than that by T73, just shows in **Figure 30**.

Aluminum alloy AA6070 in different tempers are studied to obtain higher integrated property,[21] using target plates of 20 mm thickness in tempers O (annealed), T4 (naturally aged), T6 (peak strengthened), and T7 (overaged). The result (**Figure 31**) shows that the T6 temper leads to an excellent behavior in ballistic properties comparing to O state. **Figure 31** demonstrates that in (a), (b), and (c) the bullet has penetrated the plate and held some velocity to fly more. In (c) the bullet is stopped in the plate, the plate armor exerts the protecting effect. From these test results one can know that the bullet had shot through the target for the velocity of shooting bullet from 900 to 589 m s^{-1}, and the O temper provides worse blocking capacity, whereas the block velocity is larger than 537 m s^{-1} for T6 temper. That means the alloy in different temper has quite different target capacity: T6 temper endows the materials with much better armoring capacity.

Table 10 Heat treatment on 7085 alloys in the experiment[23]

Temper	*Heat treatment*
T6	120 °C/24 h
T74	110 °C/6 h + 160 °C/10 h
RRA	120 °C/24 h + 180 °C/0.5 h + 120 °C/24 h
DRRA	120 °C/24 h + 180 °C/0.5 h + 120 °C/12 h + 180 °C/0.5 h + 120 °C/24 h
HLA	200 °C/5 min + 120 °C/24 h

Abbreviations: DRRR, dual-regression and re-aging; HLA, high-temperature and the subsequent low-temperature aging; RRA, regression and re-aging.

Heat treatment of metals under high pressure can endue different properties. The heat treatment of AA2024 under heat-induced pressure during restricting expansion-deformation has been calculated by ABAQUS platform.[22] The experimental results indicate that high heat-induced pressure can be generated on 2024 products, which is approximately 503 MPa at 500 °C when 42CrMo is used as the mold material. Moreover, the pressure distributions on both the bottom and lateral sides are relatively uniform, the result is shown as **Figure 32**.

The influence of tempers T6, T74, RRA, Dual RRA, high-temperature and the subsequent low-temperature aging (HLA)

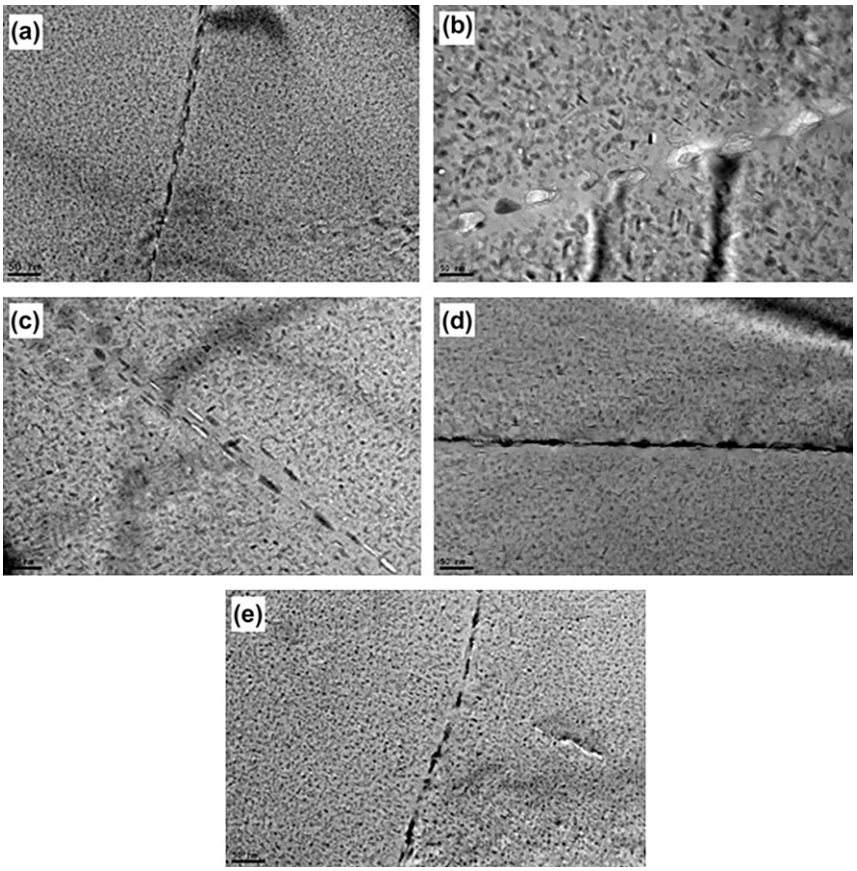

Figure 33 Transmission electronics microscope microstructure of the AA7085 alloy under different heat treatment (a) T6; (b) T74; (c) regression and re-aging; (d) dual RRA; (e) high-temperature and the subsequent low-temperature aging.[23]

on exfoliation corrosion of AA7085 aluminum alloy has been investigated.[23] The heat treatment process is shown in Table 10. The results show that RRA improved exfoliation corrosion resistance without sacrificing the strength compared to T6 temper. DRRA improved exfoliation corrosion resistance equivalent to T74 temper and maintained the strength similar to RRA. The HLA decreased the strength and corrosion resistance compared to the T6 temper. Figure 33 shows the corrosion result after different heat treatment.

The grain boundary corrosion is inhibited in (b), (c), (d) tempers from these microphotographs, compared with other tempers. It is seen that the precipitates both inside grains and in grain boundary neighborhood are changed from longer bars to shorter bars, even dotted distribution by T74 and RRA tempers, which improve the binding capacity of the grain boundaries. The RRA regression treatment changed the precipitates in grain boundary much more effective, the DRRA leads to a spherical precipitates (Figure 33(c)). That is clear that for Al–Zn–Mg–Cu alloys the HRRD treatment could improve the microstructure nearby grain boundary very much, therefore the ductility, toughness, and corrosion resistance as well are improved under the precondition of keeping high strength. HLA, namely, double aging treatment, optimized the precipitates with more uniform distribution and size. Also, the grain boundary precipitates are improved as well (Figure 33(e)).

Table 11 The impact of solutionizing treatment temperature on the composite performance[24]

Composition of composites	*Solutionizing*	*R_m (MPa)*	*A5 (%)*
15% SiC_p (5 μm)/2024Al	495 °C, 40'	416.1	2.63
	500 °C, 1 h	478.5	0.92
	520 °C, 1 h	546.6	1.26

2.13.6.3 Heat Treatment of Aluminum Matrix Composites

Aluminum matrix composites, especially short fiber and particulate reinforced aluminum matrix composites (PRAMC), with high specific strength, specific stiffness, good high temperature properties and wear resistance, are widely used in the aerospace, automotive, and electronics fields. Therefore, the study of the effect of heat treatment on the improvement of mechanical properties of PRAMC is of great significance. In

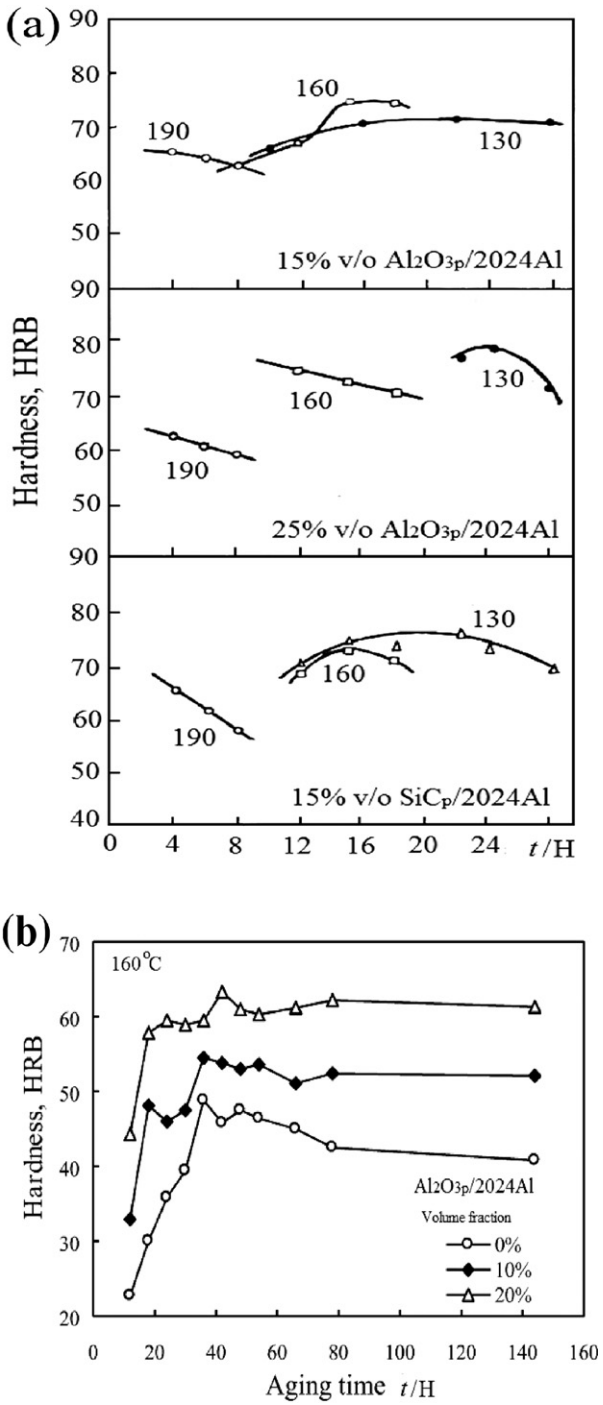

Figure 34 The aging behavior of particulate reinforced aluminum matrix composites by (a) powder metallurgy; (b) cast.[24]

view of this, a series of study are carried out on the effect of heat treatment process on the mechanical properties of PRAMC. The results were as shown in **Table 11** and **Figure 34**.

As shows in **Table 11**, with the increase of the solutionizing treatment temperature in a certain range, the strength of the PRAMC is improved, however, the failure elongation decreases slightly. From **Figures 34(a)** and **34(b)**, it can be drawn a conclusion that aging process which can obtain best properties of the composites varies from the fraction and type of reinforcements, the aging temperature and aging time, which can obtain best properties both decrease obviously.[24]

2.13.7 Conclusions

1. Heat treatment is a particular thermodynamic approach to improve the mechanical properties, corrosion resistance, workability, dimensional stability, and some other characteristics of metal materials especially of aluminum alloys.
2. Solutionizing can make the aluminum alloy products a SSS and a more homogeneous distribution of alloying elements in the aluminum matrix, preparing for the next aging process to obtain better property.
3. Aging process can endow the products with fine precipitation in the microstructure and higher hardness, the temperature – time scheduling can provide various property change for different purpose, such as peak aging makes higher hardness, but over-aging makes better corrosion resistance.
4. In processes of heating, temperature holding, cooling, the defects/faults could occur due to heterogeneous heating and cooling, complex structure, etc. The protective measures for various situation are described.
5. Heat treatment in restricted frames can provide more precise size and shape stability for complex castings/forgings with various compositions.
6. Multi-step heating and cooling process gives the heat treated parts much better property, even better resistance to corrosion, exfoliation, and corrosion cracking as well.
7. The PRAMC have stronger sensitivity to solutionizing and aging temperature and time, usually the temperature is lower, and the time is shorter at peak aging property.

2.14.1 Introduction

Various heat treatment practices are employed for different copper alloys. In case of single-phase copper alloys, cold working is followed by recrystallization annealing for improvement of properties. However heat treatment of copper alloys is quite often critical. There are alloys like bronzes where microsegregation attracts special attention to the heat treater. Due to wide gap between liquidus and solidus lines the solidification of alloys like tin bronzes exhibits coring and so under such circumstances the homogenization treatment is called for. Again there are important duplex alloys like alpha–beta brass which may be subjected to hardening treatment. Annealing as a final heat treatment or as a means for stress relieving is not uncommon in copper alloys. Several copper alloys like copper–aluminum, copper–zinc–aluminum, and copper–aluminum–nickel show martensitic transformation. Also there are possibilities of formation of precipitates of intermetallics in many of these martensitic alloys; hence heat treatment of these alloys is judiciously decided depending upon the target microstructures and thus the properties. For example, in a shape memory alloy aging precipitate formation is not welcome in many cases whereas aging precipitates in similar alloys are made to be formed deliberately under demand of situations. So a wide variety of heat treatments are employable in copper alloys of different compositions and property requirements. It is for this reason, a detailed analysis of heat treatment practice, principles behind the evolution of microstructures, and the purpose thereof are presented in this chapter.

Nickel alloys, in general, contain alloying elements like copper, iron, chromium, etc. The single-phase alloys are subjected to recrystallization annealing following cold working. On the other hand solution treatment followed by aging is a very common heat treatment for important alloys like Monel, Inconel, Hastelloy, and others. In each case, there are specific criticalities with respect to proper microstructure achievement through heat treatment and a thorough understanding of the phenomenological issues concerning the above is required. It is for this reason the present chapter has dealt with the heat treatment practices of nickel alloys, the anticipated difficulties, and the required precautions to achieve the desired set of properties. Also the heat treatment of nickel-base superalloys are highlighted.

2.14.2 Copper and Copper Alloys

Copper is well known for its outstanding electrical conductivity which is just next to silver. Copper and its alloys possess excellent corrosion resistance and ease of forming and

 doi:10.1016/B978-0-12-803581-8.09196-7

finishing. Its face-centered cubic (f.c.c) structure accounts for its good ductility. Other distinguishing properties exhibited by copper include very good thermal conductivity and non-magnetic properties. The heat treatment and consequent changes in properties of copper and its alloys are elaborately discussed in subsequent sections. The major commercial grades of copper are:

- oxygen free high conductivity copper (OFHC);
- tough pitch copper; and
- phosphorous deoxidized copper.

'OFHC' is the highest purity copper with at least 99.98% purity. Its electrical conductivity is equivalent to 101% International Annealed Copper Standard (IACS). It is also called as electrolytic tough pitch copper with oxygen content of 0.02–0.05% as Cu_2O. **Figure 1** is the microstructure of cast wire bar of tough pitch electrolytic copper (99.95% Cu; 0.03% O_2) showing the presence of Cu_2O in the interdendritic region. Because of its high purity,electrolytic tough pitch copper is the most expensive among all grades of copper and therefore its applications are limited to electrical industries.

'Tough pitch copper' is produced by the process of fire refining. It contains about 0.04–0.08% oxygen in the form of Cu_2O (0.4–0.8% Cu_2O). Its electrical conductivity is equivalent to 100% IACS conductivity. This copper is tough. The lower the oxygen content of this copper, the higher the so-called 'pitch' and vice versa, hence the term 'tough pitch.' Tough pitch copper is susceptible to hydrogen embrittlement.

'Phosphorous deoxidized copper' is another grade of fire refined copper which is deoxidized by phosphorous. As small as 0.04% phosphorous is retained in this copper which lowers the conductivity of copper to 85% IACS. This grade of copper has good hot and cold workability and is not susceptible to hydrogen embrittlement.

The other grades of copper include silver-bearing copper (7–30 oz t^{-1} of silver), arsenical copper (about 0.3% As) and free cutting copper (about 0.6% tellurium).

2.14.2.1 Copper Alloys

The major copper alloys are the following:

1. Brass:
   A. Single-phase alpha brasses (up to 36% Zn). There are two categories of alpha brasses namely; red brass (5–20% Zn) and yellow brass (20–36% Zn).
   B. Two phase α–β brasses (54–62% Zn).
2. Bronzes:
   A. tin bronze,
   B. silicon bronze,
   C. aluminum bronze, and
   D. beryllium bronze.
3. Cupronickel.
4. Nickel–silver alloys – these are also called nickel brasses. These are the alloys containing copper, nickel, and zinc. Though they do not contain silver, they have an attractive silver luster and therefore termed as nickel–silver alloys. They have moderately high strength and good corrosion resistance.

The term bronze is used to any alloy of copper containing principal alloying element (up to 12%) other than zinc or nickel. The term was originally applied to those copper alloys which contained tin as the sole or principal alloying element. Commercial bronzes are principally the alloys of copper with tin, silicon, aluminum, or beryllium as alloying element.

The commonly employed heat treatment processes to copper and its alloys are:

- homogenizing,
- annealing,
- stress relieving, and
- precipitation hardening.

Most of the copper alloys are single-phase solid solutions and are non hardenable by heat treatment. Therefore first three heat treating processes are used for these alloys as the case may

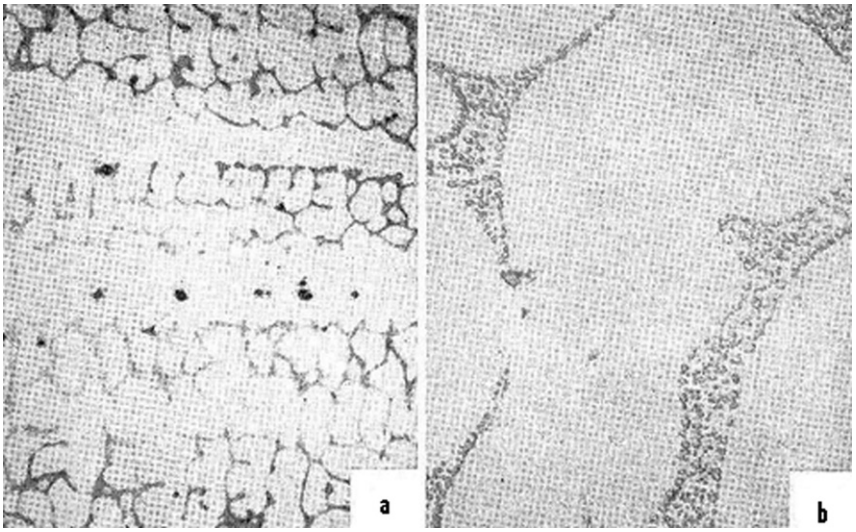

Figure 1 Microstructure of cast tough pitch electrolytic copper showing (a) cells of dendrites (the intersections of dendritic arms with surface of polish) and Cu_2O particles outlining the dendritic cells. The black spots are pores or holes in the cast metal; $\times$ 50, (b) same as in (a) at higher magnification ($\times$ 500). Cu_2O particles are resolved clearly and are seen to be of globular morphology.[1]

be. A brief account of these heat treatments in context with copper alloys is given in the subsequent sections with reference to the corresponding phase diagrams.

2.14.2.2 Homogenization

Homogenization treatment is very commonly applied to castings and cast billets of copper alloys. In this treatment, the cast alloy is heated to a temperature high enough so that diffusion of atoms within the alloy is relatively rapid, but still safely below the nonequilibrium solidus, so that burning of the alloy does not occur. The nonequilibrium solidus temperature depends on the composition of the alloy, its nature, so on. If burning occurs, the shape of the casting is impaired and physical properties also deteriorate. The alloy is held at this temperature for a long period of time depending on the freezing range of the alloy and massiveness of the casting so that the micro-segregation or the so-called coring is eliminated or at least reduced to a great extent. The alloys having wide freezing ranges such as tin (phosphor) bronzes, silicon bronzes, and copper–nickel alloys are invariably cored after solidification under industrial practice. Though commercial copper-base alloys such as α-brasses, α-aluminum bronzes, and beryllium bronzes are also cored, the degree of microsegregation is less. In these alloys, coring is generally eliminated during primary mill processing followed by normal annealing process. Formation of a cored dendritic structure during solidification of castings under nonequilibrium conditions, as in industrial practice, is very common in solid solution alloys. Solid solution crystals usually grow as dendrites. There is large concentration gradient of alloying elements from interior of the dendrite (called core which forms at higher temperature) to its surface which is lastly solidified at lower temperature. This results in coring. The core is enriched with respect to high melting constituent that raises the solidus point while the surface of the dendrite is richer in low melting constituent of the alloy that lowers the solidus point. That is, during nonequilibrium cooling solidification range is widened. Because of the large difference in composition of alloy constituents these portions tend to etch differently and an etched microsection may reveal inhomogeneous composition within a dendrite or grain. **Figure 2** is the microstructure of as-cast 70:30 brass (cartridge brass) showing cored crystals of alpha-solid solution throughout. Apart from segregation of low melting alloy constituent in interdendritic region, a brittle excess phase may also appear which is a characteristic defect commonly associated with cast alloys. This inhomogeneity in composition increases with increasing cooling rate and it also depends on freezing range of the alloy. Such an inhomogeneous cast structure lowers several properties, viz., mechanical, physical, and chemical properties of the alloy. This structure leads to poor ductility and toughness due to frequent brittle phase formation in the interdendritic region. A concentration gradient between dendritic core and dendritic surface leads to the formation of galvanic microcouples which make the many commercial castings susceptible to intergranular corrosion. Because of the nonuniformity of composition across the casting, properties are also nonuniform. Coring can be eliminated by homogenization treatment during which the composition of the alloy is

Figure 2 Microstructure of as cast 70:30 brass; cored crystals of α-solid solution throughout.[2]

equilibrated and thus ductility, toughness, and corrosion resistance are improved. Also properties become uniform across the section of the casting.

The process of homogenization involves diffusion of atoms across concentration gradient. Diffusion of atoms occurs in both the directions, that is, from core to surface of dendrite and vice versa. Diffusion of atoms is thermally activated process and it increases exponentially with increasing temperature. Higher the temperature less will be the time of homogenization. Since diffusivity of atoms varies from alloy-to-alloy, the time and temperature required for homogenization also vary with the type of alloy. In addition, both these parameters vary with degree of segregation and grain size of the casting. High tin–bronzes (above 8% Sn) are well known for extreme segregation. Diffusion and homogenization are both slower and rather difficult in tin (phosphor) bronzes, silicon bronzes and copper–nickel alloys as compared to most other copper alloys. Therefore these alloys are usually subjected to prolonged homogenization treatment. In these alloys, temperatures of homogenization are generally kept about 50 °C below the solidus temperature (**Figure 3**) and the soaking time varies from 3–10 h or even more.

Figure 4 illustrates the effect of homogenization temperature on ductility, tensile strength (T.S.), and yield strength (Y.S.) of phosphor bronze containing 92 wt% Cu, 8% tin, and small amount of phosphorous and traces of other elements. The improvement of ductility with increasing temperature is apparent from this figure. Being a thermally activated process, the progress of homogenization is a function of both temperature and time. This effect has been illustrated by taking an example of another as cast copper alloy namely, 85% Cu–15% Ni in **Figure 5**.

The microstructure of the chill-cast 85% Cu–15% Ni alloy presented in **Figure 5** is composed of dendrites of single-phase α-solid solution. The dendritic coring is apparent in this

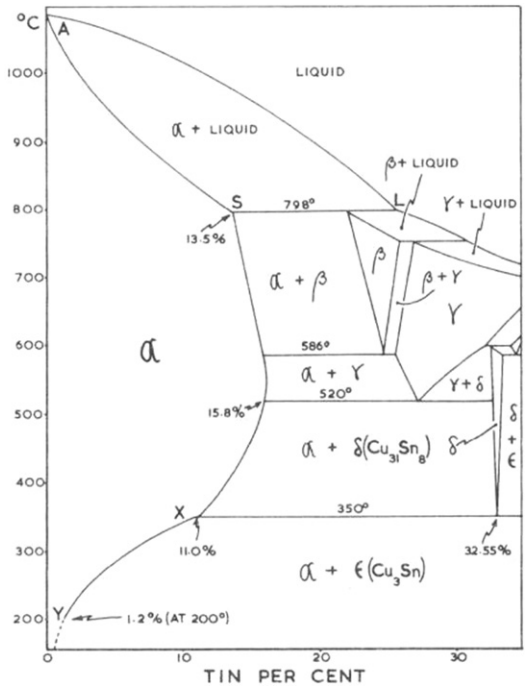

Figure 3 Copper-rich end of the copper–tin phase diagram.[2]

microstructure. When this alloy is homogenized at 750 °C for 3 h only a slight change in cored dendritic structure took place as shown in Figure 5. During annealing, the counter diffusion of atoms of nickel and copper between the nickel-rich cores and copper-rich surfaces of dendrites results in decrease of composition differences to some extent and thus slightly reduced the height of the hills and depth of the valleys. When both the temperature and time of homogenization of the above alloy increased to 950 °C and 9 h, a remarkable change in microstructure occurred as shown in Figure 5(c). The as cast dendritic structure is completely eliminated and a homogeneous grain structure has been developed. Grain boundaries are irregular in shape and are frequently encountered in the cast and homogenized solid solutions. Dark particles are inclusions of copper oxide or nickel oxide.

An initial cold work treatment is often given to cast ingot or billet. This helps in speeding up the homogenization process. Table 1 gives the schedule of homogenization treatment for some typical copper-base alloys.

2.14.2.3 Annealing

The principal heat treatment applied to pure copper and solid solution copper alloys is the recrystallization annealing following the cold working. Cold working is generally carried out

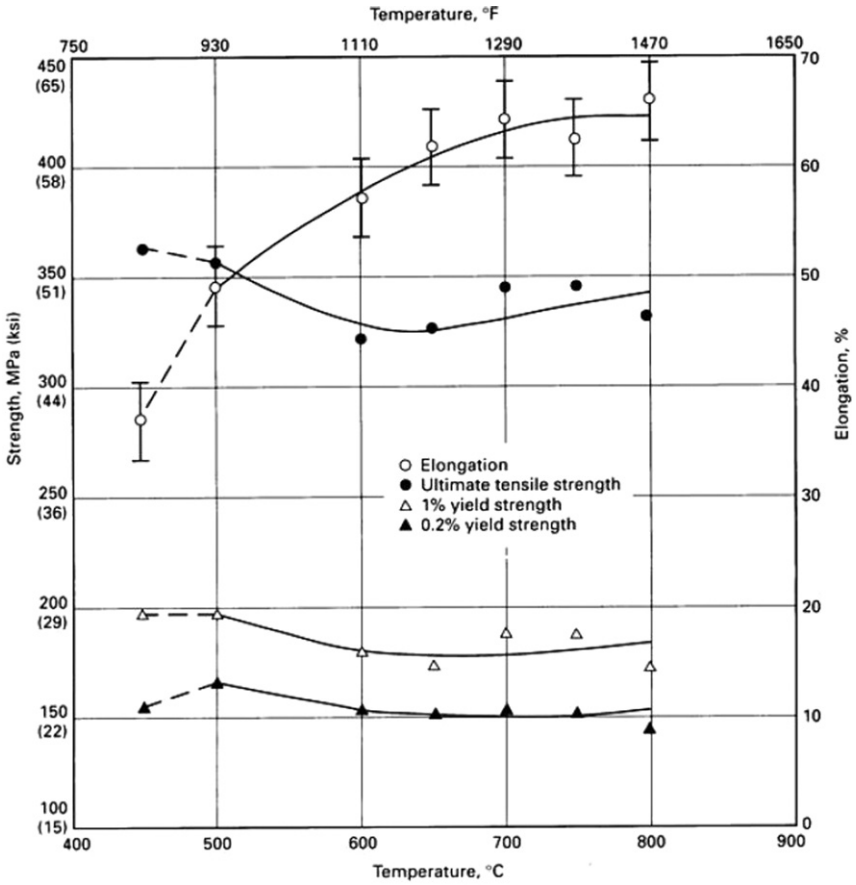

Figure 4 Effect of homogenization temperature on mechanical properties of C52100 (phosphor bronze, 92% Cu–8% Sn) alloy annealed for 4 h.[3]

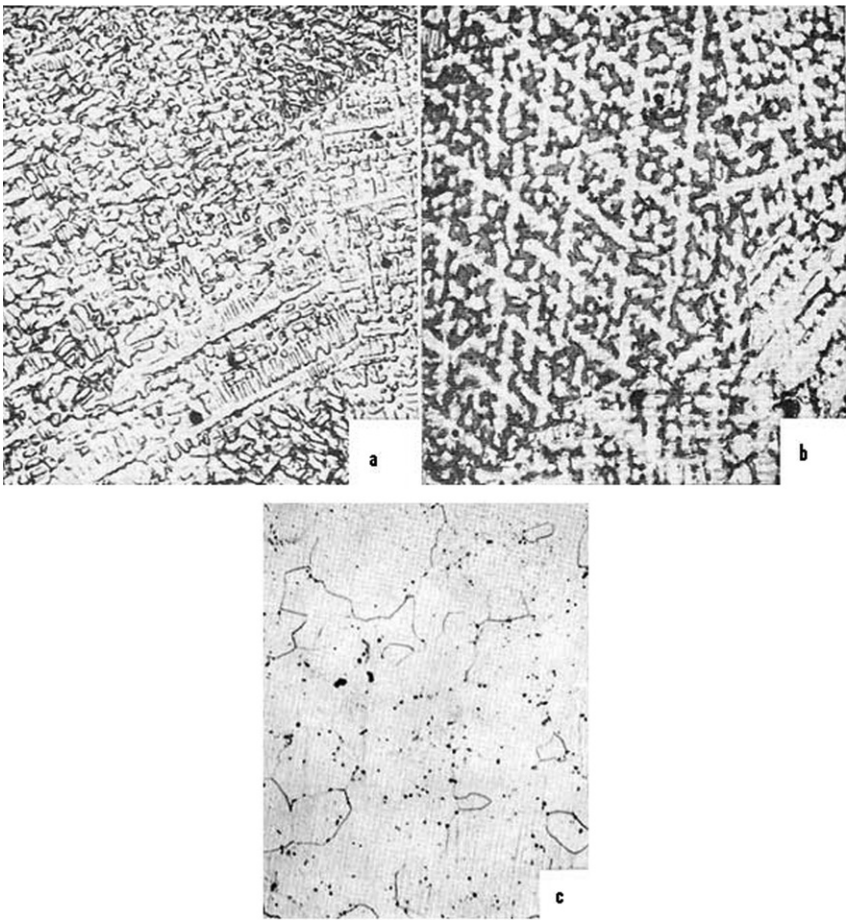

Figure 5 Copper–15% Ni alloy (a) chill cast; × 50, (b) same alloy heated for 3 h at 750 °C; × 50, and (c) heated for 9 h at 950 °C.[1]

Table 1 Schedule of homogenizing treatment for some copper alloys

Material	*Temperature (°C)*	*Time (h)*	*Remarks*
Copper–nickel–chromium alloy billets (alloy C71900) to prevent cracks, seams, etc.	1040–1065	4–9	To prevent cracks and seams
Phosphor bronzes (8–10% Sn) C52100 and C52400	775	5	To reduce embrittlement in billets and slabs that are to be cold formed
Cast cupronickels (70:30 Cu:Ni) C96400	1000	2	Protective atmosphere is to be used. The alloy is cooled to 400 °C in furnace and then in air

Source: Ref. [3].

below $0.4T_m$, where T_m is the melting temperature of the metal or alloy in Kelvin. Plastic deformation of polycrystalline metallic material not only causes a permanent change in its external shape but also brings about changes in internal structure. The internal structural change may be a change in shape and size of grains, generation of lattice imperfections, and development of a texture and so on. The principal kind of lattice imperfections generated during cold working are the dislocations. Of the lattice imperfections generated, dislocations are of great concern. Dislocation density is increased from as low as $10^{10}\,m^{-2}$ in annealed state to as high as $10^{16}\,m^{-2}$ in heavily deformed crystals.[4] All these imperfections produce a lot of lattice distortion and raise the internal energy of the metal or alloy. The type of distortion produced may vary with the type of deformation process such as rolling, swaging, forging, etc. Of the total energy expended in cold working, about 10% remains stored within the crystalline metal and the remaining is lost as heat. The major contributor to the stored energy (called inherent energy) is increased dislocation density. All these imperfections give rise to internal stresses. The increased internal energy makes the metal thermodynamically unstable at any temperature. The free energy of such a metal is higher than it is in as-annealed state. The change in size and shape of individual crystals (or grains) occurs through processes called slip and twinning. The principal process of plastic deformation is slip. Multiplication of dislocations on several slip systems upon plastic deformation leads to their interaction with each other and this restricts their

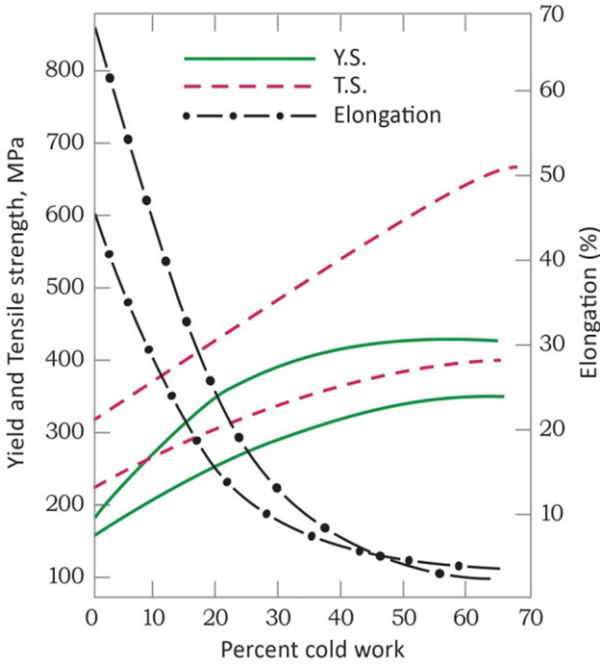

Figure 6 Effect of cold work on strength and ductility of copper and brass. The lower curves are for copper and the upper ones are for brass.

motion. The consequent effect is that for further plastic deformation to take place, higher magnitude of load or stress is required. The material is said to be work (or strain) hardened. Thus cold working results in increase of hardness, Y.S., T.S. but also reduction in ductility (or % elongation) and toughness of a ductile material. **Figure 6** illustrates the effect of percent cold work on strength and ductility of copper and brass. It also increases electrical resistivity because the increasing number of point and line defects incoherently scatters the movement of free electrons. In addition, the chemical reactivity also increases due to cold working.

In order to relieve internal stresses and to improve properties by way of microstructural refinement, the metal or alloy is subjected to annealing heat treatment. Stored internal energy is the driving force for a cold worked metallic material to undergo structural changes and to restore strain-free grains due to annealing heat treatment. Once the metal or alloy is annealed it becomes soft and ductile and is capable of deforming further if so required. When a series of cold reductions are needed, intermittent annealing processes are also required. One or more number of intermittent annealing may be required depending on the extent of reductions needed. Annealing may be a final heat treatment for the concerned metal or alloy in the final product form. When series of cold reductions are required, the first intermittent annealing is preferred to carry out at a temperature well above the recrystallization temperature to cause grain growth and achieve extra softness so that less work is required in the next cycle of cold reduction. But in such case, the temperature of subsequent annealing must decrease to attain a fine grain structure after last annealing process. For copper and brass mill alloys, grain size is the standard means of evaluating a recrystallization annealing.

The basic purpose of annealing is to soften and improve ductility of the copper and its alloys which has been work hardened so that further deformation can be facilitated. The process involves heating the cold worked metal to a temperature that produces recrystallization. Recrystallization temperature generally ranges from 0.3 to $0.6T_m$, where T_m is the melting temperature in Kelvin. Generally recrystallization process is carried out at about $0.4T_m$ or higher where migration of high-angle grain boundaries is possible. The factor $0.3T_m$ is common for pure metals after considerable amount of deformation. Recrystallization temperature is an indicator of the temperature at which a metal must be annealed to get the desired softness. This temperature depends principally on degree of prior cold working. Higher the degree of cold working, lower is the temperature of recrystallization. As the degree of cold working increases, the number of lattice defects also increases which in turn makes the metal thermodynamically more unstable as mentioned earlier. Hence recrystallization occurs at a lower temperature and in shorter time. **Figure 7** illustrates the effect of prior cold work on annealing behavior of pure copper. If the degree of cold working is less than about 10%, recrystallization generally does not occur. The recrystallization temperature is high if the degree of cold working falls in between 10 and 20%. A minimum of 20% cold reduction is normally required for recrystallization. In many instances a high degree of cold working is desirable to achieve a fine grain structure after final annealing. Since the rate of diffusivity of atoms increases with increasing annealing temperature, a shorter annealing time (t) is required for a given degree of cold working at higher annealing temperature (T). The incubation period is also shorter at higher annealing temperature and high degree of cold working. This time t of recrystallization is expressed as[5]:

$$t = t_0 \exp(Q/RT) \quad [1]$$

where t_0 is a constant, Q is activation energy for recrystallization and R is universal gas constant. Both t_0 and Q vary with temperature. During recrystallization, strain-free new crystals are formed at the expense of distorted grain structure. The process comprises of two steps, namely, nucleation and growth. Nucleation of new crystals takes place preferentially at grain boundaries and twin boundaries. Higher the degree of cold working higher will be the rate of nucleation (N) and less will be the rate of growth (G) of new nuclei. Hence finer will be the grain size. Similarly a higher rate of heating results in higher N and therefore favors the formation of fine grain size after recrystallization gets over. After recrystallization, a uniform grain structure is obtained. Grain size is the standard means of evaluating a recrystallization anneal in copper and brass mill alloys. This process of recrystallization is often called primary recrystallization.

The presence of impurities also affects recrystallization temperature. Very pure metals have a lower recrystallization temperature than impure metals.[4] Even a very small concentration of solute atoms raises the recrystallization temperature, the degree of rise being dependent significantly on the nature and concentration of solute atoms. As the solute concentration increases, recrystallization temperature rises to a maximum at certain value of solute content. With further

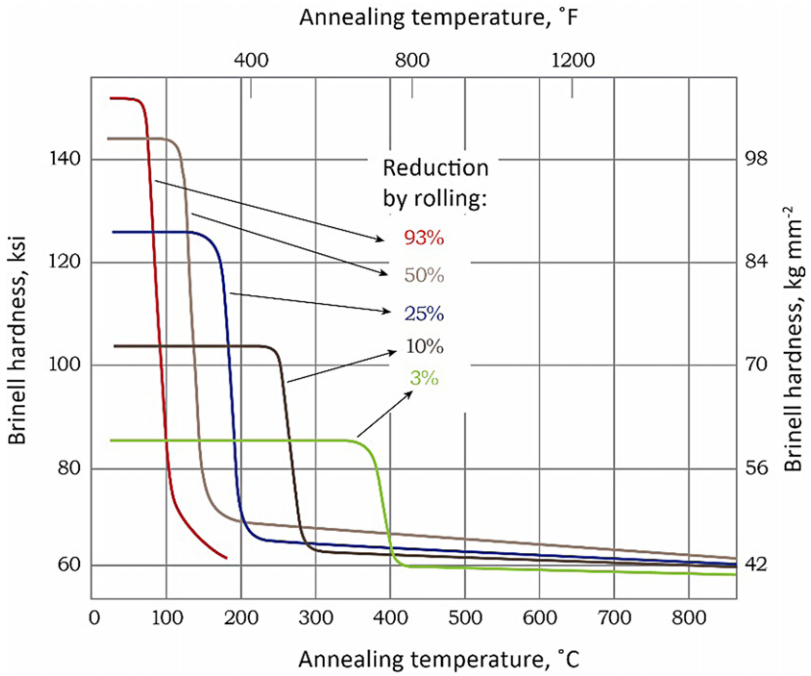

Figure 7 Effect of degree of cold working on the annealing process of pure copper.[3]

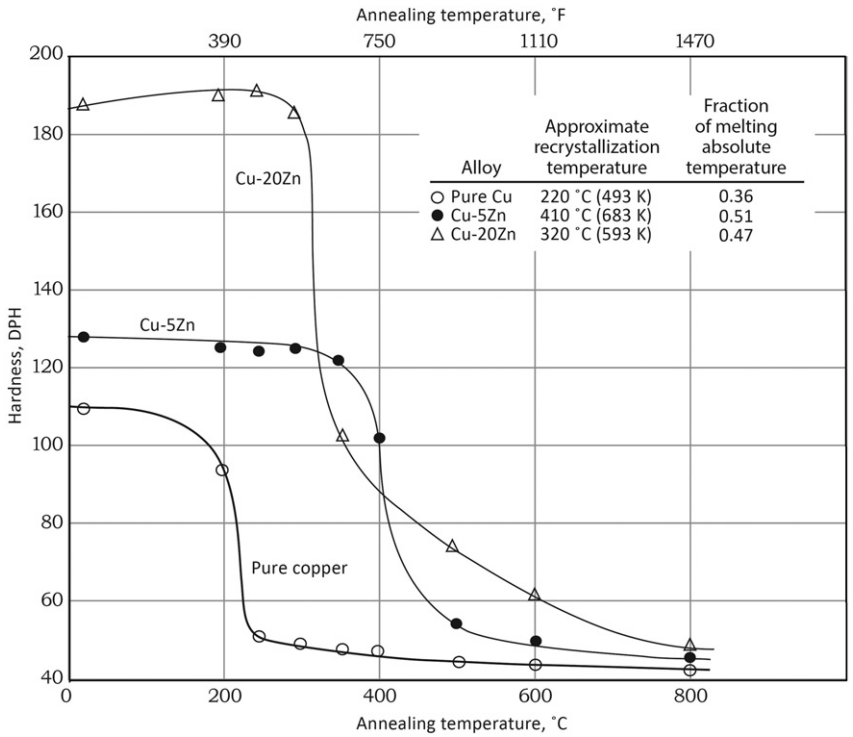

Figure 8 Illustration of effect of zinc content in copper on annealing process. The alloys were cold worked to 60% reduction in thickness at 25 °C.[3]

increase of solute concentration, the recrystallization temperature decreases. This is illustrated in Figure 8. It can be noted from this figure that as the concentration of zinc exceeded about 10%, recrystallization temperature decreased. The increase in recrystallization temperature at lower solute content is believed to be due to strain aging effect.

At low concentration, solute atoms form Cottrell atmospheres around dislocations. These atmospheres restrict the

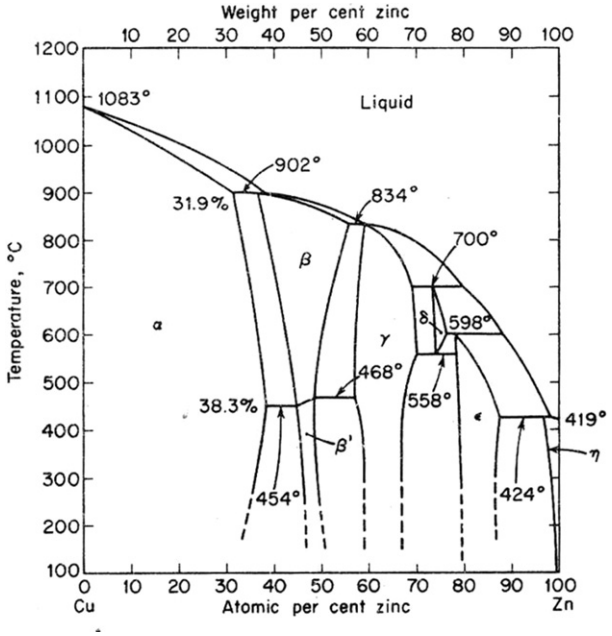

Figure 9 Copper–zinc phase diagram.[1]

movement and rearrangement of dislocations, which is required for the formation of recrystallization nuclei. Solute atoms are also attracted toward grain boundaries. Atoms at grain boundaries also retard their movement and thereby retard nucleation and growth of recrystallization nuclei. When solute concentration increases, saturation occurs at these sites and further increase of recrystallization temperature becomes improbable. Melting temperature of Cu–Zn alloys decreases with increasing concentration of zinc (**Figure 9**). This is the reason for lowering of recrystallization temperature of brasses when zinc content exceeds about 20%. Thus a small concentration of solute atoms is able to raise recrystallization temperature. For instance, an addition of 0.05% silver to copper is able to raise the recrystallization of temperature of pure copper from 140 °C to about 340 °C. In case of copper–zinc alloys, addition of zinc up to about 10% raises the activation energy for mobility of solute atoms and thereafter it decreases as its concentration is increased up to 20% in copper.

2.14.2.4 Stress Relieving Treatment

As the name implies, stress relieving treatment is applied to shaped articles in which the stresses are introduced during fabrication processes. These stresses called residual stresses are frequently tensile in nature and may be introduced during machining, cutting, welding, brazing, casting, or mechanical shaping processes of fabrication. In context of copper and its alloys, this treatment is very commonly used for relieving residual stress of cold formed parts. Cold forming is done to improve strength and hardness of the part or component due to strain hardening effect but at the same time ductility is reduced. Since cold forming is associated with generation of host of crystal imperfections, in particular, the dislocations, the elastic strain, and residual stresses are left in the part after forming operation. If these residual stresses are tensile in

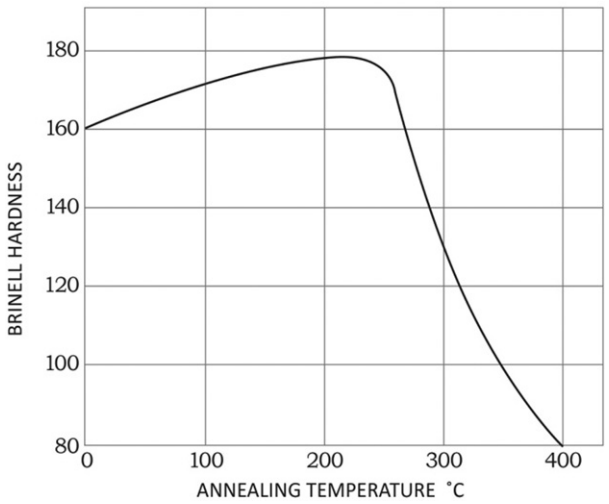

Figure 10 The relationship between hardness and annealing temperature for cartridge brass.[2]

nature and are of sufficient magnitude, these may cause stress corrosion cracking while the parts are stored in warehouse for relatively long periods of time or otherwise exposed to specific environments during service.

For instance, in brasses containing more than 15% zinc, stress corrosion cracking (also popularly known as season cracking) can occur if sufficient magnitude of residual tensile stresses is left from the previous cold forming operation and if the part is exposed to an environment containing traces of ammonia. The problem of season cracking is more pronounced with the cold formed brass parts such as caps, cartridge cases for rifles, caps for incandescent lamps, pipes for air-coolers, etc. Stress relieving heat treatments are carried out by heating the parts, generally, to below the annealing temperature that do not cause recrystallization and hence softening of metal. The properties that are derived due to cold working should not be affected significantly following stress relieving treatment. For this, the temperature of the stress relieving treatment must be kept low but then time must be prolonged to achieve relief of residual stresses. In fact lower temperature stress relieving treatment (generally up to the partial recovery stage of annealing during which excessive point imperfections are eliminated) causes a slight improvement of hardness and strength of heavily deformed alloy. This is illustrated for cold worked 70:30 brass in **Figure 10**. Seemingly, this is due to strain aging effect. Percentage elongation remains unaffected. Stress relieving treatment allows higher external loads to be applied, increases fatigue resistance and impact strength, lowers the susceptibility to brittle fracture, intercrystalline corrosion, and prevents warpage.

2.14.3 Heat Treatment of Copper

The principal heat treatment applied to pure copper is recrystallization annealing following the cold working. Though recrystallization temperature of pure copper is taken as 270 °C ($0.4T_m$), in practice the recrystallization of pure copper is carried out at much higher temperature. The

principal reason is to reduce the time of recrystallization and hence to economize the process. In practice, most recrystallization treatments of pure copper are carried out in air in the temperature range of 375–700 °C. The intermediate temperature, that is 600 °C, is very common. The temperatures used for annealing various grades of cold worked copper are given in Table 2. In the annealed state electrolytic tough pitch copper (C11000) possesses Y.S. of 69 MPa, T.S. of 220 MPa and percent elongation of 45 (in 50 mm gage length of specimen).[6]

However, time and temperature must be controlled to avoid danger of grain growth. A temperature greater than 700 °C is avoided to prevent excessive oxidation of copper (Figure 11). Once recrystallization gets over, copper is quenched in cold water such that the oxide scales formed at the surface may completely flake off, leaving behind a very clean shiny surface of pure reddish copper. In case of annealing oxygen bearing copper, hydrogen in the furnace atmosphere must be maintained to a minimum value to avoid any embrittlement. For instance, when annealing temperature is less than about 480 °C the hydrogen content of the atmosphere should not exceed 1%.

2.14.3.1 Heat Treatment of Brasses

Like pure copper, single-phase alpha brasses are frequently subjected to recrystallization annealing treatment. In fact a single-phase alloy does not undergo any phase transformation; therefore structural refinement through recrystallization of cold worked alloy remains the only means of toughening. Controlled degree of recrystallization or recovery fixes the magnitude of hardening by cold working. It is to be understood that intensive strengthening of single-phase alloy can lead to work softening and to avoid this, low temperature annealing is carried out. Since alloying elements raise the recrystallization temperature, cold worked alpha brasses are generally recrystallized in the temperature range of 700–730 °C. In case the temperature of recrystallization annealing exceeds 700 °C, the furnace atmosphere must be controlled to overcome the problem of excessive oxidation as well as discoloration of the surface. The recrystallization annealing temperatures of some representative brasses (wrought) are given in Table 3. Figure 12 illustrates the microstructural

Table 2 Annealing temperatures for various grades of cold worked copper

Wrought copper	*Common name*	*Temperature (°C)*
C10100–C10300	Oxygen free high conductivity copper (99.9% Cu)	375–650
C10400–C10700	Oxygen free silver-bearing copper	475–750
C10800	Oxygen free low phosphorous copper	375–650
C11000	Electrolytic tough pitch copper	250–650
C11100	Electrolytic tough pitch, anneal-resistant copper	475–750
C11300, C11400, C11500, and C11600	Silver-bearing tough pitch copper	400–475
C12000	Phosphorous deoxidized copper, low residual copper	375–650
C12200	Phosphorous deoxidized copper, high residual copper	375–650
C12500, C12700, and C1300	Fire refined, tough pitch copper with silver	400–650
C14500	Phosphorous deoxidized, tellurium copper	425–650
C14700	Sulfur copper	425–650

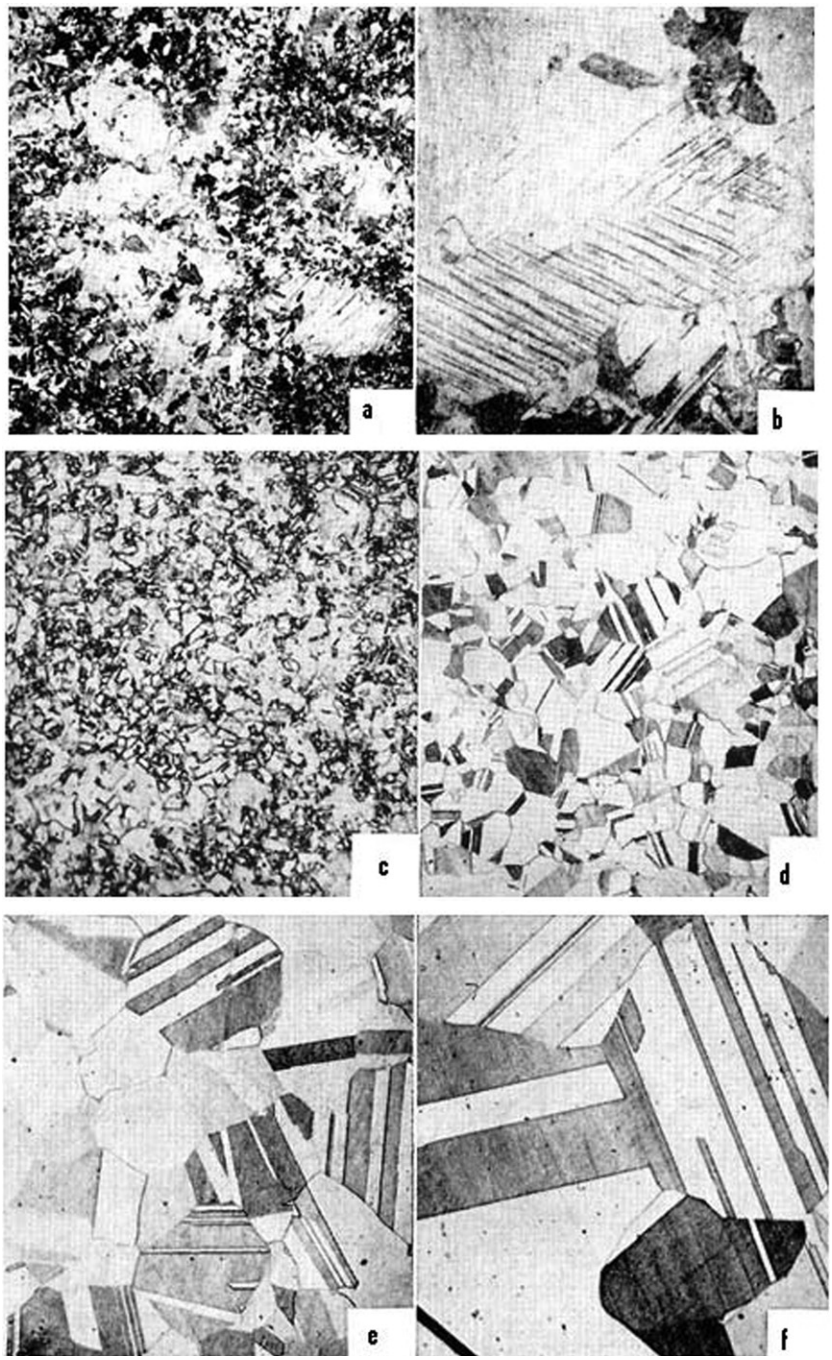

Figure 12 Alpha brass cold-rolled 60% and annealed for 30 min at (a) 300 °C, × 75, (b) same at higher magnification (× 500) where the structure of new crystals is somewhat better resolved, (c), (d), (e), and (f) at 400, 500, 650, and 800 °C, respectively at × 75.[1]

changes that occurred in cold-rolled (60%) α-brass with increasing temperature of annealing for a fixed time of 30 min. It can be noted that recrystallization is almost completed after annealing at 400 °C. Further increasing of temperature of annealing resulted in grain coarsening. Figure 12(a) shows tiny new crystals which are not resolved very well here and some areas of the cold deformed structure containing strain markings are also evident. Figure 12(b) is the same microstructure as in Figure 12(a) with higher magnification (× 500) showing that new crystals resolved somewhat better. The average grain diameter of the new crystals found to be 2 μm. Figure 12(c) is the microstructure of the same specimen reheated for 30 min at 400 °C. At this temperature recrystallization has been completed and some grain growth has occurred. The grain size estimated to be about 20 μm. Same specimen when reheated for 30 min at 500 °C, the microstructure shows an additional grain growth with grain diameter of about 45 μm (Figure12(d)).

On annealing the same specimen at 650 and 800 °C, further grain coarsening is apparent from Figures 12(e) and 12(f). Grain size increased to about 150 and 250 μm, respectively.

Often a low temperature stress relieving annealing treatment is applied to alpha brass articles to relieve internal residual stresses generated during cold forming process. It has been observed that sometimes cold-formed alpha brass articles crack spontaneously without the influence of external stress, as for instance, when such articles are stored in warehouse. Examples of such articles include cartridge cases of rifles, brass caps, aircooler pipes, caps for incandescent lamps, etc. In the cold formed articles or parts, the residual stresses are mostly tensile in nature. When exposed to corrosive atmosphere, in particular, the atmosphere containing small amount of ammonia and sulfur dioxide (as usually found in industrial atmosphere), cracking in brass articles takes place at the grain boundaries. Such type of cracking is called season cracking. Figure 13 exhibits microstructure delineating stress corrosion cracking in an α-brass.

In order to eliminate the problem of season cracking, brass articles are often subjected to stress relieving at low temperature. However, this treatment is frequently accompanied with some reduction of hardness of brass; so the time and temperature of annealing is properly controlled to minimize reduction of hardness.

Dual-phase alpha–beta brasses are generally given a hardening treatment followed by tempering treatment. These alloys consist of 38–46% Zn (Figure 9). These alloys at ambient temperature have two phases namely α and β′. β′ phase is ordered CuZn intermetallic compound characterized by high hardness coupled with brittleness. β-phase, which is high temperature disordered CuZn is soft and allows hot working of the alloy.

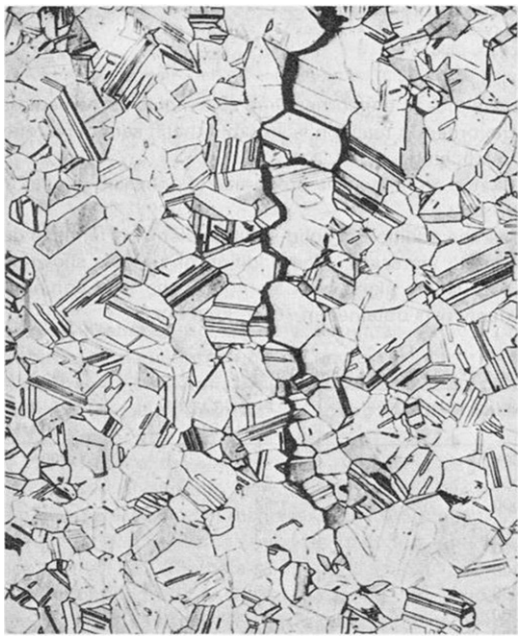

Figure 13 Stress corrosion cracking in alpha brass.[8]

Alpha phase is quite soft and ductile. Most widely used α–β′ brass is well known Muntz metal. Hardening of this alloy involves heating to about 850 °C where single-phase β exists. This is followed by quenching to room temperature. Quenching results in suppression of most of the α-phase while most β-phase is retained as is apparent from the microstructure of water-quenched Muntz metal shown in Figure 14. Subsequent tempering treatment in the temperature range of 100–500 °C results in more of the α-phase precipitated out from the supersaturated solid solution. Tempering curve shows a hardening peak at about 300 °C (Figure 15). Thus it is possible to heat treat alpha–beta brasses.

Figure 14 Microstructure of water-quenched Muntz metal. β′-phase is light and α-phase is dark.[8]

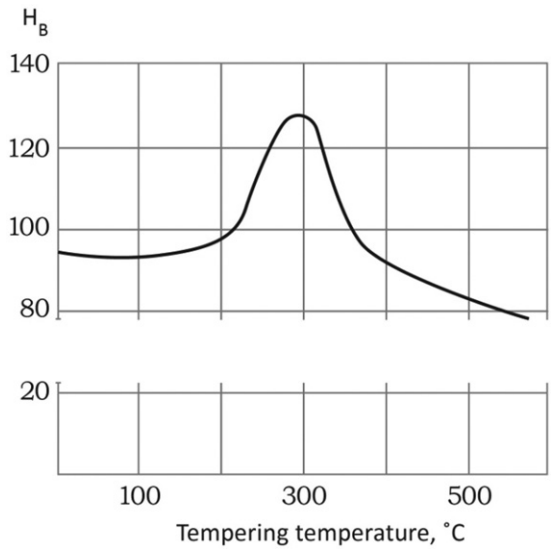

Figure 15 Tempering curve for α–β brass quenched from 850 °C.[7]

2.14.3.2 Heat treatment of Bronzes

2.14.3.2.1 Tin bronzes

Tin bronzes are also called as 'phosphor bronzes' due to the presence of small amount (0.01–0.5%) of phosphorous used as deoxidizer in casting. The wrought alloys usually contain 1–10% tin. Copper containing up to about 6% tin are soft alloys whereas those containing more than 6% tin are hard. The copper-rich end of equilibrium phase diagram of Cu–Sn alloy shown in Figure 3 indicates a long freezing range over useful compositions. When an alloy containing about 6% tin is solidified under normal industrial conditions to ambient temperature, a high degree of coring results. This heavy coring arises due to very low diffusivity of copper and tin into each other. This low diffusivity of copper and tin into each other leads to formation of copper-rich α-dendrites surrounded by small particles of tin-rich δ-phase ($Cu_{31}Sn_8$) which is hard and brittle. The equilibrium ε-phase (Cu_3Sn) is suppressed due to sluggishness of structural changes below about 400 °C. As a result ductility of the casting is greatly reduced. In order to make this alloy amenable to cold working, prolonged homogenization treatment is applied to castings. Phosphor bronzes with 8–10% tin are homogenized in the temperature range of 700–775 °C for a period of 5–6 h to promote diffusion of copper and tin atoms. Eventually the δ-phase is dissolved and uniform α-phase is produced. Subsequent cooling is done quite rapidly to prevent the precipitation of ε-phase (Cu_3Sn). Thus uniform single-phase α is retained at ambient temperature. The homogenized alloys are ductile and therefore can be cold worked. The cold worked tin bronze (C50500) is annealed in the temperature range of 475–675 °C while other phosphor bronzes (C51000, C52100, and C52400) are annealed at 475–675 °C.

2.14.3.2.2 Aluminum bronzes

Like brasses, aluminum bronzes also fall in two categories: single-phase alpha-aluminum bronzes with less than about 8% aluminum and dual-phase alpha–beta aluminum bronzes with aluminum 8–12% plus small amounts of iron (0.5–5.0%), silicon (up to 2%), nickel (up to 5%), and manganese. Both iron and nickel improve strength and hardness and refines the grain but nickel is less effective than iron. Silicon imparts machinability while manganese promotes soundness in the casting. alpha-aluminum bronzes are ductile and therefore are cold workable. Cold working improves strength and hardness. Moreover, these bronzes possess good corrosion resistance against atmosphere and water. Single-phase alpha-aluminum bronzes containing iron up to about 3% are effectively strengthened by cold working. The structure consists of iron-rich particles in alpha phase. Annealing of alpha-bronzes is carried out in the temperature range of 550–870 °C. Iron containing alloys require annealing temperature at higher end of the range. Alloys without iron, are annealed in the temperature range of 595–650 °C. Aluminum bronze castings are annealed at 620–670 °C.

Alpha–beta aluminum bronzes are heat treatable. Their heat treatment can be explained with reference to copper-rich portion of the Cu–Al phase diagram (Figure 16). Consider the slow cooling of Cu–10% aluminum. Slow cooling to ambient temperature yields a dual-phase microconstituent composed of α and γ_2 (Cu_9Al_4). Upon reheating the alloy, the eutectoid $\alpha + \gamma_2$ start transforming to $\alpha + \beta$ above eutectoid temperature of about 565 °C. Further heating results in dissolution of α until at about 910 °C where the structure is composed of completely single-phase β solid solution. Quenching the alloy from this single-phase region from about 960 °C produces a nonequilibrium phase named β' called martensite; Figure 17 micrograph showing needle like martensitic microstructure.

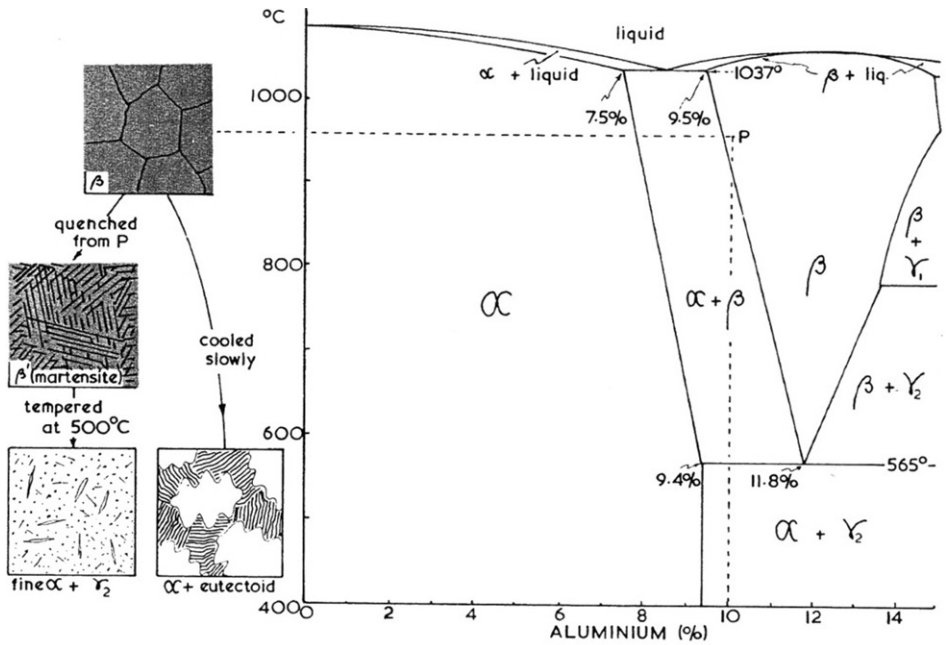

Figure 16 Cu–Al equilibrium phase diagram (copper-rich end). The microstructural sketches indicate the types of structures normally produced commercially.[2]

This martensite is similar to the martensite produced in steel and exhibit similar characteristics. Tempering of β' phase at about 500 °C results in precipitation of a fine aggregate of α and γ_2 phases (Figure 18).

2.14.3.2.3 Beryllium bronzes

The solubility of beryllium in copper decreases from about 2.7% at about 870 °C to about 0.2% at ambient temperature (Figure 19). This suggests that Cu–Be alloy is amenable to precipitation hardening. These alloys are also called beryllium bronzes or beryllium copper. The alloys of copper containing beryllium are perhaps the strongest among the family of copper-base alloys known. The T.S. of these alloys may range from 1300 to 1400 MPa after heat treatment. The high strength together with good electrical conductivity makes copper–beryllium alloys particularly suitable for electrical applications such as electrical contacts and relays. The high strength in these alloys is derived from heat treatment. Heat-treated alloys find wide applications as structural members in spacecraft and aircraft. These alloys are also used as non-sparking tools and springs. Spring properties of Cu–2.25Be–0.25Ni alloy approach those of steel springs together with nonrusting characteristics. Beryllium bronze containing about 2.25% Be are used where high strength is required. The response to precipitation hardening in these alloys is enhanced when a small amount (from 0.5 to about 2%) of nickel or/and cobalt is added to these alloys. The small amounts of elements act as grain refiners and they also increase the stability of the supercooled solid solution. A study carried out on Cu–(0.77–4.0%) Be alloys solution treated at 800 °C and aged at 350 °C for several hours shows that the alloy containing as low as 0.77 % beryllium does not respond to age hardening (Figure 20). On increasing the beryllium concentration a hardening peak is observed only when beryllium content is 2.39% or more. This suggests that copper–beryllium alloys with about 2.25% or more respond to effective age hardening. For this reason most of the commercial beryllium bronzes generally contain about 2% or more of beryllium though a significant hardening has been

Figure 17 Microstructure of 90:10 aluminum bronze water-quenched from 900 °C (showing martensitic β' structure).[2]

Figure 18 Microstructure of the same alloy as in Figure 17 after tempering at 500 °C showing tempered martensite. Martensitic β' transformed to a fine aggregate of $\alpha + \gamma_2$ structure.[2]

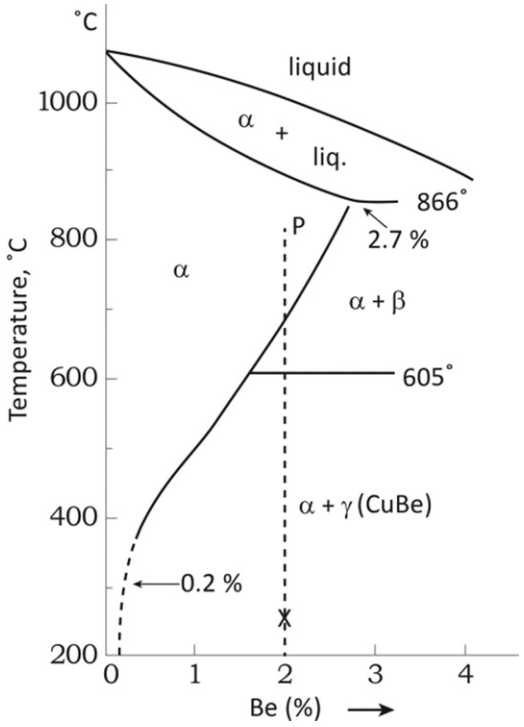

Figure 19 Equilibrium phase diagram of copper–beryllium alloy (copper-rich end).[2]

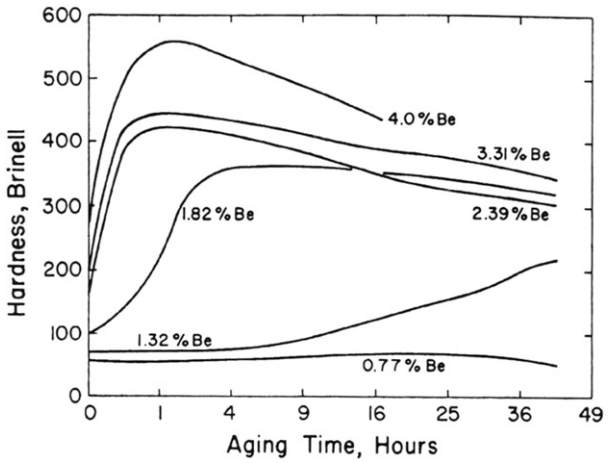

Figure 20 Aging curves of Cu–Beryllium alloys quenched from 800 °C and aged at 350 °C for various times.[9]

shown by Cu–1.82% beryllium after 4 h of aging. Commercially, copper–beryllium alloys are available in two basic classes, namely, high-strength copper beryllium and high-conductivity copper–beryllium alloys. The former alloys develop moderately high strength with good conductivity while the latter alloys develop good ductility with slightly lower level of strength after heat treatment. For high-strength beryllium bronzes, solution treatment is performed at a relatively lower temperature of 790 °C while high-conductivity beryllium bronzes are solution annealed at higher temperature, that is, at about 900 °C. Generally, the minimum specified solutionizing temperature is 700 °C (Figure 21, top). Any temperature less than the minimum specified may result in lower hardness after precipitation hardening treatment; this may be due to incomplete dissolution of alloy content in alpha phase. The alloys containing higher amount of cobalt are solution annealed in the temperature range of 750–950 °C (Figure 21, bottom). An excessive temperature above the upper specified limit may cause grain coarsening in wrought products and overheating in both wrought and cast products. Coarse grain size impairs the formability while overheating introduces brittleness and makes the alloy poor responsive to precipitation hardening. Solution annealing of beryllium copper requires careful control.

Soaking time is also of prime concern as it affects the enrichment of alpha-solid solution with respect to beryllium. Shorter times may result in undissolved beryllium rich phase in the α-solid solution. As a consequence the solid solution will be less enriched with respect to beryllium which in turn lowers the strength and hardness of the alloy after precipitation hardening treatment. Figure 22 is a microstructure of 97.5% Cu, 2.25% Be, and 0.25% Ni alloy quenched from the solution treatment temperature of 800 °C. The presence of undissolved β-constituent is evident in this microstructure. On the contrary, longer times may result in excessive grain growth, in particular, in thin sections of wrought alloys and oxidation as well.

It is recommended to allow a soaking time of 3–5 min for thin sections such as fine wire, 15 min–1 h for thin-walled tubes and small castings. Heavy sections (usually above

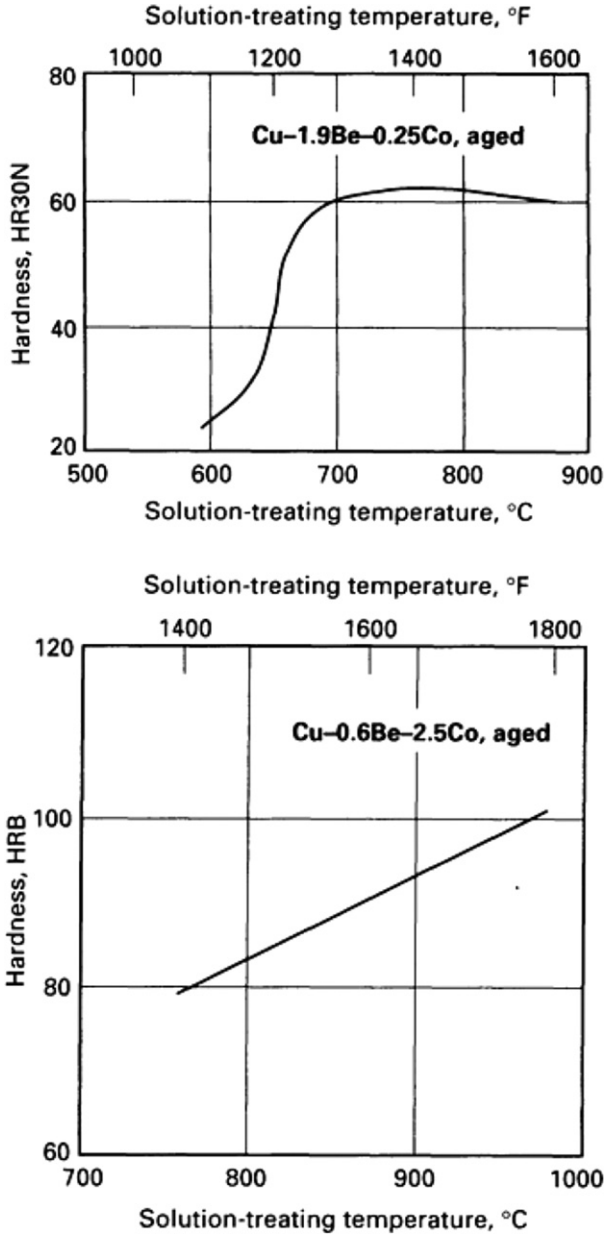

Figure 21 Effect of solution treatment temperature on hardness of C17200 and C17500 alloys after aging.[3]

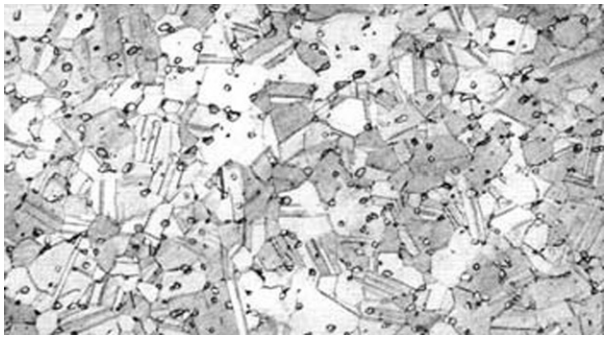

Figure 22 Microstructure of Cu–2.25Be–0.25Ni alloy after quenching showing presence of undissolved β-phase.[1]
