about 25 mm) requires a soaking time of 1–3 h at the rate of 1 h duration for each 25 mm section thickness. As the cast structure contains large amounts of micro-segregation within the dendrites a prolonged time may be used for cast products to homogenize the structure. A minimum of 3 h of soaking at solution annealing temperature is recommended for castings. Often a nonoxidizing atmosphere, such as hydrogen, is desirable if solution annealing temperature is 800 °C or more. Under oxidizing atmosphere, oxygen may diffuse inward and oxidize beryllium, thereby cause the surface to remain soft after subsequent aging. The soft surface severely lowers fatigue strength, which is particularly detrimental when the alloy is used for corrosion resistant springs subjected to reversed stresses that are of highest in magnitude at the surface. Thus a careful solution annealing treatment is required to attain a desirable combination of mechanical properties, grain size, and dimensional tolerances without excessive oxidation. The oxide layer formed on the precipitation hardened parts can be removed by chemical treatment or by abrasive cleaning.

Following soaking, quenching operation constitutes the most important part of heat treatment in beryllium bronzes. Once soaking is over, the alloy is quenched immediately without any quench delay. Any delay may lead to partial precipitation. Quenching is recommended to be carried out at the highest possible rate so that there is minimum chance for precipitation of second phase; at the same time quenching must be not so high to cause distortion or warpage of the alloy part. In the as-quenched condition the alloy is supersaturated with respect to alloy content and is soft so that any cold forming (e.g., by forging, swaging, or machining), if needed can be performed at this stage. Most of the commercial beryllium bronzes are supplied in solution annealed or as-annealed and cold worked condition.

The copper–beryllium alloys are finally precipitation hardened by aging to attain the desired combination of mechanical and physical properties. The high-strength beryllium bronzes are generally aged to peak hardening condition. The alloys not aged to maximum strength and hardness are regarded as underaged while the alloys aged beyond the maximum achievable strength and hardness are termed overaged. Under aging (UA) copper–beryllium alloys results in improvement of toughness, uniform elongation, and fatigue strength. Overaging of the alloy increases its electrical and thermal conductivities and dimensional stability as well. Copper–beryllium alloys are not amenable to natural aging even after prolonged holding at room temperature. This is indicative of the fact that either Guinier–Preston (GP) zones are not formed in this alloy or the GP solvus is below room temperature; however further study in this regard is warranted. The allowable time of aging depends on the temperature of the furnace as well as on the requirement of properties. If the motive is to produce maximum hardness, at high aging temperature, a precise control of aging time is essential to avoid overaging. The aging temperatures for high-strength wrought copper–beryllium alloys generally vary from 260 to 370 °C. The time required to reach peak properties is lower at higher aging temperature than at the lower temperature. The time at aging temperature further depends on whether the alloy is only in as solution treated condition or it is cold worked too after solutionizing. The time of aging varies from 2 to 3 h. The lower time is preferred for cold-formed alloys. The standard age hardening cycle for high-strength castings alloys comprises of aging for 3 h at 320–340 °C. The standard precipitation hardening schedule for both wrought and cast high-conductivity beryllium bronzes is 2–3 h of aging at 480 °C. Solution treating and precipitation hardening treatment temperature and time for some beryllium bronzes are given in **Table 4**. All these alloys are rapidly quenched from the solution treating temperature. Thin sections such as strips can be cooled in circulating air. Heavier sections need water quenching. Further, shorter times at solution temperature are desirable to minimize the danger of grain coarsening, in particular for thin sections.

Table 4 Solution treating and precipitation hardening schedule of some beryllium bronzes

Alloy	*Solution treatment*		*Ageing treatment*	
	Temperature (°C)	*Time (h)*	*Temperature (°C)*	*Time (h)*
C17000	775–800	1/2–3	300–330	1–3

C17300	775–800	1/2–3	300–330	1–3
C17500	900–925	1/2–3	455–480	1–3
C17510	900–925	1/2–3	455–480	1–3

Source: Ref. [3].

The wrought alloys are frequently subjected to cold forming after the solution treatment and quenching. This influences the attainable strength after subsequent precipitation hardening treatment. The final attainable strength further varies with the degree of cold working carried out. The cold-work hard temper produces maximum strengthening effect after aging. **Figure 23** illustrates the aging time required for development of maximum strength in solution annealed, 1/4 hard, 1/2 hard, and hard C17200 (Cu–1.9% Be–0.2% Co + Ni) strip aged at various temperatures in a recirculating air furnace.

Table 5 gives the precipitation treatment and the resulting properties attainable in C17200 flat products. It can be noted that the strength properties of the solution-annealed alloy increases with increasing amount of cold deformation (1/4 hard, 1/2 hard, and hard) and concurrently the ductility property reduces significantly. There is not much decrease of electrical conductivity. The strength properties are superior when the alloy is aged at lower temperature for longer period of time than when aged at higher temperature for shorter times.

The above discussion shows that copper–beryllium alloys containing small amount of cobalt and nickel display a significant precipitation strengthening effect. However, their plasticity and toughness decrease significantly with improvement of strength after aging process, which compromises the safety of these alloys. Under different working conditions, there are often special requirements for the fatigue properties, toughness, formability, creep properties, and other properties of alloys. In order to meet these special requirements, a multistage aging process has been applied to Cu–(1.7–2.0%)Be–(0.2–0.3%)Ni–(0.1–0.2%)Co alloy by Yanchuan Tang *et al.*[6] to obtain multiple precipitation strengthening phases instead of single-stage peak

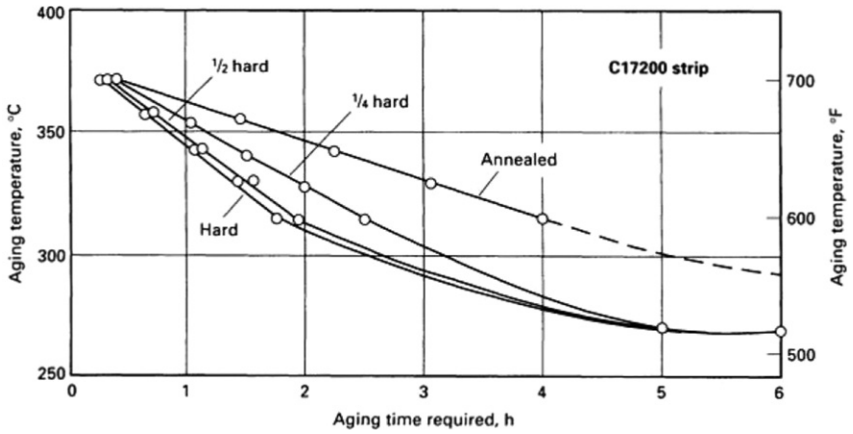

Figure 23 Aging temperature and time relationship for C17200 Cu–Be alloy strip showing aging time required to attain maximum strength in annealed, ¼ hard, ½ hard, and hard C17200 strip aged at various temperatures.[3]

aging process. In this study, they solution annealed the alloy samples at 780 °C for 20 min, quenched in water to room temperature and applied three aging treatments: (1) UA at 320 °C for 30 min and quenched to room temperature, (2) normal aging (NA) at 320 C for 180 min and (3) interrupted aging (IA). Results of the tensile testing showed that the alloy under IA condition exhibited a marked hardening response though the yield and T.S. have been still slightly lower (only about 3%) than those of NA condition. However, the uniform elongation has been found to increase significantly (about 17%) after IA treatment as against the NA condition. The IA condition also increased the tension toughness of the Cu–Be–Ni–Co alloy suggesting its ability to resist crack propagation. Furthermore, the same alloy in the IA-treated condition displayed much superior fracture toughness than in NA condition as can be noted from the load–displacement curves shown in Figure 24.[6] Both the load required for fracture and the total energy absorbed during fracture have been found to increase by about 20% and more.

2.14.3.2.4 Silicon bronze

The solubility of silicon in copper is maximum (that is 5.3%) at about 852 °C and it decreases with decreasing temperature (Figure 25). The eutectoid reaction at about 555 °C is very slow and therefore under normal cooling conditions a single-phase α-solid solution is retained at ambient temperature in copper alloys containing less than 5% silicon. These alloys are termed as silicon bronzes. Being single-phase, these alloys are not susceptible to precipitation hardening. Mechanical properties of these alloys are comparable to those of mild steel and the corrosion resistance exhibited by these alloys is comparable to that of copper. The popular heat treatment applied to silicon bronzes is annealing treatment after cold working which is performed at 475–700 °C.

2.14.3.3 Cupronickels

Cupronickels are binary alloys of copper and nickel. Copper and nickel form a series of solid solutions. Accordingly these are single-phase alloys. Hence they are not susceptible to heat treatment. They can be hardened only by cold working. Commercial cupronickels generally contain up to 30% nickel. Cupronickels have high corrosion resistance together with resistance to corrosion fatigue. They also resist corrosive and erosive actions of rapidly moving seawater. The corrosion resistance of cupronickels increases with increasing nickel content. The electrical resistivity of these alloys also increases with increasing nickel concentration. Cupronickels are moderately hard also but tough and ductile. Cupronickels with 10 and 30% nickel are very commonly employed for condenser, distiller, evaporator, and heat exchanger tubes. The very common heat treatment applied to cupronickels is annealing after cold working. Annealing after cold working of cupronickels containing up to 30% nickel (Alloys C70600, C71000, and C71500) is performed at 600–825 °C.

2.14.3.4 Chromium Coppers

The phase diagram of copper–chromium (Figure 26) shows that the alloys containing chromium from 0.4 to 1.0% are characterized as precipitation hardening alloys.

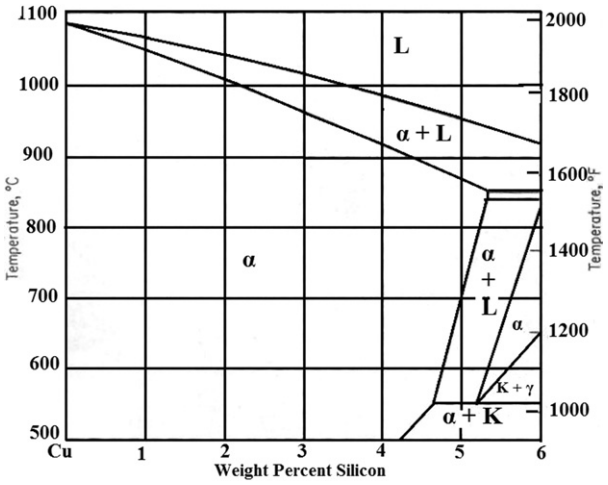

Figure 25 Copper-rich portion of the copper–silicon alloy system.[8]

In the precipitation hardened state these alloys display a reasonably good T.S. coupled with good electrical conductivity (80% IACS). These alloys are solution treated in the temperature range of 950–1010 °C where a single-phase is obtained and cooled rapidly after soaking. However due to differential melting temperatures of copper and chromium, there is a preferred chromium–chromium coordination in the solidified alloy which influences the subsequent aging treatment in a great way. Unless proper care is taken, nonuniform distribution of precipitates may quite often result in the final microstructure. Solution treatment is generally carried out in a controlled atmosphere or in salt bath in order to prevent scaling and internal oxidation. In the solution treated condition the alloys are soft and ductile and therefore can be cold formed if desired. Following this, aging is carried out in the temperature range 400–500 °C for several hours (typically 4 h or even more) depending on the combination of strength and electrical conductivity required. A typical aging cycle is 450 °C, 4 h or more.

2.14.3.5 Zirconium–Copper Alloys

Copper alloys containing 0.13–0.3 % zirconium are solution treated at 900–980 °C and quenched rapidly (as in water). Aging is performed at 500–550 °C for 1–4 h. The strengthening is imparted by coherent Cu_3Zr-type precipitates. It is recommended to minimize the holding time at solution annealing temperature so as to eliminate the danger of excessive grain growth which may occur due to high diffusivity of zirconium at this temperature. Because of the high diffusivity of zirconium at solutionizing temperature, it requires less time for dissolution and hence there is no need for longer soaking time. Moreover, excessive time of soaking may cause internal

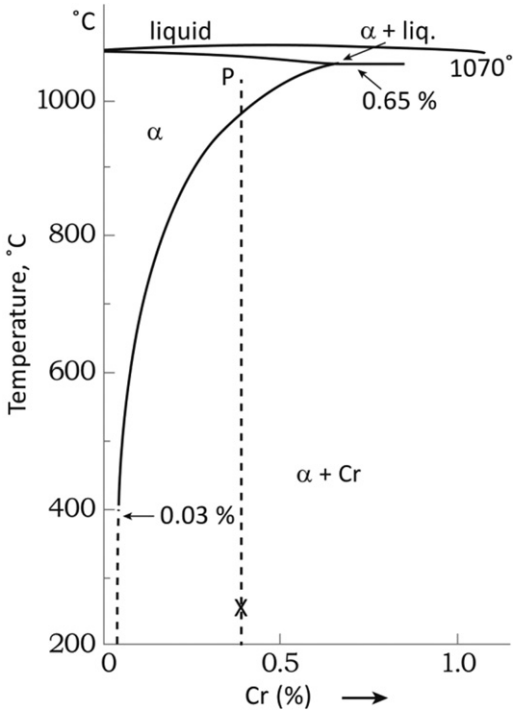

Figure 26 Equilibrium phase diagram of copper–chromium alloy (copper-rich end).[2]

oxidation by reaction of zirconium with the furnace atmosphere. If desired, cold working can be done before aging. In such condition, aging temperature may be reduced to the level between 375 and 475 °C. Prior cold working provides more nucleation sites for precipitation at dislocations and thus accelerates aging.

Other single-phase copper alloys namely cupronickels (10–30% Ni) and nickel–silver alloys are generally annealed after cold working in the temperature range 600–825 °C. Silicon bronzes are annealed at 475–700 °C.

2.14.3.6 Copper–Chromium–Zirconium Alloys

Copper–chromium–zirconium alloys are precipitation hardening alloys developed for high temperature applications where material must meet an optimum combination of mechanical properties coupled with high electrical and thermal conductivities. These alloys derive the best combination of physical and mechanical properties through precipitation hardening treatment. The heat treatment consists of solution treatment followed by rapid quenching (as in water bath), cold working, and aging. The schedules of heat treatment of two Cu–Cr–Zr alloys are given in **Table 6** and the resultant properties are given in **Table 7**. Both these alloys exhibit comparable mechanical property values but the latter alloy displays high electrical conductivity after identical heat treatment. Strengthening in these alloys results due to fine dispersion of Cu_5Zr and chromium precipitates which develop during aging treatment. This microstructure imparts resistance to softening at elevated temperatures. These alloys find applications in resistance welding electrodes, spot welding adaptor shanks, and others where high electrical conductivity and good resistance against softening are required.

Table 6 Schedule of heat treatments of Cu–Cr–Zr alloys

Alloy designation and composition	*Solution annealing treatment*	*Ageing treatment*
ZollernCuCrZr (Cu–0.85Cr–0.09Zr)	970 °C, 20 min/water quench	475 °C, 2 h
KabelmetalCuCrZr (Cu–0.65Cr–0.10Zr)	980 °C, 60 min/water quench	475 °C, 2 h

2.14.3.7 Copper–Nickel–Silicon–Chromium Alloy

Apart from the advantageous properties mentioned earlier, beryllium–copper alloys suffer from some drawbacks. Beryllium present in the beryllium bronze is detrimental to human life as well as to environment. The alloys are difficult to recycle after use. In this context, researchers have been studying various other copper alloys as substitute for toxic beryllium bronzes. One such alloy investigated by Huei-Sen Wang *et al.* is Cu–7.4Ni–1.3Si–1.2Cr. This alloy is developed for mold tooling application. When cast conventionally, this alloy exhibits a coarse grain structure (grain size of about 200 μm) embedded with large size precipitates and substantial microsegregation of the alloying elements. Huei-Sen Wang *et al.* processed this alloy through powder metallurgy route. The powder of the alloy was produced by argon atomization process with average size of 25 μm. The powder was consolidated to bulk form by hot pressing followed by sintering to obtain dense mass. The average grain size of the hot pressed and sintered product has been found to be 100 μm. The alloy samples were solution treated at 970 °C for times up to 10 h and subsequently quenched in water. The samples were precipitation hardened at 450 °C for up to 6 h. The best results were observed at 8 h solution treatment at 970 °C followed by 6 h aging at 450 °C. After aging a subgrain structure with grain size less than 30 μm was observed.[11] The alloy was found to exhibit average T.S. of up to 820 MPa and average thermal conductivity of 110 $W\,m^{-1}\,K^{-1}$. The strengthening was produced due to fine dispersion of nanometer size β-Ni_3Si and δ-Ni_2Si precipitates in fine grain size matrix as shown in **Figure 27**. Based on the thermal conductivity and the T.S. developed in the Cu–Ni–Si–Cr alloy Huei-Sen Wang *et al.* suggested the potential application of this alloy for mold tooling.

2.14.3.8 Copper-Base Shape Memory Alloys

Cu–Zn–Al alloys are known to produce thermoelastic martensite. When the alloy is deformed to a different shape in martensitic and then heated to parent state, the original shape is regained; this is called shape memory effect (SME). In general Cu–*x*Zn–*y*Al and Cu–*x*Al–*y*Ni are quenched from high temperature β-phase field to produce martensites. These martensites are soft and can be deformed at a small force. Since volume change 'ΔV' accompanying martensitic transformation is very small these martensites are internally twinned; these reversible defects play important role for SME. The reversible internal faults enable the transformation of martensite to parent phase along the same path as that of the forward transformation (β–M). Influence of a rare earth element, Gd on microstructure on this shape memory alloy has been reported in the literature.[12] Stabilization of martensite is observed in memory alloys.[13] The inherent reversibility

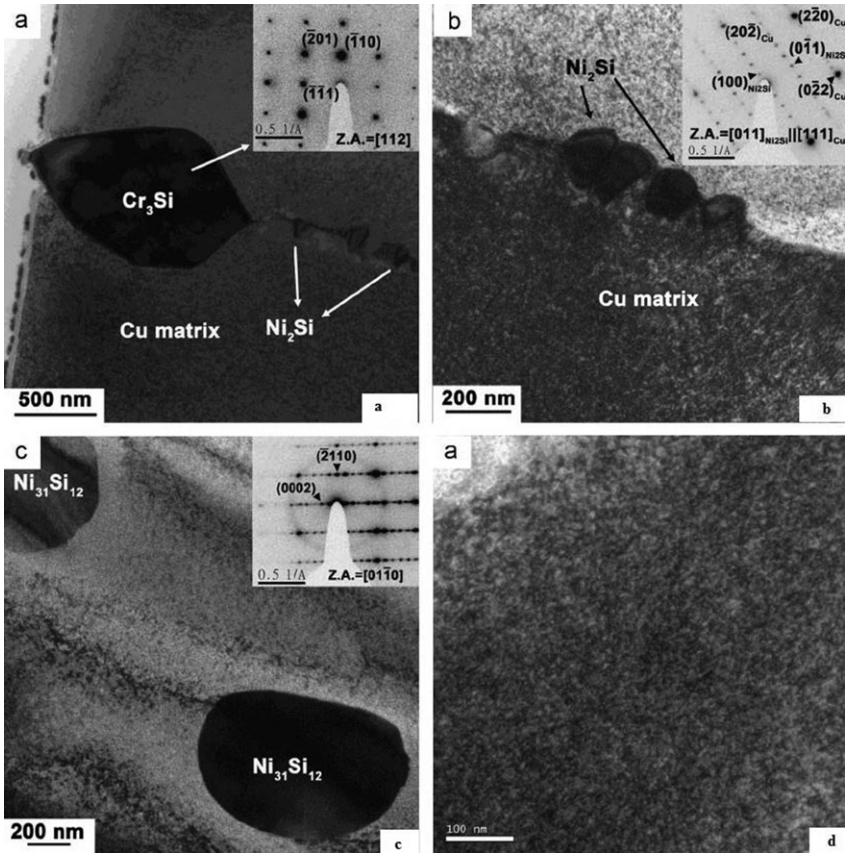

Figure 27 Bright field images of the Cu–Ni–Si–Cr alloy after 6 h aging showing microsize Cr_3Si and Ni_2Si precipitates at the grain boundaries ((a) and (b)), microsize $Ni_{31}Si_{12}$ precipitate within the grain (c), and (d) large number of precipitate particles within copper matrix.[11]

characteristics of martensitic transformation in Cu–Zn–Al and Cu–Al–Ni alloy are envisaged due to low thermal hysteresis. The repetitive use of these shape memory alloys leads to aging effect; this leads to the formation of precipitates of intermetallics which adversely affect the SME. However controlled aging of some shape memory alloys may accentuate SME behavior although in most of the cases chemical degradation is reported to have deteriorated SME in copper alloys.[14–17]

2.14.4 Heat Treatment of Nickel Alloys

Nickel is one of the most important engineering metals. It has FCC structure and does not show any polymorphic changes even up to the melting temperature. It possesses good combination of physical and mechanical properties apart from outstanding corrosion resistance against many corrosive media and good oxidation resistance. However, nickel is prone to attack by sulfur. Sulfur makes nickel embrittled due to the formation of brittle Ni_3S_2 at the grain boundaries.[18] Nickel is principally alloyed with copper, iron, chromium, silicon, and molybdenum. Based on these principal alloying elements, nickel-base alloys are categorized as: nickel–copper alloys, nickel–chromium alloys, nickel–iron alloys, nickel–chromium–molybdenum alloys, nickel–iron–chromium alloys, and so on. Nickel alloys are also popularly known by their trade names given by International Nickel Company (INCO) and these are Monels, Inconels, Nimonics, and Hastelloys.

Since nickel is attacked by sulfur, an important consideration during heat treatment of nickel alloys is the furnace atmosphere which must be free of sulfur. Embrittlement due to sulfur, if occurs, cannot be remedied.

The types of heat treatment applied to nickel alloys are as follows.

2.14.4.1 Annealing

The aim of annealing of cold worked nickel alloys is to make them soft for further cold reduction. This treatment is performed by heating the alloy to a temperature where recrystallization takes place. This temperature for nickel alloys falls in the range of 700–1200 °C depending on the type of alloy and its composition, as well as the degree of cold working. Higher annealing temperature is used where greater softening is desired. The alloy is generally slowly cooled from the annealing temperature. Effects of heat treating temperature on some room temperature mechanical properties of cold drawn Monel 400 alloy are represented in Figure 28. As stated earlier, the heat treatment temperatures for various nickel alloys are also decided by the corresponding phase diagrams. A representative phase diagram of nickel–copper alloy (Monel) is shown in Figure 29 that describes its annealing temperature.

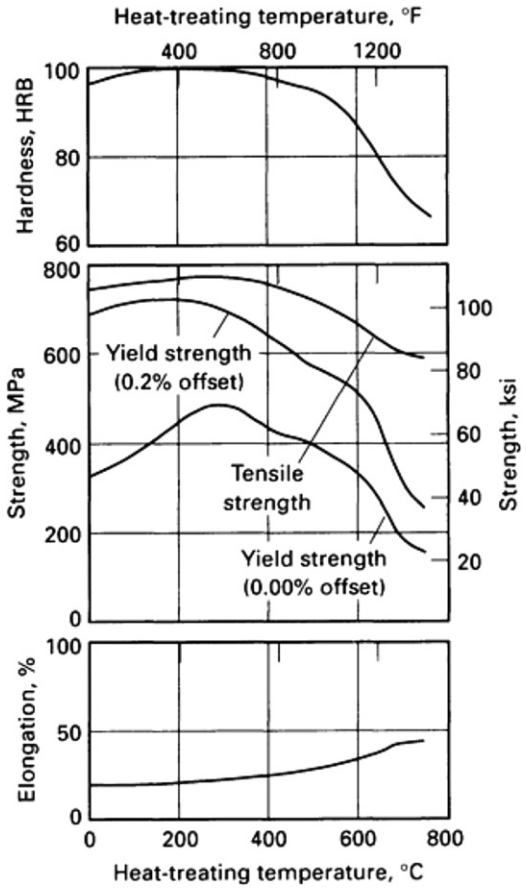

Figure 28 Effect on room temperature properties of cold drawn Monel 400 rod held for 3 h at various temperatures.[3]

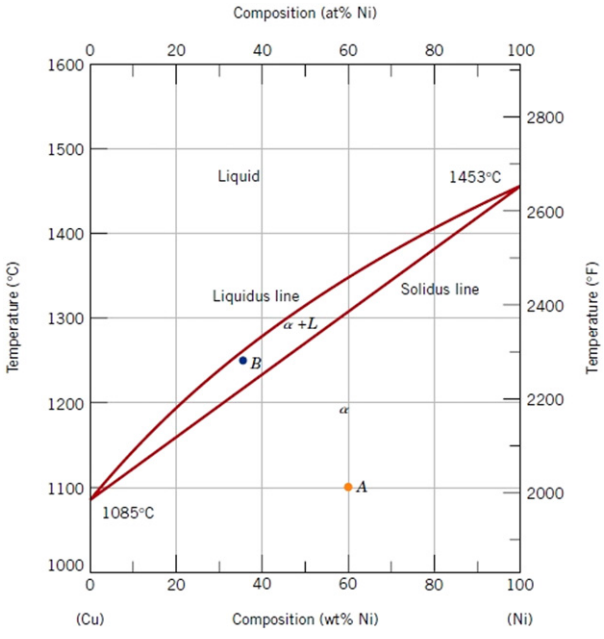

Figure 29 Phase diagram of Cu–Ni system.[19]

The annealing schedule for several nickel and nickel alloys is given in Table 8.

2.14.4.2 Solution Annealing

It is a high temperature annealing treatment applied to some specific nickel alloys so as to bring second phase into solution and cause some grain coarsening which is desirable to improve creep rupture properties. This treatment is applied at a temperature lower than the upper annealing temperature range prior to precipitation hardening. The solution treating temperatures for some nickel alloys are given in Table 9.

2.14.4.3 Stress Relieving

This treatment is applied to cold worked nickel and non-age-hardenable nickel alloys. The alloy is heated to a temperature in the range 425–870 °C and soaked without any recrystallization to occur. Only recovery part of annealing remains effective. The true temperature of annealing depends on the alloy composition and degree of prior cold working. The stress relieving temperatures used for some nickel alloys are given in Table 10.

2.14.4.4 Stress Equalizing

It is a kind of stress relieving treatment performed on cold drawn nickel alloys at lower temperature of annealing so that partial recovery takes place with the elimination of excess lattice defects, in particular, the point imperfections. The consequent effect is the restoration of electrical conductivity while there is no deteriorating effect on improved hardness and strength produced by cold working. The exact temperature of stress equalizing cold drawn alloys depends on their composition and the degree of prior cold reduction. For instance, an optimum temperature range of 230–315 °C is used for cold drawn Monel 400 rod. The applications of stress equalizing include coil springs, wire forms, and flat spring stampings. Table 10 gives the schedule of stress equalizing treatment of Nickel 200, Nickel 201, and Monel 400.

2.14.4.5 Precipitation Hardening

Alloying elements such as Al, Si, Ti, Nb, and others are added in very small concentrations either singly or in combination to make nickel and its alloys susceptible to precipitation hardening. The strength and hardness properties are improved after proper age hardening treatment. Solution treatment is carried out at a temperature where the precipitation hardening constituents dissolve into solid solution and form a single-phase. The temperature at which solution treating is performed varies widely within the temperature interval between 980 and 1315 °C. The upper limit of temperature is preferred when carbides are required to dissolve into solid solution. The time of solution treatment varies from 2 to 4 h. The exact temperature of solutionizing depends on the alloy composition. Subsequently the alloy is cooled rapidly such that supersaturated solid solution is retained at ambient temperature. In this condition the alloy is soft and ductile and it can be fabricated by cold forming

Table 8 Annealing treatment schedule for some representative nickel and nickel alloys

Material with composition	*Temperature (°C)*	*Time*	*Cooling method*

process if required. The alloy is finally precipitation hardened at 425–870 °C depending on the alloy type and its composition. Sometimes a double aging treatment is applied. The solution annealing and precipitation hardening cycles of some representative nickel alloys are given in **Table 9**. **Figure 30** is a typical representative microstructure of precipitation hardened alloy Monel K-500 showing fine precipitate of $Ni_3(Al,Ti)$ as black spots.[8]

2.14.4.6 Nickel-Base Superalloys

Nickel-base superalloys have an austenitic matrix structure. Many of these contain molybdenum and/or tungsten, which are soluble in the matrix and act as solid-solution strengtheners. In nickel-base superalloys, γ' and γ'' lead to precipitation strengthening; The γ' phase, is identified as $Ni_3(Al,Ti)$ with its crystal structure as ordered f.c.c of L12-type ordering and is

responsible for antiphase boundary (APB) strengthening. This implies that these superalloys are heat-treated for precipitation hardening by way of solutionizing followed by aging. The strength of γ' phase increases with increasing temperature and so the control of aging temperature is very important.

The γ'' phase is ordered Ni_3Nb phase and of body-centered-tetragonal structure; while γ' is the predominant matrix-strengthening phase in nickel-base superalloys, the γ'' serves as the major strengthening precipitate and it can be stabilized by addition of iron. Compositions of similar type represent INCONEL alloys X-750, 706, and 718. Again η phase in nickel–iron-base superalloys containing Ti and Al is primarily Ni_3Ti and here aluminum does not play any direct role in the precipitation strengthening. Moreover, the stability of both γ' and γ'' phases in Ni–Fe superalloys is enhanced by aluminum. Long-time exposure at about 650–750 °C leads to transformation of the γ' and γ'' phases to η and δ phases, respectively; it therefore appears that compositions of superalloys and factors determining the stability of different strengthening phases are the deciding parameters to design the heat treatment schedule.[17,18] Carbides, nitrides, and carbonitrides such as TiC, TiN, Ti(C, N), M_6C, and $M_{23}C_6$ have also been identified in the structure of many nickel-base alloys. Major type of nickel-base superalloys include Ni–Cr–Fe-based (e.g., Inconels), Ni–Mo–Fe-based (e.g., Hastelloy A and B), and Ni–Cr–Mo–Fe-based (e.g., Hastelloy C and Hastelloy X). Examples of a few nickel-base superalloys along with their heat treatment schedule are given in **Table 9**.

2.15.1 Introduction

The term 'cryogenic' pertains to something at or causing the creation of very low temperatures (typically < 193 K/-80 °C) and has a wide variety of uses in medical devices, electrical components, and superconductors used in fields such as quantum physics. While low temperatures are indeed involved in both instances, the term 'cryogenic' should not be used when referring to the field of 'cryonics,' which is of course to do with the preservation of living creatures beyond the help of contemporary medicine.

In the context of this chapter, cryogenic processing is taken to refer to a range of subzero heat treatments (cryogenic treatments or cryotreatments (CTs)) that are applied to materials with the aim of causing permanent microstructural changes and corresponding changes in mechanical properties and behaviors.

Closely related fields of interest, but distinct disciplines in their own right, are those that include activities use cryogenic fluids in conjunction with engineering materials and processes. These can be classified into two broad categories:

1. The field of investigating the 'performance of engineering materials at cryogenic temperatures' (e.g., space, electronics, physics research, and indeed the cryogenic processing equipment industry itself when designing the equipment to perform cryogenic processing).
2. The 'use of cryogenic fluids in manufacturing' (e.g., cryogenic machining, cryo-rolling, cryogenic burnishing, and cooling of operating industrial machines).

Both of these areas have crossover with cryogenic processing, for example:

- Studies that consider if materials retain their desired performance at cryogenic temperatures may give insight into what drives any changes observed even if those changes are reversible (i.e., 'disappear') when the materials are returned to ambient temperatures to be used.
- Studies that consider using cryogenic fluids as an alternative to conventional coolant in machining processes may benefit from an understanding of how much coolant could be used for how long a process before the workpiece undergoes unwanted changes.

It is this discipline of cryogenic processing that this chapter considers but links to these complementary fields are noted where necessary. The terms 'cryogenic processing,' 'cryogenic treatment' and 'cryotreatment' are used interchangeably.

This chapter first presents an overview of the development of cryogenic processing before reviewing the current state of the art. Several case studies are presented to illustrate how one might investigate the potential of cryogenic processing for a particular application in more detail.

2.15.1.1 Links with Traditional Heat Treatment

Classical heat treatments, which include bulk heating and cooling (quench hardening, tempering, and aging treatments) as well as surface treatments (such as laser hardening and induction hardening), are used widely throughout engineering to modify the microstructure and the subsequent behavior of metals. All of these methods involve subjecting a component to a controlled cycle of heating and cooling and for classical heat treatments the temperatures are always above 273 K. In ferrous metals, heat treatments are often used to make the materials harder in an attempt to improve their wear characteristics without significantly modifying their bulk properties. There are many applications where this is required to ensure a satisfactory lifetime of components and it is extremely common to treat steel components such as camshafts, crankshafts, and gears.

Less widely used is the extension of 'heat treatment' to cryogenic temperatures. Although routinely considered in the design and manufacture of industrial equipment, especially for use in medicine and the physical sciences, there is a smaller volume of work where cryogenic temperatures are used deliberately to positively modify the microstructure for strength and wear resistance.

CT involves lowering the material to temperatures below 193 K and holding or 'soaking' for a defined period of time before raising the material back to ambient temperature. The objective of CT is therefore to cause permanent changes to the microstructure of a material that enhances desired properties, with minimal or insignificant adverse effects. The process affects the entire cross-section of materials and components and is often considered as a single additional stage to a conventional heat treatment cycle (although, as discussed in Section 2.15.1.3.2, for many tools and components CT is already a part of the 'conventional' process).

By way of a simple example, in hardened steels, cryogenic processing utilizes phase transformations that occur when the material is 'soaked' by being cooled in a liquid nitrogen (LN_2) filled chamber for up to 72 h. It has been observed that the combination of these phenomena give cryogenically processed materials improved wear resistance, stress relief and dimensional stability.[1] The level of these improvements depend on the exact cooling parameters of the processing. In this context, CT can be considered as an extension of a classical heat treatment cycle; extending the effects of quench hardening and preparing steels for further carbide precipitation during subsequent tempering.

Relatively little work has been conducted to investigate the improvements that can, or cannot be made to the mechanical properties of other engineering materials. Similarly there is little information about the ability of materials subjected to the process to resist different types of wear, with the majority of studies to date focusing on the resistance of cryotreated materials to abrasive and adhesive wear, or in use as cutting tools.

2.15.1.2 A Brief History of Cryogenic Treatments

The earliest examples of subzero temperature processing comes from Swiss watchmakers. In the mid-nineteenth century, they used to leave delicate gears and the materials for watch parts buried in snow in mountain caves over the winter, having noticed that this would make gears more durable, and allow parts to be made with more precision as the materials deformed less during machining. This enabled

them to produce more reliable and longer lasting timepieces.[2] During the first half of the twentieth century tool and die-makers began freezing their tooling as they realized they could machine more parts per cutting edge than before. Some aero-engine components and even cutlery started to be treated as well. Although much of the early work has been overlooked in recent years, perhaps due to 'political circumstances' at the time, it is clear that cryogenic treatments were widely used and studied in the USSR in the first half of the twentieth century. In a translation of one of his works on the subject, originally from 1946, Gulyaev[3] clearly describes a number of effects of cryogenic treatments on steels including the martensite transformation, the effects of alloying, stabilization of austenite, and the effects of cryogenic treatments on high-speed steels and carburizing components. Many of these are still the subject of debate amongst the scientific community today.

During the Second World War, cryogenic processing was widely utilized to enhance the wear resistance of mechanical parts in machinery and vehicles, although notable research into its effects were effectively suspended until the 1960s when NASA engineers noticed that spacecraft parts exhibited different properties after returning from space. Shortly afterwards, in the 1970s and 1980s Dr. Randall Barron,[4] along with Charles Mulhern,[5] conducted what are considered the first contemporary research projects into the effects of deep cryogenic processing. In studies using lathe tools and abrasive wear experiments on a range of ferrous alloys, Barron recorded significant increases in wear resistance in some materials (up to 718% in the case of AISI D2 steel) whereas in others (AISI A2, A6, and T2 steels) cryogenic processing appeared to have no effect.

2.15.1.3 Industrial Context

2.15.1.3.1 The cryogenic processing industry

While cryogenic processing has been used as an industrial technique for over 80 years, arguably, a cryogenic processing industry has only existed for around 40 years, as awareness and understanding of cryogenic treatment has grown. While the majority of established companies can be found in the USA and the EU (primarily in the UK), interest in cryogenic treatment is growing in rapidly developing, heavily industrial economies such as India and China.

The oldest of these, 300° Below Cryogenic Tempering Services, Inc. was established in 1966 (as CryoTech), however, the majority of cryogenic treatment companies have started up in the past 30 years. The industry is therefore dominated by small- and medium-sized enterprises (SMEs).

Cryogenic treatment companies offer a range of services, including cryogenic nitrogen and helium treatments, thermal cycling, as well as pre- and post-cryotreatment tempering of finished parts and raw materials. A number of these companies additionally supply cryogenic processing equipment, both to industry and research institutions. **Table 1** summarizes the services offered by some of these companies, indicating typical soaking temperatures (T_s), times (t_s), treatment types, liquid helium (LHe_2) processing capabilities and an overview of the

Table 1 Examples of cryotreatment companies and their advertised service capabilities

Company (location)	*Soaking temperature, $T_{s,min}$ (K)*	*Time, t_s (h)*	*Treatment types*	*Liquid helium treatment*	*Equipment supplied*
300° Below Cryogenic Tempering Services, Inc. (Illinois, USA) Est. 1966	88	72 (total process)	N_2 atmosphere	No	Model 921 processor: electrical and nitrogen cooling, 682 kg capacity, 2.5 kW
Controlled Thermal Processing, Inc. (Illinois, USA) Est. 1980	88	n/a	Air cooled by heat exchange with (liquid temperature) LN_2	Yes	Applied Cryogenics, Inc processors: 0.2–1.2 m^3 capacity, post-cryo tempering, 4.4–11 kW
CryoPlus, Inc. (Ohio, USA) Est. 1994	88	10	Pre-cryo temper; LN_2 spray (vaporizes)	No	n/a
Cryogenic Institute of New England, Inc. (Massachusetts, USA) Est. 2002	88	24	LN_2 immersion	Yes	Batch and continuous cryogenic treatment equipment: 88–878 K range
Cryogenic Treatment Services Ltd. (Nottinghamshire, UK) Est. 2004	78	24	N_2 atmosphere; post-cryo temper	No	n/a
Cryogenics International (Arizona, USA) Est. 1986	78	24–62	N_2 atmosphere	No	Treatment systems up to 0.8 m^3 capacity
Frozen Solid (Cambridgeshire, UK) Est. 1998	78	Material dependent	N_2 atmosphere; post-cryo multi-stage tempering	Yes	n/a

equipment they offer. Given its scarce availability LHe_2 is offered on a limited basis for extremely low-temperature ($-269\ ^{\circ}C$) treatments.

It is interesting to note that the range of services offered by these companies reflects the variety of results highlighted in the published literature. In fact it is possible to relate most of the differences between treatment parameters offered by these companies with the microstructural changes of martensitic steels by association with their temperature- or time-dependence. These changes have been summarized in **Table 2** for reference.

Whereas the elimination of retained austenite is theoretically achieved once a material passes the martensite finish (M_f) temperature, preparation of the material for the development of smaller secondary carbides and nano-carbides is also time-dependent, meaning both lower treatment temperatures and longer soak times may have beneficial effects. In fact, as is subsequently discussed, both these changes have not only been shown to be time-dependent, but intrinsically linked. The issue of pre- or post-cryotreatment tempering is material dependent and related to the initial phase composition of any treated material.

As a result of these factors no cryogenic treatment company should offer a single, 'one-size-fits-all' CT service. CT parameters should be varied to suit the material and degree of microstructural change or performance required. For large and repeated batches of materials or parts to be treated, an optimized CT cycle may represent a significant saving in terms of overheads and reduction in the quantity of cryogenic coolant required. Indeed, for the cryogenic processing industry, it is in this optimization of processes where commercial advantage and valuable intellectual property may lie. However, the extensive materials characterization facilities and high level of expertise required to determine the parameters of these optimal processes have so far prevented acknowledged leaders in commercial cryogenic treatment services from emerging.

Table 2 Summary of the dependence of microstructural changes due to cryogenic treatment in ferrous alloys

Microstructural change	*Parameter dependence*
Conversion of retained austenite to martensite	Temperature only (theoretically)
Precipitation of nano-carbides	Time, temperature
Dispersion and refinement of secondary carbides	Time, temperature

2.15.1.3.2 Current uses of CT processes

Cryogenic treatment companies (such as those mentioned in Section 2.15.1.3.1) are involved in a combination of commercial processing and after-market treatments, with the former becoming increasingly more significant. Although initially CT services were applied almost exclusively to products in their finished forms, it has increasingly become part of larger manufacturing chains; an example of this being the treatment of cutting tool inserts prior to coatings being applied, as CT has been shown to have adverse effects on coatings such as TiN.[6] However, products such as brake disks, sports equipment, and audio cabling are often still treated in their finished forms or after partial disassembly.

Research-led and commercial CT practices differ significantly, as highlighted in **Table 3**. Likely due to the basis of many CT operations on purely anecdotal evidence rather than rigorous analysis, there are a number of examples of 'bad practice' within the commercial cryogenic processing industry, from the point of view of the research community. These include the restriction of cryogenic treatment parameters, the use of anything other than nitrogen atmosphere cooling, and the almost exclusive use of cryogenic treatment as an 'after-market' process.

2.15.1.3.3 The future of CT and its applications

Although ferrous-based alloys feature in the bulk of cryogenic processing research and constitute a significant portion of commercial CT service requirements, a number of other materials have also been shown to benefit from cryogenic treatment. Aerospace materials such as aluminum, titanium, and magnesium alloys represent a developing area for the cryogenic processing industry, while sintered cobalt-bonded tungsten carbide tool materials have also been shown to respond favorably. Perhaps most unexpectedly, cryogenic processing has also been shown to have beneficial effects on nonmetallic composite materials, such as the polytetrafluoroethylene (PTFE)/Kevlar hybrid fabric.[7]

2.15.1.4 Cryogenic Treatment Processes

While subzero treatments of materials have arguably been possible for centuries through the exploitation of naturally occurring environmental conditions, cryogenic treatments have only been practically possible since the liquefaction of a number of important gases (notably nitrogen and helium) was achieved in the late nineteenth century. Following the industrialization of these processes in the first half of the twentieth century cryogenic treatment started to be used on a significant scale in manufacturing. Since then advances in insulation,

Table 3 Summary of differences between research-led and commercial cryotreatment (CT) practices

Research	*Commercial*
Varied CT parameters	Restricted treatment parameters, often only one fixed cycle offered
Wide consensus around use of N_2 atmospheric cooling for best results	Varied cooling practices ((liquid nitrogen) LN_2 immersion, LN_2 spray, N_2 atmosphere, and LN_2 heat exchange with air)
Recognition of need to understand CT holistically within heat treatment cycles	CT typically applied as an 'after-market' process
Small batch sizes	Large batch sizes

temperature sensors, and digital controllers have allowed the development of the efficient cryogenic processors used commercially today.

2.15.1.4.1 CT technology

CT commonly involves a supply of LN_2 into a thermally insulated tank containing the parts or materials to be treated, although specialist treatments are also available using LHe_2. The cryogenic fluid can be used in one of three ways: for direct immersion of parts to perform a 'cryo-quench'; as a working fluid to cool air within the tank; or as a gas that that is circulated by fans, thereby creating a 'dry' atmosphere.

The most common practice is to carry out CT using gaseous nitrogen (N_2) as the cooling medium. Figure 1 shows a schematic diagram for such a setup in which LN_2 is held in an external tank or reservoir, before being vaporized, pumped into an insulated chamber, and blown around the parts to be treated by fans. The flow of nitrogen is controlled by the temperature inside the chamber which is measured by thermocouples. Cooling and heating rates in the chamber typically fall within the range of 0.1–2.0 K/min.

Cryo-quenching (CQ) risks causing thermal shock,[8] where damaging thermal stresses are established by large temperature gradients between the surface and bulk of a material, while cryogenic cooling of air can lead to the build-up of vapor-ice on the surfaces of components, unless all moisture can be removed beforehand. Using N_2 or helium creates a largely inert atmosphere within the tank and has neither of these drawbacks,[9] while allowing for the controlled cooling of parts and materials. Cryogenic treatments using LN_2 and LHe_2 are theoretically able to reach 77 K ($-196\,^{\circ}C$) and 5 K ($-268\,^{\circ}C$) respectively; the temperatures at which they boil. Due to its abundance (making up 78% of the earth's atmosphere) nitrogen is commonly used in CT, whereas helium is reserved for extremely specialized use.

The on-going development of cooling agents has led to the establishment of different classifications of subzero treatments. By soaking temperature these are either cold treatments which can be achieved with dry ice (CT: 273–193 K), shallow cryogenic treatments, (SCT: 193–113 K) or deep cryogenic treatments (DCT: 113–77 K) which both require LN_2.[10]

2.15.1.4.2 CT processes

Figure 2 illustrates the difference between CT cycles involving CQ by LN_2 and cooling or CT by N_2 following on from a regular heat treatment cycle in a typical quench-hardened carbon steel, and preceding a post-treatment tempering cycle. As cryogenic treatments are typically offered as an after-market service, parts and materials are subjected to an indefinite 'transition' period between regular heat treatment and CT. In reality, tempering may have been performed prior to cryogenic treatment, which at best represents wasted process time and in the worst case inhibits the effective application of cryogenic treatment; such as when tempering may cause the decomposition of retained austenite into cementite and ferrite.

The parameters that are typically controlled and varied during CT are: cooling rate, soaking temperature, soaking time, heating rate, and the position of the CT within the overall treatment cycle in cases where materials or components are to be tempered.

Compared to work performed to assess the improvement in performance of cryotreated engineering materials, relatively little work has investigated the influence of varying the parameters of the CT process itself. What work has been performed typically limits the scope of the experiments to a single material, varies either the temperature or duration at which the

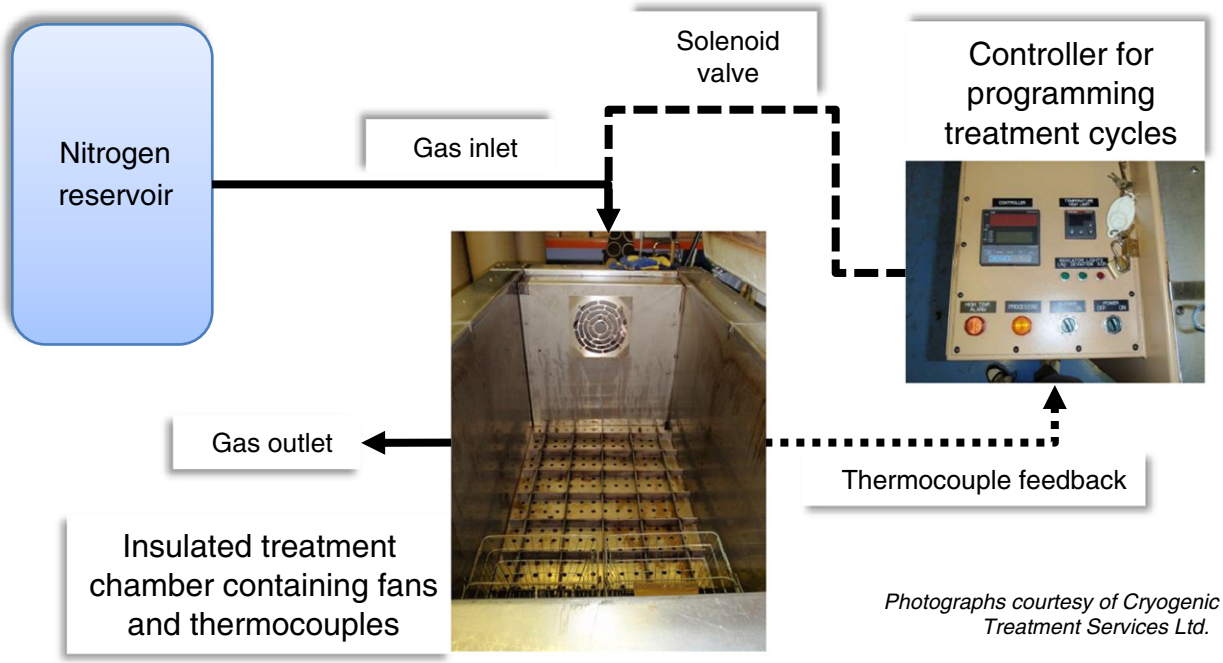

Figure 1 Schematic of equipment for cryotreatment using gaseous nitrogen cooling.

CT is performed and then assesses the improvement, or otherwise, of a mechanical performance parameter.

In their early study on AISI T8 and AISI 1045 steels, Barron and Mulhern[5] determined that the greatest increase in wear resistance for these materials could be achieved by using a low cooling rate (6 K/min), a long soaking time (24 h), and a low-temperature (77 K) soak. More recently, Darwin *et al.*[11] utilized Taguchi design of experimental methods, to determine the significance of parameters in maximizing the wear resistance of a high-chromium martensitic steel through deep cryogenic treatment. They determined that the significance of parameters was as follows: (1) soaking temperature, 72%; (2) soaking time, 24%; (3) rate of cooling, 10%; (4) tempering temperature, 2%; and that the tempering period was statistically insignificant.

One of the key commercial factors supporting the adoption of CT is its relatively low cost, both in terms of the equipment required and running costs per treatment cycle. Although a number of companies treat small batches of finished components for the automotive, aerospace, and manufacturing industries, as well as treating more novel items such as sports equipment. CT is not yet a widely used industrial process despite reported evidence indicating substantial improvements in wear resistance, hardness, and fatigue scatter reduction. The reasons for this lie in the lack of any cohesive understanding of the physical effects of CT on the microstructure and composition of treated materials, although a number of substantial studies have been carried out.[12]

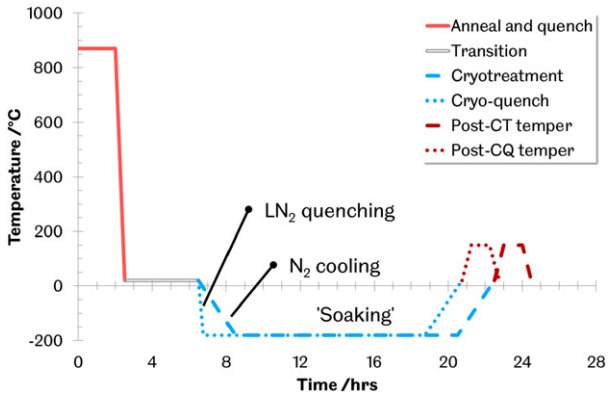

Figure 2 Cryotreatment (CT) cycles illustrating liquid nitrogen quenching and gaseous nitrogen cooling. The 'Transition' line indicates an indefinite period of time for transport and storage prior to CT.

2.15.1.4.2.1 *Case Study: Optimizing a CT process*

In a recent example of this approach,[13] simple rectangular section specimens of a particular tool steel (D2) were treated using a range of different soaking times at the cryogenic temperature. The durations ranged from 0–84 h and all other aspects of the treatment cycle remained uniform across the specimens. These treatment cycles are illustrated in **Figure 3**.

The treated specimens were then subjected to a range of microstructural analyses (e.g., SEM and XRD) and mechanical tests (e.g., hardness, sliding wear) to assess the performance variation as a result of the different process holding durations. In this particular case it was found there was an observable effect of soaking time on the precipitation of secondary carbides during subsequent tempering that lead to an improvement in the hardness and an increase in wear resistance. In all cases it was found that there is an optimum value for the duration at which the specimens were held at the cryogenic temperature.

2.15.2 Cryogenic Processing of Ferrous Alloys

Ever since its inception as a processing technique, ferrous alloys (and in particular, tool steels) have dominated both research and commercial uses of cryogenic treatments. This is due to the responsiveness of hardened steels to cryogenic

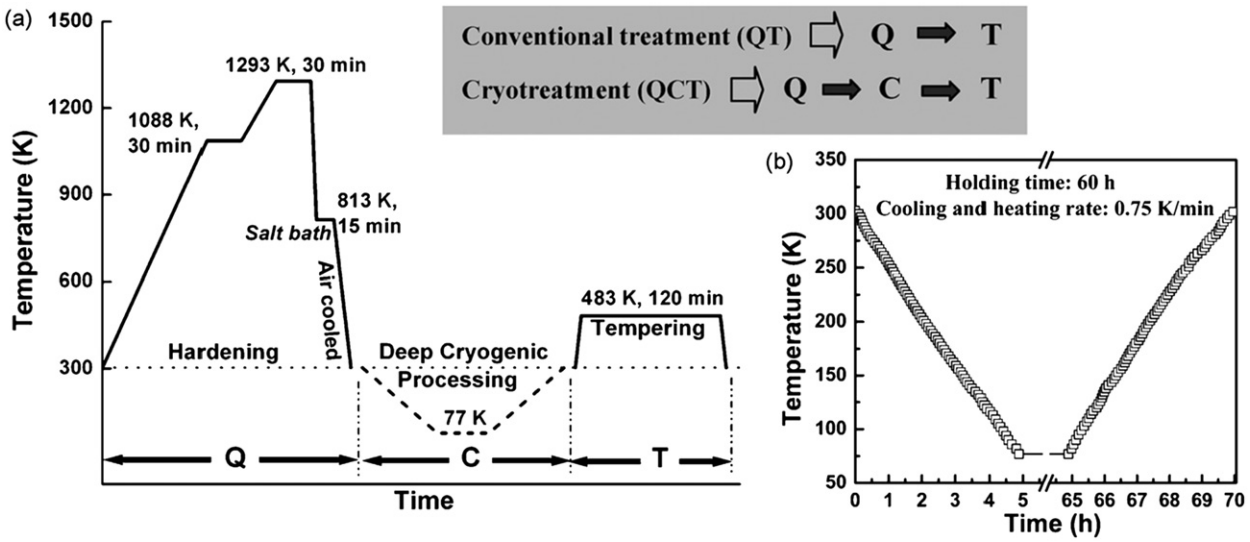

Figure 3 Schematic of (a) full heat treatment cycle, including deep cryogenic treatment, for AISI D2 tool steel and (b) detail of deep cryogenic processing.[13]

treatments that are often able to transform the majority of any retained austenite to martensite. In contrast to the reduction of retained austenite that can be achieved through tempering processes, by forming martensite at cryogenic temperatures better dimensional stability can be achieved.[14] Following hardening and cryogenic treatments it is usually preferable to temper the material to soften the virgin martensite and improve toughness, in line with conventional practice.

Cryogenic treatments have also been shown to cause additional effects in carbon steels. Of greatest focus within the research community has been the influence of cryogenic treatments on the formation of nano-carbide precipitates during tempering that further increase the wear resistance of tool steels. However, further effects have been seen in non-hardened pearlitic steels, cast irons, and stainless steels as well. A chronological summary of the relative changes in the properties and behavior of ferrous alloys due to cryogenic treatments is presented in Table 4. Immediately apparent is the vast range of effects reported in the scientific literature, that in turn, explains the range of different treatment processes on offer by commercial businesses.

This section identifies the state of the art and trends in performance modification that can typically be achieved by subjecting ferrous metals to cryogenic processing. Following this review, a selection of case studies are presented giving specific examples as to the effects cryogenic treatments have on the main ferrous alloy groups.

2.15.2.1 State of the Art

2.15.2.1.1 Mechanical properties

Although, from an engineering design perspective, the rigorous characterization of the influence of cryogenic treatments on the mechanical properties of materials may be desirable, studies that focus on strength, fatigue life, and toughness are few and far between. Hardness is the exception to this rule, with studies reporting changes due to CTs of up to 159%.[38] As hardness is commonly used as a proxy for yield strength, it might be reasonably expected that reported changes in the strength of cryotreated materials may change by similar values. However, this is not the case, with most investigators reporting no change in strength (yield or tensile) against one isolated case where a 16% increase was observed,[38] although it should be noted that very few of the studies surveyed considered strength as a separate parameter.

When it comes to reported values of impact energy (or notch-toughness) and fracture toughness, the results are perhaps surprising. While most investigators report significant decreases in the ability of hardened ferrous alloys to absorb energy following cryogenic treatments, studies involving AISI H13 hot work tool steel goes against this trend, with noticeable increases in fracture toughness reported.[18,43] The reasoning given for this increase is contradictory with previous work demonstrating greater brittle behavior in cryogenically treated AISI D2 tool steel, with both sets of investigators claiming that the fine carbide dispersion that results from cryogenic treatment and tempering is responsible. In their work on AISI D2 tool steel, Das *et al.*[30c] point to evidence of microvoids formed by the decohesion of secondary carbides on fracture surfaces (Figure 4).

2.15.2.1.2 Tribological performance

The majority of research into the effects of CT on the tribological performance of ferrous alloys focuses on their abrasive wear resistance in dry sliding conditions due to its wide relevance to industrial cutting processes and mechanical contacts founding in automotive and manufacturing fields. Beginning this vein of research is arguably the wide-ranging study by Barron, whose abrasive wear tests on 12 tool steels, three stainless steels and four others having been subjected to both shallow cryogenic treatment (SCT: 189 K) and deep cryogenic treatment (DCT: 77 K), illustrated the huge potential, as well as the significant variation, of this technique. Reporting an improvement in sliding wear resistance of 718% (in the case of AISI D2 tool steel after DCT) to the lack of any change in several others (AISI A2, A6, and T2 tool steels), this study by Barron lead to numerous others in which investigators consistently reported extreme performance improvements in some cases and no effect in others, leading Gill *et al.*[12] to comment that 'the reported magnitudes of the enhancement in wear resistance and the proposed governing mechanisms for such enhancement do not provide any unified picture.'

However, since then understanding has developed and it is clear now that the range of reported changes in the tribological performance of cryogenically treated ferrous alloys arises from the different microstructural changes that occur depending on the chemical composition and heat treatment history of the material. The most widely reported of these is the reduction or elimination of retained austenite from hardened steels[44] and its transformation to martensite. Without subsequent tempering this alone may lead to an increase in measured hardness, but a significant decrease in toughness. This effect should be seen in any hardenable steel (>0.3 wt%C) where the hardening process does not result in the complete transformation of austenite to martensite.

Also commonly reported is the appearance of numerous small carbides following cryogenic treatment and tempering.[45] These act to prevent dislocation movement and therefore inhibit local plastic deformation (increasing matrix hardness) while providing greater abrasive wear resistance. The prevalence of these carbides is linked to excess carbon that exists in the matrix following cryogenic treatment and the availability of carbide formers, and hence is seen most clearly in steels that contain significant quantities of alloying elements such as chromium, tungsten, and molybdenum, which are used heavily in cold work (AISI D-type) and high-speed (AISI M-type) steels.

Finally, and least frequently reported, is the effect that cryogenic temperatures have on dislocation density and movement during the thermal deformation that occurs (for a detailed discussion see Gavriljuk *et al.*[46] and Tyshchenko *et al.*[47]). Although not reported on as yet, it could reasonably be theorized that this effect may occur in other multiphase (e.g., ferritic–pearlitic) steels where each phase possesses different thermal expansion coefficients, resulting in additional stresses between them. This is known to be the case in the hardened steels, where the martensite formed during cryogenic treatment has different lattice parameters than that formed during the quenching process.[48] Ultimately, these changes manifest as a change in hardness[18,30a] that increases resistance to abrasion.

The combination of these effects is therefore what causes the wide range of variation reported in the tribological

behavior of ferrous alloys following cryogenic treatments. A significant body of work, which is therefore yet to be conducted, is the correlation of chemical and phase composition with pre- and post-cryotreatment heat treatment history with the resulting changes in tribological performance that would enable optimized cryogenic treatment cycles to be developed 'depending on the needs of the application' of the material. This is not a trivial endeavor and will require a concerted and coordinated effort between academic investigators and industrialists.

2.15.2.1.3 Mechanisms of microstructural change

As previously discussed, in ferrous alloys the changes in material properties and behaviors due to cryogenic treatments are thought to result from:

- The transformation of retained austenite to martensite in hardenable steels.[44]
- The precipitation and dispersion of fine carbides in steels with greater excess carbon and strong carbide forming alloying elements.[45]
- The movement and distribution of dislocations during thermal deformation.[46–47]

Higher carbon and higher alloy content steels have lower martensite start and finish temperatures (as illustrated in **Figure 5**), meaning that quenching processes alone cannot convert all of the austenite to martensite. Following quenching, the retained austenite is unstable and can decompose into martensite as a result of the thermal stresses resulting from cryogenic treatments, or the diffusion of excess carbon occurring during tempering.

1. Cleavage facets in primary carbides.
2. Cracking of primary carbides
3. Cracking at the interface between primary carbides and matrix.

White arrows indicate microvoids formed by decohesion of secondary carbides.

Figure 4 SEM micrographs of fracture surfaces of AISI D2 steel as observed by Das *et al.*[30c]

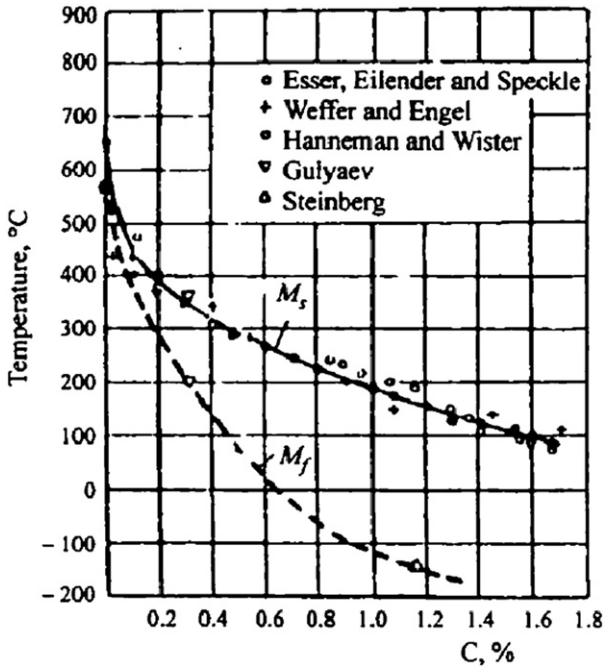

Figure 5 Effect of carbon content in steels on martensite start and finish temperatures.[3]

In their studies, Das *et al.*[30a,45,49] have thoroughly characterized the effects of cryogenic treatment on the microstructure and properties of AISI D2 tool steel, illustrating a marked rise in the proportion of fine carbides following cryogenic treatment and tempering (**Figures 6** and **7**) that is dependent on the cryogenic treatment temperature. This is thought to result from the distortion of the lattice structure, during cryogenic treatment, which leads to dislocation concentrations that carbon atoms may diffuse to during subsequent tempering.[50] The small size of these precipitates is explained by the comparatively low temperatures of tempering, the short time available for diffusion and the local availability of carbide forming elements.

The recent work of Tyshchenko *et al.*[47] and Gavriljuk *et al.*[46] explains the proposed process in more detail. Tyshchenko highlights that carbon atoms at cryogenic temperatures will be effectively immobile and hence unable to form the concentrations necessary for the formation of new precipitates while Gavriljuk suggests that the necessary carbon concentrations are formed by the plastic deformation of martensite at cryogenic temperatures. The transport of carbon atoms is facilitated by the movement of dislocations that underlies this deformation. It is therefore the time-dependent movement of dislocations that causes the relationship between the duration of the cryogenic treatment and the number of fine carbides subsequently precipitated during tempering (and therefore, the extent of change in performance seen in steels with strong carbide forming characteristics).

2.15.2.2 Tool Steels

By a significant margin, the majority of studies involving cryogenic treatments have concerned its application to tool

steels. In this section its effects on these widely used materials are briefly reviewed. Cutting tools are required to machine a wide range of materials including woods, polymers, light alloys, cast irons and steels, hardmetals, and superalloys. The properties of the material to be machined, the desired finish and production rates all impact on the specific properties required of cutting tool materials. As a result the range of materials used to make cutting tools is extensive; however their required properties fall into a manageable number of common categories: strength, hardness, wear resistance, and thermal stability.

Put simply, tool materials must be stronger and harder than the materials they are intended to cut, while their properties must be sustained at the high temperatures they experience during use. For this reason, changes in tool materials due to heat treatments should result in either thermodynamically stable structures or structures that develop beneficially upon heating (e.g., the ability of high-speed steels to 'run the temper').

In the case of a typical orthogonal cutting process (Figure 8), for example, the tool may wear by abrasion (flank face), diffusion (rake face), or by fatigue cracking and impact (which results in notching or chipping of cutting edges). Because of this combination of damage processes, a range of strategies are needed to effectively prevent rapid tool wear. It should therefore be noted that cryogenic treatments, however effective for a particular material, are unlikely to present a solution to all manner of cutting problems in isolation. Therefore exploring coatings and cutting process optimizations are also recommended.

It is often cited that the wear resistance of these classes of materials needs to be improved as cutting and metal forming tools are typically exposed to impact and sliding conditions. Therefore much research effort has been expended in conducting basic dry sliding wear tests in laboratory environments, for which it is easy to obtain specimens, conduct experiments, and provide comparative data with that obtained from industry. However, this also means that there is great variation in the work presented in the literature and released by industry as illustrated by the range of testing conditions highlighted in Table 5. The significance of the tribological conditions (load, sliding speed, and material pairing) applied is typically not considered, even though this may have a significant influence on the results.

Even today, tool steels likely account for the greatest number of cutting tools produced globally. Using the primary strengthening mechanisms of alloying (including chromium, molybdenum, vanadium, and tungsten), control of grain size

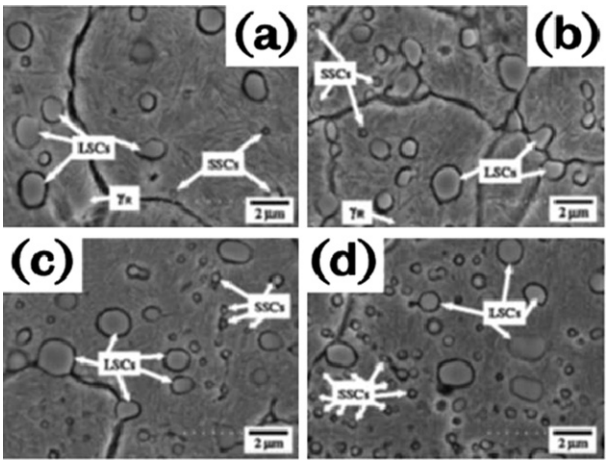

Figure 6 Micrographs showing effects of (a) conventional, (b) 'cold,' (c) shallow cryogenic, and (d) deep cryogenic treatments in AISI D2 tool steel.[30a]

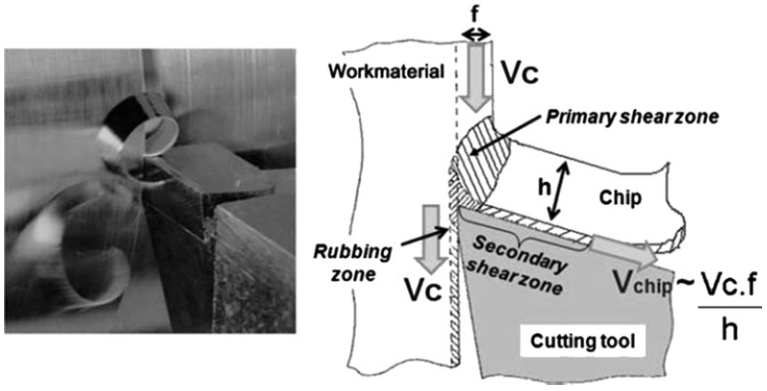

Figure 8 Standard orthogonal cutting model.[51]

(through heat treatment), and due to carbide precipitations these materials can be produced with a hardness up to 8 GPa (815 HV) and thermal stability to 1000 °C.[54]

A typical heat treatment process for a tool steel will involve austenitizing, quenching (rapid cooling by water, oil or gas), and tempering. The quenching process is designed to cause as complete a transformation of austenite to martensite as possible although, as previously highlighted (**Figure 5**), the high alloy content of tool steels can lower the martensite finish temperature to below ambient temperatures. Following quench hardening, tempering serves two purposes. Firstly, to cause the decomposition of retained austenite to martensite by allowing the diffusion of excess carbon and secondly, to allow for the nucleation and growth of carbide precipitates.

Even in the early works of Gulyaev,[3] it had been established that the sooner after quench hardening cryogenic treatment could be applied, the greater the proportion of retained austenite that could be converted to martensite. Yet today, cryogenic treatment is still commonly conducted as an 'after-market' treatment on finished or semifinished components that may have been heat treated hours, days or even months previously, thus limiting the effectiveness of CT in this respect. Furthermore, to avoid austenite stabilization, cooling from the critical temperature to cryogenic temperatures should be continuous.[55]

This is not the complete picture, however, as more recently it has been suggested that there does exist a lower temperature limit below which further transformation will not take place and that a time-dependent isothermal transformation of retained austenite to martensite may continue at cryogenic temperatures. Studying the behavior of X153CrMoV12 powder metallurgy steel using Mössbauer spectroscopy, Gavriljuk *et al.*[46] demonstrated that cooling the material to −196 °C and soaking for 96 h had no effect on martensite content, whereas soaking at −150 °C did cause the transformation of retained austenite. Findings such as these hint at substantial benefits still to be obtained by optimizing CT processes, both in terms of maximizing beneficial properties and minimizing process costs.

By reviewing the three most commonly tested tool steels from the scientific literature (AISI D2, H13 and M2) some further trends can be identified. Their nominal compositions are given in **Table 6**.

Two robust studies of note, concerning the application of cryogenic treatments to AISI D2 tool steel, are those by Collins and Dormer[15] and Das *et al.*[30a,30b] The treatment parameters adopted by these investigators are summarized in **Table 7**.

In their study, Collins and Dormer illustrated two effects influencing wear resistance following cryogenic treatment. Firstly, the complete transformation of retained austenite to martensite and secondly, the precipitation of secondary carbides following CTs. They determined that although a higher austenitizing temperature (and therefore greater retained austenite) leads to a greater hardness attainable with cryogenic treatment, the maximum wear resistance was found following a lower temperature austenitization due to the greater precipitation of secondary carbides during tempering. Lower cryogenic treatment temperatures and longer soaking

durations were found to be beneficial both in terms of maximizing wear resistance and minimizing loss of toughness.

Subsequently Das *et al.* studied the wear behavior of AISI D2 tool steel in more detail, having observed similar microstructural changes. Under pin-on-disk testing that resulted in severe delamination of the material, they determined that the increased wear resistance of the cryotreated samples was due to their resistance to subsurface plastic deformation and therefore resistance to white layer formation. While a more complete transformation of retained austenite to martensite may result in the highest bulk hardness, the fine carbide precipitates act to limit dislocation movement further and therefore inhibit plastic deformation.

The teams lead by Molinari[18] and Koneshlou[33] have studied the mechanical properties of AISI H13 tool steel in some detail, adopting very similar heat treatment parameters but with different treatment cycle orders (**Table 8**). While Molinari *et al.* applied cryogenic treatment as a final step, Koneshlou *et al.* tempered the material both before and after CT. The difference in material properties developed was significant, with Molinari *et al.* reporting no change in hardness while Koneshlou *et al.* observed a hardness change of 20% (49 HRC–5 HRC) following cryogenic treatment. It seems likely that this marked difference resulted from the quantity and stability of retained austenite remaining prior to cryogenic treatment; in the case of Molinari *et al.* the double tempering cycles will likely have resulted in the decomposition of the austenite.

More recently Perez *et al.*[43] have also studied how cryogenic treatments affect the mechanical properties and fracture behavior of AISI H13 tool steel. Of particular interest in their study was the influence of the rate of the initial cooling, which they varied through the use of different quenching media (**Table 9**). Although the rate of initial cooling did not appear to

influence the effectiveness of the cryogenic treatment the application of the subzero treatment had a pronounced effect on fracture toughness, resulting in a greater than 20% improvement. Fractography suggested that the presence of a uniform distribution of fine carbides in the cryotreated samples had resulted in a more 'ductile' fracture behavior, based on the growth and linking of microcavities, in comparison to the brittle fractures that resulted from the stress concentrating effect of more coarse carbides that are otherwise present in the material. The corresponding reduction in carbon content of the martensite, following cryogenic treatment, also contributes to a tougher matrix.

Studies involving AISI M2 high-speed steels present some mixed results. Even as early as the work of Gulyaev, variations in improvements in high-speed steel tool lives following cryogenic treatments had been reported between 40–400%.[3] More recent investigators have reported modest increases in hardness[16,18,37] along with significant improvements in toughness[16,18] and wear resistance.[18,37] In common with other studies involving tool steels, the hardness changes are not proportional to increases in abrasive wear resistance, indicating multiple contributing microstructural factors. However, beyond the conversion of retained austenite to martensite the other changes are less clear.

Treatment cycles adopted by recent investigators have varied widely. Yun *et al.*[16] explored the effects of varied duration and cyclic cryogenic treatments (**Table 10**), as well as its effectiveness after tempering had already been carried out. They determined that cycling cryogenic treatment had a greater effect than simply extending its duration, while CT following tempering still resulted in modest changes in material properties. Hot hardness was found to improve markedly that was argued to result from the formation of sub-nanometer (30–60 Å) carbides on twinning surfaces and other crystallographic defects during cryogenic treatment. Upon heating these carbides were able to grow further and compensate for the thermal effects on the matrix.

By contrast Molinari *et al.*,[18] who also studied whether cryogenic treatment was most effective before or after tempering, and to what degree tempering should be done (**Table 11**), came to different conclusions. While noticeable changes in hardness, strength, toughness, and wear resistance were reported, they observed no change in carbide distributions and even 'tempered martensite de-twinning' following cryogenic treatment. The most effective treatment was deemed to be applying cryogenic treatment following double tempering – based on other studies this would likely have resulted in a tougher material with moderately increased hardness.

Cryotreatment (C)	− 110 °C for 18 h	− 196 °C for 38 h
Treatment order	QCTT	

More recently Gill *et al.*[37] focused on the influence of cryogenic treatment temperature, with only a low-temperature temper applied subsequently (**Table 12**). They determined that hardness was most significantly improved by shallow cryogenic treatment (− 110 °C for 18 h) while wear resistance benefitted substantially from deep cryogenic treatment for a longer period (− 196 °C for 38 h). It was proposed that stresses from the austenite transformation, during cryogenic treatment, result in greater twinning and dislocations; defects to which alloying elements segregate during tempering. The lack of diffusion at cryogenic temperatures results in greater lattice distortion and decreased stability of the martensite, in comparison to that formed through tempering alone. This corresponds closely with the prevailing understanding Gulyaev described at the time.[3]

What is clear from the plethora of studies concerning cryogenic treatment of tool steels is that it can have very substantial (and often substantially beneficial) effects on their properties and in-service performance. However, care needs to be taken to treat tool steels appropriately to maximize the specific qualities required.

For instance, if maximum hardness is required a shallow cryogenic treatment applied immediately following high-temperature austenitization may provide best results. If greatest toughness is needed then perhaps the steel should be first tempered before deep cryogenic treatment to encourage a ultrafine carbide precipitation. As tool-life requires resistance to a combination of wear mechanisms, it may be preferable to perform a medium temperature austenitization followed by quench hardening, multiple deep cryogenic treatment, and tempering cycles.

Defining and expressing the relationships that allow the optimum cycle parameters to be applied, depending on material and application conditions, seems to be the next big challenge in this field.

2.15.2.3 Plain Carbon Steels

In contrast to the wealth of research involving high alloy content tool steels, there is relatively little concerning the effects of cryogenic treatment on 'plain' or low-alloy content carbon steels. As such it is difficult to draw strong correlations from the results and observations reported. Instead, more general findings are highlighted with the compositions of those steels reported in literature given in **Table 13**.

Gulyaev[3] made specific reference to the likely effectiveness of cryogenic treatments on plain carbon steels, suggesting that they would be entirely ineffective on steels with $<0.6\%$C as their martensite finish temperature lies above 0 °C (see **Figure 5**). However, Gulyaev also highlighted that even small amounts of alloying additives can significantly reduce the martensite finish temperature. At the time, cold treatment of carburizing steels was more common than for high-speed steel, as the carburized (higher carbon content) layer retains more austenite during quenching.

In some of their early work, Barron and Mulhern[5] applied varied CTs to AISI 1045 carbon steel, finding that there was no measurable change in hardness but that the retained austenite was almost completely converted to martensite. Modest increases ($\sim 10\%$) were reported in wear resistance but there was no visible carbide formation using optical microscopy. Assuming the wear findings to be accurate, finer precipitates may have developed and been responsible for the change in wear resistance.

The same observations were made by Bensely *et al.*[19] when testing the effect of cryogenic treatments on carburized En 353 low-alloy steel (with notable Cr and Ni, but lower C content). Although the retained austenite was largely converted to martensite through CTs and optical microscopy revealed no change in carbide precipitation, increases in wear resistance of up to 372% were reported. The authors attributed this improvement to fine carbide precipitates that they assumed were present. Although the carburized gear steels used by Preciado *et al.*[8] were very similar in composition, significant hardness increases (up to 17%) in the near surface region were reported alongside much more modest (up to 25%) increases in wear resistance. In this case only a low-temperature (150 °C) temper was conducted. Although the wear testing conditions of each study are difficult to

compare (10 N on 6 mm diameter ball in the former and 60–80 N on 10 mm diameter flat-headed pin in the latter), it could be speculated that the higher tempering temperature used by Bensely softened the martensite formed during cryogenic treatment while promoting a more significant fine carbide precipitation. In Preciado's study, the lower temperature tempering may have allowed the martensite to retain its hardness but prevented substantial precipitation of fine carbides.

Vimal *et al.*[25] experimented with a much higher carbon (~1%) low-alloy steel, En 31. Varying the heat treatment process order, with CTs before and after tempering, they obtained the maximum hardness and wear resistance by applying cryogenic treatments immediately after quenching, but before tempering. Observations made suggested the transformation of retained austenite and formation of fine carbides were responsible.

Similarly to studies conducted on tool steels, those (few) conducted on plain carbon or low-alloy steels allow some practical suggestions to be made. Cryogenic treatment can clearly be effective on these materials. However, if a significant increase in hardness is sought, then the composition of the material must be such that the martensite finish temperature is significantly below 0 °C – this may be true in high-carbon steels or those with strong austenite stabilizers such as Cr and Ni. If wear resistance is to be improved then the quenching and CT processes must result in excess carbide formers being present in the microstructure that can then form precipitates during tempering. Therefore low-alloy steels that contain noticeable amounts of Cr or Mo may be suitable for this treatment approach.

2.15.2.4 Stainless Steels

Stainless steels present an interesting 'challenge' when it comes to assessing the effectiveness of cryogenic treatments. While austenitic stainless steels are most common, the fact that they can be produced as ferritic or martensitic materials, with or without significant carbide precipitations arguably means they cannot be treated as a single family of materials. However, the limited quantity of published research involving these materials necessitates a combined approach. Table 14 summarizes the compositions of the stainless steels subsequently discussed. It should be noted that the AISI 3XX stainless steels are austenitic while the AISI 430 stainless is ferritic and the AISI 440 stainless is martensitic.

The earliest application of cryogenic treatments to stainless steels can be found in Barron's wide-ranging wear resistance study[4b] in which, along with a number of other carbon, alloy, and tool steels, AISI 303 (austenitic), 430 (ferritic), and 440 (martensitic) stainless steels were subjected to abrasive wear testing. Although this was an unusual test for materials that are typically not considered for their wear resistance, Barron's study indicated cryogenic treatment could affect any of these materials, with reported increases in wear resistance of 10–20%. In the case of the martensitic stainless steel, transformation of any retained austenite was likely an influencing factor, although with the other two materials it clearly could not have been. This therefore indicates that other microstructural alterations (fine carbide precipitations and/or change in dislocation characteristics) are significant factors.

Despite these seemingly significant findings, very few subsequent studies have involved stainless steels. Singh *et al.*[56] investigated the application of cryogenic treatment in improving the fatigue life of welded joints (AISI 308L) between stainless steel (AISI 304L) plates. Under high-cycle fully-reversed loading conditions, they concluded that the strain-induced martensitic transformation, which occurred during the CT process, resulted in compressive stresses that effectively raised the fatigue limit of the joints; more than doubling their fatigue lives in some cases.

Although this was another seemingly significant finding, the next major study (and by far the most robust to date) was that of Baldissera *et al.*[29] who conducted a full factorial

design of experiments approach to investigate the effects of cryogenic treatments on the hardness, strength, fatigue life and corrosion resistance of AISI 302 stainless steel. Different cryogenic soaking temperatures and times, as well as the effect of solubilization treatments were considered. CTs were found to have no significant effect on the static mechanical properties of the material, or its corrosion resistance under salt-spray. However, deep cryogenic treatment (88 K) was found to significantly improve the fatigue life of the solubilized (but not hardened) samples. Fractographic analyses revealed a number of small secondary cracks in the cryotreated material that could have originated from fine precipitates and acted to absorb energy from the cyclic loading process, increasing the nominal stress intensity required for crack initiation and therefore increasing the toughness of the material.

Studies on stainless steels are too few for strong conclusions to be drawn as to the possible benefits of cryogenic treatments. However, it does appear that subzero treatments may be effective at increasing the fatigue life of stainless steels 'after certain types of treatments.' Aside from being able to convert retained austenite to martensite, if that is what is desired, the changes in mechanical behavior reported to date appear to relate to changes in precipitation behavior, with the possibility of more subtle microstructural changes playing a role as well.

2.15.2.5 Cast Irons and Pearlitic Steels

Two other interesting, overlapping groups when it comes to the application of cryogenic treatments are ferritic and pearlitic cast irons and steels. Although not considered in much of the early work, over the past 10 years investigators have begun to study these alloys more closely. The studies subsequently reviewed involve the alloys summarized in **Table 15**.

There are currently just two groups of work in this field at present. The first, involving the team of Liu,[21] Yang,[22] and Wang[28] *et al.*, have worked extensively to characterize the factors influencing the effectiveness of cryogenic treatments on high-chromium (and therefore austenite retaining and carbide forming) cast irons. More recently the present authors have focused on 'plain' graphitic cast irons[34,35] and pearlitic steels.[40,57]

In their studies, investigators Liu and Yang *et al.* observed that cryogenic treatments following subcritical heat treatments were more effective than air cooling in transforming retained austenite to martensite and promoting the formation of fine secondary $(Fe, Cr)_{23}C_6$ carbides in high-chromium cast irons. While the maximum hardness (+57%) of these materials can be achieved by subcritical heating to around 550 °C before quenching directly in LN_2, the maximum wear resistance (+15%) was obtained by heating to around 600 °C before cryogenic quenching. The reported observations suggested that while the lower temperature treatment resulted in a more complete austenite to martensite transformation, the higher temperature allowed for a greater precipitation and growth of fine secondary carbides, which enhanced the abrasive wear resistance further.

Using a very similar alloy to their colleagues' previous studies, Wang *et al.* further explored the influence of high-temperature treatments on these alloys, with destabilization treatments conducted at 900–1150 °C before air cooling or cryogenic quenching. It was reported that secondary carbides were more uniformly distributed following cryogenic treatment, while the proportion of martensite also increases. In this case both maximum hardness (+15%) and wear resistance (+19%) were found following cryogenic quenching after destabilization treatment at between 1000–1100 °C.

In their recent studies, the present authors have concentrated on characterizing the wear performance of cryogenically treated gray cast irons and pearlitic steels under different dominant wear mechanisms and contact conditions. Investigating the effectiveness of cryogenic treatment on EN-GJL-250 gray cast iron and EN1, a mild steel, Slatter *et al.*[34] recorded 200% and 400% increases, respectively, in their resistance to wear under repetitive hammering impact. Phase transformations were not possible as the low-alloy content and slower cooling (in the case of gray cast iron) prevents austenite being retained; it decomposing to ferrite and cementite instead. No change in precipitation behavior was observed either.

Conducting sliding wear tests on SAE J431 G10 gray cast iron and EN10083 C50R pearlitic steel break disk materials, Thornton *et al.*[35,40] recorded significant increases in the wear resistance of each material. In the case of gray cast iron this was up to +81% at high contact pressures and low sliding speeds, with negligible changes observed at low contact pressures and high sliding speeds. While the hardness of the gray cast iron was not affected by the CT, the hardness of the pearlitic steel was found to have increased by around 20%. This was coupled with a more consistent improvement in wear resistance of 15–20% across all contact pressures tested and visible signs of a shift to a more brittle dominant wear mechanism (with more extensive cracking and pitting visible in cryotreated specimens). As with the previous study by Slatter *et al.*, there were

Table 15 Compositions of cast irons and pearlitic steels reported in the literature (P, S omitted; balance Fe)

wt%	*C*	*Si*	*Mn*	*Cr*	*Mo*	*V*	*Other*

EN10083 C50R[40]	0.47	0.18	0.75	0.03	<0.01	–	0.03Ni

no obvious microstructural changes to explain these changes. Further analysis of the pearlitic steel using X-ray diffraction, electron-backscatter diffraction, and transmission electron microscopy ruled out the possibility of the presence and transformation of small quantities of retained austenite or fine carbide precipitations resulting from cryogenic treatments.[57]

These findings lead to the conclusion that a more fundamental change in the materials was responsible. It is theorized that a change in dislocation distribution or density due to the cryogenic treatment process could result in a change in the residual stress state and therefore wear behavior of the materials tested. These studies are further elaborated upon as case studies that may provide outline methodologies for assessing the basic tribological performance of cryogenically treated ferrous alloys.

2.15.2.6 Case Studies

2.15.2.6.1 Impact wear resistance of low carbon steel and lamellar graphite cast iron

2.15.2.6.1.1 Introduction

This case study outlines investigations into the influence of cryogenic treatment on the impact wear resistance of low carbon steel and lamellar graphite cast iron. This has been selected because it provides more detailed insight into the types of mechanical performance improvement that can be seen with cryogenic treatment of carbon steels and cast irons, and also because there is very little literature that discusses the impact wear resistance of cryogenically treated engineering materials. It also provides a basic methodology that could be used for assessing the potential using CT in a particular application.

2.15.2.6.1.2 Impact wear

Percussive impact wear mechanisms arise from two or more bodies impinging normally or otherwise to each other. These mechanisms typically involve elements of elastic and plastic deformation, when impact energy is high and depending on the ductility of the materials, and/or fatigue accompanied by wear debris as a result of crack propagation. This mechanism is commonly found in a great many mechanical devices.

Impact wear resistance of materials can be investigated in numerous ways – by firing multiple projectiles being propelled into a stationary target/specimen by gravity, a fluid stream, or magnetic fields and in the case of single impact events a projectile fired by gas propelled barrel. That said, the majority of the previous experimental work conducted in this area has used a reciprocating hammer-type test rig to generate the cyclic percussive impact and it is this type that was used here to subject both untreated and cryogenically treatment specimens to impact. These types of tests rigs are simple to design and construct.

2.15.2.6.1.3 Experimental details

For the purpose of comparing results, it is important to characterize the contact that is produced by the test rig geometry. In this case, the rig impinged a 15 mm chrome steel ball normally to the specimen surface at 10 Hz (impacts per second). The striker had a closing velocity of 0.45 m s^{-1} and an impact energy of 0.22 kJ. Applying analyses demonstrated by Goldsmith[58] and Hertz[59] the contact stress was calculated to be 1.8 GPa. The material specification equivalent to that of the ball is EN 31 or AISI 52100. The hardness of the balls was in the range of 700–900 HV with a maximum surface roughness of 0.125 μm.

The cast iron material used was EN-GJL-250 lamellar graphite cast iron (average hardness of 235 HV) and the low carbon steel used was EN 1A (average hardness of 175 HV).The form of the specimens was circular disks, 50 mm in diameter, cut from an as-cast bar of each material. For simple tests such as these it is useful to keep the geometry of the specimens as simple as possible as this allows isolation of the fundamental material performance, aids comparison at a later date and makes creating a robust dataset easier. Each specimen was cut and ground to be 10 mm thick with a uniform surface finish (0.5 μm).

Two sets of specimens were prepared for each material, one set was cryogenically processed and the other set was left untreated. To the naked eye, the specimens that were cryogenically processed were indistinguishable from those that were left untreated and had similar macro-hardness. When compared to the calculated contact stress of 1.8 GPa the measured hardness values, and therefore the yield strength of the materials tested, indicates that deformation of the material in the contact zone is likely.

Both material types were subjected to identical cryogenic processing using a cryogenic chamber similar to that described in Section 2.15.1.4. All of the specimens were placed in the chamber at room temperature and were then gradually cooled down to $-180\ ^{\circ}C$ over a period of 4 h. The chamber was then held at this temperature for 16 h to ensure uniform transformation in all the specimens. The specimens were then brought back up to room temperature over another period of 4 h. To remove any potential thermal residual stress all the specimens were then subjected to a post-process temper. The specimens were then heated to $170\ ^{\circ}C$ over a period of 2 h. This temperature was held for another 2 h and then was allowed to return to room temperature, again over a period of 2 h.

Five different test lengths were conducted; 4500 impacts, 9000 impacts, 18 000 impacts, 36 000 impacts, and 72 000 impacts. Each test was performed with a new specimen and a new striker and was repeated. The specimens and strikers were cleaned in ethanol prior to testing.

All specimens were examined with a microscope, photographed and measured with a profilometer before and after testing. The total wear was assessed by geometry change due to the very small fraction of the overall specimen mass being removed. Geometry change is also preferred as mass that can be 'moved' via plastic deformation to a position where it can bear little or no load and this is a phenomenon that is undetected by mass difference techniques. Wear scar volumes were estimated by modeling the wear scars as spherical caps and using the recorded scar geometry to calculate an estimated wear scar volume. The form and nature of any visible wear debris was also recorded along with any notable features.

2.15.2.6.1.4 Results

2.15.2.6.1.4.1 Specimen overview and wear scar morphology

2.15.2.6.1.4.1.1 Untreated specimens

The wear scars can be easily seen by the naked eye as roughly circular craters on the surface of the specimens and the wear debris visible varied in size and nature. In general, the wear

debris visible on the low carbon steel specimens can be characterized as small amounts of fine dark colored debris with more metallic particles visible after the longer tests and for the lamellar graphite cast iron large metallic flakes were visible. In all cases a negligible amount of debris was adhered to the ball. Each wear scar was examined under a microscope and any observations regarding the condition and form of the edge and nearby debris were also recorded. In general, the low carbon steel wear scars (**Figure 9**) exhibited smooth, well-defined edges, some scars were slightly oval in shape and there was pitting of the scar surface indicating that there was material removal. The lamellar graphite cast iron wear scars were rougher, but still had well-defined edges. The scars were generally regular in shape with some evidence of cracking around the scar edge as shown in **Figure 10**.

2.15.2.6.1.4.1.2 Cryogenically processed specimens

The low carbon steel specimens had very little visible wear debris, even after the longer tests; whereas there were small amounts of dark, and after the longer tests more metallic looking, debris on the untreated specimens. Again, in all cases a negligible amount of debris was adhered to the ball. The wear scar edge present after the 4500 impact test was very clean and well defined. Longer tests had slightly rougher, cracked edges, but otherwise clean and well-defined wear scar (**Figures 11** and **12**). All the wear scars created had grinding marks (from the surface preparation) clearly visible in the wear scar crater, the number of marks observed to be inversely proportional to test length, indicating a mixture of brittle fracture, and plastic deformation in the impact zone.

After the 4500, 9000, and 18 000 impact tests the cryogenically treated lamellar graphite cast iron specimens all had clearly visible wear scars with grinding marks still distinguishable in the crater too. Each specimen had fine, dark colored ring of wear debris around the edge of the wear scar crater. The specimens subjected to 36 000 and 72 000 impacts had thicker rings of wear debris (**Figures 13** and **14**) and in the case of the 72 000 impact test some of the wear debris were several millimeters away from the impact zone. The predominant feature of the untreated lamellar graphite cast iron was rough, but still well-defined wear scar edges with some evidence of cracking (**Figure 10**). The wear scars created on the untreated specimens also did not leave any evidence of grinding marks in the wear scar craters. The grinding marks

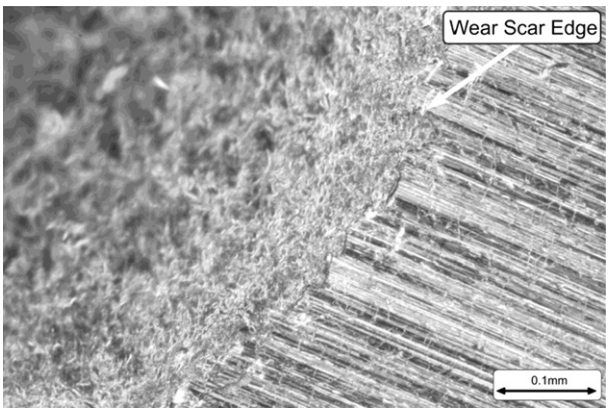

Figure 10 Section of wear scar edge of a lamellar graphite cast iron specimen subjected to 72 000 impacts.

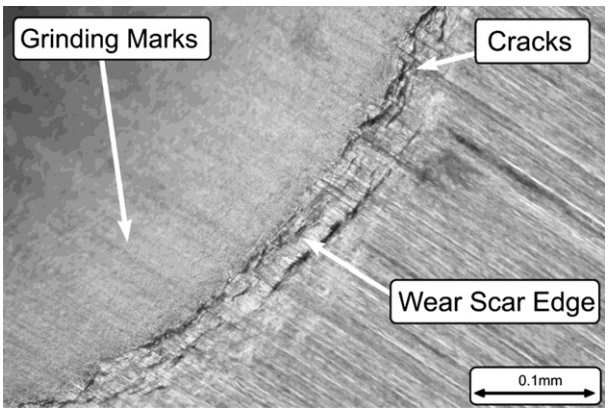

Figure 12 Wear scar edge on a cryogenically processed low carbon steel specimen subjected to 72 000 impacts.

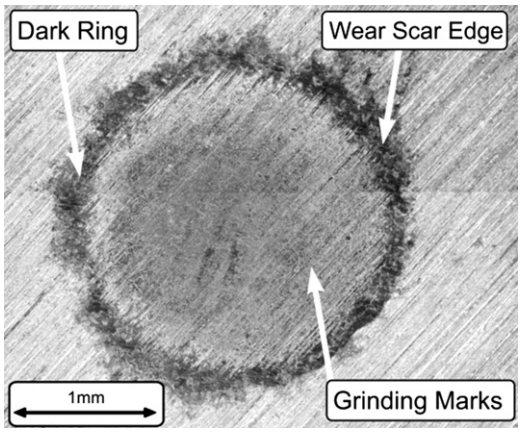

Figure 13 Wear scar from a cryogenically processed lamellar graphite cast iron specimen subjected to 72 000 impacts.

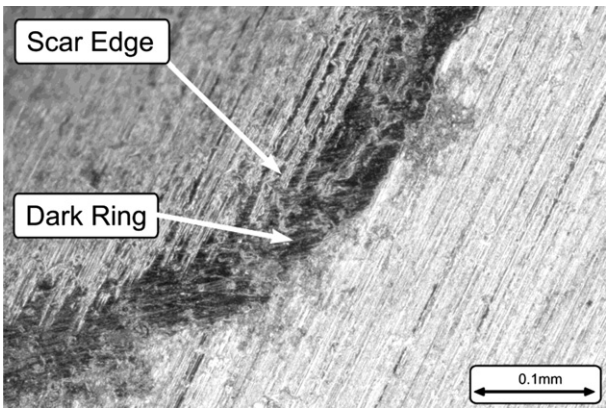

Figure 14 Wear scar edge from a cryogenically processed lamellar graphite cast iron specimen subjected to 72 000 impacts.

visible on the processed specimens after testing (**Figures 9** and **10**) are wider or flatter indicating plastic deformation.

These differences suggest that the cryogenic processing has modified the material properties so that plastic deformation 'wear' is the predominant wear mechanism rather than brittle fracture as was the case with the untreated specimens. The suggestion that the material has been modified is supported by the difference in wear debris that was visible. The untreated specimens produced large metallic flake-like debris whereas cryogenically processed specimens produced much finer darker particles.

2.15.2.6.1.4.1.3 Wear scar measurement

A profilometer was used to confirm the optically measured wear scar diameters and to investigate the nature of wear scar 'shoulders.' Traces were taken across the center of each wear scar and the typical profiles for each of the specimen types after the 72 000 impact tests are shown here.

Three different diametric measurements were taken across the center of the wear scar and the averages of these are shown in **Figure 15**. The maximum and minimum measured values are indicated by the error bars. **Figure 15** clearly shows that the cryogenic processing improves the impact wear resistance of the low carbon steel specimens. For all test lengths the average wear scar diameter of the cryogenically processed specimens is between 55 and 80% that of the corresponding test for an untreated specimen. The results of the lamellar graphite cast iron are less clear cut. It is clear that for the longer tests the cryogenic processing has improved the impact wear resistance of the specimens to a similar extent to that of the low carbon steel. That said, however, for the shorter tests it appears that when considering the wear scar diameter, the cryogenic processing has reduced the ability of the material to resist impact wear.

The profiles shown in **Figure 16** show that the size of the wear scars on the cryogenically processed low carbon steel specimens is clearly smaller, in depth and diameter, than the

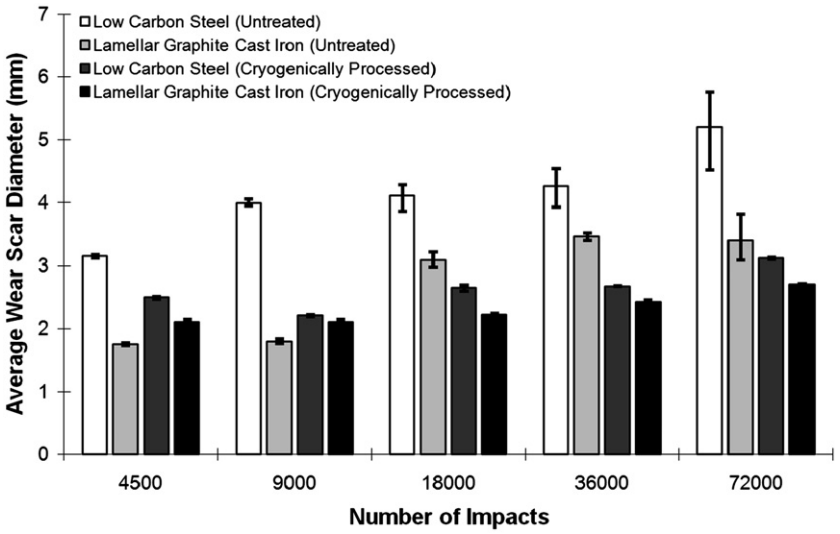

Figure 15 Average wear scar diameter vs. number of impacts for cryogenically processed and untreated low carbon steel and lamellar graphite cast iron specimens.

scar present on the untreated low carbon steel specimens for the same number of impacts. As mentioned previously, the untreated low carbon steel specimens exhibited plastically deformed shoulders and this phenomenon is also present in the cryogenically processed specimens. It is interesting to note that the size of the shoulders has not decreased to the same degree as the overall size of the wear scar. This suggests that the cryogenic processing has not reduced the ductility of the material at the expense of improving the wear resistance. That said however, the level of surface cracking around the wear scar edges has increased on the processed specimens (compare **Figure 9** with **Figure 12**) suggesting that the ductility has actually been reduced as the load on the material has exceeded the plastic limit.

Figure 17 shows the difference in wear scar profile between the untreated and cryogenically processed lamellar graphite cast iron specimens subjected to 72 000 impacts. As with the low carbon steel specimens the wear scar is smaller after processing. The difference in wear scar depth is less than before, but the plastically deformed shoulders are minimal on the cryogenically processed specimens. This suggests that the processing modifies the cast iron in such a way to reduce the ductility of the material. Comparing the images of the wear scar edges supports this statement as the surface cracking visible on the untreated material (**Figure 10**) is not visible on the edges of the processed cast iron (**Figure 14**).

2.15.2.6.1.4.1.4 Estimation of wear scar volume

Using the wear scar profilometry data an estimation of wear scar volume can be made using the spherical cap method (**Figure 18**). Again, the overall trend is that of the results presented so far in this section in that the processed materials

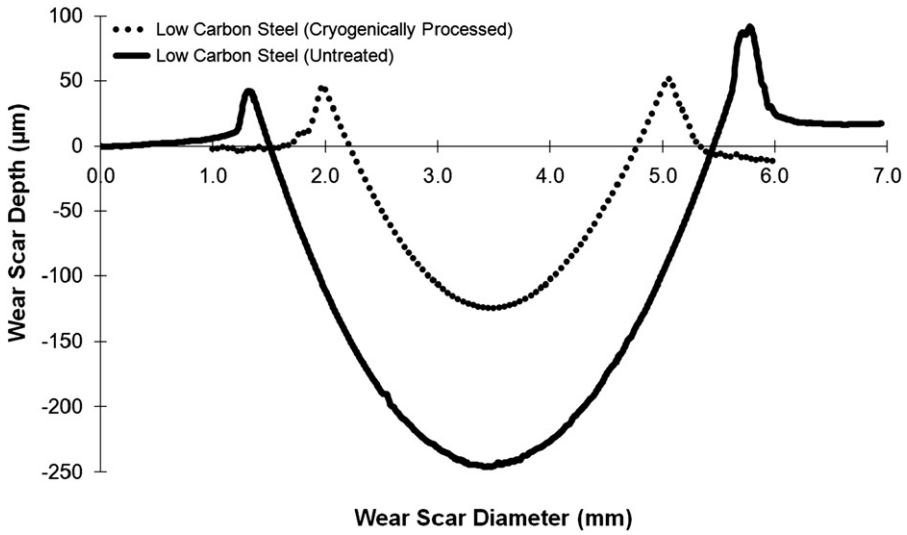

Figure 16 Profiles of wear scar on untreated and cryogenically processed low carbon steel specimens after 72 000 impacts.

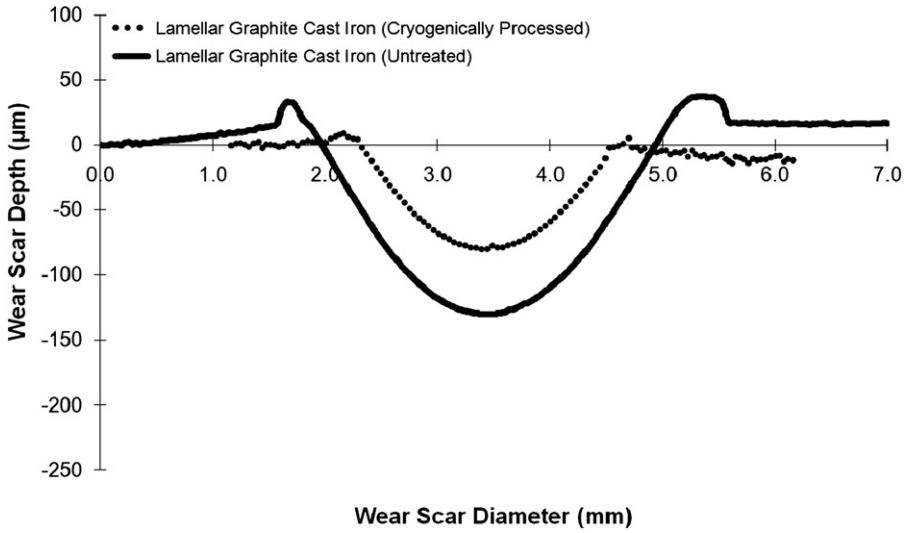

Figure 17 Profiles of wear scars on untreated and cryogenically processed lamellar graphite cast iron specimens after 72 000 impacts.

exhibit improved resistance to impact. The cast iron has the greatest change in wear volume between the untreated and treated specimens. Given the magnitude of measured error for these particular results it seems likely that there is a microstructural reason for this rather than simply experimental variance, however a detailed microstructural analysis would need to be performed.

2.15.2.6.1.4.1.5 Comparison with a 'traditional' heat treatment process

Figure 19 compares the estimated wear scar volumes for the lamellar graphite cast iron specimens presented here with those estimated during work on laser hardening of lamellar graphite cast iron.[19] For clarity, only the results for the 72 000 impact tests are included. As part of that investigation, lamellar graphite cast iron specimens were subjected to laser transformation hardening in an attempt to improve their resistance to impact wear. Several different sets of laser operating parameters, primarily energy density and speed, were used when treating the cast iron specimens and these induced different levels of localized phase transformations in the surface of the material. These specimens were then subjected to identical tests as those described earlier. The best performing laser treated cast iron specimens exhibited similar levels of wear to the best performing cryogenically processed cast iron specimens tested for the work presented here. It appears that the potential of improving the wear resistance of lamellar graphite cast iron is similar to that of more classical heat treatment in the form of the laser hardening process.

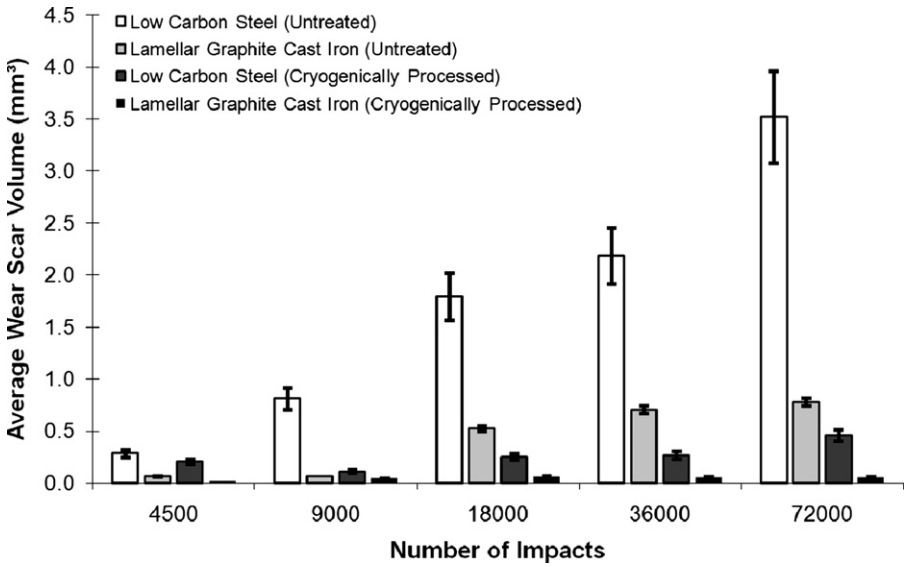

Figure 18 Average wear scar volume vs. number of impacts.

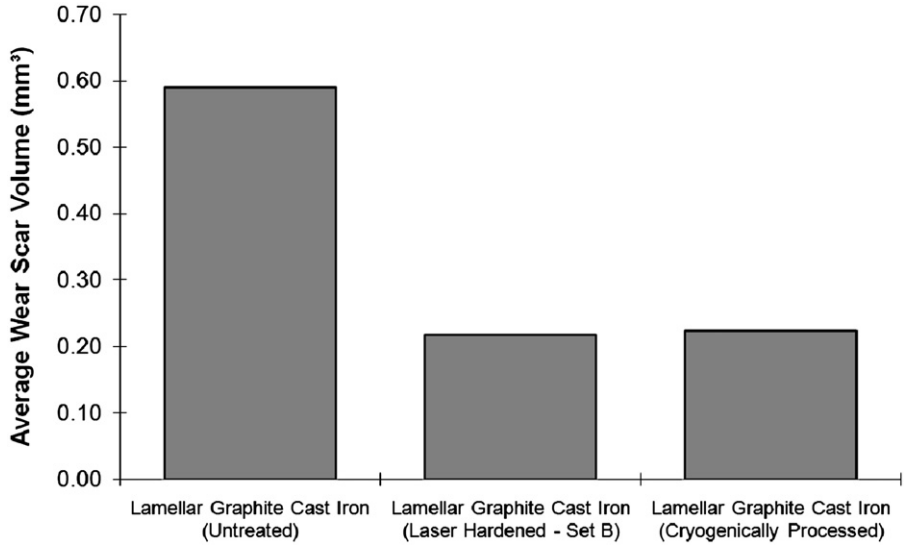

Figure 19 Comparison of wear scar volume for lamellar graphite cast iron specimens subjected to 72 000 impacts.

2.15.2.6.1.5 Summary

This case study shows that cryogenic processing can have a positive effect on the wear resistance of Fe–C alloys. It also demonstrates how relatively similar materials respond differently to the same treatment. The low carbon steel that was tested using the impact wear test rig showed some improvement to its ability to resist impact wear but more investigation would be required to confidently say if the improvement was 'significant' as described in the literature.[1] The lamellar graphite iron also showed improvement in its ability to resist impact wear and the general level of improvement was greater than the low carbon steel.

In general, the wear mechanisms observed in all specimens were as typically found in impact wear studies. Where there is a high impact velocity, which is considered to be the case throughout this work, and therefore high impact energy, if there is a soft material in the contact plastic deformation occurs with ductile extrusion away from the contact. This was observed particularly in the untreated specimens subjected to 72 000 impacts and, as can be seen in **Figure 16**, the low carbon steel specimen exhibits large shoulders as a result of the plastic deformation. The 'softer' material, the steel (**Figure 9**), exhibited smooth wear scar edges that further support the presence of this wear mechanism.

This case study also illustrates one of the difficulties of assessing cryogenically treated materials as it is clear that much more data would need to be collected to have a high level of confidence in the performance improvements seen and their subsequent repeatability. This would reveal any unknown artefacts of the test procedure, such as changes in the loading conditions, even though the measured variance is small. Similarly, small microstructural flaws in the material, coincident to the loading of those particular specimens, could suddenly accelerate the wear process.

2.15.2.6.2 Sliding wear resistance of pearlitic brake disk materials

2.15.2.6.2.1 Introduction

This case study reviews investigations concerning the influence of cryogenic treatments on the sliding wear resistance of hypo-eutectoid pearlitic carbon steel and lamellar graphite pearlitic cast iron brake disk materials.[35,40,57] These have been selected because, although they are commonly commercially cryo-treated components, there is almost no coverage of them in the scientific literature. As anecdotal commercial evidence suggests cryogenic treatments may substantially increase the life of these components, preliminary tribological studies and microstructural observations were conducted in an attempt to provide some scientific verification.

2.15.2.6.2.2 Requirements of brake rotor materials

Brake rotors are invariably required to withstand a range of conditions, which are strongly influenced by their specific applications. In light goods vehicles (LGVs), sports cars, whether used for motor racing, locomotives, or aircraft, brake rotors need to provide consistent performance throughout their design life. Composites and light alloys offer a range of benefits including weight saving and therefore reduced fuel consumption,[60] high performance at extreme loads and temperatures,[61] as well as improved thermal stability.[62]

Nonetheless, traditional materials such as-cast irons and plain carbon steels still dominate markets in terms of volume produced, due to their low cost, ease of manufacture and good machinability, as well as a high heat capacity which lends itself to thermal stability. These factors are crucial as brake disks must absorb the vast majority of the kinetic energy of the vehicle during braking, much of which is inevitably converted to heat. Even in typical LGV applications, brake disk temperatures may reach 700 °C.[63]

Furthermore, the parameters of braking cycles vary significantly. Typical LGV brake rotors may be subjected to longer applications of low braking forces (to gently slow and stop the vehicle) while racing cars will exert very high braking loads for short periods of time on their braking systems. Temperature requirements for motorsports brake rotor materials are therefore substantially higher, hence the wide use of ceramics and composites. Conversely, brake rotors for domestic vehicles are expected to have long fatigue lives (often as long as the life of the whole vehicle); therefore steels and cast irons are still desirable.

2.15.2.6.2.3 Experimental details

The commercial brake disk materials selected for this study were SAE J431 G10 (a lamellar graphite cast iron) and AISI 1050/EN10083 C50R (a medium carbon steel). Material compositions are given in **Table 16**.

The brake disk materials were tested as finished rotors (with modifications made away from the wear track to fit them to the test rig). Their surfaces had a machined finish with a roughness of around 2.5 µm. Both materials had pearlitic–ferritic microstructures while SAE J431 G10 also contained lamellar graphite flakes and sulfide inclusions.

All specimens were subjected to the same deep cryogenic treatment cycle, illustrated in **Figure 20** and summarized as: cooling at 1–2 K min^{-1} to 93 K, soaking for 24 h, heating at 1–2 K min^{-1} back to ambient temperature with a low-temperature stress relief cycle conducted at 60 °C for 1 h.

The testing program involved Vickers macro- and micro-hardness tests (20 kgf/196.2 N and 0.05 kgf/4.905 N, respectively), pin-on-disk sliding wear testing using a Plint TE99 (BICERI/Eyre) Universal Wear Testing Machine (**Figure 21**) 15 mm diameter hardened AISI 52100 chrome steel balls (**Table 17**), volume-loss wear measurements using measurements made with a 2D stylus profilometer (**Figure 22**) and subsurface microstructural observations using optical and

scanning electron microscopy. Given the changes subsequently reported for the pearlitic carbon steel, additional samples were later prepared for transmission electron microscopy.

Sliding wear tests were conducted over a range of initial Hertzian contact pressures and sliding speeds in each case. As it is difficult to replicate realistic brake cycling conditions in a laboratory environment, these were chosen to provide comparative data when a dominant wear mechanism could be clearly defined. In the case of SAE J431 G10 GCI brake rotors, this involved contact pressures of 375.0, 562.5, and 750.0 MPa and sliding speeds of 1.34, 1.78, and 2.24 m s^{-1}. Similarly, C50R carbon steel rotors were subjected to contact pressures of 1000, 1300, and 1600 MPa at a fixed sliding speed of 1.18 m s^{-1}. Optical and scanning electron micrographs were generated from untreated and cryotreated brake rotors not used in testing, to ensure that the observed microstructures were not affected by thermal or mechanical conditions resulting from wear testing.

2.15.2.6.2.4 Results

2.15.2.6.2.4.1 Hardness

While neither the bulk hardness (**Table 18**) or matrix hardness (**Table 19**) of the gray cast iron (G10) material was substantially affected by the cryogenic treatments, the carbon steel (C50R) was shown to respond significantly, with 28 and 17% increases in hardness determined during macro- and microhardness testing respectively.

2.15.2.6.2.4.2 Wear testing

Similarly to the hardness results, wear tests of the G10 and C50R brake rotors displayed very different results. In the case of the GCI rotors, the changes in measured wear rates following cryogenic treatment were highly variable (**Figure 23**) with a weak trend toward increasing benefits of cryogenic treatments in improving wear resistance under higher contact pressures. When changes in wear rates were considered against overall sliding distance (**Figure 24**) another weak trend with an apparent negative correlation between increased wear resistance and longer sliding distances. Optical microscopy of wear scars revealed no dominant change in wear mechanism from predominantly abrasion and pitting.

By contrast, sliding wear testing of the carbon steel brake rotors showed a consistent, if statistically small, increase in wear resistance following deep cryogenic treatment over all the contact conditions tested (**Figure 25**). The mean reductions in wear rate at initial contact pressures of 1000, 1300, and 1600 MPa were 14.4, 12.1, and 22.7%, respectively. However, observations of the worn surfaces (**Figure 26**) revealed no substantial change in the dominant wear mechanism that was, once again, abrasion and pitting.

2.15.2.6.2.4.3 Microstructural observations

In neither case did optical microscopy reveal any obvious changes in microstructure that may explain the observed changes in mechanical performance of either material. Darkfield optical micrographs (**Figure 27**) revealed a mixture of coarse (A) and fine (B) pearlite was the dominant structure in G10 specimens, along with lamellar graphite flakes (C) and manganese sulfide inclusions (small bright spots). In C50R specimens (**Figure 28**) the microstructure again consisted of coarse (A) and fine (B) pearlite interspersed with a smaller number of ferrite grains (C). Scanning electron microscopy allowed these structures to be resolved further, but again did not reveal any obvious microstructural changes due to CT processes.

Given the consistent changes measured in its hardness and wear resistance, the microstructural characterization was continued for the carbon steel (C50R) using transmission electron microscopy to obtain evidence for any change in nanoprecipitation behavior or dislocation structure that may have occurred due to deep cryogenic treatment. The micrographs generated (**Figure 29**) revealed similar nano-precipitates in both untreated and cryotreated samples. These ranged from 50–150 nm hexagonal, to 10–50 nm spherical and tiny

(<10 nm) rod-like precipitates. Observations made along phase interfaces revealed no evidence of change although, qualitatively, there did appear to be fewer dislocations in the cryogenically treated samples.

2.15.2.6.2.5 Summary

This case study illustrates that cryogenic processing can have a significant positive effect on the wear resistance of pearlitic carbon steels, although its influence over lamellar graphite cast irons remains unclear. It also demonstrates the innate difficulty in identifying the fundamental microstructural changes that are responsible, given the need for nanoscopic investigations that are beyond the reach of most providers or users of cryogenic treatment processes. It is also challenging to make representative observations of microstructures on the basis of commercial components, where geometric factors may influence the homogeneity of the structure produced in different regions during manufacturing.

In the case of the cast iron, the differential between rates of thermal contraction of the graphite flakes and adjacent phases may have resulted in damaging stresses being exerted. This, in turn, may have reduced the self-lubricating properties of GCI[64] that are dependent on the shearing of graphite flakes along precise crystallographic planes.[65]

The increases in hardness (>15%) and wear resistance (>15%) for the pearlitic carbon steel tested are significant and support the need for further study, as there are other microstructural changes that remain to be explored. For instance nano-precipitates may have been obscured, in the present study, along grain boundaries or at phase interfaces, while changes in the distribution of dislocations throughout the material may significantly influence its mechanical performance.

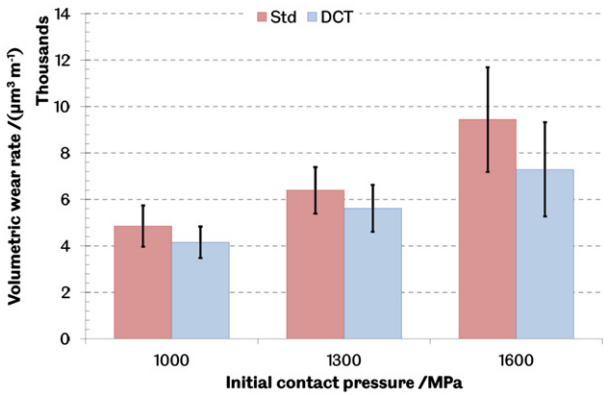

Figure 25 Volumetric wear rates ($\pm 1\sigma$) determined from carbon steel brake pin-on-disk tests.

2.15.3 Cryogenic Processing of Nonferrous Alloys

Considering the wide use of nonferrous metals, particularly in structural applications and machine tools, there is a disproportionate focus on ferrous-based alloys as the target of cryogenic processing research and commercial endeavor. This is probably because much of the early research in this area was driven by tool manufacturers requiring greater wear resistance and the oft-reported 'fact' that cryogenic processing relies on converting the any retained austenite into martensite. That said, light alloys such those based on aluminum, titanium, and magnesium, represent a developing area for cryogenic treatment with a view to minimize the trade-offs that are made in performance at the expense of mass reduction. A much smaller area of focus considers whether cryogenic treatment has potential to be applied to nonmetallic composite materials.

This section identifies the state of the art and trends in performance modification that can typically be achieved by subjecting nonferrous metals to cryogenic processing and then offers a selection of specific examples of its use across the main light alloy families and cobalt-bonded tungsten carbide.

2.15.3.1 State of the Art

When compared to the volume of work conducted to investigate the cryogenic treatments on ferrous materials, the body of work investigating its effect on nonferrous materials is very

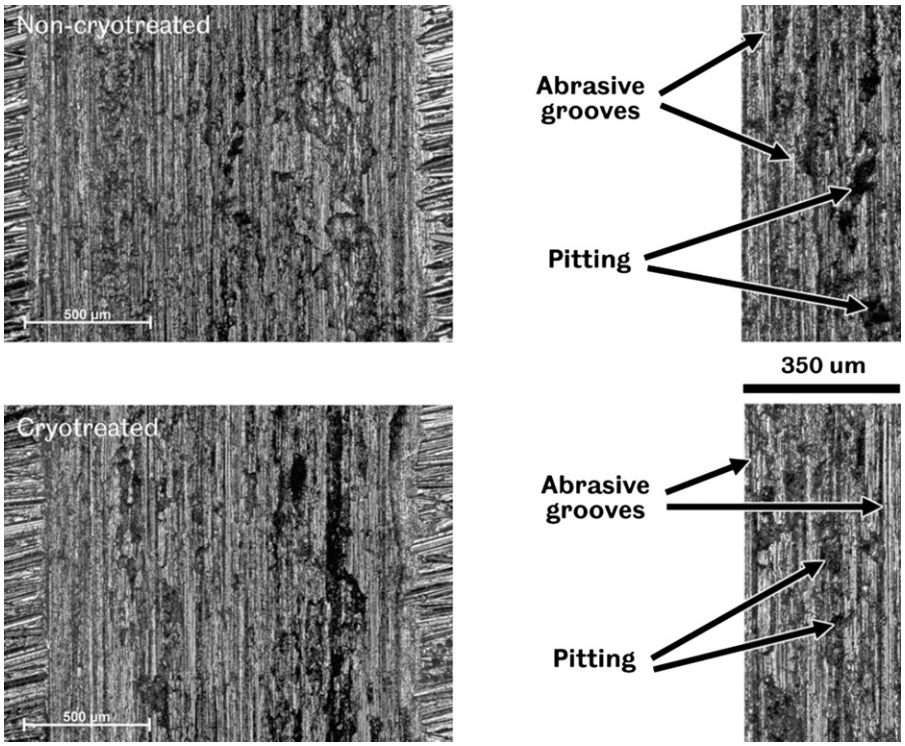

Figure 26 Typical wear scars developed in (top) standard treated and (bottom) cryotreated C50R disks.

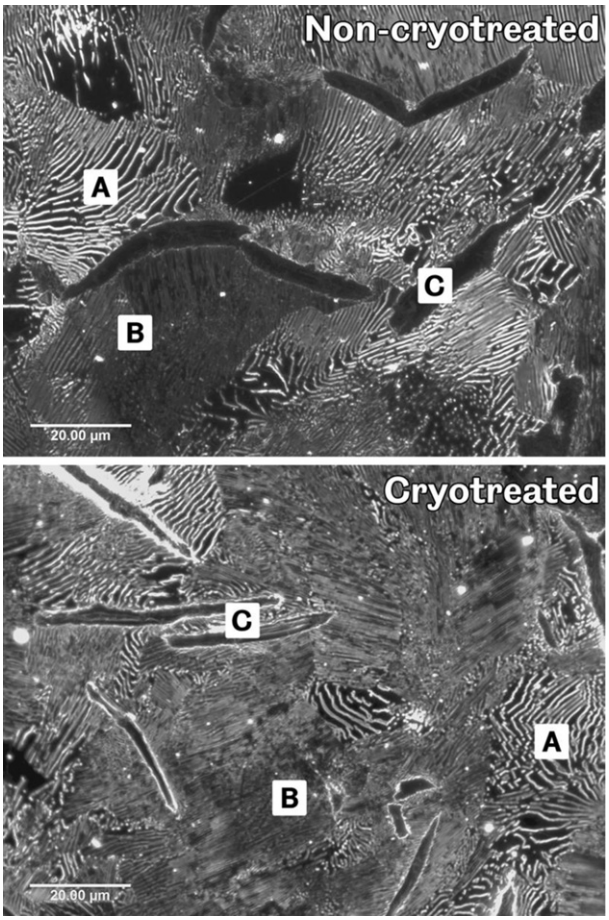

Figure 27 Optical micrographs of non-cryotreated (top) and cryotreated (bottom) SAE J431 G10 material.

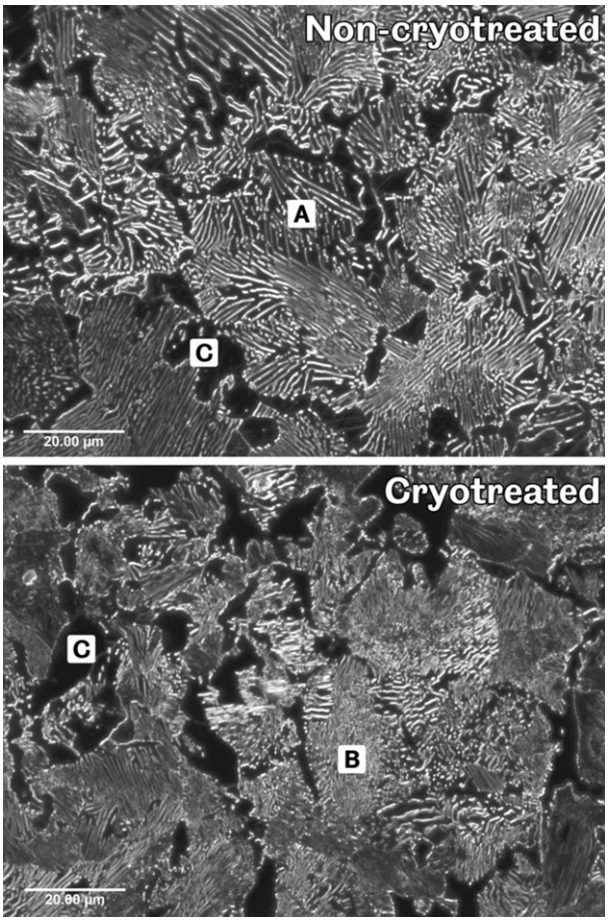

Figure 28 Optical micrographs of non-cryotreated (top) and cryotreated (bottom) C50R material.

small. Much of the effort has been focused on the performance of these classes of materials when used in components that typically operate at cryogenic temperatures (e.g., in space) or their response to being subjected to a manufacturing process that has a cryogenic element to it (e.g., cryogenic machining, rolling, or friction stir welding) rather than a cryogenic treatment process as defined here. The varied but preliminary studies conducted to date clearly demonstrate the need for greater investigations into the effects of cryogenic treatments in light alloys.

The broad approach to investigating the behavior of these materials is similar to that used for ferrous materials; specimens are subjected to a fixed CT process followed by a range of mechanical tests and microstructural analyses.

In the same way that there are common microstructural changes caused by cryogenic treatment to be found across ferrous materials the same is true for nonferrous metals and this is most often described as taking the form of a microstructural refinement of some description. For example, in titanium alloys it appears that cryogenic treatment changes the morphology of β particles which means the now coarse divorced eutectic β phase particles penetrate the matrix and thus strengthen it against crack propagation. Broad observations described as 'refinement of grain size' and 'microstructural stabilization' are also regularly made for many light metal alloys but without conclusive evidence being presented.

These microstructural changes are often presented in attempts to explain changes in the performance of materials subjected to cryogenic treatment that result from common engineering assessments. It is often suggested that the bulk macro-hardness of the material changes and that this is dependent on the parameters of the treatment process, usually the length of the soak at a particular cryogenic temperature. If this is optimized then some materials show potential for an improvement in their hardness, but this is often restricted to an 'apparent hardness increase' reported by users of a treated component rather than a robust laboratory analysis.

Improvement in hardness is often an area of interest because of its role in wear performance. As with ferrous metals, for nonferrous materials to be subjected to contacts across a range of loads and lubrication regimes is an increasingly common occurrence, particularly as component lightweighting becomes more prevalent in the automotive and aerospace industries. The largest gains to date have been seen in magnesium alloys but the process has competition in this area in the form of the much more mature coating technologies. Although the bulk of work carried out to investigate cryogenic processing of nonferrous metals has considered alloys of

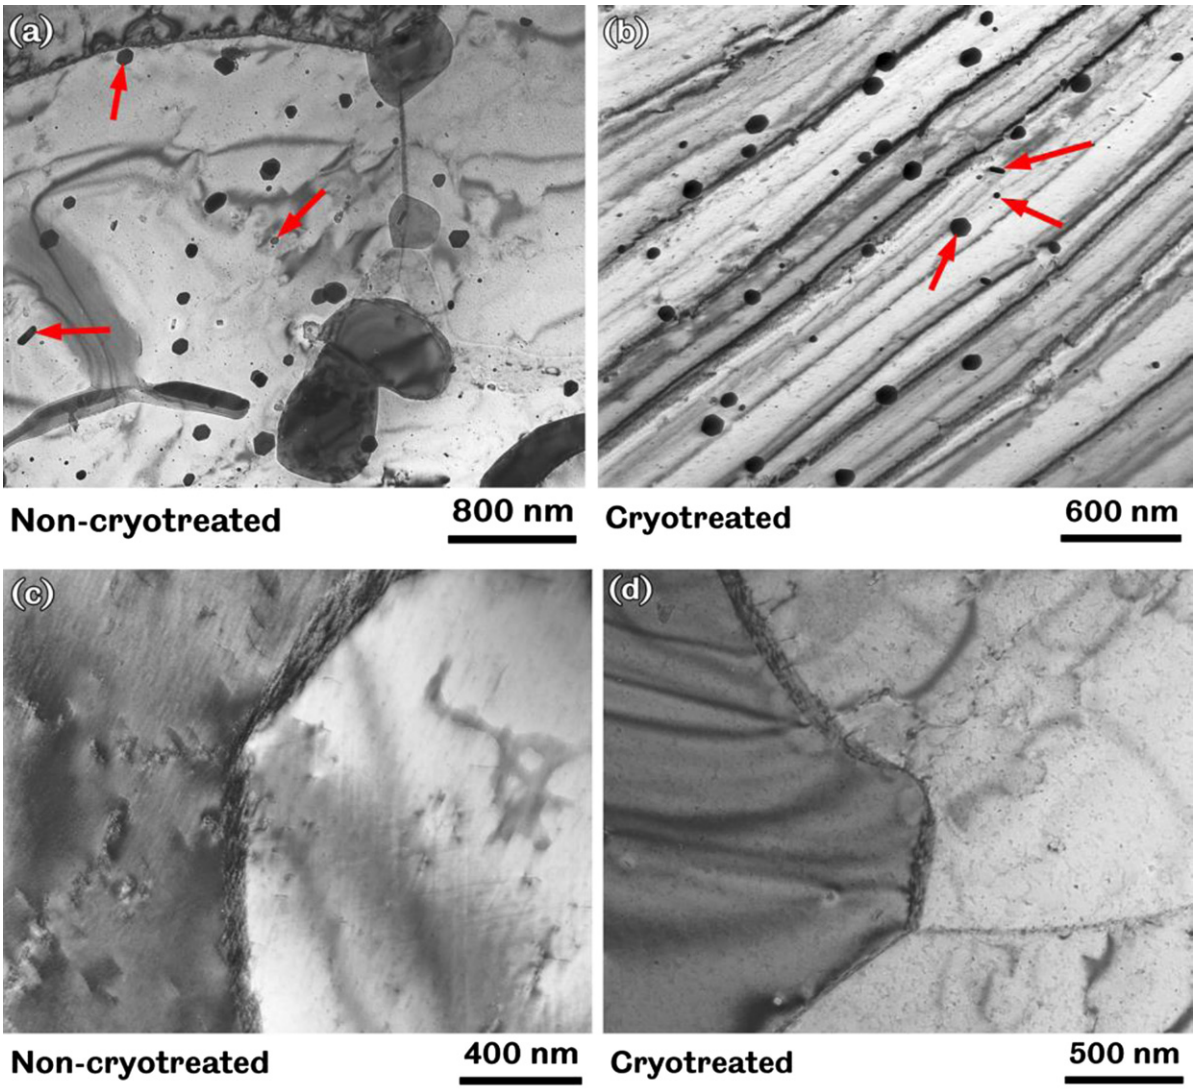

Figure 29 TE micrographs showing: (a) non-cryotreated and (b) cryotreated nano-precipitates in ferrite; (c) non-cryotreated and (d) cryotreated ferrite–ferrite grain boundaries.

aluminum, titanium, and magnesium some consideration has been given to other nonferrous alloys. These studies tend to consider the response of one particular parameter of one particular alloy so therefore it is very difficult to draw any cross-cutting conclusions. Examples of these studies include; the improvement of the thermal conductivity of a proprietary copper alloy[66] and improving electrical discharge machining (EDM) by treating the electrodes.[67] An emerging area is the consideration of cryogenic processing as a suitable treatment for composite materials, particularly those with a metallic component such as metal–matrix–composites (MMCs).[68]

Although a niche area of work, cryogenic processing has also been shown to have beneficial effects on nonmetallic composite materials, such as the PTFE/Kevlar hybrid fabric.[7] Typically used as bearing liner materials due to their tribological properties, PTFE and Kevlar exhibit poor adhesion to the resin binder due to their chemically inert nature. Cryogenic treatment was shown to improve the wear resistance of the hybrid material, with the improvement suggested to be as a result of increased mechanical interlocking of the phenolic resin used, as a result of the fabric roughening at cryogenic temperatures.

2.15.3.2 Aluminum Alloys

As the oft-cited mechanisms behind cryogenic processing are similar to those behind ageing, it seems likely that aluminum alloys that are age-hardenable should also respond to cryogenic processing. Work conducted with a view to investigating this hypothesis on AA6061 discovered that adding a deep cryogenic soak (optimized to be in the range 18–21 h) in between a quenching and ageing treatment had an effect on its performance.[69] When compared to AA6061-T6 the cryogenically processed material had up to three times the hardness and when subjected to a simple milling process showed an improvement in roughness ($1.4R_a$–$0.7R_a$). Both of these effects are attributed to the formation of fine precipitates during the cryogenic

processing. Similarly, AA 6106-T4 subjected to DCT and micro-abrasion tests demonstrated a 26% reduction in wear rate.[70]

Efforts to improve the resistance of aluminum alloys to crack growth, either through fracture or fatigue, have led to attempts to apply cryogenic treatment to these types of materials. A 7075-T651 alloy was cryogenically treated at −196 °C (77 K) caused a 12% increase in the Charpy impact energy, but without any significant change in strength or hardness. It is interesting to note that specimens held at their soak temperature for 2 h showed no significant improvement, whilst those treated for 48 h did, indicating a time-dependent microstructural change is likely responsible.[71]

Research attempting to improve the wear resistance of aluminum overhead conductor suspension clamps recorded a 20% increase in the lifespan of the conductor wire material along with a reduction in damage to the suspension clamps. This was judged to have occurred as a result of an increase in 'ultra-fine distributed precipitates' following cryogenic treatment.[72]

This effect and the inhibiting effect of increased dislocations following cryogenic treatment are discussed by Wang *et al.*[73] in their study on the effects of cryogenic pretreatments on the mechanical performance of friction-stir-welded joints in 2024-T351 aluminum alloy. In testing, they observed improved elongation before fracture in samples having undergone cryogenic treatment.

2.15.3.3 Magnesium Alloys

The recent trend for lightweighting engineering components in the aerospace and automotive sectors has seen a significant increase in the use of magnesium alloys because of their low relative density. In automotive components, where it is beneficial to reduce rotating/moving mass, there are many sliding contacts where wear resistance is critical. As one of the generally cited benefits of CT is to improve wear resistance, it seems worthwhile to attempt to apply it to magnesium alloys. Similarly, although many magnesium alloys have adequate creep resistance at ambient temperatures, their limitations are quickly reached at the elevated temperatures found in automotive powertrain components. As one might expect with its near universal use when a magnesium alloy is specified AZ91, particularly because of its castability, is commonly used as the material to be treated.

Studies investigating the effects of cryogenic treatment on AZ91 magnesium alloy have observed improved wear resistance after DCT at −196 °C (77 K).[74] A >60% reduction in wear rate of an Mg–Zn–Gd alloy following deep cryogenic treatment by direct immersion in LN_2 have also been achieved. Following treatment, the alloy was observed to contain a substantially greater volume fraction of secondary phase particles, to which the increase in wear resistance was attributed, and it had changed from a disordered solid solution to an ordered solid solution.[75]

Efforts to improve the creep resistance of AZ91 magnesium alloy by using a cryogenic treatment have resulted in improved wear resistance after DCT at −196 °C (77 K).[74] The improved creep behavior was attributed to morphological changes which prevented grain boundary sliding at high temperatures.

Tests to determine the tensile properties of an extruded Mg–Gd–Y–Zr(Mn) alloy at cryogenic temperatures have shown a significant increase in tensile strength, yield strength, and elongation before fracture, which is attributed to the precipitation of a large number of 'rod-like, tree-like, and chrysanthemum-like' features within the microstructure. While direct immersion in LN_2, or CQ may lead to thermal shock and brittleness of materials, these investigations seem to show that the microstructural changes due to DCT may have a more significant effect on the performance of a material.[76]

It appears that there is at least some degree of consensus about the mechanism behind observable mechanical improvements that can be made to magnesium alloys using cryogenic processing.

Tests on AZ31 magnesium alloy[77] subjected to range of DCT soak times (2–48 h) using electron microscopy techniques and pole figure analysis suggest that cryogenic processing causes changes in grain orientation. This change is attributed to a frame-like twinning process and results in a reported increase in hardness and tensile strength but this improvement is highly dependent on the length of the soak. This means that any specific application would need optimizing to ensure repeatable results.

Similar work on AZ31, and also ZK60, shows that there are changes to the grain orientation accompanied by second phase precipitate strengthening[78] again resulting in reported improvements in hardness and tensile strength. A more quantitative analysis[79] adds to these findings by stating that for AZ91 the sizes of the precipitates are refined from 8–10 μm to 2–4 μm. It has also been suggested that, in the case of AZ91 in particular, the improvement in hardness is facilitated by the aluminum atoms jumping to defect sites as the material contracts at low temperature[80] and then forming the basis for nucleation of precipitates during the final aging process.

2.15.3.4 Titanium Alloys

There is very little known about the effect that cryogenic processing has on titanium and its alloys. This is due to the general understanding that cryogenic processing is a 'heat' treatment and that commercially available titanium alloys are not amenable to thermal hardening. Some research has attempted to investigate the effect of CT on titanium alloys but the results are inconclusive and are often arrived at obliquely during research not directly considering the problem.

In dentistry, nickel–titanium alloys are commonly used as an alternative material to stainless steel for endodontic tools which are used to remove material during root canal therapy. CT of these types of instruments results in a small increase in measureable micro-hardness, but no apparent 'hardness' improvement when used clinically,[81] or in their wear resistance.[82]

What can be broadly described as 'materials at low temperature' research, such as conducted by the space community, often produces insight that crosses over into cryogenic processing. Mechanical tests performed on a Ti–2.5Cu alloy immersed in LN_2 at temperatures of 77 K found that that both the ductility and low-cycle fatigue life of the alloy was improved.[83] It was concluded that nano-scale precipitates

hinder the movement of dislocations, thereby preventing crack formation.

Commercial alloy grades of titanium, such as Ti–6Al–4V, are commonly used in components where they are subjected to tensile loads. CT has been used to modify the plasticity of Ti–6Al–4V and, when combined with a suitable ageing process, this can be improved by >20% with no change in microhardness but at the expense of some (5%) reduction in tensile strength. It is suggested that this improvement is due to the CT reducing the β phase content of the material thus decreasing the resistance to dislocation movement. The combination of CTs and aging treatments appears to cause the formation and interaction of dislocation networks, resulting in the formation of twins within the microstructure.[84]

Due to their low shear modulus, titanium alloys regularly undergo surface engineering (usually a deposition-type coating) when they are subjected to sliding contacts. Cryogenic processing has potential to be used in lieu of a coating for these applications and it has been reported that DTC can produce a slight increase in hardness, due to grain refinement, giving improved resistance to sliding wear. It has also been reported that the increase in hardness is linear with soak temperature and soaking time.[85]

Due to their reputation as 'difficult to machine' materials titanium alloys have been the focus of a significant proportion of the development of cryogenic machining. There has been a considerably less effort expended investigating the potential of cryogenically processing the material prior to processing using conventional machining techniques (i.e., non-cryogenic machining).

Due to its high electrical resistivity, titanium is difficult to process using EDM techniques. Many avenues (such as ultrasound assisted EDM, dry EDM, and indeed cryogenically cooling the electrode) have been explored to improve the efficiency of EDM for titanium alloys, including cryogenically processing the workpiece prior to machining operations being performed. A 24 h DCT soak has been found[86] to improve the machinability of Ti 6246 by allowing up to 8.5% improvement in material removal rate in an EDM drilling operation. Claims for EDM operations using proprietary titanium alloys producing greater improvements have also been made.[87]

The wear rate of the tool is also a significant consideration in EDM processes and this was reduced by around 30%. The surface roughness measured inside the holes improved by up to 10%. It is suggested that these improvements are as a result of the reduction in electrical resistivity and conductivity (as measured using a standard four probe setup) but it is unknown how the cryogenic processing causes this change in a titanium alloy.[86]

2.15.3.5 Cobalt-Bonded Tungsten Carbides

In the last decade, attention has partly shifted from the application of cryogenic treatments to tool steels, to its application to sintered, cobalt-bonded tungsten carbide tool materials. These materials (often referred to as 'hardmetals' or 'cermets') are inherently harder and more wear resistant, with greater thermal stability, and are therefore commonly used for high volume manufacturing operations. When combined with appropriate coatings they can sometimes be used in high-speed machining and hard machining operations as well.

Although very minimal work has been done to characterize the mechanical properties of cryogenically treated sintered carbides to date, alongside a variety of tool wear and tool-life studies the hardness of these materials has been reported. Summarized in **Table 20**, it can be seen that the hardness changes reported are far more moderate than those reported for tool steels. However, these data suggest that cryogenic treatments may significantly improve the hot hardness[88] of

complex WC–Co alloys, while only shallow cryogenic treatments (163–193 K) may be required[89] for this to happen.

Due to their prevalence as cutting tools, and the relative difficulty with which laboratory samples can be made from sintered carbide materials, the majority of studies to date have focused on tool-life and tool wear. The results from these have generally indicated benefits to the application of cryogenic treatments, as summarized in **Table 21**. However, as might be expected and supported by observations made by the present authors,[92] increases in hardness and predominantly abrasive wear resistance is typically accompanied by a decrease in toughness. In the case of cutting tools this may lead to more unexpected catastrophic failures if the material properties are not properly characterized and cutting parameters adjusted accordingly.

Generally speaking, it has been reported that cryogenic treatment diminishes the adhesion strength of common tool coatings (such as TiN and (Ti, Al)N) resulting in an overall decrease in tool-life,[93] although cryogenic treatment has consistently been found to improve the tool-life of uncoated carbide tools.[94] The reason for this weakening of the interface between coating and substrate is thought likely to be due to the difference in thermal contraction between the two materials during cryogenic treatment.

During cutting operations, tools are subjected to high temperatures and therefore it is important that any changes as a result of a heat treatment or coating process are stable at those temperatures. A good indicator of this is the relative performance of tools under dry and wet, continuous and interrupted machining processes – the latter conditions leading to greater cooling and lower temperature rises in the tool material.

Based on the studies of Yong *et al.*[95] and Gill *et al.*[96] (**Figure 30**), it appears as though at least some of the changes resulting from cryogenic treatments are not thermodynamically stable. Yong *et al.* reported that the improvement in tool-life due to deep cryogenic treatment could be increased by 10% when milling a medium carbon steel with coolant, as opposed to without. During turning operations, Gill *et al.* observed that

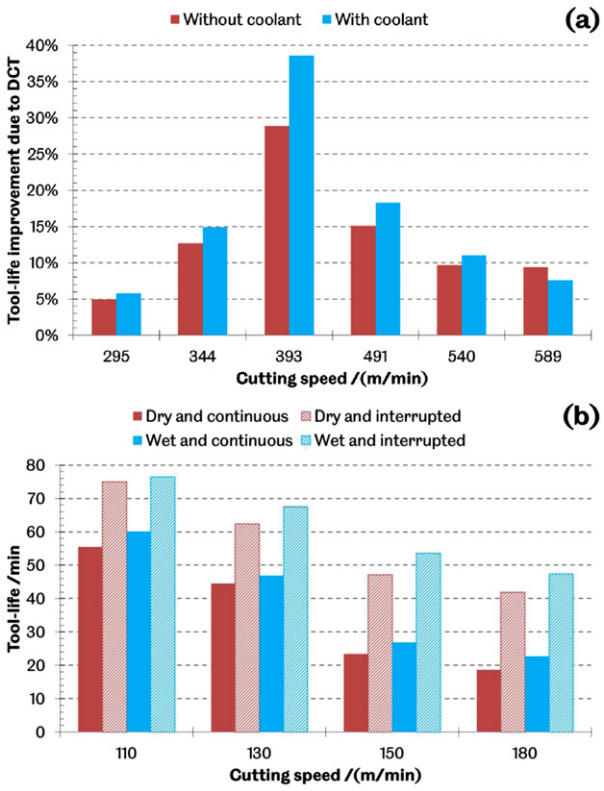

Figure 30 Influence of cutting conditions on performance of cryotreated WC–Co cutting tools[57] based on studies by (a) Yong *et al.*[95] and (b) Gill *et al.*[96]

interrupting the cutting process (disengaging the tool from the workpiece) was more effective in prolonging the life of cryo-treated tungsten carbide inserts than by using coolant.

Numerous process factors influence the properties of WC–Co materials, with the physical effects responsible tending to concern the concentration of cobalt binder or carbon near the surface, compressive stresses induced in the WC phase due to cobalt hardening, and the precipitation of fine eta-phase carbides. Reported microstructural changes due to cryogenic treatments are often not backed up by robust characterization techniques and are sometimes contradictory. For instance the shrinkage/densification of the cobalt binder,[91] enlarging of the carbide grains[88] and resulting in fine eta-phase carbide precipitates[88,90,97] have all been suggested to play a role.

In a particular study of note, Gisip *et al*. performed a series of energy-dispersive X-ray spectroscopic analyses at increasing distances from the edges of flouted router bits used to machine medium-density fiberboard. Their chemical analysis illustrated a significant reduction in the rate of removal of binder phase and carbide grains from the surface following cryogenic treatment. There was also less tendency for high-temperature oxidation and corrosion to occur.

The range of tool-life and tool wear studies available for cobalt-bonded tungsten carbides paints a compelling picture that cryogenic treatments can offer significant benefits. However, to date, the explanation from rigorous microstructural studies are lacking, thus preventing more widespread adoption of the technique.

Acknowledgments

The authors wish to acknowledge the assistance of Cryogenic Treatment Services Ltd. (UK) (http://www.195below.co.uk/) for carrying out the deep cryogenic treatment on the specimens and the Materials Engineering Research Institute (MERI) at Sheffield Hallam University (UK) (http://www.shu.ac.uk/meri) for the use of their facilities to capture a number of the wear scar images used in the case studies presented.

EDITOR-IN-CHIEF

Saleem Hashmi is emeritus professor in the School of Mechanical & Manufacturing Engineering at Dublin City University, Ireland. He founded the School in January 1987, in addition to setting up the Materials Processing Research Centre (MPRC), a research centre of excellence in the field of materials processing.

In 1990, Professor Hashmi established Advances in Materials and Processing Technologies (AMPT), a much-needed international conference in materials processing. He continues to be the chairperson of the steering committee for this series of conferences. In 1998 he was appointed as editor-in-chief of Elsevier's *Journal of Materials Processing Technology* and continued in this role until 2008.

In 1995, Professor Hashmi was awarded the higher doctorate degree of DSc, by the University of Manchester, the highest academic degree any university in the UK can award.

Professor Hashmi has supervised or co-supervised 112 PhD and 55 MEng research students to successful completion. Over the years he has also acted as an external examiner and expert assessor for PhD candidates and engineering departments with universities in Ireland, the UK, India, Pakistan, Bangladesh, Hong Kong, Canada, Australia, and Malaysia. He has published in excess of 460 papers and 25 books so far.

Professor Hashmi was the editor-in-chief for Elsevier's 13-volume major reference work *Comprehensive Materials Processing* which was published in 2014.

He has been appointed as the editor-in-chief for Elsevier's *Materials Science and Materials Engineering Reference Module*, a 14-section online resource comprising around 3500 reviewed articles. This launched in December, 2015 and is constantly being updated.

VOLUME EDITORS

Imtiaz Ahmed Choudhury is currently a professor at the Department of Mechanical Engineering, University of Malaya (UM), and has been with UM since 1996. He received his Bachelor degree in Mechanical Engineering from Bangladesh University of Engineering and Technology (BUET), MEng from Asian Institute of Technology (AIT), Thailand, and MSc in Mechanical Engineering from Arizona State University, USA. He obtained his PhD from Dublin City University. He started his career as an assistant engineer in a gas transmission and distribution company, Dhaka, Bangladesh. He worked as a maintenance engineer in a power station for 3 years in Libya. He started his academic career in 1982 as an assistant professor in an engineering college, Bangladesh. Since then, he has been working in academia. Imtiaz's research interests include traditional/nontraditional machining with vegetable oil-based lubricant, tool condition monitoring, machining difficult-to-cut and high strength materials, injection molding and application and use of solar energy. He has been a member of a panel of judges for the SME innovation award 2011–2013, Malaysia, under the category of "Manufacturing Sector." He was a Senate member of the University of Malaya. He has authored and coauthored about 100 papers in referred journals, more than 60 conference papers and some book chapters published in Elsevier works. He has also been a reviewer of various international journals. Imtiaz is a Fellow of Institution of Mechanical Engineers, UK (IMechE), and a life Fellow of Institution of Engineers, Bangladesh (IEB). He is a chartered engineer, UK (CEng).

Professor Shahjahan Mridha was born in Bangladesh and obtained his BSc and MSc in Metallurgical Engineering at the Bangladesh University of Engineering & Technology (BUET), Dhaka, and PhD at the University of Leeds in UK (1980) on Gas Nitriding of Low Alloy Steels. Since 1972 he has worked at the Department of Metallurgical Engineering, BUET for 20 years as a faculty member except for 1986–1987 where he was a Commonwealth Academic Staff member at the University of Birmingham, UK, working on Plasma Nitriding.

Professor Mridha was a senior research fellow at the University of Strathclyde, UK from 1989–1994 and worked on laser processing of aerospace materials in collaboration with UK Ministry of Defence. In late 1994 he moved to Nanyang Technological University (NTU) in Singapore where he was employed as an associate professor until 2001, working on semiconductor materials, composite and intermetallic coatings.

In January 2002 he joined the International Islamic University Malaysia (IIUM) as professor, later assuming the position of Head of the Department of Manufacturing and Materials Engineering. He left IIUM in July 2012 to join the Department of Mechanical and Aerospace Engineering at the University of Strathclyde (UK) as a Leverhulme Trust Professor, and remains there presently as visiting professor.

Professor Mridha has published more than 150 journal and conference papers. His research contributions are primarily on microstructure–properties relationships, semiconductor materials and surface modification of light alloys and steel using high power laser and TIG torch melting technology. He is the pioneer of TIG torch techniques for surface coating applications. Professor Mridha is subject editor of the *Metallic Materials* section in Elsevier's *Reference Module in Materials Science and Materials Engineering* launched in December 2015.

In addition to his academic career, Professor Mridha worked as an international consultant for the United Nations Industrial Development Organization (UNIDO) from 2001 until 2007, delivering expert advice and training to engineers working in manufacturing industries in the Indian and African continents.

Bekir Sami Yilbas is a distinguished professor in the Mechanical Engineering Department, King Fahd University of Petroleum and Minerals, Saudi Arabia. He received his PhD in Mechanical Engineering from Birmingham University, and was awarded a doctorate of Engineering at Birmingham in 2005 due to his significant contribution to his field of study. He has received numerous awards as recognition of his research work. Some of these include President of India's Prize for 1988 by Indian Royal Engineering Society, Technology Prize for 1990 by Science and Technology Foundation in Turkey, Best Research Award for 1997, 2002, 2007 by King Fahd University of Petroleum and Minerals, Silver Jubilee Medal by Silesian University of Technology, Donald Julius Groen Prize for 2007 by Institution of Mechanical Engineers (IMechE), Distinguished University Professor award at King Fahd University of Petroleum and Minerals, 2008 – present by King Fahd University of Petroleum and Minerals, Professor W. Johnson International Gold Medal for 2008 by Advances in Materials and Processing Technologies (AMPT) Steering Committee, Professor Fryderyk Staub Golden Owl Award by World Academy of Metals and Manufacturing, Almarai's Distinguished Scholar Prize by King Abdulaziz City of Science and Technology.

Bekir Sami Yilbas has published 720 journal papers in reputable international journals and presented over 100 papers at international conferences. He has 12 patents issued and is the subject editor of *Arabian Journal of Science and Engineering* and editor of *Journal of Fluids*. He has served as an editorial board member of international journals, including the *International Journal of Machine Tool and Manufacture Design, Research and Application, International Journal of Subsurface Sensing Technologies and Applications, Journal of Materials Processing Technology, Journal of Achievements in Materials and Manufacturing Engineering, International Journal of Nanomanufacturing*, and *Archives of Materials Science and Engineering*, and has received numerous awards as recognition of his research work.

Index 381

PREFACE

Finish manufacturing processes are final stage processing techniques which are deployed to bring products to a stage where they are ready for marketing and putting in service. Over recent decades, a number of finish manufacturing processes have been developed by researchers and technologists. Some of these new processes have been documented and illustrated both individually and collectively in relation to application in specific areas. The advancement of tools of physics has resulted in considerable changes to these processes, and the precision with which they can be applied. The reporting of these developments are sometimes fragmentary, and this reference work provides a more connected and thorough review of these processes.

Comprehensive Materials Finishing is the primary reference source for researchers at different levels and stages in their career both in academia and industry. This reference work encompasses the knowledge and understanding of many experts into a single, comprehensive work. Containing a combination of review articles, case studies, and research findings resulting from research and development activities in both industrial and academic domains, this reference work focuses on how some of these finish manufacturing processes are advantageous for a broad range of technologies. These include applicability, energy and technological costs, and practicability of implementation. A wide range of materials such as ferrous, nonferrous, and polymeric materials are covered.

This work details the three foremost and distinct types of finishing processes: surface treatment, finish machining processes, and surface coating processes. Surface treatment refers to properties of a material being modified without otherwise changing the physical dimensions of the surface. Finish machining processes involve a small layer of material being removed from the surface by various machining type processes to render improved surface characteristics. Surface coating processes are where the surface properties are improved by adding fine layer(s) of materials with superior surface characteristics to improve the service life of the surface being coated. Each primary surface finishing process is presented in a separate volume, comprising chapters on many of the following relevant specific processes as follows:

Volume 1: Finish Machining and Net-Shape Forming: developments in conventional finish machining processes (honing, lapping, polishing, burnishing, and deburring), fine grinding, free EDM, laser finishing, electrical discharge grinding (EDG), electro-chemical honing (ECH), electrochemical discharge grinding (ECDG), electrochemical grinding (ECG), electrochemical turning (ECT), micro-machining process, and high-speed machining.
Volume 2: Surface and Heat Treatment Processes: This contains aspects of heat treatments, stress relieving, annealing, normalizing, hardening, tempering, austempering, martempering, carburizing (pack, liquid, gas, and post carburizing treatments), nitriding (gas and plasma), salt bath (boriding, chromizing, cyaniding, and carbonitriding), phase transformation of the outer surface (induction, flame, laser, electron beam, and anodizing).
Volume 3: Surface Coating Processes: Plating (electroplating, alloys (bronze/brass and others), chromium, dense chromium, copper and tin, gold, silver and other precious metals, zinc and nickel, electroforming, electroless nickel, hot dip galvanizing, selective/brush plating, surface finish coatings, air spray painting, and chemical vapor deposition (CVD)).

Finishing processes are at the core of successful production of marketable products and address recent progress in materials finishing technologies and science as well as covering recent developments in specific manufacturing processes involved with finishing of products for applications in all areas of engineering, biomedical, environmental, health and safety, and monitoring and control. The in-depth study of these finishing processes as presented in these volumes will assist scientists and engineers in the selection, design, and usage of materials, whether required in small- or large-scale uses across industries.

The initiations for this project began in 2014 and by January, 2015, I had selected the volume editors – Bekir Yilbas, Imtiaz Choudhury, and Shahjahan Mridha and we met with Gemma Tomalin, Joanne Williams, and Graham Nisbet at the Elsevier office in Oxford to finalize the table of contents and plan the project. Throughout 2015, the volume editors and I worked resolutely to select topics to be covered, invite authors, and review their manuscripts, eventually getting all content ready for production by the end of 2015. In 2016, authors returned their proof corrections and final files were produced. To create a work of this scale, the most in-depth reference ever published on materials finishing processes and surface engineering, relies on a collaboration of authors, editors, and the team at Elsevier. I would like to thank the many dedicated authors, whose contributions will be an essential reference for materials scientists and engineers. Each chapter has been reviewed by one of the volume editors, leading experts in their fields, whose knowledge and expertise have proved invaluable. I am indebted to each volume editor and their dedication to making their volume an exhaustive and relevant resource for the scientific community for many years to come. Finally, on behalf of myself and the volume editors, I would like to thank Gemma Tomalin and Joanne Williams at Elsevier for their support, cooperation, and good humor throughout this project – from the first meeting in early 2015, to the publication mid-2016.

MSJ Hashmi
Editor-in-Chief
Dublin City University, Dublin, Ireland

INTRODUCTION TO SURFACE COATING PROCESSES

Surface finish plays a major role in manufacturing processes. A high-quality surface finish is one of the key parameters determining whether the parts being manufactured will be accepted or rejected. In addition, surface finish becomes critically important when many parts are assembled to form a final product. There are several methods to produce the desired surface finish; however, the cost, ease of operation, precision, and local effects are the main concerns for the selection of the processes to achieve the desired surface finish. Although some methods appear to be the only solution to meet the required surface finish criteria, the large-scale production of such surfaces limits the practical applications of these methods. In addition, after effects of the process, such as reduction in fracture toughness, residual stress formation, surface hardness alteration, and nonuniform distribution of elemental composition, are the common concerns during selection of the processes. When surface treatment involves thermal processing, such as high energy beam interaction, formation of high residual stresses becomes unavoidable because of the high temperature gradient formed in the surface vicinity. However, introducing an annealing process to reduce residual stresses may not be applicable for certain surfaces because of alteration of the surface finish, such as highly textured polymeric surfaces; in some cases, it requires state-of-the-art equipment and dedicated human power, which in turn increases the treatment cost. However, electrical and chemical processes involve local alteration of surface chemistry and, in some cases, cause modification of the elemental composition of the surface. Although an electropolished surface is essentially balanced, the local galvanic differences caused by polishing give rise to stress formation in the surface region. In addition, the surface peaks can be dissolved earlier than the valleys of the surface because of the variation in the current concentration over the protrusions. This, in turn, results in rounding of the surface profile. Nevertheless, surface finish and the associated processes are still in progress and require further research studies to meet the desired quality with minimal environmental hazards.

In general, three main characteristics of the surface are considered when measuring the surface finish of the substrate materials: lay (form), surface roughness, and waviness. Although these characteristics are critically important for practical applications, surface roughness and waviness become crucial for reducing friction on the surface. In bearing applications, frictional losses play a major role in energy loss due to heat dissipation. In addition, they have detrimental effects on the bearing potential of the surface once the surface roughness increases due to surface scratches under a dynamic load. In some cases, stick-slip friction can take place during the sliding action of bearings, which also depends on surface finish. Therefore, friction and wear conditions depend greatly on the surface texture parameters. Contact and noncontact methods are used to assess the surface finish of substrate materials. Contact methods use a stylus indenter across the surface while producing surface profiles. Noncontact methods provide texture details of the surface. Depending on the assessment accuracy and nature of the surface, both methods can be utilized to measure the surface profiles. However, the stylus tip gives rise to fine surface scratches, which are not favorable for the assessment of optical surfaces such as lenses and mirrors. Speculative inconsistencies in surface roughness measurements are introduced by different equipment, which result in misunderstandings and confusion in measurement accuracy. In particular, developments in the pharmaceutical and biotechnology industries require new designs of different geometric configurations and sizes of valves and pipes with specific surface finishes. Consequently, a unified description of surface texture assessment and measurement accuracy becomes vital in such industries. In general, various parameters, including grit size, tool load, feed rate, lubricant used, and others, affect the surface finish. However, the surface texture quality of the end product is mainly assessed by the surface roughness average value, which is identified as the centerline average or arithmetic average. The surface roughness value is defined as the average value of the departures from its centerline through a prescribed sampling length and the measured values expressed as the root mean square.

One interesting area of research in surface finish is associated with the enhancement of the hydrophobic characteristics of a surface. Changes in climate result in extreme dust storms, particularly in the Middle East region. Solar energy-harvesting devices, such as photovoltaic panels, are affected by dust accumulation on the protective cover surface. This, in turn, results in operational difficulties in terms of reduced energy-harvesting efficiency and device life cycle. To create a self-cleaning effect on the soiled surfaces, re-engineering of active surfaces of such devices becomes essential, as does mimicking nature (eg, lotus leaves, shark skin, rose petals). In this case, two important features of such surfaces are the focus: micro/nano texturing and reducing surface energy through chemical processing. To improve surface hydrophobicity, several methods have been reported and strategies have been introduced.[1–10] The adopted methods are related to the multi-step procedures and are involved with mostly harsh conditions that require specialized reagents. Some of these methods are associated with phase separation,[1] electrochemical deposition,[2] plasma treatment,[6] sol-gel processing,[7] electrospinning,[8] laser texturing,[9] and solution immersion.[10] The main purpose of these processes is to modify free energy of the surfaces through changing compositions via chemical and physical reactions. However, surface texturing has many challenges, including cost-effective processing, short processing duration, reduced initial capital for equipment, and trained human power requirements. In general, a cost-effective, one-step process of surface texturing is demanding and requires extensive research and development in the area of surface engineering. Crystallization or etching of optical surfaces under controlled environments generates surface textures composing micro/nano structures, which improve surface hydrophobicity significantly.[9] However, due to the molecular distortion and optical scattering of the crystallized/etched surface, optical

transmittance of the textured surface is significantly reduced.[9] This limits the application of the textured surfaces when transmittance of a visible spectrum of light is required. Laser texturing of optical surfaces can also provide improved hydrophobic characteristics at the surface; however, due to high residual stresses, the practical application of the textured surfaces becomes limited.[9] Although reconstruction of surfaces textured by using polydimethylsiloxane (PDMS) has been reported,[11] the process involved and the characteristics of the reproduced surface require further investigation to achieve an exact copy of the surface finish, particularly for surfaces with complicated geometric configurations.

Chapters in This Volume

3.1 Electroless Plating of Pd Binary and Ternary Alloys and Surface Characteristics for Application in Hydrogen Separation
3.2 Tuning of the Microstructure and Surface Topography of Hot-Dip Galvanized Coatings
3.3 Surface Finish Coatings
3.4 Residual Stresses in Thermal Spray Coating
3.5 Laser Texturing of Materials and Surface Hydrophobicity
3.6 Surface Texture Properties of Co–Ni Alloys Formed with Unipolar and Bipolar Plating
3.7 HVOF Coating of Nickel Based Alloys: Surface and Mechanical Characteristics
3.8 Laser-Based 3D Printing and Surface Texturing
3.9 Hydrophobicity and Surface Finish
3.10 Atomizers and Finish Properties of Surface Coatings
3.11 Gas Nitriding of H13 Tool Steel Used for Extrusion Dies: Numerical and Experimental Investigation
3.12 Hot-Dip Galvanizing Process
3.13 Finishing and Post-Treatment of Thermal Spray Coatings
3.14 High Velocity Oxy-Fuel Spraying and Surface Finish
3.15 Electroless Plating as Surface Finishing in Electronic Packaging
3.16 Hard Coatings on Cutting Tools and Surface Finish
3.17 Topological Evaluation of Surfaces in Relation to Surface Finish
3.18 Evaluation of Surface Finish Quality Using Computer Vision Techniques
3.19 Effect of Surface Roughness on Wetting Properties
3.20 Surface Preparation and Adhesion Tests of Coatings
3.21 Powder Metallurgical Processing of NiTi Using Spark Plasma Sintering
3.22 Spark Plasma Sintering of Lead-Free Ferroelectric Ceramic Layers
3.23 Electrochemical Processing and Surface Finish

The materials presented in all the chapters in this volume are sufficient to explain different laser processing techniques and their applications in practice. Six chapters describe surface hydrophobicity and characterization of surface finish, five chapters deal with the various aspects of electroplating and surface finish, and three chapters detail different spraying operations and surface characteristics. The remaining chapters provide insight into the 3D printing and coating evaluations pertinent to the surface finish.

Concluding Remarks

This volume covers the fundamentals, technologies, and recent developments in surface finishing pertinent to scientific and engineering applications. The chapters presented in this volume are self-contained in terms of their descriptions of the physical processes involved and the practical applications in industry. Surface analysis at a micro/nano level, characterizations, and processes involved are presented in detail. The current research associated with surface finishing applications is included in the introduction sections of all chapters, and the future trends in surface finishing technologies are also discussed; these form the guidelines for researchers and engineers in this field. Readers should find this volume to be a great source of pertinent information and relevant literature.

Acknowledgment

The editor expresses his deep appreciation to all the authors and co-authors of the chapters contained in this volume for all their hard work and devotion to preparing their individual chapters. The editor greatly acknowledges the support provided by the Deanship of Scientific Research of King Fahd University of Petroleum and Minerals.

3.1.1 Basic Aspects of Electrochemical Deposition

The electrochemical deposition technique involves electrodeposition or electroplating, electroless deposition, and displacement deposition; in all cases, a metal layer is deposited on a substrate.[1]

In the electroplating process for electric-conductive material, the deposition of a metallic layer is achieved by the presence of a negative charge on the substrate, which is immersed into a solution that contains a salt of the metal. The substrate is the cathode of an electrolytic cell and the electrons are supplied by an external power supply. The metallic ions of the salt with positive charge are thus attracted to the surface, which provides electrons to reduce the ions depositing the metal on the substrate surface.[2]

Compared with electrodeposition, electroless plating (ELP) can cover all surface types, regardless of size, shape, and electrical conductivity of the substrate. Electroless and displacement depositions have one basic feature in common: no power supply is required to produce the deposition reaction.[3] In the electroless deposition process, the electrons are provided to the support surface by a reducer (Red), which is present in the electroless bath. On the other hand, in the displacement deposition process, the substrate provides the electrons, becoming the electron-donating species.[3]

3.1.1.1 Electroplating

3.1.1.1.1 General principles

The electrodeposition of metals consists of the reduction of metal ions from different electrolyte solutions on top of a surface to be coated.[1] **Figure 1** shows the operation principle of the electroplating process.[2]

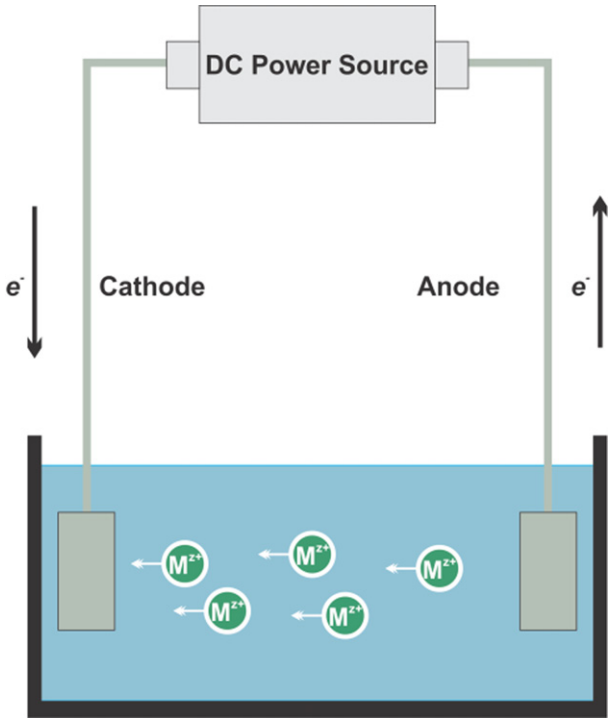

Figure 1 Schematic illustration of electroplating.

This phenomenon is represented by the next reaction [1]:

$$M^{z+}_{solution} + ze^{-} \xrightarrow{Surface} M_{lattice} \quad [1]$$

In this process, z electrons are supplied by an external power supply. However, in a simplified illustration, it is possible to consider that there are immobile metal ions in the metal lattice permeated by a gas of free electrons (reaction [2]).

$$M^{z+}_{solution} \xrightarrow{Surface} M^{z+}_{lattice} \quad [2]$$

According to this equation, a metal ion M^{z+} is transferred from the solution into the ionic metal lattice. This process requires the transfer of z electrons (e^{-}) from an external electron source to the electron gas in the metal M.[1] The equilibrium potential of the electrode (E), associated with the reaction [1] of the metal/metal ion electrode when there is no flowing of current ($I=0$), could be represented by the Nernst equation [3]. Note that this potential is defined with respect to a reference electrode potential.[1]

$$E_{[I=0]} = E^{o} + \frac{RT}{zF}\ln[M^{z+}] \quad [3]$$

where R, T, z, and F are the universal gas constant, absolute temperature, electron numbers, and Faraday's constant, respectively, and $[M^{z+}]$ is the concentration of metallic ions. However, when a current is flowing in an electrochemical cell, the electrode potential differs from eqn [3] and the difference between both potentials is known as 'overpotential.' This 'overpotential' is necessary to overcome the real limitations of the overall electrode reaction.[1]

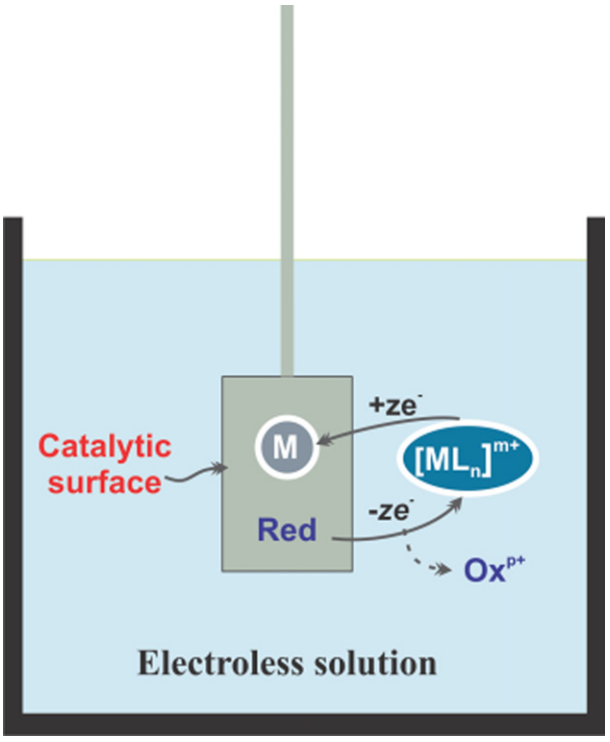

Figure 2 An electrolytic cell for electroless deposition of a metal M from an aqueous solution which contains a reducing agent (Red).

3.1.1.1.2 Main electroplating features

The main features of the deposit are governed by the growth processes of the crystals. The key factors are the composition of electroplating solutions, the current density (current/electrode area), the mass transport and the shape, structure, surface morphology, and metal (or alloy) employed in the electrode.

During the initial step, each nucleus grows independently of each other. However, in the next stages, the overlap between diffusion fields around the growing nucleus can be observed.[1] The growth of the first crystals could be achieved mainly by the lateral spreading of a layer or nucleation–coalescence mechanism. These formation processes affect the deposit features.

On the other hand, the solutions used by the deposition of the metals and alloys contain several inorganic and organic additives. These components (and impurities) could affect the crystal-building processes due to the fact that they can be present as adsorbates on the electrode surface.[1]

3.1.1.2 ELP

3.1.1.2.1 General principles

Unlike electroplating, the electrolytic cell for electroless deposition does not contain power supply, and the anodic/cathodic reactions occur on the surface of the substrate.[1] A scheme of the ELP setup is shown in **Figure 2**. The plating baths used for electroless deposition are more complex and contain a complex compound of the metal to be deposited, a reducing agent, complexing agents, stabilizers, and buffering agents as main components.[1]

The overall reaction of electroless metal deposition could be expressed as:

$$x[ML_n]^{m\pm} + y\text{Red}_{\text{solution}} \xrightarrow{\text{Catalytic Surface}} xM_{\downarrow} + xn\text{L} + y\text{Ox}^{p+}_{\text{solution}} \quad [4]$$

where $[ML_n]^{m\pm}$ is a complex ion of reducible metal, $\text{Red}_{\text{solution}}$ is the reducing agent, M is the metal atom, $\text{Ox}^{p+}_{\text{solution}}$ is the oxidation product of the reducer, and L are the ligands. The catalytic surface may be the substrate itself or the catalytic nuclei of the dispersed metal M that could act as specific surface sites on a non-catalytic substrate surface.[1] In addition, the homogeneous reaction between $[ML_n]^{m\pm}$ and $\text{Red}_{\text{solution}}$ in the bulk solution must be inhibited.

The selection of the L ligands of the central metal should be such that the obtained complex ions $[ML_n]^{m\pm}$ are moderately stable. Otherwise, a strong metal–ligand interaction could inhibit the discharge of the reduced metal on the support surface.[4] The brightness and the good adherence of the coating to the support are the main features of the deposits obtained by ELP. However, if the reaction occurs between the metal ion M^{z+}, not from $[ML_n]^{m\pm}$, and the same reducer, a little amount of powder without adherence could be obtained.[4] In the case of palladium, this powder is black and does not have mechanical resistance.

The metal deposition in ELP could be separated into two electrochemical semi-reactions [5] and [6], of reduction and oxidation[1] that occur at the same electrode–electrolyte interphase. Thus, in the substrate there are two catalytic sites, anodic and cathodic sites.[1]

$$y\text{Red}_{\text{solution}} \xrightarrow{\text{Catalytic Surface}} y\text{Ox}^{p+}_{\text{solution}} + ze^- \quad [5]$$

$$x[ML_n]^{m\pm} + ze^- \xrightarrow{\text{Catalytic Surface}} xM_{\downarrow} + xn\text{L} \quad [6]$$

3.1.1.2.2 Catalytic aspects

From the view point of catalysis, the main reaction in ELP is the oxidation of the reducer. The metal ability to catalyze this reaction allows the deposition of a metal by ELP.[5] However, there is not one unique metal that could act as a good catalyst for the oxidation of all reducing agents at specific reaction conditions.

Cu is an excellent catalyst for H_2CO oxidation but is inactive for hypophosphite and dimethylamine borane (DMAB) oxidation.[5] Ni and Co exhibit activity for different reductants such as NaH_2PO_2, $NaBH_4$, DMAB, and NH_2NH_2; however, these metals are poor catalysts to H_2CO oxidation. Palladium could be considered as the best catalyst for all reducing agents. The combination of its nobility and the resistance to dissolution in an electroless bath has converted Pd in the universal catalyst to start the electroless deposition.

Ohno *et al.*[6] reported the potentials of several reductants when the current density was kept at 1.0×10^{-4} A cm^{-2}. These values are shown in **Figure 3**. The observed tendency could be taken as a starting point for the design of electroless baths. However, it is important to analyze each case, to optimize the catalytic behavior of several metals in different types of ELP solutions.

3.1.1.2.3 Mechanistic overview

Several mechanisms have been proposed for electroless deposition reactions with different reducing agents.[7] Van den Meerakker proposed a mechanism that takes into account both the electrochemical and the catalytic nature of the process.[8] The proposed mechanism represents most of the common features of the metal electroless deposition. However, the mechanism fails to describe it on nonconductive surfaces, and also with metal particles deposition in solution. On the other

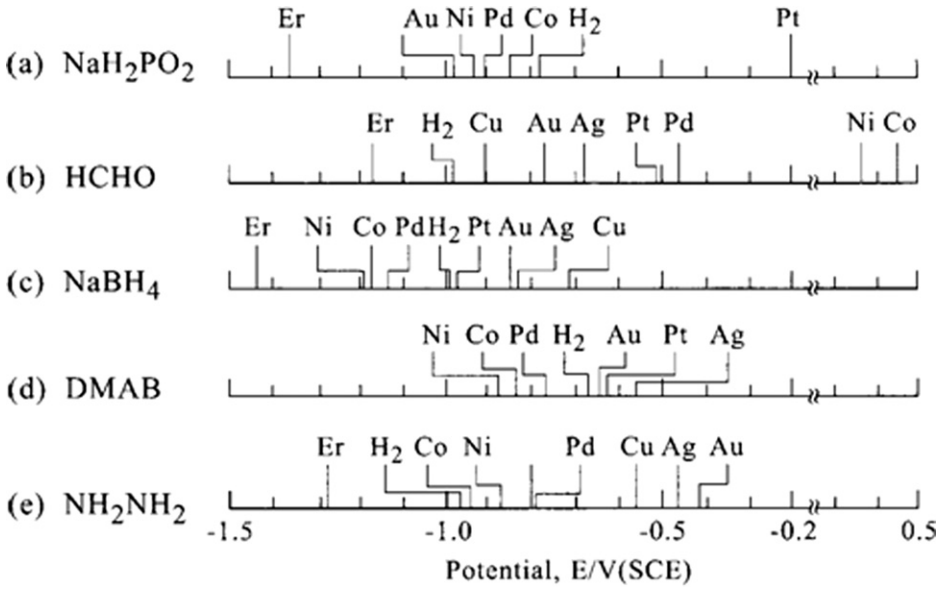

Figure 3 Catalytic activities of metals (as potentials measured at 10^{-4} A cm^{-2}) for anodic oxidation of different reductants. Er, thermodynamic oxidation–reduction potential of reductant; H_2, reversible hydrogen electrode potential in solution used to study oxidation of each reductant.[6] Reprinted from Electrochemical Science and Technology: Ohno, I.; Wakabayashi, O.; Haruyama, S. Anodic Oxidation of Reductants in Electroless Plating. *J. Electrochem. Soc.* **1985,** *132*, 2323–2330. Reproduced with permission from The Electrochemical Society.

hand, some reductants could present different steps and global reactions depending on the bath pH (alkaline and acidic) and the metal to deposit. A more realistic approach would be to look for each specific system with particular conditions and substrates.[8] O'Sullivan claims that this mechanism is a good starting point for the study of a mechanism in a particular metal-reducing agent system.[5]

The universal mechanism was developed according to the following features, which are common to several electroless systems[8]:

1. The electroless deposition processes are produced only on some catalytic metals, which are recognized as effective to hydrogenation–dehydrogenation reactions;
2. The evolution of hydrogen gas is always present;
3. Poisons for hydrogenation–dehydrogenation reactions act as stabilizers in almost all electroless processes; and
4. The deposition rates are normally accelerated by the pH increase.

The unified mechanism could be summarized by the following reaction scheme:

Anodic:

$$\text{Dehydrogenation:}\quad \mathrm{RedH} \longrightarrow \mathrm{Red}^{\bullet}_{ads} + \mathrm{H}^{\bullet}_{ads} \qquad [7]$$

$$\text{Oxidation:}\quad \mathrm{Red}^{\bullet}_{ads} + \mathrm{OH}^{-} \longrightarrow \mathrm{RedOH} + e^{-} \qquad [8]$$

$$\text{Recombination:}\quad \mathrm{H}^{\bullet}_{ads} + \mathrm{H}^{\bullet}_{ads} \longrightarrow \mathrm{H_2}\uparrow \qquad [9]$$

$$\text{Oxidation:}\quad \mathrm{H}^{\bullet}_{ads} + \mathrm{OH}^{-} \longrightarrow \mathrm{H_2O} + e^{-} \qquad [10]$$

Cathodic:

$$\text{Metal deposition:}\quad [\mathrm{ML}_n]^{m\pm} + ze^{-} \longrightarrow \mathrm{M} + n\mathrm{L} \qquad [11]$$

$$\text{Hydrogen evolution:}\quad 2\mathrm{H_2O} + 2e^{-} \longrightarrow \mathrm{H_2}\uparrow + 2\mathrm{OH}^{-} \qquad [12]$$

where, RedH represents the reducing agent, which is adsorbed on the surface of the deposited metal[5,7]; and then it is dissociated to form the radical $\mathrm{Red}^{\bullet}_{ads}$ and atomic hydrogen $\mathrm{H}^{\bullet}_{ads}$(reaction [7]). The electrons that are necessary to reduce the metal ions to the metal are supplied by reactions [8] or [10]. The contribution of each of these two reactions defines the efficiency of the reductant. The formation of gaseous hydrogen could be obtained by both the anodic reaction [9] and cathodic reactions [12].[7]

The evolution of the H_2 gas in electroless deposition systems is a phenomenon that requires to be understood in order to elucidate both the mechanism of deposition and the effect on the deposit morphology through the H inclusion.[5] This H inclusion is produced by the absorption of H in the lattice of the electroless deposit, which was previously an adsorbed H intermediate (reaction [13]).[5]

$$\mathrm{H}^{\bullet}_{ads} \longrightarrow \mathrm{H}^{\bullet}_{bulk} \qquad [13]$$

Avoiding the stress caused by H absorbed in the progress of electroless deposition could allow the application of electroless layers in areas where the metallization of smooth surface is desired.[5]

3.1.1.2.4 Surface conditioning

Several surfaces do not show catalytic activity for ELP, for example, polymers, nonconductors, noncatalytic metals, noncatalytic semiconductors, ceramic, and glass. Thus, these surfaces have to be conditioned prior to the electroless deposition. This process could normally be broken down into three steps: surface preparation, sensitization, and activation.

In order to improve the adhesion and the catalytic nuclei seeding, the surface preparation normally needs an etching process to modify the noncatalytic substrates.[2]

During the sensitization process, the adsorption of the reducing agent takes place, as Sn^{2+} or N_2H_4.[8] Then, the sensitized surfaces are activated by exposure to a solution containing Pd^{2+} and HCl to produce the Pd nuclei.[9]

The overall reaction can be seen in the following equation (eqn [14]).

$$y\mathrm{Red}^{q+}_{\mathrm{solution}} + x\mathrm{Pd}^{2+} \longrightarrow y\mathrm{Ox}^{p+}_{solution} + xPd^{0} \qquad [14]$$

3.1.1.2.5 Conditions and chemical composition of different metal solutions

Normally, ELP solutions include the components shown in **Table 1**. Additives in small quantities are usually employed to improve the solution stability and to achieve the desired physical properties of the deposited film.[7]

The composition of ELP baths for different metals such as Pd, Ag, Cu, Au, Ru, Ni, and Co are displayed in **Table 2**.

Table 2 also includes the pH values employed which normally depend on the selected reducing agent. For example, borohydride is limited to a high alkaline medium; the amineboranes are used from mildly alkaline to mildly acidic baths.[4] However, hydrazine can reduce metal ions under both acidic and basic conditions. In an alkaline medium, it is a strong reducing agent[28] which allows the deposition of thick films when high pHs are employed.

Different components (see **Table 2**) are used as stabilizer agents such as ammonium chloride and Na_2EDTA in palladium–ammine complex compounds. When NH_4Cl is used as stabilizer and hypophosphite is the reducer, the bath stability is reached because the concentration of $[Pd(NH_3)_4]^{2+}$ remains constant.[4] Instead, the Na_2EDTA stabilizer ability is achieved by a ligand substitution. However, the resulting solution requires higher temperature for metal reduction than ammonia based baths, due to its higher stability.[4]

Table 1 Components of an electroless plating bath

Component	*Purpose*
Metal salt	Source of metal to be deposit
Reducing agent	To provide the electrons to the metal reduction
pH adjuster	pH adjustment
Complexing agent	To form metal complex avoiding the excess of free metal ion
Additives	To improve bath stability or deposit properties

3.1.2 Electroless Deposition of Pure Metals

3.1.2.1 Palladium

The electroless deposition of palladium coatings has been widely reported in the literature.[4,29,30] The deposition from a hydrazine plating bath was first reported by Rhoda[31] in 1959 using palladium in the form of tetra-amine di-chloride $[Pd(NH_3)_4]Cl_2$.

It was found[29] that the deposition rate increases with temperature, hydrazine, and Pd concentration. A spontaneous precipitation in the bulk of the bath occurs in the absence of EDTA, which is commonly utilized as stabilizer. On the other hand, a decrease in the plating rate with time was observed, which was attributed to the catalytic decomposition of hydrazine by palladium. One of the major challenges of the development of the homogeneous palladium coating was the improvement in the stability of the plating bath by a proper selection of additives and stabilizers.

Ma *et al.*[30,32] reported a detailed experimental study conducted to model the electroless palladium plating kinetics. They analyzed the effect of temperature, initial Pd and hydrazine concentration, and agitation speed on the plating deposition rate. It was shown that hydrazine was the limiting reactant for the studied range of initial Pd metal ion concentrations (between 8.2 and 24.5 mM). Furthermore, it was demonstrated that the ELP of Pd was strongly affected by the external mass transfer in the absence of agitation (**Figure 4(a)**). An increase in both the Pd deposition rate and solution conversion was observed with the agitation rate up to about 400 rpm. A higher agitation rate did not produce further improvements (**Figure 4(a)**).

The morphology of the Pd coatings is significantly affected by the rate of agitation. In the film without agitation, the surface morphology is composed of small tightly knitted Pd clusters (**Figure 4(b)**). On the other hand, the morphology formed by the bath agitation at a rate of 50 rpm was under the shape of loosely packed small clusters. In the case of Pd plating, at an agitation rate of 200 rpm and later at 400 rpm, the SEM images suggested that the Pd deposition was noticeably more uniform and smooth in appearance with relatively larger clusters and cauliflower-like morphology (**Figure 4(b)**).[32]

3.1.2.2 Nickel

The plating baths for electroless deposition of Ni are composed mainly of nickel sulfate (source of Ni), sodium hypophosphite (reducing agent), and chemicals to prevent precipitation of insoluble nickel hydroxide. They are operated at temperatures between 333–358 K and the pH is maintained in an acid range for bath stability. However, the evolution of hydrogen could lower the pH; to prevent this, alkaline salts of Na and K or ammonium ions are usually added to the bath. For plating baths with hypophosphite as reducing agent, a wide range of plating baths with pH ranging from 4 to 11 has been reported. During electroless Ni deposition, P is co-deposited. At low pH values, coatings with higher phosphorous content (up to 25 at% at pH 4) are obtained. In the alkaline range, films with less than 1 at% of phosphorous are synthesized. One important pH-dependent property of nickel coatings is the fact that films grown using acidic baths exhibit good adhesion characteristics to steel. Very likely, this is why those film types are more common in industry. Alkaline baths tend to have a higher deposition rate with the concomitant result of decreased stability.[33]

In addition to hypophosphite, three reducing agents are frequently used to nickel electroless deposition: sodium borohydride ($NaBH_4$) (pH 12–14), hydrazine (pH 8–11), and DMAB $(CH_3)_2NHBH_3$, (pH 6–10). Hydrazine based plating baths are used to obtain pure nickel coating. However, the instability of the baths at high temperature and the cost of hydrazine have limited its use at industrial level.[34]

The Ni coatings grown in acidic bath using hypophosphite (high P content) have an amorphous or liquid-like structure.[35] Heat treatment to about 603 K produces semi-crystalline face-centered-cubic (fcc) nickel interspersed with intermetallic

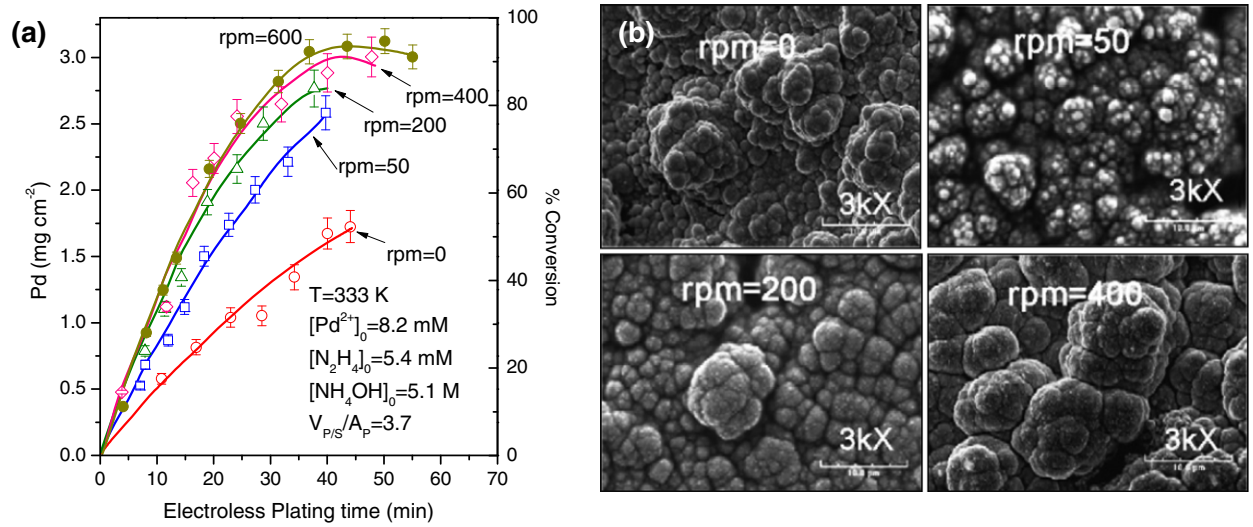

Figure 4 Effect of plating bath agitation on: Pd plating rate (a) and coating morphology (b). Reprinted from Ayturk, M. E.; Ma, Y. H. Electroless Pd and Ag Deposition Kinetics of the Composite Pd and Pd/Ag Membranes Synthesized from Agitated Plating Baths. *J. Memb. Sci.* **2009**, *330*, 233–245. © Elsevier 2009.

compounds such as Ni_3P; the grain size of the Ni fcc structure increases when temperature increases.[35]

3.1.2.3 Silver

The plating baths used in the Ag deposition are very unstable and short-lived, with the formation of silver power throughout the solution. It has been found that the addition of small amounts of 3-iodotyrosine or 3, 5-diiodotyrosine improves the bath stability. Considering that the bath stability are markedly affected by the pH, Kubota and Koura[36] studied the effect of different synthesis parameters. They found that as the plating time increases, the pH of the bath changes with the concentration of silver nitrate, mainly at an initial pH below 10.5.

The deposition rates for the electroless Ag plating are strongly influenced by the temperature and hydrazine concentration. Baths containing $AgNO_3$, NH_4OH, and hydrazine are unstable at temperatures higher than 333 K, due to the evaporation of excess NH_4OH.[30] Even though a higher concentration of the reducing agent resulted in an increase in the deposition rate, the stability of the silver bath was altered as evidenced by a decrease in the pH of the bath (<10). At a hydrazine concentration of 5.4 mM (range studied 1.8–5.4 mM), the bulk precipitation of the Ag metal was evidenced when the processes were conducted without agitation.[30] On the other hand, the ELP of silver is strongly affected by the external mass transfer. In the same way as for Pd depositions, the agitation rate produces an increase in the silver deposition rate and the conversion of the plating reaction (**Figure 5(a)**).

Ma *et al.*[30,32] reported that the Ag electroless process produces deposits with nonuniform growth with a tendency to grow more in the perpendicular direction to the surface of porous stainless steel substrates. As it can be seen in **Figure 5**, the silver deposition morphology was considerably affected by the bath agitation. The silver morphology of films synthesized in static baths (0 rpm) consisted of randomly distributed clusters with different shapes and sizes (**Figure 5(b)**). On the other hand, the morphology of films obtained in a bath with stirring produced relatively more uniform clusters. Due to the agitation of the plating bath, the heat dissipation via convection is further enhanced, minimizing both heat and mass transfer limitations and resulting in faster plating rates, with higher conversions. Together with the bath agitation, increased plating temperature and reducing agent concentration assist in forming uniform and improved nucleation sites, thus allowing higher conversions and faster plating rates.[30]

3.1.2.4 Copper

The plating solutions used for copper electroless deposition are often composed of copper sulfate, a complexing agent such as EDTA, a reducing agent, a stabilizer, and NaOH to adjust the pH. Traditional ELP uses formaldehyde as reducing agent; however, other reducing agents have also been used, namely glyoxylic acid, hypophosphite, sodium bisulfate ($NaHSO_3$) and sodium thiosulfate pentahydrate ($Na_2S_2O_3 \cdot 5H_2O$). The selection of the bath compositions depends on some empirical rules.[37] It has been pointed out that in order to allow the complexing of all cupric ions, the ratio of EDTA/Cu should be set about 2.5, whereas pH values are best adjusted between 12.5 and 13.5. So far, various attempts have been made to improve plating quality as well as rate and bath stability[38,39] Kaliaguine and coworkers[37] found that the concentration of EDTA and NaOH in the plating bath is the most important factor affecting the deposition rate of Cu. The Cu deposition was enhanced by increasing the concentration of NaOH, $CuSO_4$, and HCHO and decreasing the EDTA content.

The surface morphology evolution of copper deposits obtained under several conditions using formaldehyde or glyoxylic acid as reducing agent has been reported[40] in the literature. Due to the acidic nature of glyoxylic acid and its

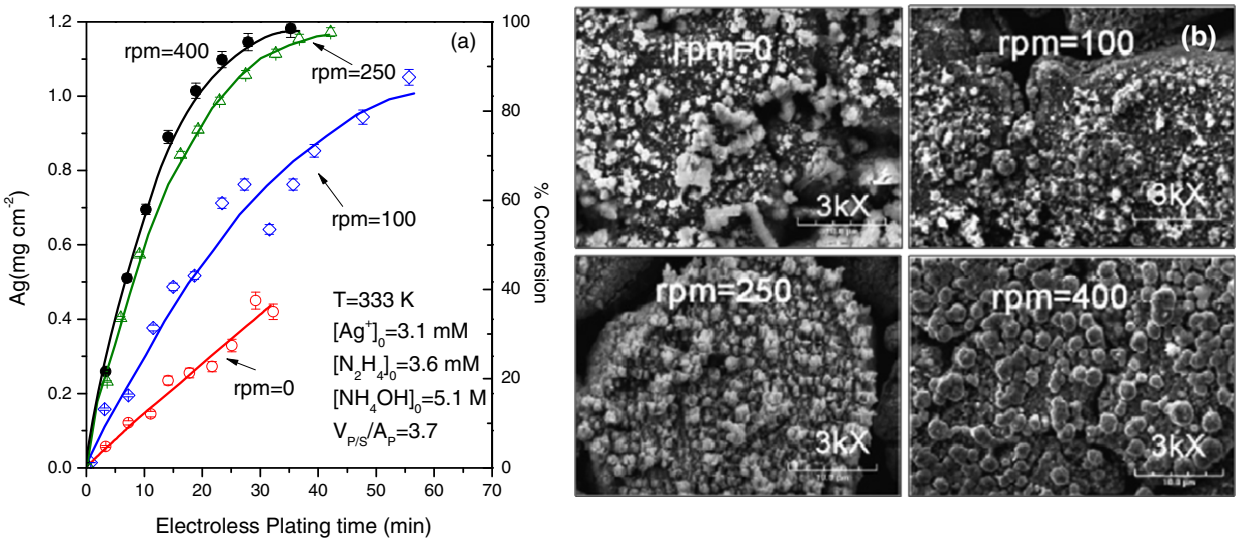

Figure 5 Effect of plating bath agitation on: Ag plating rate (a) and coating morphology (b). Reprinted from Ayturk, M. E.; Ma, Y. H. high sensitivity to temperature and concentration, it is not so easy to control the plating bath containing glyoxylic acid as it is to control those with formaldehyde. In addition, the used concentration of the copper sulfate is relatively low when a lower concentration of glyoxylic acid is employed at high temperature. With the increase of the glyoxylic acid concentration, the plating bath becomes unstable at 343 K, which makes the solution unable to sustain prolonged plating. When the temperature is lowered to 318 K, although the concentration of glyoxylic acid is even higher, the plating remains relatively stable. By replacing formaldehyde with glyoxylic acid, it is possible to obtain a smoother surface in the electroless copper deposit, which could be due to the fine grains on the surface of the deposits from glyoxylic acid solutions in the early stage of the plating process. In a plating bath with a high concentration of glyoxylic acid and at high temperature (343 K), although the 120 min deposit has large grains on the surface, the surface morphology of the earlier stage deposit consists of small grains. At low temperature (318 K), plating baths with a high concentration of glyoxylic acid and formaldehyde give the smoothest surface finish.[40]

3.1.3 Palladium Binary Alloys

Electroless deposition has been widely used to synthesize several binary and ternary palladium based alloys in order to be used as membranes for hydrogen separation within other applications. Investigations of film compositions and structures, and the effect that synthesis variables produce on them are of great importance in order to develop new materials and improve their properties. Even though it is a widely used technique for the synthesis of Pd and Pd-alloy films, one of the major problems related to the ELP method is the difficulty in obtaining a uniform alloy composition on thickness. Alloying is most commonly achieved by the coating-diffusion method. This technique consists in the sequential or co-deposition of the metals followed by high-temperature diffusion treatment under reductive (H_2) or inert (Ar, N_2) atmosphere to promote the alloy formation. In order to obtain layers without composition gradients on thickness, treatments at high temperatures and longer times are required for sequential electroless deposited layers. On the other hand, the simultaneous deposition of two metals facilitates the contact between the pure metals and improves alloy formation. With the aim of achieving uniform alloy coatings through electroless deposition, a substantial amount of study has been carried out on a wide variety of support materials (metals and ceramics) and using several characterization techniques. X-ray diffraction (XRD) is widely used to study the phase evolution and/or phase transition under annealing conditions. The morphology and atomic composition of both the top and cross section view of the films are determined by Scanning Electron Spectroscopy (SEM) coupled with Energy Dispersive Spectroscopy (EDS). In order to study the surface segregation under annealing and permeation conditions, X-ray photoelectron (XPS) and Low energy ion scattering (LEIS) spectroscopies have been employed to determine the composition of the near-surface region and top-most surface layer, respectively.

3.1.3.1 Sequential and Co-Deposition of PdAg Alloys

As it is well known, palladium and silver are completely soluble in the solid state and form the fcc (face-centered-cubic) phase in all the composition range. The synthesis and characterization of both sequential deposition[41,42] and co-deposition[43] of PdAg have been widely reported in the literature using hydrazine-based palladium plating baths. Films obtained by sequential deposition need stronger heat treatments, longer times or higher temperatures for alloy formation compared with films obtained by co-deposition. Nevertheless, simultaneous deposition presents certain difficulties in obtaining films with homogeneous morphology and desired bulk composition. Ma *et al.*[42] presented a comprehensive work regarding the isothermal nucleation and growth kinetics of PdAg alloy phase by using *in situ* time-resolved high-temperature X-ray diffraction (HTXRD). The HTXRD data indicated that the formation of the fcc PdAg alloy was observed once the target annealing temperature was reached. However, the extent of the phase transformation for the film annealed at 823 K was smaller than the one observed for the films annealed at 773 and 873 K (**Figure 6**). From the SEM top-surface view, it could be seen that the typical surface morphology of the films annealed at 773 and 823 K was in the form of dendrite silver, in contact with the underlying Pd layer. For the film annealed at 823 K, large clusters of Ag dendrites were observed, which presented varying sizes and shapes with respect to the annealed morphologies at 773 and 873 K. As a result, the predominant presence of Ag-dendrites significantly affected the contact area and the planar shape of the original interface between the Pd and Ag layers. The presence of defects and imperfections in the morphology can also have a substantial effect on the nucleation and growth processes, and thus in the formation of the PdAg alloy phase. The higher defect density observed in the film annealed at 823 K could be the reason for the lower extent of alloy formation at this temperature (**Figure 6(a)**). From the EDS data, it was possible to observe a more heterogeneous distribution of Pd and Ag in the thickness of the film annealed at 823 K, compared with those annealed at 773 and 873 K (**Figure 6(b)**). The agreement between the HTXRD kinetics data, the cross section SEM images and the EDS line scans indicated that the deposition morphology had a significant effect on the PdAg alloy phase growth kinetics. From the HTXRD experiments, the authors reported a quantitative analysis of the PdAg alloy phase nucleation and growth kinetics of annealing at 773, 823, and 873 K. The difference in estimated activation energies of deposition might be related to the presence of heterogeneous nucleation sites, defects and imperfections at the original interface between Pd and Ag layers.

The effect of deposition time on morphology and homogeneity on PdAg alloy formation was studied by Bosko *et al.*[11] They prepared PdAg membranes by sequential deposition on top of alumina or NaA modified porous stainless steel substrates. By reducing the thickness of each deposition step to *ca.* 1 ± 0.1 μm, the PdAg alloy formation was obtained with thermal treatment at 773 K in H_2 atmosphere during 110 h.[11] The EDS analyses of the film with shorter deposition cycles showed homogeneous atomic composition up to 15–20 μm deep. As shown in **Figure 7**, the PdAg (90 min) film showed a

compact film with few defects formed between two well-defined layers. On the other hand, the film synthesized with shorter deposition cycles showed a higher defect density in thickness (Figure 7). This difference was related to the dendritic growth of silver layers. Therefore, these results suggest that the use of a higher number of Ag depositions increased the detrimental effect of the silver dendritic growth.

The co-deposition of PdAg alloys has also been reported in the literature[43,44] Yeung *et al.*[43] studied the effect of plating parameters on the microstructure and performance of co-deposited PdAg membranes synthesized from hydrazine-based plating baths containing Pd and Ag precursors. The presence of Ag in the plating bath inhibited the deposition of Pd resulting in a decrease of the overall deposition rate. Co-deposition of Pd and Ag was favored for plating solutions with low ammonium content, elevated temperatures, and a moderate hydrazine/metal ratio.

3.1.3.2 Sequential and Co-Deposition of PdRu Alloys

The PdRu alloys could be deposited by sequential deposition or co-deposition followed by annealing at high temperature. Sequential plating may not produce fully homogeneous films considering the elevated Tammann temperature of metals ($T_{\text{TammannRu}} = 1310$ K, $T_{\text{TammannPd}} = 914$ K), while the composition of some co-plated films has been shown to vary with plating time, concentration of reducing agent, metal ion concentration and synthesis temperature.[17]

The synthesis of PdRu alloy films in the range of 5–10 wt% of Ru from a EDTA-free bath was reported by Way *et al.*[45] The coating composition is enhanced in Pd content with respect to the bath. In this study, these authors claimed that the incorporation of Ru to the plating bath improves the substrate coverage allowing to obtain thinner films. On the other hand, Braun *et al.*[17] studied the effect of synthesis variables on the morphology, substrate adherence and composition of PdRu co-deposited films. Films prepared using EDTA-free plating baths present more heterogeneous morphology if compared with films prepared with EDTA under the same conditions (Figure 8). For the PdRu coatings obtained without EDTA and higher hydrazine concentrations (Figures 8(b) and 8(f)), a higher dendritic morphology with growth in height were observed. On the other hand, the film with the lowest concentration of hydrazine (Figures 8(b) and 8(d)) presents a less heterogeneous morphology, probably due to a lower reaction rate.

Homogeneous and defect-free films were obtained employing baths at low pH, moderate to high agitation speeds and high concentration of hydrazine, using EDTA as a stabilizer and temperatures near 323 K (Figures 8(a), 8(c), and 8(e)).

3.1.3.3 Sequential Deposition of PdCu Alloys

We have found only one article in the literature reporting co-deposition of PdCu alloys by electroless methods. In this study, the authors used palladium–cyanide complexes and formaldehyde as reducing agent.[46] The preparation of PdCu alloys by ELP is commonly achieved by the sequential deposition of Pd and Cu layers followed by annealing at high temperature. For sequential deposition, the plating of Pd using a palladium–ammonia complex on top of a Cu layer could not be performed since ammonia partially dissolves copper. Hence, palladium should be plated first followed by copper and then, the deposits should be annealed.

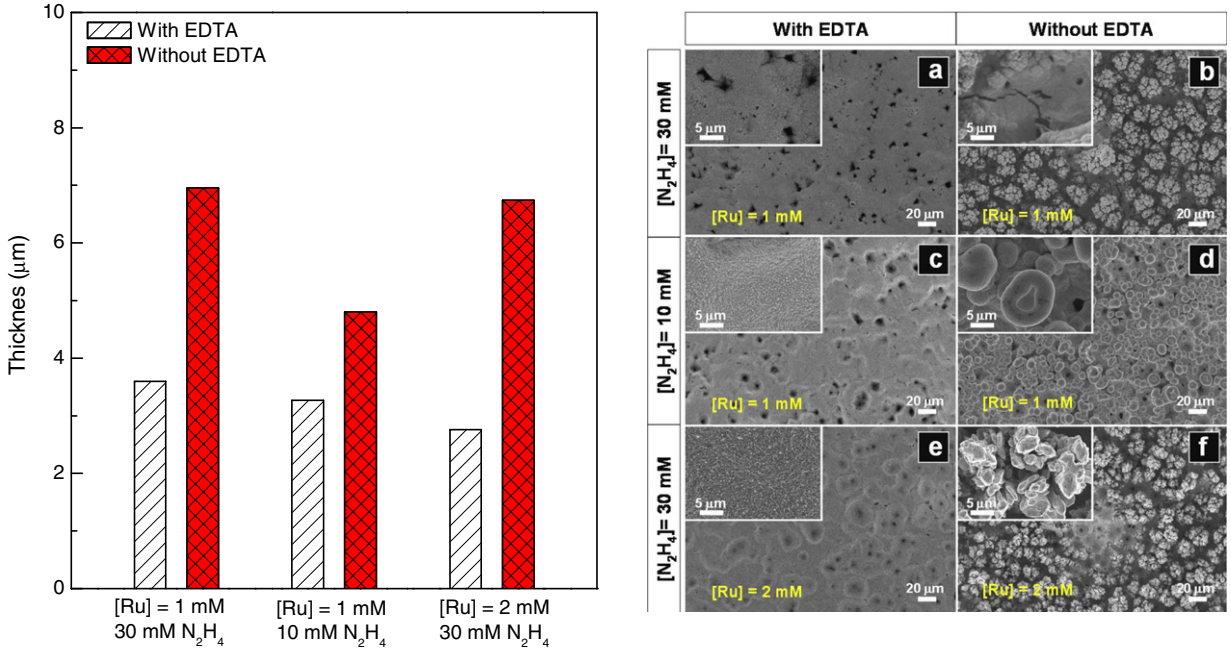

Figure 8 Hydrazine concentration effect on PdRu film morphology synthesized with EDTA (a, c, e, and g) and without EDTA (b, d, f, and h). Electroless deposition conditions: [Ru + Pd] = 10 mM, [Ru] = 10 mM, T = 323 K, pH 11.5. Three 1 h co-depositions. Reprinted from Braun, F.; Tarditi, A. M.; Cornaglia, L. M. Optimization and Characterization of Electroless Co-Deposited PdRu Membranes: Effect of the Plating Variables on Morphology. *J. Memb. Sci.* **2011**, *382*, 252–261. © Elsevier 2011.

The PdCu system is structurally different from the PdAg where only the fcc phase is formed throughout the composition range and temperature. Palladium and copper are not fully miscible below 873 K. The system forms a continuous series of disordered fcc solid solution above 873 K and at all temperatures when the palladium composition is higher than 65 at%. At a composition of palladium about 40 at% and ordered bcc (body-centered-cubic) phase with a CsCl like structure is found below 873 K. Additionally, there exist two more structure types with a Cu_3Au related lattices at Cu compositions higher than 70 at%.[47]

HTXRD has been used by Ma *et al.*[48] to study the Pd–Cu phase transformation of electroless films deposited on top of porous stainless steel substrates. During the annealing at temperatures between 773 and 873 K, there can be a maximum of five phases present, namely pure Pd and pure Cu phases, the Pd-rich and Cu-rich fcc phases and one bcc phase. The application of the Avrami model indicated that the nucleation and growth of the fcc phase were one dimensional in nature. The rate-limiting process of the solid-state transformation was the bulk diffusion of Cu into Pd. To completely form the fcc phase (with *ca.* 15 at% Cu) at 773 K, annealing during 225 h would be needed.[48]

After annealing, the morphology of the layer looks like a porous Pd/Cu layer on top of a nonporous Pd/Cu alloy. Ma *et al.*[48] claimed that the porous Pd/Cu alloy was caused by the Kirkendall effect which occurred when two metals with unequal diffusion coefficients underwent interdiffusion. In this case, the voids were formed when Cu atoms diffused faster than the Pd atoms. The Kirkendall porosity has been previously observed on the Cu side of Pd/Cu diffusion couples. Another reason for the voids could be the fcc–bcc transition. Indeed, the change in the lattice structure and the lattice parameter could cause irreversible structural transformation.

3.1.3.4 Sequential Deposition of PdAu Alloys

The PdAu alloy formation from ELP of sequential palladium and gold layers on top of ceramic tubes was studied by Goldbach *et al.*[49] The authors deposited a thin film of gold on top of a Pd layer. For the deposition of the Au layer, they used a cyanide-free plating bath. The analysis of the alloy formation as a function of time at different temperatures showed that the alloying of the separate metal layer required about 168 h at 873 K and more than 500 h at 773 K under hydrogen stream. In contrast, Tarditi *et al.*[16] reported fcc PdAu alloy formation at 773 K during 120 h in hydrogen stream for multilayered Pd/Au films synthesized on top of porous stainless steel disks. The difference observed could be attributed to the fact that Goldbach *et al.*[50] prepared a bilayered Pd/Au film consisting in a thin gold layer on top of a Pd film, whereas Tarditi *et al.* deposited a multilayer film alternating layers of Pd and Au.

In order to optimize the synthesis and homogeneous alloy formation in thickness, Goldbach *et al.*[50] reported the synthesis of PdAu nanostructured layers. The as-synthesized samples are formed by *ca.* 30 nm wide Au layers and 250 nm wide Pd layers sequentially deposited on top of ceramic support tubes (Figure 9). The veined multilayer pattern observed by SEM-EDS in the as-prepared film disappeared and the Pd and Au EDS traces became flat after one day of annealing at 773 K

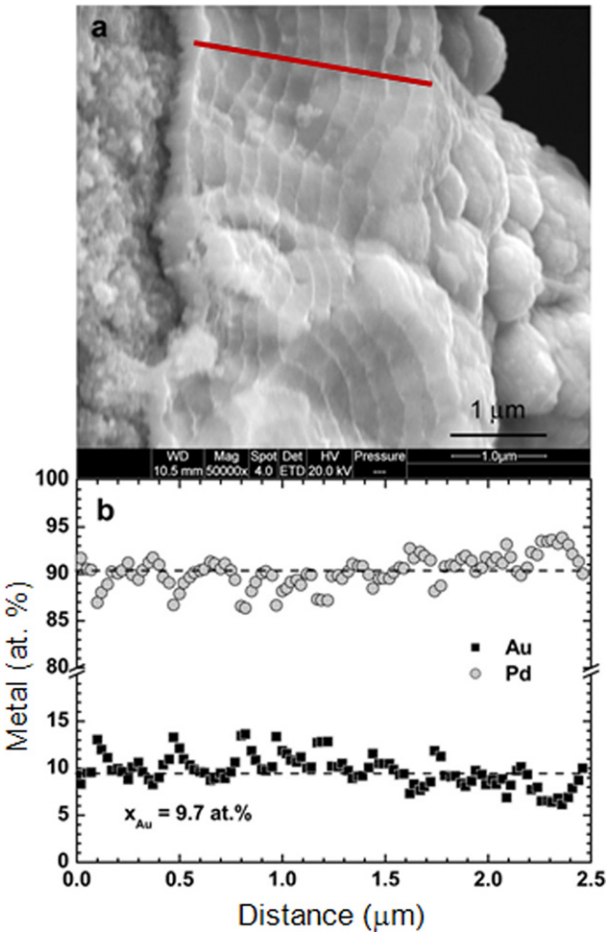

Figure 9 Cross sectional SEM image of freshly prepared Pd/Au multilayer film (a); EDS scan along the line marked in the SEM image (b). Reprinted from Braun, F.; Tarditi, A. M.; Cornaglia, L. M. under atmospheric H_2 pressure, which indicated that the homogenization of the multilayer proceeded rapidly under those circumstances. The improved alloying of nanostructured PdAu electroless deposited films could be attributed to the much extended interface between the two metals in comparison with a bilayer film with the same total thickness.

3.1.4 Palladium Ternary Alloys

Recently, there has been increasing interest in studying the synthesis and characterization of some Pd-based ternary alloys because of their superior properties concerning hydrogen permeability and/or chemical resistance. Ternary alloys containing copper or gold have a higher H_2S resistance corrosion than pure palladium membranes which experiment surface and bulk formation of PdS_4. Cornaglia and coworkers[13,51–54] reported the synthesis and characterization of PdCuAu, PdCuAg, PdAgAu ternary alloys. The alloys films were synthesized on top of porous stainless steel substrates by

sequential electroless deposition of the pure metals. A summary of the compositions of the plating bath and the experimental conditions used for the electroless deposition of Pd, Cu, Au, Ru, and Ag are shown in Table 3. Prior to the metal deposition, the sensitizing-activation of the substrate using a $SnCl_2$ and $PdCl_2$ acidic solution was performed at room temperature for all the alloys.

3.1.4.1 PdAgAu Alloys

PdAgAu ternary alloys with different atomic composition ($Pd_{83}Ag_2Au_{15}$, $Pd_{74}Ag_{14}Au_{12}$, $Pd_{78}Ag_9Au_{13}$, and $Pd_{75}Ag_{16}Au_9$) have been obtained by the sequential electroless deposition method on top of porous stainless steel disks previously modified with alumina or ZrO_2.[51,52] Palladium, silver, and gold were deposited in this order.[52] The three-metal deposition cycle was repeated for the films to achieve a target thickness of ~14 μm. The ternary films were annealed at 773 or 873 K in H_2 to promote metallic interdiffusion and alloy formation. The XRD patterns after annealing at 773 K during 120 h in hydrogen stream display an incomplete fcc alloy formation as illustrated by the appearance of small shoulders in the main peaks assigned to the fcc structure (Figure 10). These shoulders are more pronounced in the film with higher silver content (Figure 10(b)). With a second annealing at 873 K for 48 h, a complete alloy formation was evidenced (Figure 10),[52] displaying a homogeneous alloy composition on thickness.[51] The PdAgAu film with higher

silver atomic composition ($Pd_{74}Ag_{14}Au_{12}$) presents a more heterogeneous morphology with a higher density of defects (Figure 10), which could be related to the heterogeneous nucleation and dendritic growth of silver deposits obtained by the electroless method.

Way and coworkers[55] also investigated the PdAuAg alloys deposited on top of porous zirconia-coated stainless steel tubes (YSZT). The YSZT was activated for Pd ELP by spraying a solution of Pd acetate in chloroform onto the substrate using an airbrush, followed by a heat treatment in air to 623 K to decompose the organic ligand. Prior to the plating, the activation layer was reduced by submerging the substrate in a mixture of ammonium hydroxide, hydrazine, and water. In this case, the metal deposition was in the order Pd, Au, and Ag. The sample was annealed at 773 K during 120 h in H_2(3.5%)/Ar. From the XRD spectra, it could be observed that the PdAuAg peaks are not symmetric, which indicates that complete alloy formation did not occur.

3.1.4.2 PdAgCu Alloys

In order to obtain homogeneous PdAgCu alloys, palladium, silver and copper were deposited in this sequence by electroless deposition on top of ZrO_2 modified porous stainless steel disks.[53] Plating times for Pd (323 K), Ag (333 K), and Cu (303 K) were adjusted to achieve the desired metal composition. After electroless deposition of Cu, the films were immediately immersed in 0.01 M HCl to neutralize any residual plating solution, followed by rinsing with DI water and ethanol to facilitate drying and prevent oxidation of the copper layer. In addition, Cu on the surface partially or completely dissolved in the plating bath. Therefore, the first metal layer applied to the support was always Pd, then Ag and finally a Cu layer was applied on top of the Pd–Ag layers. The film was then heated up to 773 K in hydrogen atmosphere in order to form a homogeneous palladium–silver–copper alloy by thermal diffusion. After annealing at 773 K for 48 h, it was possible to observe the formation of two phases, the fcc and bcc of the PdAgCu alloy (Figure 11). When the annealing time increased, the fcc/bcc ratio increased,[54] which is consistent with the data reported in the literature for the PdCu binary alloy.[56] Although Ag was deposited between Pd and Cu, no peaks corresponding to the PdAg binary alloy were observed in the patterns even after 162 h up to 773 K (Figure 11).

The fraction of the fcc and bcc phases (X_{bcc} and X_{fcc}) for the PdCuAg synthesized films was estimated from the integrated intensities of their main peaks, (110) and (111) for the bcc and the fcc phase, respectively. In order to apply this procedure to obtain the total concentration of palladium, it was assumed that as the Ag concentration in the bulk is low it does not introduce any considerable modification in the lattice parameter and therefore does not modify the data obtained from these expressions.[13,53] Then, the concentration of Pd in each phase was calculated from the lattice parameter using the equations previously reported.[56] The evolution of X_{bcc} and X_{fcc} as a function of annealing time at 773 K is shown in Figure 11(c). After 162 h at 773 K in H_2, only the feature corresponding to the fcc phase was observed by XRD (Figure 11) for a PdAgCu film with a palladium atomic composition of about 72%.[53]

SEM surface micrographs of the PdAgCu samples show a uniform and smooth morphology, with no evidence of dendritic growth.[53] It is well known that the Cu surface morphology of samples prepared by electroless method exhibits much smaller agglomerated particles than those observed in the Pd plating films where the typical cauliflower structure is present.

3.1.4.3 PdCuAu Alloys

PdCuAu ternary alloys with different composition were synthesized by the sequential electroless deposition technique on

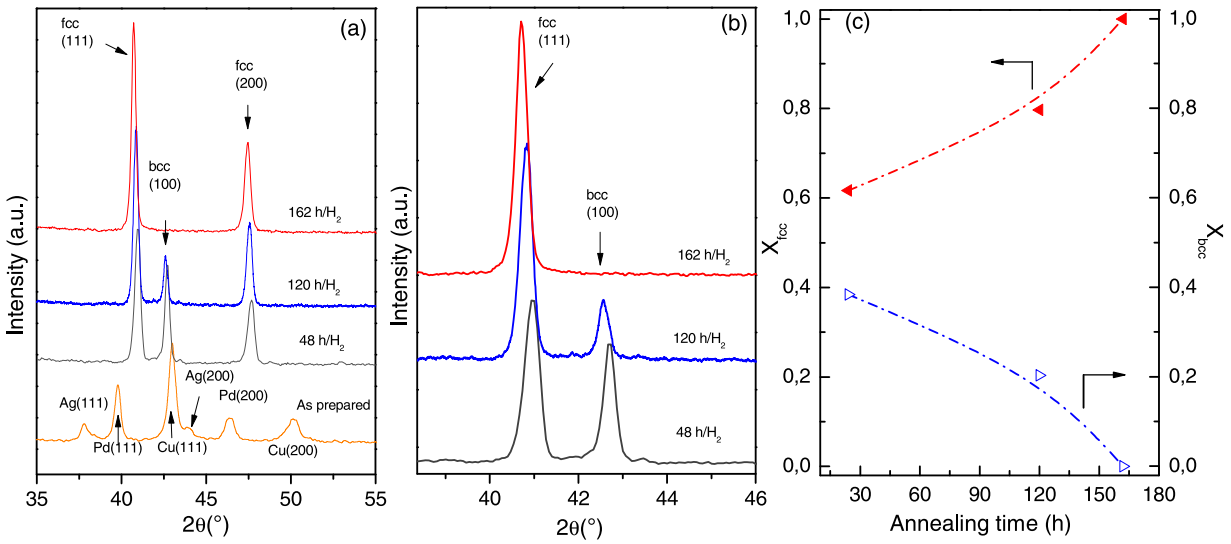

Figure 11 X-ray diffraction patterns of the PdAgCu ternary alloy films corresponding to the as synthesized samples and after annealing up to 773 K in H_2 at different times (a). Short scan of the (111) fcc peak and the (100) bcc peak for the PdAgCu film (b). X_{fcc} and X_{bcc} as a function of annealing time. Reprinted from Tarditi, A. M.; Cornaglia, L. M. Novel PdAgCu Ternary Alloy as Promising Materials for Hydrogen Separation Membranes: Synthesis and Characterization. *Surf. Sci.* **2011**, *479*, 246–255. © Elsevier 2011.

top of ZrO_2 modified porous stainless steel disks. For the synthesis of PdCuAu alloy samples, palladium (323 K) was deposited first, followed by Au deposition (333 K). The Cu plating (303 K) was performed on top of the Pd–Au layers, previously activated with $SnCl_2$ and $PdCl_2$. Plating times for Pd, Au, and Cu were adjusted to achieve the desired metal composition in all cases. The sample was then heated up to 773 K in H_2 at atmospheric pressure (101.32 kPa) in order to form a homogeneous palladium–gold–copper alloy by thermal diffusion. To obtain a higher film thickness, a second set of Pd, Au, and Cu layers was applied, followed by a second heat treatment at the same temperature.[54] The samples studied can be divided into two main groups based on their Cu concentration: the $Pd_{60}Cu_{37}Au_3$ and $Pd_{62}Cu_{36}Au_2$ samples, with a higher Cu composition and the $Pd_{70}Cu_{26}Au_4$, $Pd_{67}Cu_{24}Au_9$ and $Pd_{71}Cu_{26}Au_3$ samples with a lower Cu content. XRD patterns of the samples with lower Cu atomic concentration $Pd_{70}Cu_{26}Au_4$, $Pd_{71}Cu_{26}Au_3$ and $Pd_{67}Cu_{24}Au_9$ display complete fcc alloy formation after annealing in hydrogen at 773 K for 120 h. No evidence of the bcc crystalline phase or impurities was detected. In contrast, after annealing at the same temperature for 120 h, the XRD patterns of the $Pd_{60}Cu_{37}Au_3$ and $Pd_{62}Cu_{36}Au_2$ samples indicated the formation of a pure bcc crystal structure. The morphologies of the PdCuAu electroless deposited were homogeneous formed by cauliflower-shaped clusters with well-defined borders. The sample $Pd_{62}Cu_{36}Au_2$ shows a smoother surface, with less defined cluster borders, which could be attributed to the higher Cu content of this sample.[54] The morphology of this sample is similar to that of PdCu samples synthesized by the electroless method.[48]

3.1.5 Applications in Hydrogen Purification

Hydrogen has been considered as an ideal energy carrier for the near future. It can be obtained from renewable raw materials using a variety of energy sources, and it can be transformed into valuable energy forms with high efficiency and without detrimental environmental effects. Moreover, hydrogen is an important raw material in numerous industries, such as computer, metallurgical, chemical, pharmaceutical, fertilizer, and food industries.

Hydrogen can be used for electricity generation in fuel cells with a variety of applications in transportation and stationary power generation. To avoid deactivation of catalytic surfaces in low-temperature PEM fuel cells, H_2 must be nearly free of carbon monoxide, including other impurities such as hydrogen sulfide.

As a result of the increasing demand for high purity hydrogen, palladium-based membranes have received much attention in the last decade.[57–60]

Pd and Pd-alloys are able to separate hydrogen selectively because of the high solubility and diffusivity of this gas in their lattice. Molecular H_2 dissociates on a Pd catalytic surface to form H-atoms, which diffuse through the Pd bulk. The association of the atoms on the opposite surface of the membrane to produce H_2 molecules completes a process that could produce infinite separation selectivity.

The Pd membrane effect on the separation of a H_2 containing mixture is mainly determined by two parameters: permeability and the separation factor. The ideal separation factor (called perm-selectivity or selectivity) is defined as the ratio between a hydrogen pure gas flux to the flux of another pure gas at the same operating conditions.

The hydrogen permeability (Pe) can be expressed by the following equations:

$$\mathrm{Pe} = \frac{J_{\mathrm{H_2}}}{(P_{\mathrm{perm}}^{0.5} - P_{\mathrm{ret}}^{0.5})/L} \quad [15]$$

$$\mathrm{Pe} = D.\mathrm{S} \quad [16]$$

where J_{H2} [mol m^{-2} s^{-1}] is the hydrogen flux, P_{ret} and P_{perm} are the hydrogen partial pressure on the retentate and permeate sides, respectively, and L is the membrane thickness. D and S are the H atom diffusivity and solubility.

The dense metallic membranes can be classified into two groups: self-supported and composite membranes. Self-supported membranes are generally thick (higher than 25 μm) to have physical strength and exhibit inferior hydrogen permeability. Supported or composite membranes are formed by thin Pd-based films supported on porous substrates and constitute an economic option to overcome these limitations.

Generally, there are three main techniques to deposit metallic thin films onto porous supports: ELP, chemical vapor deposition, and physical sputtering. Among the methods developed for coating Pd or Pd-alloy films, ELP gives uniform deposition on complex shapes and any type of supports, produces hardness on the deposited film, and requires very simple equipment.[32,43,61]

Porous ceramic materials, glass, and metal were successfully used as supports for palladium membranes. Ceramic supports have robustness, chemical stability, and superior upper temperature limit. It has been reported that porous ceramic supports with rougher surfaces and larger pores favor the adhesion of the palladium films.[62] Porous metal supports as conductive substrates can be formed into various shapes and have engineered, interconnected porosity with different pore sizes. Furthermore, porous stainless steel (PSS) supports are promising substrates due to their good mechanical strength, more resistance to cracking, operation at high pressures, thermal expansion coefficient similar to that of Pd, and also because of the simplicity of module construction. Composite Pd/PSS membranes, welded on both ends to nonporous stainless steel tubes, can be easily assembled and integrated into an associated process. Nevertheless, the big pores and roughness of the PSS surface impair the preparation of a thin defect-free Pd membrane on porous stainless steel substrates.[63] Then, the pore size of the substrate and its surface roughness could be modified with an intermediate component.[64] The penetration of this material into the pore structure of the substrate would lead to a more compact structure. Thus, when the material is submitted to large temperature changes, the thermal expansion between both components will have lesser effects. This intermediate is also expected to be a diffusion barrier to inhibit the migration of the substrate components to the Pd layer, which will deteriorate the performance of the composite membrane.[65,66]

Yun and Oyama[62] made use of the Pd or Pd alloy layer thickness for a rough estimation of the materials cost, and of

H_2 permeance to evaluate the production yield, for industrial H_2 separations. For this comparison, they selected the ELP method for the deposition of Pd because of its ease of application for any shape or substrate compared with other methods. Substrate material effects were assessed using two factors (top layer thickness and H_2 permeance) for composite Pd membranes prepared by ELP (Figure 12).

Membranes using Vycor glass as a substrate require thicker separation layers to overcome the low mechanical stability of the glass and the difference in the thermal expansion coefficients of the materials. Membranes employing porous stainless steel also need a thick Pd or Pd alloy layer to obtain a continuous separation layer due to the broad distribution of pore sizes and their large size in the metal substrate. Thick Pd or Pd alloy metal layers result in high membrane preparation costs with low H_2 production yield. They concluded that the most desirable Pd membranes for practical applications should be prepared by the ELP technique on porous alumina substrates.

However, they did not consider the cost of porous supports and charges of fabrication. Moreover, in their analysis they did not discuss the effect of diffusion barriers applied to PSS substrates. PdAu layers with very low thickness and high selectivity (<90 000) have been obtained employing Y-ZrO_2/stainless steel porous filters (2.3 μm thick, $Pd_{95}Au_5$ composite membrane).[56]

3.1.5.1 Hydrogen Permeation Properties

Pure palladium films suffer hydrogen embrittlement particularly due to phase transition of the palladium hydride when exposed to hydrogen at temperatures below the critical temperature of 566 K. This hydrogen embrittlement can be overcome by alloying palladium with Ag or Au.[67] In this way, the α–β Pd–H transition temperature significantly decreases thus improving the membrane thermal stability and the tolerance to thermal cycling.

Binary Pd alloys of Au and Ag were also shown to have higher hydrogen permeability than pure Pd by McKinley in 1967[68,69] (Figure 13). This early research was done using cold-worked foils; this fabrication technique produces homogeneous films with precisely controlled compositions. However, the foils produced are generally limited to thicknesses greater than 25 μm.

The reasons for the permeability increase are complex. However, it could be related to the increase of H atom solubility and diffusivity that accompanies the expansion of the Pd lattice by insertion of the relatively large metal atoms.[68] In the case of binary palladium-alloys, Yun and Oyama[62] proposed that H_2 permeance is generally proportional to the average atomic distances of the alloys. This result is in line with the hydrogen permeation mechanism which is controlled by the diffusion of atomic hydrogen through the metal lattice. A longer atomic distance would facilitate this process.

In the last few years, measurements of hydrogen transport through ternary alloy membranes have also been reported.[51,54,70–72] Wang *et al.*[70] synthesized a $Pd_{69}Ag_{30}Ru_1$ alloy membrane by electroless co-deposition and reported that its permeability was three times higher than that of pure Pd. However, the hydrogen selectivity was not reported; hence, the high permeability could be due to the presence of defects.

Employing self-supported membranes, Bredesen and coworkers[71] studied the addition of a number of minor ternary components on PdAg alloys, ~$Pd_{75}Ag_{20}X_5$(X=Au, Mo, Cu, Y) through the magnetron sputtering technique; in all cases, they observed lower H_2 permeability than either pure Pd or the PdAg binary. Coulter *et al.*[72] reported self-supported 25 μm thick $Pd_{86}Au_6Pt_6$ alloy membranes with high H_2 permeabilities that depend on the sputtering conditions.

Authors studied several ternary alloys, PdAgCu, PdCuAu, and PdAgAu, deposited by sequential ELP on porous stainless steel substrates modified with Al_2O_3 or ZrO_2.

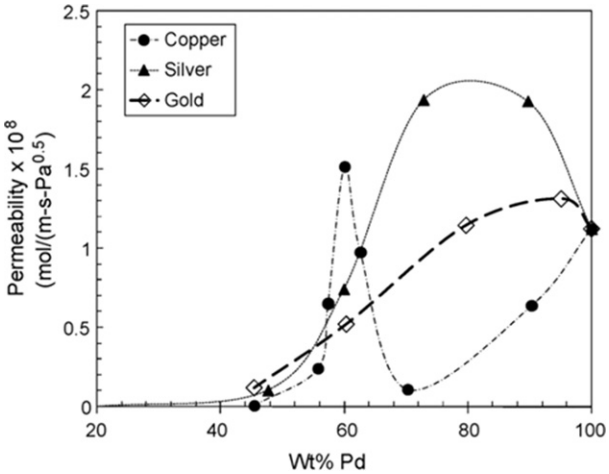

Figure 13 Hydrogen permeability as a function of alloy composition for alloys of palladium with copper, silver, and gold at 623 K. Reprinted from Gade, S. K.; Payzant, E. A.; Park, H. J.; Thoen, P. M.; Way, J. D. The Effects of Fabrication and Annealing on the Structure and Hydrogen Permeation of Pd–Au Binary Alloy Membranes. *J. Memb. Sci.* **2009**, *340*, 227–233. © Elsevier 2009.

Figure 14 shows the hydrogen flux measured for $Pd_{90}Ag_{10}$, $Pd_{98}Ru_2$, $Pd_{91}Au_9$ and both $Pd_{78}Ag_9Au_{13}$ and $Pd_{69}Cu_{14}Au_{17}$ ternary alloys and a Pd reference membrane at different temperatures as a function of $\Delta P^{0.5} = (P_{perm}{}^{0.5} - P_{ret}{}^{0.5})$. Linear relationships between flux and $\Delta P^{0.5}$ confirm that H-atom diffusion is the limiting step of hydrogen transport rates for all films. $Pd_{90}Ag_{10}$, displays the highest hydrogen flow among these films at 723 K. Note that all membranes have thickness equal to 14 μm, except the PdRu layer.

Permeability varied within this membrane set as $Pd_{90}Ag_{10} > Pd_{78}Ag_9Au_{13} > Pd > Pd_{91}Au_9 > Pd_{70}Cu_{13}Au_{17}$. In brief, the PdAgAu ternary membrane displayed lower permeability than the $Pd_{90}Ag_{10}$ alloy membrane, but higher permeability than the other membranes over this temperature range. Note that for all these membranes, the ideal H_2/N_2 selectivity was higher than 10 000.

Hydrogen permeability of related binary and ternary Pd alloys reported by several researchers are summarized in **Table 4**. Relevant examples selected from the literature are included as well as permeability of the membranes presented in **Figure 14** measured at temperatures from 623 to 723 K. The H_2 permeation measurements performed in our group showed that the ternary alloy membrane with less Ag and higher Au content ($Pd_{78}Ag_9Au_{13}$) exhibited higher permeability than the $Pd_{75}Ag_{16}Au_9$ alloy membrane. However, to study the influence of metal composition on permeability, the evaluation of H_2 transport through PdAgAu alloy membranes in a wide range of metal compositions would be necessary.

In the case of PdCuAg alloys, Ling *et al.*[77] using Density Functional Theory (DFT) calculations predicted solubility, diffusivity, and permeability of hydrogen at elevated temperature for a wide range of alloy compositions. From these predictions, they found that the permeability of H increases with Ag concentration for alloys with the same amount of Cu. For a $Pd_{67.1}Cu_{25.9}Ag_7$ ternary alloy, they reported a predicted permeability normalized to pure Pd of about 0.25. This value is close to the data obtained by Tarditi *et al.*[13] for membranes with a similar composition synthesized by the sequential ELP of Pd, Ag, and Cu on top of tube PSS supports.

Zhao *et al.*[76] also investigated a series of PdCuAg membranes with at least 70 at% Pd to elucidate the interdependence between alloy structure and H_2 permeability. They reported compensation between activation energy and the corresponding pre-exponential factor of the H_2 permeation laws obtained for membranes with differing alloy stoichiometry (**Figure 15**). The compensation effect indicates that atomic H diffusion in the bulk PdCuAg alloys remains the permeation rate-determining step down to 2 μm membrane thickness. In addition, the activation energy for H_2 permeation declines with increasing PdCuAg lattice constant, in general. This is in agreement with trends for H binding energies in interstitial lattice sites and transition states of PdCuAg alloys observed in DFT calculations.[77]

The effect of the fabrication method of Pd composite membranes prepared by different methods was evaluated by Yun and Oyama[62] considering H_2/N_2 selectivity and the top layer thickness. However, the H_2 selectivity showed no direct dependence on the Pd thickness but was affected by defects or pinholes on the surface, which are determined not by the thickness but by the quality of the top metal layer. Compared with other membrane preparation techniques, the ELP method allows the easy preparation of Pd membranes using simple equipment and any type of support with high selectivity and low Pd layer thickness.

3.1.5.2 H_2S Treatment: Hydrogen Inhibition Transport and Flux Recovery

The effect of H_2S, a common component of fossil-derived syngas, on Pd-based membranes has been studied. H_2S can block hydrogen dissociation sites and can also cause Pd-sulfide formation, which has lower hydrogen permeability than Pd. Alloying Pd with one or more components such as Au or Cu has been employed to improve its response to H_2S.[73,78,79] Most of the literature reports have been focused on H_2S/H_2

mixtures and only few of them studied the effect of CO, CO_2, H_2O, and H_2 mixtures containing H_2S.[74]

PdCu alloys have been extensively studied for sulfur tolerance; their responses to H_2S exposure are complex functions of alloy composition, crystalline phases, and exposure conditions. Alloys with Cu content lower than 30 at% form low-permeability bulk corrosion layers[78] at moderate temperatures, whereas high Cu content alloys exhibit complete inhibition of hydrogen transport, likely due to a combination of surface sulfide formation and site blocking by adsorbed H_2S.[80] In addition, Au has been used to improve the H_2S response of Pd.[79] At low concentrations (Au wt%$\leq$10), Au prevents bulk sulfide formation and partially preserves permeability when exposed to H_2S/H_2 mixtures.[79]

Recently, ternary Pd alloys have been considered for their potential to improve both permeability and H_2S response.[51,54,70–72] The few published reports of the H_2S response of ternary membranes were carried out mainly on self-supported membranes deposited by magnetron sputtering.[71,72] $Pd_{87-89}Au_{7-5}Pt_6$[72] and a series of $\sim Pd_{75}Ag_{20}X_5$ (X=Au, Mo, Cu, Y) alloys[81] synthesized by sputter deposition methods were applied to study H_2S responses in water gas shift and H_2/H_2S mixtures. All Au-containing ternary alloys exhibited the smallest fractional flux loss upon exposure to H_2S.

In our group, we investigated PdAgAu and PdCuAu alloy membranes synthesized by ELP, finding that they do not experience bulk sulfide corrosion even when exposed to 100 ppm H_2S/H_2.[51,52,54]

Seeking to combine the H_2S tolerance of the PdAu and PdCu binary alloys and the high permeability of the PdAg, ternary PdAgAu, and PdCuAu alloys prepared by sequential ELP were investigated. After annealing and pure hydrogen permeation measurements, 100 ppm H_2S/H_2 were added to the feed gas to evaluate the inhibition of H_2 transport by H_2S. Then, after 24 h of H_2S exposure at 663 K, the feed gas was changed back to pure hydrogen to study H_2 flux recovery. Figure 16 shows measured permeabilities as a function of time on stream during H_2S exposure and during subsequent recovery in H_2. All membranes present a large decrease in H_2 permeability after the introduction of H_2S. The primary cause of the rapid decrease is site blocking by adsorbed H_2S.[51] The permeability of pure Pd, and to a lesser extent $Pd_{90}Ag_{10}$, continued to decrease all over the H_2S exposure period, evidence of growth of a low permeability bulk sulfide scale. At the end of

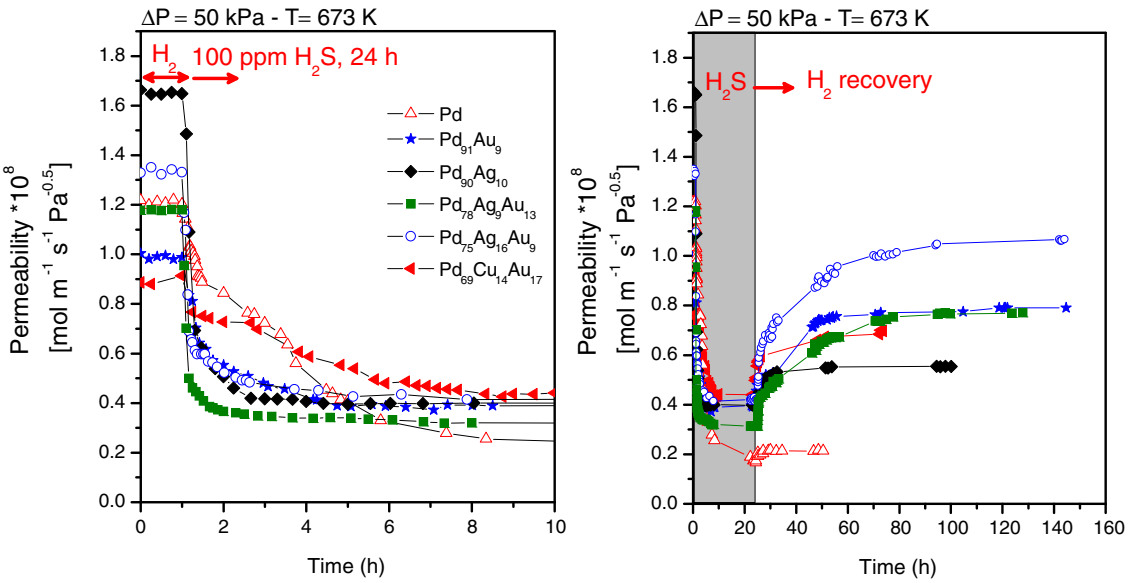

Figure 16 Permeability during the H_2S fed through the membranes as a function of time. H_2S treatment conditions: T=673 K, [H_2S]=100 ppm, time=24 h, ΔP=50 kPa. Reprinted from Braun, F.; Tarditi, A. M.; Miller, J. B.; Cornaglia, L. M. Pd-Based Binary and Ternary Alloy Membranes: Morphological and Perm-Selective Characterization in the Presence of H_2S. *J. Memb. Sci.* **2014**, *450*, 299–307. © Elsevier 2014.

the 24 h H_2S exposure, the membranes displayed the following order of permeability decrease: $Pd_{69}Cu_{14}Au_{17}$ (45% decrease) $< Pd_{91}Au_9 < Pd_{78}Ag_9Au_{13} < Pd_{75}Ag_{16}Au_9 < Pd_{90}Ag_{10} <$ Pd (85% decrease).

Pd and the $Pd_{90}Ag_{10}$ binary membrane showed only very small recoveries upon removal of H_2S, with no significant improvement over time. This behavior is also characteristic of formation of stable, low permeability bulk sulfide layers at the membrane surfaces. The Au-containing ternary alloy membranes displayed high values of H_2 flux recovery. However, none of these alloys recovered all of their original H_2 permeability at 673 K. Strongly adsorbed S and/or formation of thin two-dimensional sulfide layers could prevent the complete recovery at 673 K. XRD analysis of the H_2S-exposed PdAgAu, PdCuAu, and PdAu membranes revealed fcc alloy structure with no evidence of bulk sulfide formation.

To study the effect of temperature on the H_2 recovery, two full cycles of H_2S exposure at 673 K, recovery in H_2 at 673 K, followed by recovery at 773 K were carried out for $Pd_{69}Cu_{14}Au_{17}$ alloy film (Figure 17).[54] The complete hydrogen recovery observed after H_2 treatment at 773 K can be explained by considering two types of S adsorbed on the surface of the films: a weakly adsorbed S, which can be removed at 673 K and a strongly adsorbed sulfur/surface sulfide, which needs a higher temperature to be removed (773 K). The PdCuAu membranes were stable after a total of 550 h, including the annealing at 773K, the pure hydrogen permeation measurements and the H_2S-hydrogen recovery cycles.

The ideal H_2/N_2 selectivity ($< 10\,000$) of the ternary alloy films deposited by sequential electroless deposition on top of porous stainless steel substrates remained unchanged after H_2S treatment followed by hydrogen recovery, suggesting that the exposure/recovery process did not impair the structural integrity of the films.

3.1.6 Surface Properties of Pd Binary and Ternary Alloys

Surface composition is an important parameter in understanding the behavior of alloys in a wide range of applications such as catalysis, corrosion, and membrane separation processes and it is often different from bulk composition. The exposure of an alloy film to different atmospheres (H_2, CO, H_2S) and temperatures can produce preferential surface segregation in either beneficial or detrimental ways. The preparation of Pd-based alloy membranes with controlled metal surface composition and structure is very challenging. For this reason, a quantitative description of the phenomenon is necessary in order to make the appropriate changes in the bulk alloy composition to enhance or inhibit specific segregation behavior.

3.1.6.1 Surface Segregation of Clean Surfaces

XPS and LEIS spectroscopy are the most common techniques employed to determine the composition of the near-surface region and the top-most surface layer, respectively, of the Pd alloy films. Pd surface segregation under hydrogen atmosphere has been reported for the PdAg system. Shu *et al.*,[82] through XPS surface characterization of PdAg self-supported membranes, concluded that the chemisorption of hydrogen induces palladium surface segregation. In the same way, we have previously reported a higher Pd surface concentration in a PdAg sample after treatment in H_2(5%)/Ar at 673 K, when it was compared with the sample without treatment.[83,84]

To estimate the relative atomic distribution of the elements as a function of depth into the surface, both angle-resolved and Ar^+-sputter depth profiling, XPS measurements were performed. In addition, to characterize the top-most atomic layer of the surface region, LEIS spectroscopy analysis was carried out. Angle resolved XPS (ARXPS) experiments provide

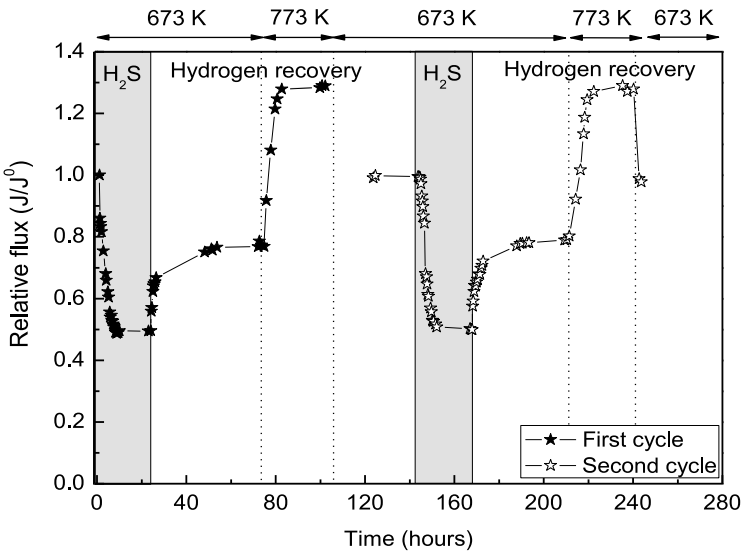

Figure 17 Relative hydrogen flux (J/J^0) during the 100 ppm H_2S/H_2 treatment and subsequent flux recovery for the $Pd_{69}Cu_{14}Au_{17}$ membrane. Reprinted from Tarditi, A. M.; Imhoff, C.; Braun, F.; Miller, J. B.; Gellman, A. J.; Cornaglia, L. PdCuAu Ternary Alloy Membranes: Hydrogen Permeation Properties in the Presence of H_2S. *J. Memb. Sci.* **2015**, *479*, 246–355. © Elsevier 2015.

detailed information about composition within the XPS-accessible near surface of *ca.* 6 atom layers.

Figure 18 summarizes surface characterization data obtained from the $Pd_{67}Cu_{24}Au_9$ (fcc phase) sample after annealing at 773 K for 120 h.[85] ARXPS results show that Cu concentration increased with increasing emission angle (more surface sensitive), while the Pd relative concentration decreased in the same way. These data suggest Cu segregation to the top-most surface region for the fcc $Pd_{67}Cu_{24}Au_9$ alloy.

Additionally, in order to have an indication of the elements distribution in a deeper region, Ar^+-sputtering XPS depth profiles were performed. The atomic compositions of Pd, Cu, and Au as a function of the etching time are plotted in **Figure 18**. The Pd atomic composition decreased with etching time while the Cu concentration increased. At larger depths, the Pd, Cu, and Au concentrations reached steady state, and are close to the bulk compositions measured by EDS. Note that the Ar^+-sputtering depth profile for $Pd_{67}Cu_{24}Au_9$ differed from the element distribution observed in the near-surface region (ARXPS) where Cu segregation to the top-most surface region was observed.

To characterize the top-most atomic layer of the surface region, LEIS analysis using 1 keV He^+ ions was performed. The time-dependence of the LEIS data provides evidence of a changing composition depth profile in the underlying layers due to sputtering effects (**Figure 18**). Note that the Pd concentration increases within the LEIS accessible near-surface region while the Cu concentration decreases, which is in agreement with the results of the ARXPS experiments of $Pd_{67}Cu_{24}Au_9$. For all PdCuAu films, the Pd composition of the near-surface region is above the bulk composition, and the Pd content in the top-most surface region is below that of both the bulk and the near-surface. This pattern could be related to the migration of Cu from the atomic layers immediately below the top-layer to the top-layer, as reported for other alloy systems. In contrast with the Pd and Cu behavior, the Au composition of the PdCuAu ternary alloys determined by XPS and LEIS did not show a significant difference with respect to the bulk composition.

The behavior of several Pd binary and ternary alloy membranes is compared in **Figure 19**. PdCuAu films displayed a similar surface segregation behavior as the PdAu alloy synthesized by the electroless method. In both cases, the near-surface region (XPS) became enriched in Pd with respect to the atomic bulk composition determined by EDS. On the other hand, for the PdCuAg, PdAuAg, PdAg, and PdCu alloys the near-surface region seems to be depleted of palladium with respect to the bulk composition (**Figure 19**). As shown in **Figure 19**, the segregation behavior observed in the PdCuAu electroless deposited films is different from that reported for the PdCuAg alloys, where a co-segregation of Cu and Ag in the near-surface region and Ag-enrichment to the top-most surface layer takes place. This is likely related to a different interaction of the minority component, Au for the PdCuAu system and Ag for the PdCuAg alloy, with the parent PdCu binary.[53,85]

3.1.6.2 Surface Segregation After of H_2S Exposure

The effect of local sulfur contamination at the surfaces of the materials, which may be undetectable by EDS and XRD, were studied on the Pd foil and the ternary alloys after 3 h of H_2S exposure through XPS composition depth profiles. The atomic compositions of Pd, Ag, Au, and S as a function of etching time/depth are shown in Video 1. The Pd foil has a significant sulfur content (S > 10 at%) throughout the ~40 nm profiling experiment. In contrast, the depth profiles of the PdAgAu alloy displays only very weak S signals at the top-surface (etch time = 0), which disappear before the etch depth reaches ~10 nm.

These results suggest that Au also imparts corrosion resistance to the PdAg binary. Au preferentially segregates to the surfaces of both the PdAu binary and the PdAgAu ternary alloys; high surface concentrations of Au are likely linked to the lack of reactivity of the alloy surfaces toward H_2S.

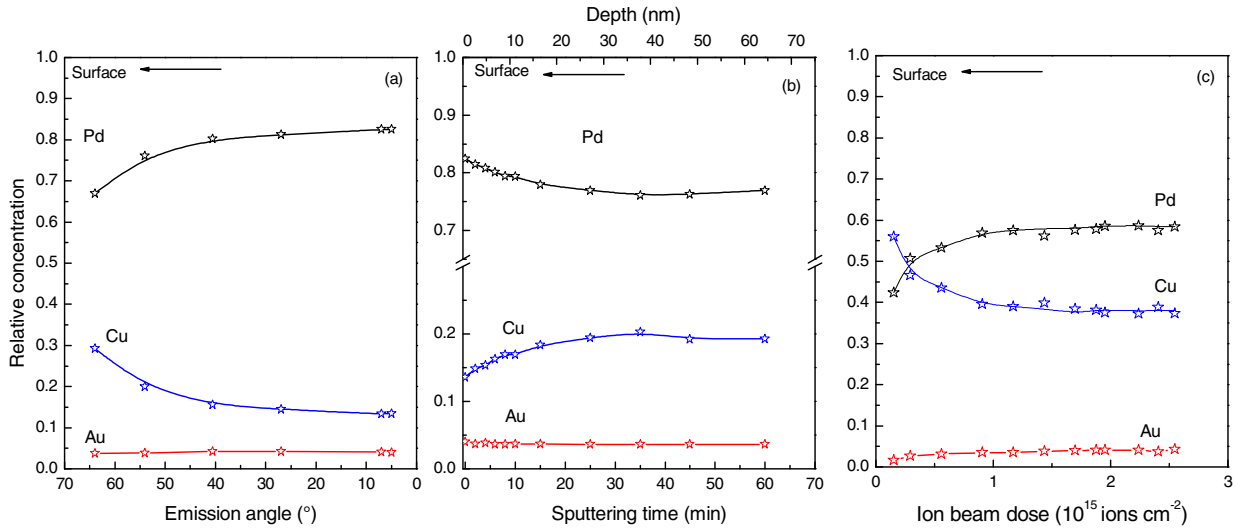

Figure 18 ARXPS and Ar^+-sputtering XPS depth profile (a, b); Pd, Cu, and Au LEIS concentration as a function of the ion dose (c) for the fcc $Pd_{67}Cu_{24}Au_9$ ternary alloy film after annealing up to 773 K. Reprinted from Tarditi, A. M.; Imhoff, C.; Miller, J. B.; Cornaglia, L. Surface Composition of PdCuAu Ternary Alloys: A Combined LEIS and XPS Study. *Surf. Interface Anal.* **2015**, *47*, 745–754. © Elsevier 2015.

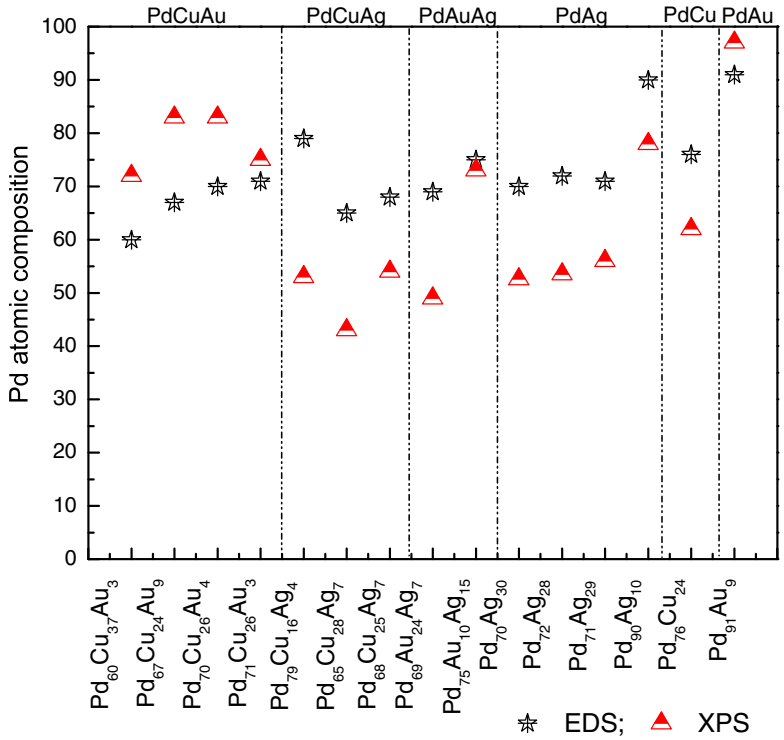

Figure 19 Atomic surface (XPS) and bulk (EDS) composition of Pd-based binary and ternary alloys synthesized by sequential electroless deposition and subsequent annealing at 773 K in hydrogen.

The high H_2S tolerance of the PdAgAu alloys is consistent with the Au enrichment at the surface and the pure-component standard free energies of sulfides formation at 623 K: Au_2S (-8901 J mol^{-1}), Ag_2S ($-63\,427$ J mol^{-1}), and Pd_4S ($-132\,005$ J mol^{-1}).

Our work illustrated the resistance of PdAgAu alloys to bulk corrosion by H_2S. It suggests that fabrication of a ternary alloy membrane based on the high-permeability PdAg binary, but with an Au component specifically for H_2S tolerance, could be an effective strategy for improving the membrane performance in extreme environments.

PdCuAu films also showed low sulfur content on the top-surface after H_2S exposure, which disappears about 10 nm into the bulk. The depth profiles of these films after the hydrogen recovery treatment at 663 K 48 h, followed by treatment at 773 K 24 h, show very low sulfur content ($\sim$3%), in agreement with the hydrogen flux recovery observed through the films.

3.1.7 Conclusions

ELP has been defined as a controlled autocatalytic deposition of a continuous layer on a catalytic surface by the reaction of a metal complex and a chemical reducing agent. Compared with electrodeposition, ELP can cover all surface types, regardless of size, shape, and electrical conductivity of the substrate.

Electroless deposition has been widely used to synthesize several binary palladium-based alloys in order to be used as membranes for hydrogen separation within other applications. For the development of homogeneous Pd coatings when the reducing agent was hydrazine, it was required to improve the stability of the plating bath by means of the proper selection of additives and stabilizers.

One of the major problems related to the ELP method is the difficulty of obtaining a uniform alloy composition on thickness. Alloying is most commonly achieved by the coating-diffusion method that requires temperatures in the 773–873 K range. Much effort is still needed for the development of new plating approaches and plating baths allowing the co-deposition of coatings with a homogeneous composition in thickness, thus avoiding the treatments at high temperatures.

Pd and Pd-alloys are able to separate hydrogen selectively because of the high solubility and diffusivity of hydrogen atoms in their lattice. The H_2 selectivity of Pd membranes is determined not only by the thickness but by the quality of the top metal layer. Compared with other membrane preparation techniques, the ELP method allows the easy preparation of Pd membranes using simple equipment and any type of support with high selectivity and low Pd layer thickness. The employment of an appropriate modifier/diffusion barrier for the porous stainless steel substrate allows obtaining Pd-based layers with very low thickness and high selectivity.

The synthesis and characterization of some Pd-based ternary alloys have been reported because of their superior properties concerning hydrogen permeability and/or chemical resistance. Ternary alloys containing copper or gold present higher H_2S resistance corrosion than the pure palladium membranes which experiment surface and bulk formation of PdS_4.

PdCuAu, PdCuAg, and PdAgAu ternary alloys films were synthesized on top of modified porous stainless steel substrates

by sequential electroless deposition of the pure metals. The ideal H_2/N_2 selectivity ($<10\,000$) remained unchanged after the H_2S treatment followed by hydrogen recovery, suggesting that the exposure/recovery process did not impair the structural integrity of the films.

For all PdCuAu films, Pd composition of the near-surface region is above the bulk composition, the Pd content in the top-most surface region is below that of both the bulk and the near-surface. This pattern could be related to migration of Cu from the atomic layers immediately below the top-layer to the top-layer, as reported for other alloy systems. In contrast, the Au composition did not show a significant difference with respect to the bulk composition. However, in the case of the PdCuAg alloys, a co-segregation of Cu and Ag takes place in the near-surface region as well as a Ag-enrichment to the top-most surface layer.

In the case of PdAgAu alloys, their high resistance to bulk corrosion of H_2S could be related to Au surface segregation. Au preferentially segregates to the surfaces of both the PdAu binary and the PdAgAu ternary alloys; high surface concentrations of Au are likely linked to the lack of reactivity of the alloy surfaces toward H_2S. It suggests that fabrication of a ternary alloy membrane based on the high-permeability PdAg binary alloy could be an effective strategy for improving the membrane performance in extreme environments. However, the evaluation of H_2 transport through PdAgAu alloy membranes in a wide range of metal compositions would be necessary to learn how the metal content influences the H_2 permeability.

Using suitable bath compositions and synthesis strategies, it is possible to synthesize binary and ternary Pd-based alloys to be applied as membranes for hydrogen separation. These synthesis strategies could be useful for the development and improvement of materials for application in other areas as jewelry and dental devices, among others.

3.2.1 Recent Developments in Metal Composites Incorporated in Hot-Dip Galvanized Coating

Despite the advances made in the discovery of new materials that could replace steel in various applications, the extraction and consumption of steel did not show a decrease considering the various statistics on the overall usage of various metals. Steel is used in various forms and it is an integral part in the construction, automobile, and allied industries.[1] Steel undergoes corrosion when exposed to different environments and during its application. There are various techniques to mitigate corrosion of steel structures, such as cathodic protection, anodic protection, alloying, cladding, addition of inhibitors, protective coatings, and metallic coatings. Various types of protective coatings are widely used to prevent corrosion of steel based on the ease of their application and long-term protection. Zinc coating is widely applied because active zinc metal corrodes more preferentially than steel substrate by a cathodic reaction that prevents steel from undergoing corrosion. Different types of zinc coating such as hot-dip galvanizing (batch or continuous), electroplating, metalizing (zinc spraying), mechanical plating, and zinc-rich paint are concomitantly applied on the basis of their application and exposure conditions.

Among them, the hot-dip galvanization process offers a unique combination of superior properties such as high strength, formability, light weight, corrosion resistance, low cost, and recyclability. The process of hot-dip galvanization has seen phenomenal growth during the past decades since its origin back in the eighteenth century. Hot-dip galvanized coatings are known to provide two types of corrosion protection for steel: barrier and galvanic (cathodic). The formation of intermetallic phases or alloys during galvanization depends on the diffusion rate of zinc into the steel substrate and the subsequent alloying reaction between iron and zinc.[2] Such structural modifications during the galvanization process not only improve the performance of the zinc coating but also could dramatically reduce the cost escalation in the process of galvanization. The numerous literature reports from different sources suggest various improvements in the galvanizing process and in the modification of pretreatment or post-treatment of the galvanized specimens. Analyzing the literature reports and reviews, it is clear that the microstructure as well as the surface modification have implications in improving the service span of the galvanized structure.

The performance of hot-dip galvanic coating formed on steel depends not only on the alloy composition of the outer layer but also significantly on the composition of the inner alloy layers at the coating substrate interface and also on the surface topography.[3,4] Further, the presence of barrier layers and through incorporation of certain metal oxides or mixed oxides or preformation of a dispersed metal oxide prior to galvanization can significantly improve the performance of the galvanized coating, thereby improving the coating span when exposed to a myriad of environmental conditions. The main problem of galvanic coating during its outdoor exposure is the noncolumbic loss in the zinc coating without exposing the under-steel substrate. Hot-dip galvanized coating consists of a heterogeneous assembly of different phases composed of mainly Fe and Zn, which are formed due to metallurgical reactions between iron and zinc when a ferrite substrate is immersed into molten zinc.[5] After solidification, the coating consists of an outer layer of 100% zinc (η layer) and inner layers, called alloy layers, consisting of intermetallic phases of iron and zinc such as zeta (ζ) layer (94% Zn–6% Fe), delta (δ) layer (90% Zn–10% Fe), and gamma (Γ)

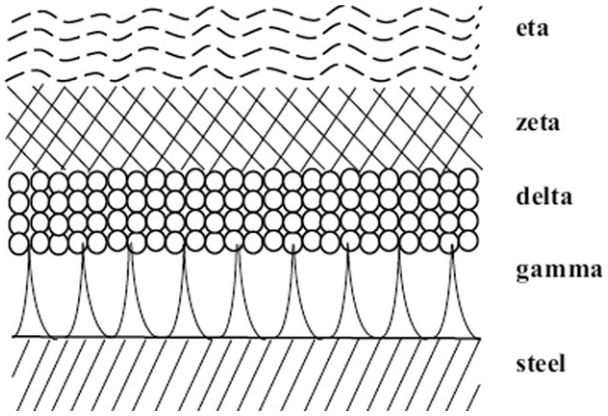

Figure 1 Schematic representation of various alloy layers of Fe and Zn formed by conventional hot-dip zinc coating.

layer (75% Zn–25% Fe), as shown in Figure 1.[6–8] The modification of the Fe–Zn alloy structure during its solidification could definitely improve the metallurgical characteristics of the zinc coating. The modified Fe–Zn alloy layer can be predicted to act as a quasi-stable alloy–oxide layer preventing the penetration of aggressive ions into the coating substrate interface. Thus, by acting as a barrier layer in galvanization, the property of the finished product can be improved. This could have implications in reducing the cost of the process by reducing zinc consumption during galvanization.

As already mentioned, incorporation of certain additives such as metal alloys, metal composites, and mixed metal oxides can modify the alloying character of the Zn–Fe alloy phase, which could improve the inner alloy structure of the galvanized coating. There are various metals such as Al, Mg, Cd, Cu, Ni, Co, Mn, V, and Sb that have been demonstrated to have higher corrosion resistance than pure Zn and that have been used as alloying elements in hot-dip galvanizing.[9–21] However, the thermal processes by which the galvanization reactions progress and different melting temperatures and the solubility of the metals adversely affect the Zn–Fe alloy structure. It remains to be determined whether certain metals have extremely limited solubility due to different melting temperature compared to zinc, and this makes the alloying reaction more complex.

The formation of intermetallic phases or alloys during galvanization depends on the diffusion rate of zinc into the substrate and the subsequent alloying reactions between iron and zinc.[22,23] The bonding strength between the substrate and the coating mainly depends on the surface feature of the metal substrate. The conventional hot-dip process involves laborious steps like degreasing, pickling, fluxing, and heating of the substrate before galvanization. Hence, the formation of the preformed oxide layer or incorporation of metal oxides and metal mixed oxides in the galvanizing bath lead to modifications in the alloy structure of the inner layers. In the present chapter, we discuss various methods including alloying by oxides and formation of a barrier layer as well as a preoxidized layer of metal oxide during hot-dip galvanization process.

There are plenty of literature reports available on modification of molten zinc bath by using metal oxides, rare earth oxides, and mixed oxides that were incorporated in galvanizing bath or formed as a dispersed inner layer or as a superficial layer in conjunction with the Zn–Fe alloy layer. Incorporation of the metal oxides not only could improve the inner alloy structure but also could reduce the consumption of zinc, which makes the process more economical. Metal oxides play a versatile role in the development of heterogeneous catalysis, gas sensors, and corrosion and wear protection materials.[24–29] High-performance hot-dip zinc coatings can be developed by the incorporation of individual and mixed metal oxides such as nano ZnO, nano TiO_2, CeO_2, CeO_2–TiO_2 , Al_2O_3–ZrO_2, FeO, and MnO_2 into the hot-dip zinc coating.[30–37] The incorporation of Al_2O_3–ZrO_2 and Al_2O_3–TiO_2 mixed oxides into galvanizing bath yields aluminium-rich zinc coatings with high sliding and wear resistance. The interior layers of the coatings are also known to possess high stability against corrosion, and many different mechanisms illustrate that corrosion resistance of the coating was improved with these types of additives in the molten zinc bath.[38–42] High corrosion resistance and better physical characteristics of the coating were achieved, as evidenced during analysis by different techniques.

Physical properties such as hardness, thickness, wear resistance, and weldability characteristics of the coating were found to be superior compared to the conventional zinc coating, as evidenced from literature reports.[43–48] The merit of any type of protective coating is the long-term protection it extends to various steel structures exposed to a myriad of exposure conditions. Other than sacrificial action in the case of zinc-rich coating, metal oxide like that in the inner or dispersed layer in the alloy phase could act as a barrier that could mitigate the penetration of certain types of aggressive ions such as Cl^- and ClO_4^- that cause pitting corrosion of steel surfaces and lead to catastrophic failure of giant steel structures. Use of Ni as an alloy metal is a viable alternative to some toxic metals presently used in galvanization.[49–54] It is clear that the extent of barrier protection of the coating was significantly improved, as revealed from various performance analyses including layer-wise electrochemical characterization of the coating under specific conditions.[14] In this case, substantial barrier protection in the coating due to the reinforcement of the metal oxide inner layer or dispersed metal layer was achieved. The interior layers of the coating exhibited relatively higher barrier protection characteristics compared to the outer layer, as evidenced from potential decay analysis of the coated specimens undergoing salt spray test and real-time impedance analysis.

3.2.2 Influence of Metal Oxides on Hot-Dip Galvanization Process

It has been proven that the presence of oxides in the inner layers could modify the Fe–Zn alloy phases, because it is clear that the metal underneath is protected at the same time that sacrificial action of Zn is improved due to the presence of oxides. It is understood that certain rare earth oxides, including Ti and Ta oxides, were also included in the molten zinc

bath.[31,34] These oxides that have their own certain unique alloying reactions when forming alloy phases could improve the property of the galvanized specimens exposed to specific conditions. Incorporation of nano TiO_2 in the hot-dip zinc coating has been known to facilitate phosphating and also to improve paintability of the galvanized structure. The hot-dip galvanized coatings with high corrosion resistance, effective barrier protection, good anti-fouling characteristics, and improved surface quality can be achieved by CeO_2–TiO_2 incorporation.[36,37] These composites not only yield individual characteristics of the additive incorporated in the coating but also provide a new range of reaction modification during the process. But there are certain drawbacks that arise during using these oxides due to their poor wettability in the zinc melt and also due to nonoptimum concentration of the oxide in the melt that lead to reduced homogeneity and distribution of the oxide blended in the zinc melt.

These issues are clearly discussed in this chapter based on the recent research advances made in the field and based on the evidence of various analyses of the improved galvanization process. Wettability of the oxides in the zinc melt can be improved by using relatively small proportions of various oxides that are to be blended with the zinc melt and through agitation and modification of surface morphology of the oxides or composites before blending with molten zinc. The consistency and homogeneity of the melt can be enhanced by blowing inert gases and by uniform mechanical stirring to avoid segregation or settling of metal oxides within the melt. From the literature reports, and based on the results from the authors' preliminary studies, the amount of metal oxides incorporated into the galvanizing bath can be optimized to 1–2 g, depending on which type of oxide is being blended in the melt.

The use of nano zinc oxide, cerium oxide, nickel oxide, titanium oxide, and iron oxide was widely used in various types of zinc coating and protective coating.[55–61] These oxides have certain special properties such as anti-microbial property, photocatalysis, wear resistance, corrosion resistance, and others, which can be well utilized for fabricating hybrid zinc coating for specific applications. One thing to be emphasized is that the amount of nano oxide in the molten zinc bath should be optimized depending on the reaction conditions such as temperature, agitation, and withdrawal speed of the specimen from the molten bath. To obtain homogeneous distribution of the metal oxide within the melt, a lower concentration of metal oxide is usually beneficial in that it could improve the galvanizing reaction between Fe and Zn and it provides reinforcement to the coating with uniform thickness.

Another report sheds light on the effects of micro-sized and nano-sized oxide particles on corrosion resistance and hydrolytic degradation of an epoxy coating during exposure. It was reported that the developed coating has shown better tolerance against corrosive electrolytes when incorporated with nano-sized and micro-sized ZnO particles. The corrosion resistance of the nano composite coating was considerably greater than that of the one reinforced with micro-ZnO particles, as revealed from the literature. The size of the particle has a profound effect on augmenting certain characteristic properties of the deposit. By tuning the size of the nanomaterials and optimizing their amount in the melt, we could modify the inner alloy structure of the deposit. The reinforcement resulted from oxide incorporation, and the modification in the alloy structure of the coating could improve the tolerance of hydrolytic degradation upon exposure to the corrosive electrolyte. Certain physical properties such as hardness, thickness, and wear resistance of the galvanized coating can be improved through incorporation of nanomaterials, which could have some specific applications. The behavior of the epoxy coating reinforced with nanoparticles exposed to corrosive medium reveals that the hardness and cross-linking density of the coating are considerably lower than that of the conventional hot-dipped sample and the sample reinforced with the micro-sized ZnO particles.

Certain other types of metal oxides that were found to be beneficial in enhancing the life of galvanized substrates are ZnO, TiO_2, and CeO_2, which have anti-microbial properties and are also good photocatalysts; therefore, these oxides could be well utilized for zinc coating exposed to water. Titanium dioxide (TiO_2) has been used as a self-cleaning and self-sterilizing material to coat different tools, including sanitary ware, food tableware, and cookware.[62,63] The anti-microbial effects of TiO_2 are activated by its photocatalytic behavior, which is totally dependent on ultraviolet and/or visible light irradiation. The effect of incorporation of titanium dioxide on the physical, electrochemical, and biocidal characteristics of hot-dip galvanic coatings is known to be highly corrosion-resistant with the least biogrowth when used in inclement weather. Although sometimes the metal oxides incorporated in the molten metal can become segregated during the alloy formation, this can be controlled by continuous agitation or by optimizing the concentration and withdrawal speed of the steel coupons from the galvanizing bath. The physical characteristics of the coatings were found to be improved by TiO_2 incorporation. The resistance of the coating against biogrowth can be studied by quantifying the number of microorganisms on the coating surface after immersing in natural sea water containing microorganisms.

Nano ZnO is a promising material due to its easy method of synthesis, nontoxicity, anti-corrosion, and biocidal activities. ZnO that can form a permeation barrier coating[64] is material generally recognized as safe by the US Food and Drug Administration. ZnO nanoparticles are much more effective agents than micropowders for controlling the growth of different microorganisms. Some authors[65–68] have reported that the smaller the particle size, the greater the efficiency in inhibiting bacteria growth. Moreover, several works have proved that the anti-microbial activity is also dependent on the concentration used.[69–72] The higher the concentration of ZnO nanoparticles and microparticles, the higher the antibacterial effect achieved. These results indicate that increasing the active surface area enhances the anti-microbial activity. This observation complements the idea that addition of ZnO nanoparticles in the zinc coating could have beneficial effects in controlling the microbiologically influenced corrosion.

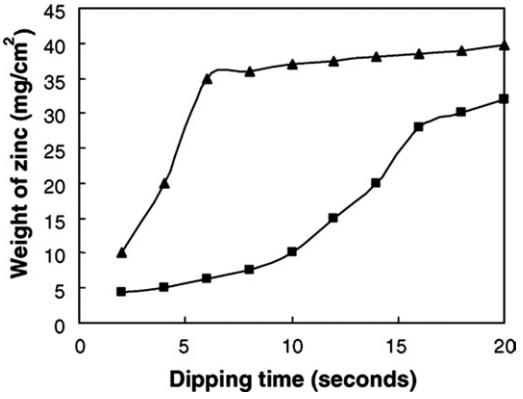

Figure 2 The amount of zinc (mg cm^{-2}) consumed during the galvanization process as a function of dipping time of the substrate: (▲) pure zinc coating and (■) oxide-incorporated coating.

Tuning of thickness is of prime importance and comes into play when using metal oxides in the molten bath. Although obtaining thick intermediate phases is beneficial because it would lengthen the protective life of galvanized coatings, it is not desirable from a mechanical standpoint because the thickness increment of the brittle intermediate phases could facilitate delamination and spalling of the coatings.[73,74] Moreover, excess thickness of the coatings would imply unnecessary use of zinc metal, which is impractical from an economic standpoint. In fact, coating overgrowth is problematic in several types of steels, including silicon-killed steels, where the reaction kinetics between iron and zinc is so rapid that simply reducing the hot-dip duration does not suppress the problem. Under this circumstance, it is advisable to use the process that could provide optimum performance with minimum zinc drainage.

One other work suggests the benefit of the FeO intermediate layer in zinc alloy coating. Presence of iron oxide in the alloy layer creates mixed potential during its exposure, thereby lowering the dezincification process during exposure. The report also contemplates reducing the zinc consumption during galvanization. The amount of iron present in the outermost layer of the iron oxide containing zinc coating can be attributed to the ejection of the oxide layer (FeO) during Fe–Zn outburst reactions. **Figure 2** shows the zinc drainage during galvanization with and without an oxide layer. Moreover, the iron present in the outermost layer could reduce the rate of zinc dissolution, which could not happen in the case of pure zinc coating.

One other important revelation regarding the use of nanomaterials as additives in zinc melt is that it could influence the topography as well as microstructure of the zinc coating. These materials that have high surface area could provide a smooth coating morphology and well-defined grain feature with spangle formation in special cases of zinc coating. This modified surface feature could mitigate the corrosion rate and could reduce the self-corrosion rate of the galvanized coating. The improved surface feature reduces the wetting tendency of the coating during various exposure conditions, and the glossy surface finish could improve the life span of the zinc coating.

3.2.3 Methods for Incorporation of Metal Oxide or Composite in the Galvanization Process

As the issues related to overgrowth and adhesion of the galvanized layer become more pertinent considering the performance and the economics of the galvanized coating for various application, it is necessary to discuss how to optimize the conventional process steps in conjunction with modern improved techniques to develop hybrid coatings that are more advantageous, have better tolerance for corrosion, and are economically viable. Several advanced coating methods were developed that can be suitably mimicked in conventional methods of galvanization through procedural modification and through additive components. The various methods identified involve formation of the monolayer or dispersed layer of metal or an alloy preceding galvanization, thermal decomposition of the substrate under controlled conditions, and blending the molten zinc bath with suitable additives. Each of these methods has its advantage and drawbacks when applied in conjunction with the galvanization process. Blending with suitable additives such as metal oxides, nanomaterials, and alloys is rather simple and beneficial compared to other process modifications.

3.2.3.1 Formation of Predeposited Metal Oxide Layer: Wet Coating

Among the various techniques that can be inculcated in conventional process sequences is the fabrication of a metal, metal oxide, or alloy layer over the steel substrate prior to hot-dip zinc coating. Here, presence of a certain metal layer such as Ni, Mn, ZnO, or Ni–P that serves as a physical barrier could influence the inner layer growth and the consumption of zinc during galvanization. It is clear that formation of a predeposited layer of metal, alloy, or metal oxide could have a profound influence on formation of the inner alloy structure and on the sacrificial action of the pure zinc outer layer during its course of exposure. The dispersed layer or thin layer of metal can be formed through the wet/dry deposition technique. Here, the techniques such as electrodeposition, electroless, dip coating, and vacuum coating are applied based on their suitability. Electrodeposition method can be applied to the substrate using an optimized plating bath for Ni, Zn, Ti, or Fe and by adjusting the rate of deposition through optimizing the current and time. Moreover, by means of electroless coating, an efficient Ni or Ni–P alloy layer can be applied by using a standardized bath where more or less uniform coating than electrodeposition can be obtained over the steel substrate. In dip coating, a thin layer of metal can be formed over the steel substrate by dipping the substrate in a bath of suitable metal salt solution containing a reducing agent. The reducing agent reduces the metal forming as a thin layer over the substrate. The metal oxide dispersed layer can be formed by either electrodeposition or heating the metal surface with the preformed metal layer that forms an oxide layer prior to hot-dip galvanization. During electroless coating, the thickness of the alloy layer can be controlled by adjusting the time of deposition.

One other report delves into formation of iron oxide over steel prior to galvanization. The steel coupons preformed with iron oxides can serve as a barrier layer for galvanized coupons. The iron oxide dispersed layer is formed prior to galvanization by impressing the steel coupons with required current in a suitable medium and the formation of a tenacious oxide layer is affected. Then, galvanization is performed with the oxide inner layer. It has been reported that the iron-rich inner layer can have greater resistance to corrosion than the pure zinc layer in normal galvanized coatings.[75–79]

Electrodeposition of crystalline ZnO thin films from aqueous solutions in the presence of suitable bath reagents has been reported.[80–83] In such cases, a thin film of ZnO is formed by the wet deposition technique, and further widespread studies have been performed by different groups regarding improvement of the coatings.[84–87] Galvanized coatings prepared with a pulse electrodeposited nickel inner layer can be produced with a uniform, void-free structure using a pulse-current waveform upon nickel deposition.[88] The pulse electrodeposition has more advantages than normal electrodeposition, whereby uniform and pore-free deposition with refined grained features can be obtained over the steel substrate. The small pulses of varying time intervals could be generated that ensure refurbishing the substrate or solution interface through replenishing with Ni ions. A typical microstructure of galvanized steels precoated with nickel consists of two apparent Zn–Ni intermediate layers and a nickel layer that survives the galvanization. The uniformity of these layers can be ensured by providing a nickel precoating of adequate thickness in relation to the hot-dip duration.

3.2.3.2 Vacuum Coating Techniques

In vacuum coating, a monolayer or a few layers of metal can be applied by sputtering, which is a chemical vapor deposition technique. The coating can be provided to small and larger area surfaces. One other advantage of vacuum coating is the formation of certain metals that are unable to deposit through the wet coating technique. Ti and Ta or Zr and Ir can be applied as monolayers to the steel substrate through vacuum coating. The monolayer formed by this technique is more adherent, uniform, and compatible to apply further galvanized layers. One other form of thin film formation of metal oxide is by metal organic chemical vapor deposition. The vacuum technique of metal coating is advantageous over other conventional solution phase methods despite its high cost. One thing to be noted here is that the thickness of the coating should not exceed a few monolayers because that could affect the galvanization process.

3.2.3.3 Direct Blending of Molten Bath with Metal Oxides

From the literature review, it is clear that there are many processes by which we can incorporate metal composites as metal oxides and mixed metal oxides through bath modifications that could modify the Fe–Zn alloy layer. Various metal oxides such as ZnO, NiO, FeO, ZrO_2, CeO_2, and TiO_2 have been used as oxides and as composites in galvanized steel substrate. The metal oxides can be directly added to the molten bath or as alloys that could be easily mixed within the molten melt. The amount of additive in the molten bath can be optimized for a homogeneous mix of metal oxide or alloys and the zinc melt. When adding various proportions of metal oxides, care should be taken to avoid agglomeration of oxides over the melt surface. This could ensure a homogeneous distribution of metal oxides within the molten zinc bath. Generally, the molten bath with incorporated oxides is agitated or stirred mechanically to avoid segregation of the oxide particles in the melt.

In this method, the metal composites are first blended in the molten metal bath and the same process as in the case of conventional metal alloy coating follows; therefore, the unique incorporation of various types of metals, alloys, metal oxides, and mixed oxides is possible. The advantage of applying each technique lies in its usage, mode of application, exposure conditions, and cost. Each method has its advantage and drawbacks, but based on the requirements we can shuttle between different conventional techniques in conjunction with modern coating methods.

3.2.3.4 Preoxidation of Steel Prior to Hot-Dip Zinc Coating

The type of steel substrate used in hot-dip zinc coating is noteworthy. For galvanization, steels with different elemental compositions have been used based on their applications for specific purposes. The presence of elements such as Si, Mn, C, Al, and Ti in various steel grades can influence the wetting nature of the steel surface by zinc and on zinc diffusion or penetration, forming various inner alloy layers including zinc consumption. To improve the galvanization process, depending on the steel type, preoxidation and annealing are used under controlled experimental conditions and by using reduced atmosphere. There are some common approaches that are used to improve the wettability of the steel and to develop hot-dip zinc coating with steels with varying alloy contents. One method involves the preoxidation of the steel substrate with high Mn or Si content.[89–96] This forms a porous Mn–Fe mixed oxide layer on the steel surface. The Fe in the mixed oxide should then be chemically reduced during the annealing process by an extremely dry atmosphere and form the Fe_2Al_5 inhibition layer with the dissolved Al from the liquid Zn bath on top of MnO, allowing growth of the Zn layer. The effect of cold rolling the hot-rolled steel with an oxide layer with a thickness of approximately 8 μ improved the wetting property of the steel for galvanization, and this has been investigated in detail.[97]

The preoxidation of the metal surface under controlled conditions in the reducing atmosphere can have a beneficial influence during formation of Fe–Zn alloy phases. There is also a report of an improvement in the wettability by changing the Al concentration in the bath, the bath temperature, and the temperature of the steel.[98] Cho and De Cooman suggest two additional methods: one involving annealing at high dew points to provoke internal Mn oxidation and the other involving flash coating of the surface with pure Fe.[99,100] These methods of pretreatment of steel prior to hot-dip

galvanization improve the wettability, alloying reactions, and other key properties of the coating. Reports are also available regarding corrosion-resistant characteristics of Fe–40Al intermetallic surfaces due to prior oxide formation. The oxidizing behavior of the alloying elements in the surface, if any, can form adherent oxide layers with effective protection characteristics.[57]

3.2.4 Implication of Metal Composites for Performance of Zinc Alloy Coating

Use of various types of metal composites such as metal oxides, mixed metal oxides, and nano metal oxides can have profound effects on the performance of hot-dip galvanized structures. As detailed in the previous section, the metal oxides that are incorporated in the zinc melt could modify the alloy structure and the mechanism of alloy formation between Zn and Fe. It is already proven that nano metal oxides and micro-sized oxides can improve the surface morphology and microstructure of the deposit. This could enhance the corrosion performance of the coating. In the case of metal oxides, one of the shortcomings is its uniform distribution within the zinc melt and its wettability nature. This is surmounted by optimizing the concentration of the additive (composite) and through uniform agitation of the molten melt. The physical and mechanical properties such as hardness, thickness, adhesion, weldability, wear resistance, and porosity of the developed coating with incorporated metal oxides and mixed oxides can be significantly improved in comparison with conventional hot-dip zinc coating. The corrosion tolerance of the galvanized coating may have a marginal improvement in comparison to the normal zinc coating. This has been experimentally proven by results from different electrochemical analyses and also by using certain accelerated corrosion testing. In the case of conventional galvanized steel coupons, the self-corrosion rate of the coating is greater; this behavior of coating deterioration, in addition to its sacrificial action, decreases the life span of the zinc coating. The self-corrosion rate can be drastically reduced in zinc coatings incorporated with metal oxides, as evidenced from a survey of recent research reports.

Different methods and instrumentation techniques are followed to study the efficiency of the developed coating for its overall performance and its applicability to different end uses. Various physico-chemical tests such as hardness, thickness, adhesion weldability, wear resistance, bend test, and smoothness are conducted per the standard test procedure to determine the improvement in the coating and its applicability. Long-term immersion studies are performed to assess the potential decay characteristics of the galvanized coupons under saline conditions. The change in electrode potential with respect to a saturated calomel electrode can be measured at regular intervals for a period of 30 or 60 days, as the condition warrants. Salt spray test can be performed per the ASTM B.117 standard for a period of 30 days at 35 °C to determine the deterioration of the zinc coating under aggressive conditions. The edges of the preweighed coupons should be covered with adhesive tape before placing the coupons in the salt spray chamber. The corroded coupons should be washed with 10% ammonium per sulfate ($[NH_4]_2S_2O_8$) solution at room temperature, dried, and weighed.

The results obtained from various observations predict that there is a remarkable improvement in the performance of the developed hot-dip zinc coating. By examining some of the literatures on the effect of certain oxides on hot-dip zinc-coated products, it is confirmed that these oxides are proven to be beneficial for improving the properties. The incorporation of TiO_2 in the coating has resulted in substantial enhancement of the hardness of the zinc coating. The additional incorporation of Al_2O_3 along with TiO_2 causes little further improvement in the hardness of the coating. The incorporation of TiO_2–ZnO composite in the coating can cause a significantly substantial reduction in thickness of the coating, as also evidenced in other reported studies regarding composite-reinforced hot-dip galvanic coating.[35,101] This could be due to the reinforcement of the metal oxides and the composite nature of the coating.

3.2.4.1 Physico-Chemical Properties of Metal Oxide Containing Hot-Dip Zinc Coating

The hardness value of a coated metal depends on many factors, and the most important one is the composition of the deposit layer. The hardness values for pure zinc-galvanized and galvanized layer over zinc oxide as a barrier layer are 50 and 58 HVN, respectively; however, in the case of Ni–P as a barrier layer, the hardness value is improved up to 70 HVN. The presence of ZnO or Ni–P as a barrier layer not only enhances the adhesion between the steel substrate and the galvanized layer but also inhibits the diffusion of zinc. However, due to the dispersed nature of the barrier layer, a local Fe–Zn outburst reaction occurs, facilitating high zinc diffusion.[46,101] The controlled diffusion of zinc reduces the coating thickness and enhances the adhesion between the coating and the substrate. The interdiffusion also improves the formation of more compact and regular alloy phase formation between Fe and Zn. The presence of mixed oxide composites in the molten zinc bath can reduce the alloying reaction between zinc and iron, resulting in lower thickness of the coating.

Adherence of the coating can be evaluated by first making the steel coupons bent, and then the coating can be tested for appearance of any peeling or cracks. After bending, the surface should not have any surface blemishes or peeling layers. This is in accordance with the already reported evidence on ZnO-incorporated hot-dip zinc coating.[55,101–103] This predicted the good alloying nature and the compact structural characteristics of the coatings. The observation of the thinner coating reveals more compact alloy layers, as observed in the case of zinc coating incorporated with ZnO.

Another type of oxide that shows inferior properties when added to zinc melt is V_2O_5. It is reported that with V_2O_5-incorporated zinc coating there would be several surface cracks, with peeling of outer layers after bend tests.[104] As the thickness of the coating increases, it is likely to develop more surface cracks during bend tests. Generally, incorporation of composites into the coating also results in improvement in

adherence of the coating. This is attributed to the fact that in the presence of inert metallic composites on the surface of the substrate, the diffusion of zinc during galvanization is lowered. The hot-dip zinc coating developed through incorporation of metal oxides and mixed oxides normally reveals a pore-free surface finish that shows the absence of iron on the galvanized surface. This reflects that during alloying mechanisms, zinc uniformly covers itself over steel and the formation of spangles shows good surface features of the zinc coating.

An important set of properties of galvanized steel is its weldability and paintability. It is clear that weldability of the oxide-incorporated coating is superior to conventional galvanized coupons. The surface pore features of the zinc coating prepared with nano oxides improves the paintabillity or phosphatization of the coating, which extends the life of the coating further.

3.2.4.2 Enhancement in Surface Topographical Characteristics

The surface morphology as well as the microstructure of the hot-dip galvanized coating can be significantly improved by the addition of various types of alloys, metal oxides, and inner layer oxides, as reported elsewhere.[37,54,55] It has been reported that incorporation of certain metal oxides could alter the crystal morphology and, depending on the size of the particles incorporated, the crystallite size may also vary.

As discussed, the performance of zinc coating depends not only on the outer surface feature of the coating but also significantly on the microstructure and inner layer morphology of the Fe–Zn alloy layers. Presence of certain oxides such as ZnO, TiO_2, or NiO or the presence of a preformed ZnO, Ni–P, and FeO layer can have a great influence on the improvement of the coating structure and the overall performance of the zinc coating. **Figure 3** shows the Ni-rich inner layer and ZnO inner layer that are formed within the Fe–Zn alloy matrix. Certain metal oxides that act as a barrier or inner oxide layer also improve the surface and grain features of the deposit. The formation of Ni and ZnO inner layers shows that the zinc drains, and thus formation of inner alloys could be controlled such that a uniform and porous surface finish is achieved in the hot-dip zinc coating.

The large crystals created better surface coverage for the coatings incorporated with nano metal oxides. The size of the metal oxides and their distribution in the Fe–Zn alloy phase modifies the microstructure of the coating. Similar to the reported results,[105–107] micropores and cavities are obtained on the surface of these types of coatings. However, the number of the pores is less in the case of the coatings incorporated with nano metal oxides, and this may be due to the surface sealing effect created by nanoparticles compared to micro-sized particles. It should be noted that when using nanoparticles as zinc bath additives, we have to control or tune the size of the particles and their surface features to achieve homogeneous distribution in the melt.

Incorporation of nano metal oxides causes structural refinement of the zinc coating that improves the surface topography of the deposit. Normally, the surface was homogeneous without any surface blemishes or peeled layer, revealing better adhesion of the coating when nano oxides of optimum quantity are incorporated. The surface roughness is normally less compared to conventional hot-dip zinc-coated structures. By optimizing the concentration of additives incorporated in the galvanizing bath, the segregating nature and powdery appearance of the coating can be improved. **Figure 4** shows SEM images of a typical hot-dip zinc coating with ZnO and V_2O_5 incorporated.

Certain metal oxides when added to the molten bath have been found to segregate, and this could lead to an inhomogeneous surface with the appearance of micro-voids caused by

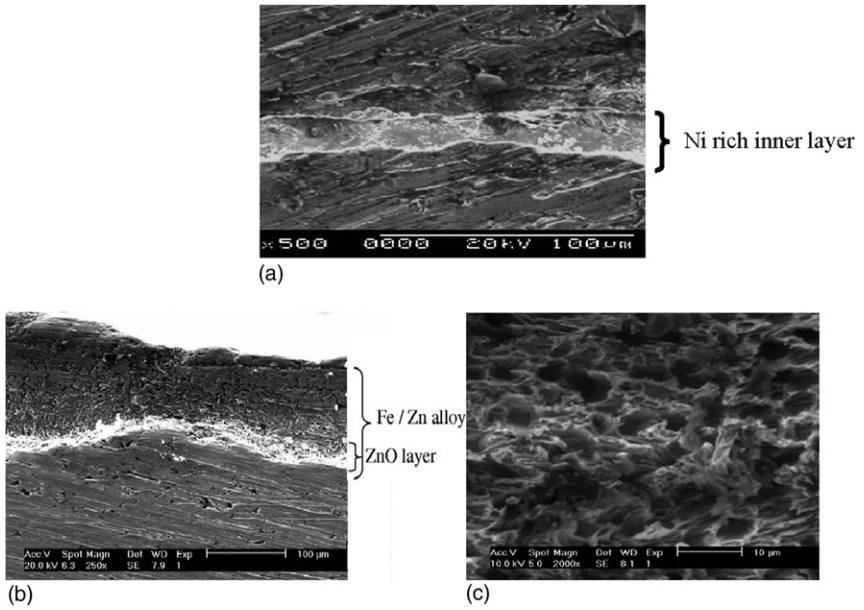

Figure 3 (a) Ni-rich layer, (b) ZnO inner layer, and (c) surface morphology of ZnO-incorporated hot-dip zinc coating.

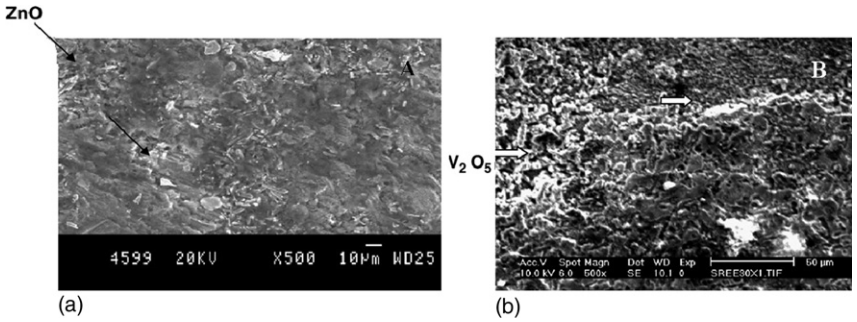

Figure 4 Surface topography of the hot-dip zinc coating with (a) ZnO and (b) V_2O_5.

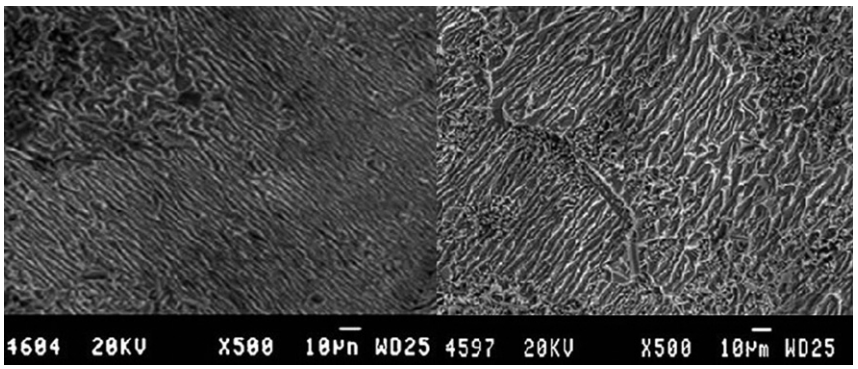

Figure 5 Surface morphology of pure Zn coating and TiO_2-incorporated zinc coating.

segregation. **Figure 4** reveals the segregating nature of surface oxides during the addition of V_2O_5. This can be due to non-wetting behavior of these oxides in the melt that results in formation of surface oxides with ridged morphology. Generally, the ridged spangle surfaces are populated with precipitates present in relatively large size.[108,109] Here, oxides such as ZrO_2 and V_2O_5 undergo segregation above a certain concentration, which leads to poor quality surface features for the galvanized coating. However, these oxides in the form of metal alloys are beneficial for improving characteristic properties of the coating. **Figure 5** shows the surface morphology of a typical zinc coating with pure Zn and one with TiO_2 incorporated.

The pure zinc coating or the coating with 5% Al or Mg alloy results in spangle formation after annealing. The features and size of the spangles depend on the withdrawal speed, temperature, and the alloying reaction with Fe and Zn. A very smooth surface with characteristic spangle formation can be achieved with certain types of oxides and alloy melts in the nano domain, provided that it has an optimum concentration. The nano size and the good wetting property of other oxides such as NiO, MnO_2 , CeO_2, and others can be used for developing hot-dip zinc coating with improved properties and superior surface features.

Color variations in hot-dip zinc coatings occur with changes in molten zinc bath temperature and with different concentrations of Mn. The color change is attributed to the MnO_2 formation. The formation of the Mn oxide film introduces a visible light interference effect with a specific surface color, certain film thickness, and refractive index of oxides. Tomita also reported that the color variations were due to the different thicknesses of the Mn oxide film on the coating surface.[110]

The presence of Mn in the Zn melt can significantly influence the microstructure and Fe–Zn alloy phase distribution. Various literatures indicate that the presence of Mn in Zn melt could promote the δ phase, where we could expect an increase in thickness of the δ-$FeZn_{10}$ phase.[111] This can improve the galvanic character of the hot-dip zinc coating. Mn is a surface-active element in the molten Zn that tends to migrate to the surface from the bulk to form an Mn-rich layer at the surface of the molten Zn. The Mn content at the surface of molten Zn could be more than 10-times higher than that inside the melt and will be oxidized preferentially due to the direct air exposure.[112,113]

3.2.4.3 Electrochemical Characteristics of the Zinc Coating

Important properties that concern the use of zinc coatings are primarily corrosion and formability. The progress of corrosion in different types of galvanized coatings can be investigated by using the electrochemical impedance spectroscopic technique, open circuit potential (OCP) decay, polarization character, weight loss method, and accelerated salt spray test.

Performance of the coating regarding corrosion tolerance under different exposed conditions must be determined. The OCP of the galvanized coupons fabricated with different types of metal oxides shows steady but high negative (cathodic)

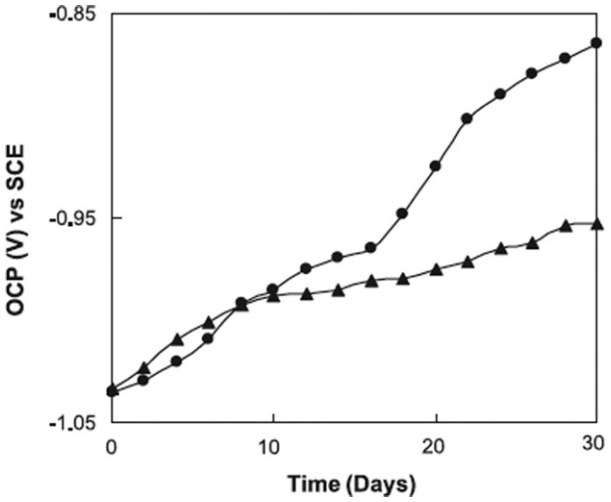

Figure 6 Open circuit potential decay curves of galvanized coupons during long-term immersion test. Medium: 5% NaCl at 30 °C, stagnant condition. (●) Pure zinc coating. (▲) With dispersed Ni under-layer.

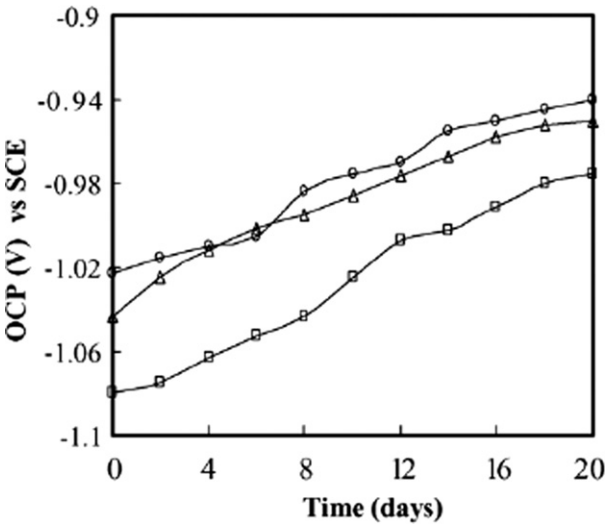

Figure 7 Variation in open circuit potential of the three different galvanized coupons compared to time of exposure during immersion in 5% NaCl solution as a function of nickel concentration in the coating. (○) 0.08% Ni; (Δ) 0.12% Ni; and (□) 0.18% Ni.

potential values during the initial hours of immersion in the electrolyte. The high negative OCP exhibited by the coupons can be attributed to the better alloying reaction between Zn and Fe and to the sacrificial nature of the top pure zinc layer. When Ni is used as barrier layer or a dispersed under-layer, the formation of inner alloys becomes modified. Although corrosion potential of nickel on steel is nobler when compared with steel substrates, nickel can provide some degree of protection by acting as a barrier to aggressive ions.[14,54] The uniformity of the coating, compact layering structure, low surface energy of bright crystals due to their smooth surface, and smaller amount of surface segregation can enhance the polarization tolerance of the coating. The penetration of Cl^- or ClO_4^- ions can also be prevented effectively by the under-layer of nickel coating, as revealed from various reports. Figure 6 shows the potential decay of the pure zinc coating and Ni-dispersed hot-dip zinc coating. Also, regarding the concentration of an additive element, there can be a shift in the potential for exposure. Figure 7 shows the variation in the OCP of the steel coupons with different concentrations of Ni in the alloy layers. Here, the one with the higher concentration of Ni exhibits more cathodic potential initially during the exposure, which can be attributed to the mixed potential of the outermost alloy coating. The shift in cathodic potential is gradual during exposure to 5% NaCl solution, as revealed in Figure 7.

It is clear that we can lower the dissolution rate of zinc in the presence of certain alloying metals such as Ni and Mn, which can act as a barrier layer, thereby significantly reducing the self-corrosion rate of Zn. This is observed with respect to some types of hot-dip zinc coatings containing multiple alloying elements. One other possibility for lower dissolution of Zn is the formation of comparatively stable corrosion products that are formed with certain types of additives that extend protection from corrosion to the underneath substrate.

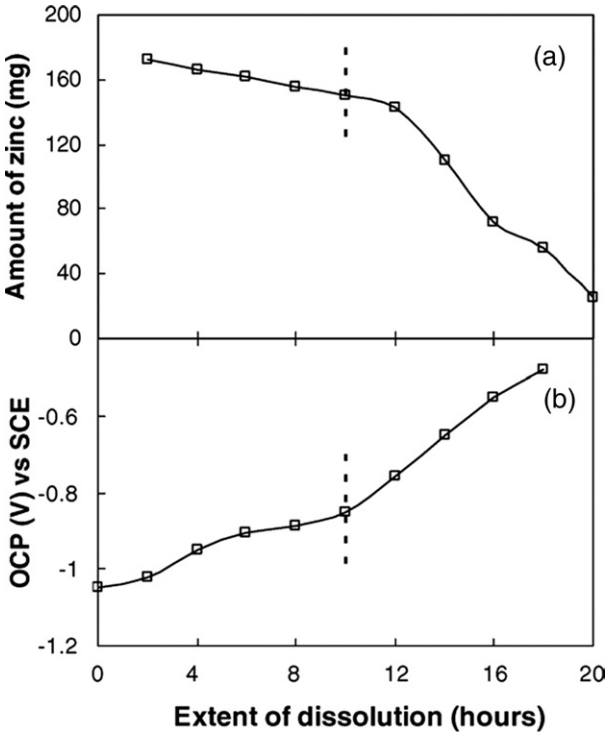

Figure 8 (a) The amount of zinc present in different layers of the galvanic coating formed on iron oxide layer. (b) The variation in open circuit potential (OCP) with respect to exposure of inner/deeper layers of galvanic coating formed on iron oxide layer.

In the case of galvanized coupons containing the highest concentration of nickel, nickel promotes a high rate of diffusion of zinc into the base metal. Nickel concentration increases in the inner layers of the nickel-containing hot-dip zinc coating, as also reported for similar coatings. Hence, any freshly

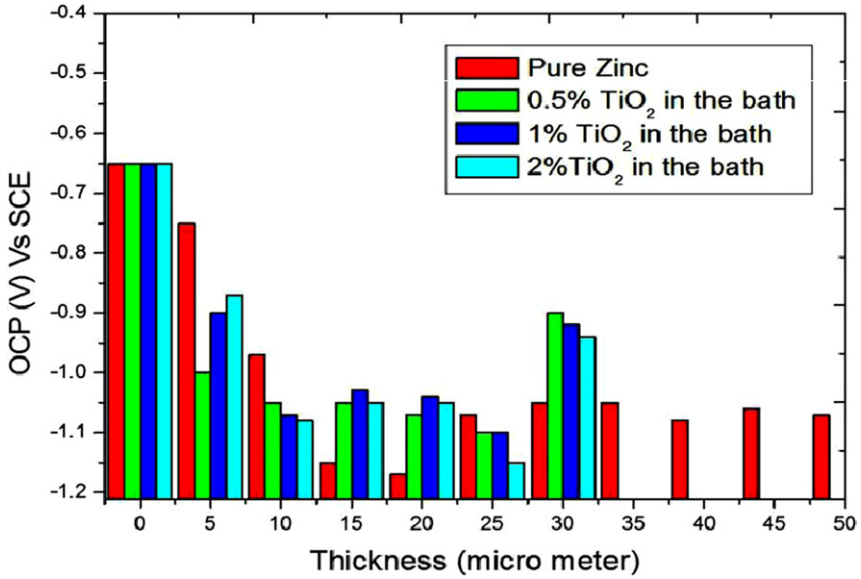

Figure 9 Comparison of layer-wise surface open circuit potential of different galvanic coatings with different concentrations of TiO_2.

opened under-layer should have more influence due to the increase in the concentration of nickel.

In some cases, the presence of oxides within the Fe–Zn alloy layer leads to a decrease in the potential decay of the zinc coating. Thus, it is clear that the zinc coating formed on the iron oxide layer exhibits high corrosion resistance due to the existence of the mixed potential and low dissolution rate of zinc with the optimum pH. The merit of the oxide-containing coating observed during OCP measurements is also notable even though the OCP parameters are not absolute to determine the corrosion rate of the coating. The oxide-containing coating also exhibits very low self-corrosion values among the two types of coatings during prolonged immersion tests. **Figure 8** compares the variation in OCP with the zinc dissolution rate under exposure of 3% NaCl solution.

It has been proven that TiO_2-incorporated hot-dip galvanic coatings can yield high corrosion resistance and less biogrowth on the surface. At the onset of corrosion, the TiO_2-incorporated coupons exhibit lower cathodic potential values do coupons coated with pure zinc. The presence of TiO_2 on the coating surface reduces the active corrosion sites and makes the coating more corrosion-resistant.[113,114] Because TiO_2 and ZnO have comparable band gaps, a synergistic effect of TiO_2 and ZnO could be predicted during the study of biogrowth on the surface of the coupons. Such synergistic action resulting in shift of electronic absorption to high wavelength regions has also been reported in the case of Zn plating with TiO_2.[115] Thus, by identifying suitable metal oxides, we can develop specific coatings to be used in many exposure conditions. **Figure 9** shows the variation in OCP with thickness of the hot-dip zinc coating with various concentrations of TiO_2.

Based on other research, it can be well explained and proven that the incorporation of nano TiO_2 in the phosphating bath can result in coatings with better electrochemical

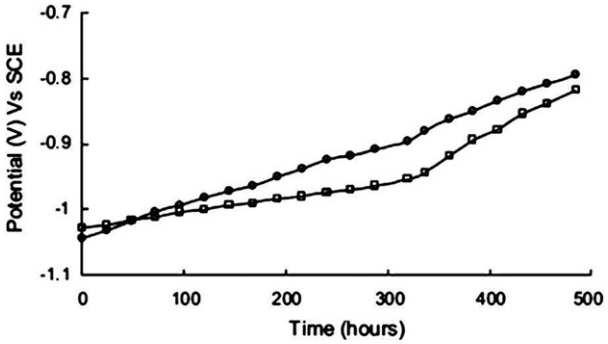

Figure 10 The variation in open circuit potential decay curves of the phosphated zinc coatings immersed in stagnant 0.5 M NaCl solution at 30 ± 2 °C (○, normal phosphate coating; □, TiO_2-incorporated phosphate coating).

stability and enhanced barrier protection characteristics. TiO_2 incorporation effectively reduces the extent of zinc dissolution. The incorporation of TiO_2 reduces the rate of active dissolution of zinc and thereby activates the process of phosphate crystallization, which ultimately yields greater thickness of the phosphate coating. **Figure 10** shows the comparison of the OCP decay curves of the phosphated zinc coating and the TiO_2-incorporated phosphated zinc coating under exposure to 0.5 M NaCl solution. The topography of the nano TiO_2-incorporated Zn coating is shown in **Figure 11**. The incorporation of nano TiO_2 into the phosphating bath can also cause structural refinement of the crystal, leading to the highest surface coverage and resulting in very high surface roughness of the coating. The roles of the nano TiO_2 composites have different mechanisms of action during the process. Their effective distribution depends on which layer is exposed or the composition of the bath (whether molten zinc or phosphating bath). In the phosphating bath, the presence of the oxide acts

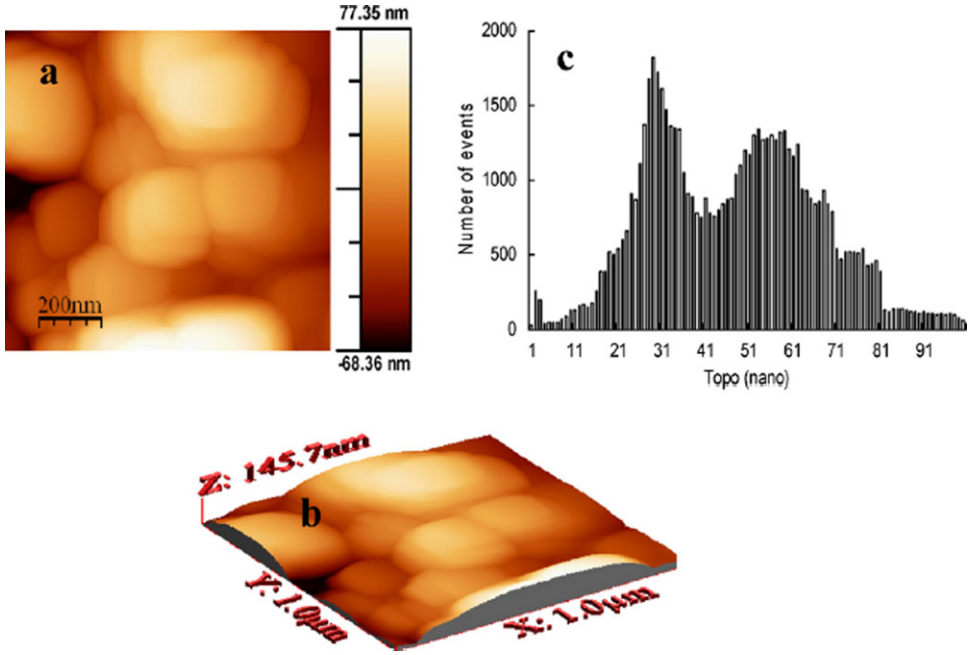

Figure 11 Atomic force micrographs of the TiO_2 coating: (a) two-dimentional image; (b) three-dimentional image; and (c) roughness distribution.

as a regulator and stabilizer to a certain extent and normally leads to a coating with a very high finish.

3.2.5 Summary

In the quest for fabrication of hybrid metal coatings, the co-influence of metal oxides and metal alloys are important for developing new coatings with superior performance for different applications. In the case of hot-dip zinc coating, which is a method that is centuries old, there are plenty of techniques, such as bath modification, pretreatment, and post-treatment, that are able to accommodate the conventional galvanization process. The present chapter highlights the recently developed coating techniques and how they can be concomitantly suited for application in the conventional hot-dip zinc coating process. In the present discussion, we briefly discussed the impact of various metal alloys, metal oxides, and mixed metal oxides on the galvanization process and the performance of the resultant galvanized product. The roles of intermetallic crystals and their *in situ* formation during the course of the galvanizing process are also highlighted.

3.3.1 Introduction

Although a particular material can be used to give a physical reality to a design, the former however fails to address every aspects of a foolproof design. A softer material may require a harder surface for protection against wear. A coarser surface may require to be smoothened for lower frictional resistance. An unattractive material may require to be esthetically improved for decorative purposes. Besides, there may be special requirements based on the demand of specific applications. Moreover, corrosion protection is nowadays a universal requirement for maintaining the device service life. All these fall under the purview of surface finishing in which the main idea is to modify the surface of a material in order to impart certain desired characteristics to it. In the absence of surface engineering, finding a material with all-round performance will not only be difficult but also costly.

Around nineteenth century, surface finishing was mainly associated with decorative purposes. However, with the passage of time the focus has shifted toward the 'functional' aspect of the process. Surface finishing is very important today and has been well established through industrial applications, researches, and patents. Various forms of surface finishing exists today, viz., finishing and polishing, conversion coatings (oxidation, anodizing), thermal coatings (carburizing – flame spraying), metal coatings (electrochemical, electroless), physical vapor deposition (PVD), chemical vapor deposition (CVD), organic coatings, etc.

3.3.2 Classification of Surface Finishing Operations

Surface finishing processes are primarily based on the principles of either removal (or reshaping) of the surface of the workpiece or adding and altering the surface with the help of external agents. Machining falls under the purview of the first principle while surface treatment and coatings fall under the purview of the second. Machining, however, smoothens out the material surface only whereas surface coatings employ a second material to be deposited on the first material to endow the specimen with certain properties which the bulk material may not intrinsically possess. The classification of surface finishing operations are given in Figure 1.

3.3.3 Types of Coating Processes

Coatings are a very flexible method of surface finishing. They can be applied on any material irrespective of metal, plastic, ceramic, etc., and over a wide range of thickness varying from a few microns to few millimeters. Coatings can be hard or soft based on the requirements. Hard coatings are in general wear

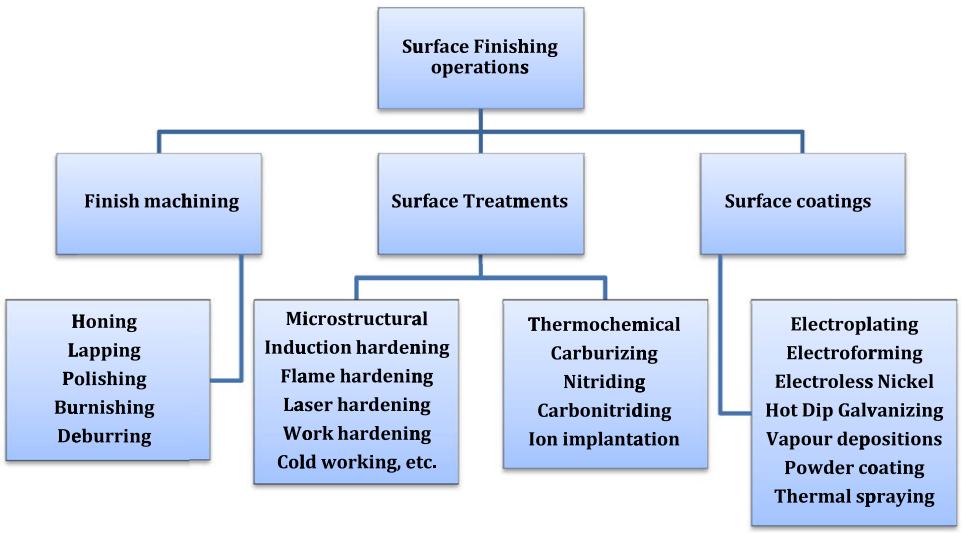

Figure 1 Classification of surface finishing techniques.

resistant while soft coatings exhibit lower friction. Besides, coatings can be deposited with appropriate combination of material to obtain desired properties. For example, certain soft materials can be embedded in the coating to bestow it with self-lubricating property. Moreover, several techniques of coating exist each having its own set of advantages and limitations. Based on the demand of application, a suitable coating process can be chosen.

Surface coating techniques can be further categorized as follows:

- Chemical and electrochemical techniques: electrodeposition, electroless deposition.
- Vapor deposition techniques: PVD, CVD, etc.
- Spraying techniques: thermal spraying, etc.
- Powder coating.

The surface finish coating techniques popularly used nowadays are briefly described in the following sections.

3.3.3.1 Electrochemical Techniques

3.3.3.1.1 Electrodeposition

Electrodeposition employs electricity to reduce cations of a desired material from a solution and coat that material as a thin film onto a conductive substrate surface. The principle works on Faraday's laws of electrolysis. Both the metal to be deposited (anode) and the substrate (cathode) are immersed in an electrochemical bath and direct current (DC) is passed. Sometimes, the bath may contain the salt of the metal to be plated. In that case the anode merely serves the purpose of completing the circuit. The coating rate may depend on the material being coated. Higher thickness can however be achieved by increasing the duration of the coating process. An electroplated layer is usually composed of a single metallic element. Nickel/chromium composites (usually called 'chrome' plating), copper, brass (an alloy), bronze (an alloy), and zinc are used for decorative applications. For functional applications zinc, tin, heavy coatings of nickel, 'hard' chromium, silver, and gold are used. Co-deposition of two or more metals is possible under suitable conditions of potential and polarization (viz., Cu–Zn alloy and Au–Sn alloy).

Electrodeposition is a very popular technique due to its simplicity of operation and bath stability. The process is extensively used in industry in the following areas:

- Protection against corrosion and wear.
- Improving the appearance of a comparatively unattractive material by coating a more expensive material over it as in the case of jewelry.

Electrodeposition suffers from a drawback of non-uniform coating thickness, i.e., the part of the substrate in proximity to the anode (metal source) displays higher thickness compared to the part which is away from the anode. This limitation can be reduced to some extent by using baths where metal ions are in complex form.

Electroplating is used to coat fasteners, jewelry, engineering components, to build up worn components, and sometimes as an undercoat for powder coating and painting.

3.3.3.1.2 Electroless coatings

Electroless nickel coating is a relatively newer technique of coating deposition. Here, coating happens chemically without the use of any electric current. The substrate to be coated is immersed in an electroless bath which typically contains a salt of nickel, a suitable reducing agent, complexing agent, and stabilizer. Apart from these, the bath may also have some other constituents (**Table 1**) depending on the coating to be developed. The cleaned substrate is immersed in the bath and the same is heated. The substrate develops a potential when it is dipped in the bath due to which both positive and negative ions are attracted toward the substrate surface and release their energy through charge transfer process. The basic chemical reactions for electroless coating are given by the following expressions:

$$R^{n+} \rightarrow R^{(n+z)} + ze$$
$$Me^{+z} + ze \rightarrow Me$$

where 'R' indicates the reducing agent and 'Me' indicates the metal to be deposited on a substrate.

Electroless coatings are an ideal choice for surface finishing due to their distinctive advantages, which are as follows:

- Uniform coating occurs even on intricate geometries. This is possible as the constituent elements of the material to be deposited are present in the solution in the form of ions. Since the substrate is fully immersed in the bath and every part of it has equal probability of getting the ions, hence the coating develops uniformly.
- As the coating happens chemically, with suitable activation, coating is possible even on non-conductors, viz., plastics, glass, etc.
- The deposits are often less porous and hence offer barrier protection against corrosive environments. They are found to display superior corrosion resistant capabilities compared to electrodeposited coatings and even hard chrome coatings.
- Electroless nickel coatings exhibit fair hardness (400–600 Hv) in as-deposited conditions which can be further enhanced to more than 1000 Hv with the help of suitable heat treatment. Moreover, with the incorporation of harder particles, viz., SiC, B_4C, etc., the hardness of the coatings can be made comparable to hard chrome coatings.

Table 1 Electroless nickel bath composition and their functions

Component	*Function*
Nickel ion	Source of metal
Reducing agent	Source of electrons
Complexants	Stabilizes the solution by forming nickel complexes
Accelerators	Activates reducing agent and accelerates the deposition
Buffers	Controlling pH (long term)
pH regulators	Regulates pH of solution (short term)
Stabilizer	Prevents solution breakdown by shielding catalytically active nuclei
Wetting agents	Increases wettability of the surfaces to be coated

- Deposits are smooth and have inherent lubricity due to their cauliflower-like microstructure.
- Coatings are solderable and hence can be applied in electrical circuit boards.
- Several materials can be co-deposited with electroless nickel to have customized properties.

3.3.3.2 Vapor Depositions

3.3.3.2.1 PVD

PVD refers to a host of techniques where the material to be deposited is converted to vapor, which is then condensed on to the surface of the substrate in the form of thin coatings. The thickness lies in the range of 0–20 μm. The desired material is ionized and atomized in either of the following ways:

- Physical evaporation
- Plasma sputtering (collisions with other atoms).

In the first method, the material is heated to temperature range of 1000–2000 °C in high vacuum (10^{-8} to 10^{-1} Torr) so that a high vapor pressure is developed, which is sufficient for condensation on the substrate. Alloys and compounds can also be deposited by evaporating separately the constituent elements in proper stoichiometric ratio or by reaction with a gas present in the environment. In case of the latter, an activation of the gases by plasma is often employed to increase its reactivity with the substrate surface. This results in increased adhesion which is normally an issue for plain evaporation-based depositions. The adhesion is poor because of the low kinetic energy of the atoms to be deposited.

In the second method, the material to be coated is ejected from the material surface by bombardment with energetic particles. It is the most widely used vapor deposition technique. In this technique, the coating material is made cathode and an inert gas, mostly Argon is introduced as a medium in which the glow discharge (plasma) is initiated and maintained. The ionized argon atoms are accelerated toward the coating material, whereby they collide resulting in the ejection of coating atoms with high energy. Sputtering can also be combined with a reactive gas giving rise to compound coatings.

Sometimes instead of plasma, an external source of ionization is employed to ionize the coating material. Sputtering process in general results in very good adhesion between the coating and the substrate compared to evaporation technique. This is due to higher kinetic energy of the atoms to be coated. Moreover, in case of sputtering, deposition rates of up to 100 μm h^{-1} can be achieved by the use of magnetrons. Sputtered coatings are commonly used as wear-resistant coatings in applications such as cooking knives and metal-cutting tools.[1] Common coatings applied by PVD include titanium nitride, zirconium nitride, chromium nitride, titanium aluminum nitride, etc.

3.3.3.2.2 CVD

CVD is a coating process in which deposition occurs by the reaction between the hot substrate and its atmosphere containing vapor or gases of the constituents of the coating material. The substrate may be heated by laser or electrical heater to temperatures in excess of 850 °C, which restricts the application of CVD to high melting point substrates only. The pressure in the reaction chamber ranges from 0.5 to 760 Torr. Lower pressure helps in attaining good adhesion and excellent deposit quality. Deposition rate is normally high (upto 40 μmh^{-1}) and is dependent on temperature and pressure. Hard coatings are deposited by this method which include nitrides, carbides, borides, and oxides, as well as structures such as diamond and diamond-like carbon (DLC) which are commonly employed for wear resistance in a variety of industries.

3.3.3.2.3 Plasma enhanced CVD technique

This process employs CVD coupled with glow discharge plasma to deposit coatings. The plasma produces high energy ions which promote deposition and hence the process can be operated at comparatively lower temperatures (up to 600 °C). The plasma also helps in sputtering the workpiece clean before deposition which enhances adhesion between the coating and the substrate.

3.3.3.3 Galvanizing

Galvanizing is the process of applying zinc coating to a more noble metal (popularly steel or iron) to prevent corrosion (rusting). Hot-dip galvanization is the most well-known method in which the steel part is submerged in a bath of molten zinc. In the bath, the iron in the steel metallurgically reacts with the molten zinc to yield a tightly bonded uniform alloy coating, which provides superior corrosion protection to steel. The simplicity of the process provides it with a distinct advantage over other corrosion protection methods. Moreover, galvanizing produces higher thickness coating (about 80 μm) of zinc compared to electroplating (about 25 μm).

Galvanizing is widely used for its ability to resist corrosion. The nature of protection offered by zinc coatings is threefold. First as a barrier, the dense coating covers the total surface and prevents contact with any corrosive environment. Second, if the coating is damaged, due to zinc's sacrificial behavior, corrosion occurs only in zinc. Finally, the natural weathering process helps in developing a natural passive layer on the surface which can then resist corrosion.

Galvanizing is used to protect large steel structural members, roofing material, etc. Tin is also often deposited using the hot-dip technique.

3.3.3.4 Powder Coatings

Powder coating is similar to painting where the substrate to be coated is in the form of a powder. The substrate to be coated is at first made ground and the powder is electrostatically charged. Then the powder is sprayed evenly on the substrate and then baked in an oven so that the powder particles melt and coalesce to form a continuous film. There are two main types of powder available in the market: thermoplastic powders, which will remelt when heated and thermosetting powder, which will not. During the curing process (in the oven), a chemical cross-linking reaction is triggered at the curing

temperature and it is this chemical reaction which gives the powder coating many of its desirable properties.

Powder coating is the youngest of the surface finishing techniques. Its inception was in Australia in around 1965. Powder coating is normally used to produce hard, wear-resistant coatings that are mainly employed for coating of metals, viz., household appliances, aluminum extrusions, drum hardware, and automobile and bicycle parts.

3.3.3.5 Diffusion Coatings

Diffusion coating is a process in which the coating is done on metal components made of iron, nickel, and cobalt under severe operating condition (elevated temperatures and corrosive environment). It provides a dense chemically bonded coating which acts as a diffusion barrier against corrosive environments. Diffusion coating can be done using three processes, viz., solid-state diffusion, liquid-state diffusion, and chemical gas diffusion.

Solid-state diffusion is used with nickel, titanium and iron, among other metals, and the vapor pressure of the coating metal must be lower than the base metal. The coating is performed in a hermetically sealed container with the base metal covered with the powdered coating material. The container is then heated in a vacuum, at a temperature of 1000–1500 °C. The coating metal melts to cover the entire surface of the base metal.

Zinc, chromium, and copper are normally coated through liquid diffusion. Liquid diffusion is usually performed in tank furnaces in which the diffusing metal interacts with the base metal's surface at 800–1300 °C. Complex diffusion coating, viz., chrome calorization and chrome-nickel plating can be achieved through this process.

In chemical gas diffusion, the material to be coated is heated into a gaseous form at a distance from the substrate surface. The gaseous chemical compounds of the coating element react with the base metal, resulting in diffusion of the metal. This gaseous phase consists of halides to ensure sublimation of the diffusing metal on the base metal's surface. The process is usually performed in specially designed furnaces at a temperature of 700–1000 °C.

3.3.3.6 Conversion Coatings

Conversion coating involves the application of a coating by spray or dipping on to a base metal to increase the corrosion protection and also sometimes used as a precursor for developing additional coatings, colors, or primers. Sometimes in conversion coating, a part of the substrate surface is converted into the coating with the help of chemical or electrochemical process. Examples include chromating, phosphating, metal coloring, and oxide coatings. The coatings are usually thin (around 2.5 μm) with a good degree of adhesion.

3.3.3.6.1 Anodizing

Anodizing is a conversion process which is widely used nowadays for surface finishing of aluminum in particular. Anodizing is an electrochemical process in which the natural oxide layer existing on the surface is increased in thickness. As aluminum exists in the anodic side of the galvanic series, it forms oxide readily which is corrosion resistant, hard and abrasion resistant. The naturally occurring layer is very thin (around 0.5 μm) and is susceptible to damage as it is attached to a more ductile material (aluminum). Hence, building up of the layer is necessary to attain the desired corrosion resistant properties.

Anodizing is carried out in the reverse process of electrolytic deposition. During anodizing, the aluminum part is made the anode (positive electrode) in an electrolytic cell consisting of an acid/water solution. The properties attained by the coatings largely depend on the temperature of the bath, for example, at 20 °C, a sulfuric acid anodizing solution will give a soft, transparent clear, easily dyed coating whereas at 5 °C, a hard, dense, and dull gray coating is produced (hard anodizing). A DC electric current is passed between the aluminum that is made the anode (positive terminal), the electrolyte, and a cathode (often lead).

When current is applied, the water in the electrolyte breaks down and oxygen is deposited at the anode. This oxygen combines with the aluminum to form oxide which builds on the oxide film always present on the surface. The acid in the electrolyte tries to dissolve this oxide and produces a porous oxide film on the aluminum surface. Coating thickness up to 25 μm is recommended for external use.

Anodizing produces a high specification metallurgically bonded finish that resists corrosion, abrasion and exposure to industrial, marine and other severe environments. Aluminum, titanium, zinc, cadmium, and magnesium are the metals that are usually anodized. Anodized aluminum is used in the aluminum window frames, commercial building fascia, etc. Aluminum castings are sometimes anodized for engineering purposes to increase surface hardness and abrasion resistance. Aluminum castings contain high levels of alloying metals such as silicon. The inclusion of these materials reduces the transparency of the anodic film and produces a greyish finish not greatly appreciated for decorative purposes. Hence, to avoid this problem, the process is carried out at low temperatures (less than 7 °C).

3.3.3.6.2 Phosphate coatings

This is a chemical conversion coating process through which thin adherent phosphate compound coatings are formed on a metal surface, viz., iron, zinc, or manganese. Among these phosphates, manganese phosphate is more suitable for wear applications. Phosphate coatings are usually applied to carbon steel, low-alloy steel, and cast iron. They can also be applied to zinc, cadmium, aluminum, and tin. Phosphate processes are hard to apply on high alloys for these alloys are likely to be immune to the phosphoric acid. In short, phosphating is one of the most useful non-metallic coatings.

3.3.3.6.3 Chromate coatings

Chromate coatings are similar to phosphate coatings. However, the chromate coatings are formed by the reaction of water solutions of chromic acid or chromium salts. The coatings can be applied to aluminum, zinc, cadmium, and magnesium. The coatings usually have good atmospheric corrosion resistance. Chromate coatings are widely used in protecting common household products, such as screws, hinges, and many hardware items with the yellow–brown appearance.

3.3.3.7 Thermal Spraying

Here the material to be coated (in powder or wire form) is heated to molten form and sprayed with high velocity on the substrate whereby they cool down and solidify to form coating. The heating in general is done electrically, either by arc or plasma. Higher coating thickness ranging up to several millimeters can be obtained through this technique. Thermal sprayed coatings are typically applied to metal substrates, but can also be applied to polymers, ceramics, or any combination thereof. Thermal sprayed coatings can be an effective alternative to several surface treatments including: nickel and chrome plating, nitride coatings, anodizing, etc. However, thermal spray technique has to be applied in line of sight only which poses several restrictions regarding coating of complex geometries and holes.

The thermal spray technique is primarily influenced by the temperature and velocity of the molten particles together with the atmosphere through which the material is sprayed. A schematic diagram of the thermal spray setup is shown in Figure 2. Lower particle velocity results in longer heating duration for the particles which in turn results in the particles attaining higher temperatures. Lower particle velocity results in porous deposits. Besides, if the spraying is conducted in air, oxide formation in coating will be higher.

Thermal spray comprises of four main processes which are as follows.

3.3.3.7.1 Electric arc spray

Electric wire arc thermal spraying utilizes the same principles as employed in wire arc welding systems. The coating material, in wire form, is electrically charged, and then contacted creating an arc. The molten droplets of metal wire are then sprayed onto the substrate using a high velocity air stream to atomize and propel the material. Arc spray coatings are very cost effective and are typically used to apply metals like pure aluminum, zinc, copper, and metal alloys such as stainless steel. Arc spray also allows adjustments to achieve varied coating texture. Electric arc spray is commonly used in automotive, aerospace, defense, infrastructure, etc. Electric arc spraying is also a favorite tool for artists in the creation of sculptures.

3.3.3.7.2 Flame spray

Flame spray, also known as oxy/acetylene combustion spray is recognized as the original thermal spray technique. It makes use of the basic principles of a welding torch with the addition of a high velocity air stream to propel molten particles onto the substrate. The coating material can be in the form of a wire, powder, or rod. Often flame spray coatings are fused after being applied to enhance bond strengths and coating density. The lower temperatures and velocities associated with conventional flame spraying typically result in higher oxides, porosity, and inclusions in coatings. Flame spray can be commonly found in industries such as oil exploration and agriculture. There are many other industries that use flame spray technology including aerospace, infrastructure, machine repair, etc.

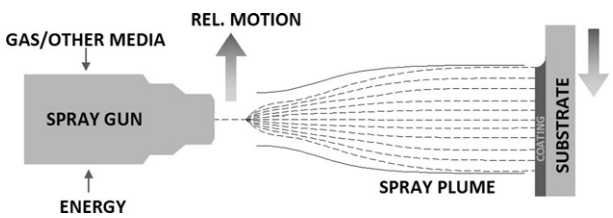

Figure 2 Schematic of thermal spray technique. Adapted from Synthetic Coatings Ltd. Available from: http://www.syntheticcoatings.ie (accessed 29 February 2016).

3.3.3.7.3 Plasma spray

In plasma spray process, plasma state is formed by introducing inert gases between two electrodes. As the plasma gas is heated by the arc, it expands and accelerated through a nozzle. When the gases exit the nozzle of the gun apparatus and return to their normal state, a tremendous amount of heat is released. A powdered coating material is injected into the plasma 'flame,' gets molten and then accelerated onto the substrate.

Because plasma-arc spraying is the most versatile of all the thermal spray processes its application can be found in the widest range of industries. Plasma spray coatings are used commonly in aerospace, automotive, medical devices, agriculture communication, etc. Ceramic coatings are most often applied using plasma spray due to their high melting temperatures.

3.3.3.7.4 High velocity oxy-fuel

The working principle of high velocity oxy-fuel (HVOF) is almost similar to that of flame spray. HVOF involves a closed combustion of fuels, viz., hydrogen, propylene, kerosene, etc. The hot flame is made to exit the chamber through a nozzle where it expands supersonically and propels the coating material toward the substrate. The extreme velocities provide the required kinetic energy which yield coatings that are very dense and very well adhered to the substrate.

Due to its simplicity of operation and quality deposits, HVOF possesses the largest share of the thermal spraying market. It is used to produce wear-resistant coatings, viz., cermets (ceramic and metal mixes), tungsten carbide, etc. As the coatings produced by cermets are very dense they are typically corrosion resistant. Inconel®, Stellite®, stainless steel, and ceramic coatings can also be produced by this method.

The coating processes discussed above are the ones popularly employed in the surface finish industry today. As can be seen each process has its own share of advantages and limitations. The application principle of different coatings processes vary. Moreover, the coatings produced by various processes differ in properties. Hence, an in-depth idea about a coating process is required before selecting it for a particular application. Figure 3 illustrates graphically the coating thickness and process temperature for the relevant coating techniques. The advantages and limitations of each of the processes are given in a nutshell in Table 2.

3.3.4 Existing Design of Coating Structures

Coatings are developed under multiple processes and with various materials, viz., metals, non-metals, composites, etc. Each type of coating may have a distinct set of properties.

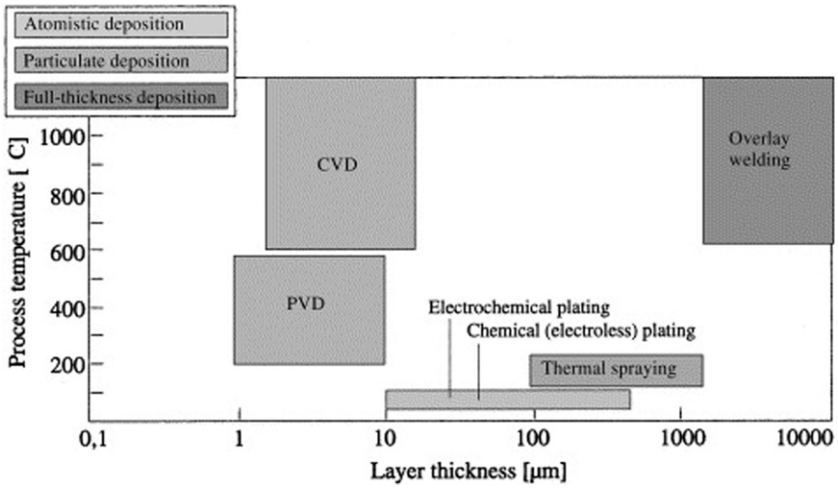

Figure 3 Typical values of process temperature and coating thickness for the surface coating methods. Adapted with permission from Ref. [2]. © Elsevier 2000.

Table 2 Summary of advantages and limitations for the coating methods

Coating process	*Advantages*	*Disadvantages*
Electro/chemical plating	• Corrosion resistance • Low processing temperature • Deposition in bore holes, slots, etc.	• Limited selection of coating materials • Relatively soft coatings • Ecologically problematic treatment baths (include cyanide, heavy metals, fluorides, oils, and greases) • Limited accuracy of surface replication
Diffusion processes	• Corrosion resistance • Good reproducibility	• Relatively soft coatings • Limited selection of base material (must be suitable for nitriding) • Long processing times • Substances from processing are damaging to the environment and to health • Post-treatment required
Chemical vapor deposition (CVD)	• High wear resistance • Economic production of thicker coatings • Suitable for bore holes, slots, etc.	• High processing temperatures • Coatings with several metals (e.g., TiAlN) are not possible • Edges become rounded (coating thickness) • Uses ecologically problematic, toxic metal chlorides
Plasma-assisted chemical vapor deposition (PACVD)	• Significantly lower process temperatures are possible than for CVD • Precise coatings • Low temperatures	• Only limited suitability for bore holes, slots, etc.
Physical vapor deposition (PVD)	• No environmentally damaging materials and emissions, no toxic reaction products • Great variety of coatings can be produced • Coating temperature below the final heat treatment temperature of most steels • Small, precisely reproducible coating thickness (accurate surface replication, true to size) • High wear resistance • Low frictional coefficient	• Bore holes, slots, etc., can only be coated down to a depth equal to the diameter or width of the opening • Corrosion resistant only under certain conditions • In order to achieve a uniform coating thickness, the parts to be coated must be rotated during processing

Besides, within the physical limits of a process, coatings can also be developed with different structures, viz., single layer, multiple layers, reinforced, graded, etc. Each of these structures may also induce some additional advantages in the coating in terms of it properties which may be beneficial to a particular surface finish application. Some of the coating structures

popular in surface finishing industries are discussed in the following texts.

3.3.4.1 Single-Layer Coatings

This is the most widely used coating structure which is easy to produce. Commercial CVD and PVD coatings are made up of one single layer often containing one structure phase. Among the most frequent are TiC, TiN, CrN, alumina (Al_2O_3), and DLC. They are usually applied directly on to the surface of a homogeneous substrate material. Consequently, to provide a high load carrying capacity of the coating composite, the substrate must possess a high hardness and a high Young's modulus. Moreover, many electrolytic and electroless coatings of metals and alloys are produced in single layer. Passivation processes like anodizing by default possesses a single layer structure.

3.3.4.2 Sandwich Coatings

In some cases, several layers of different compositions are applied on the substrate to form a sandwich coating. These types of coatings possess an equivalent property of the individual layers, or, the layers may act in synergy to address a particular issue. Metal-cutting inserts for machining austenitic stainless steel are typically CVD coated with three layers of TiC–Al_2O_3–TiN. TiC accounts for good bonding to the cemented carbide (CC) material, Al_2O_3 provides a good wear resistance at elevated temperatures and, in addition to looking good, TiN gives a clear visual indication of which edges of the insert that have been used. Besides, TiN often reduces the sticking of the work material.

3.3.4.3 Graded Coatings

A graded coating composition or structure improves the load carrying capacity by offering smoother transitions in mechanical properties from those of the hard and stiff coating to those of the softer and more flexible substrate. In this way, the contact load can be distributed over larger areas, which reduces the maximum contact stresses and the stress at the coating/substrate interface.

Successful graded surface layers on steel have been produced by nitriding or carbonizing since many decades, and the examples of forming tools and machine components taking advantage of these treatments are abundant. Today, graded coatings are utilized also in commercial PVD coatings such as Ti(CN). Moreover, graded coatings have also been developed for Ni–P coatings which offer better corrosion resistance compared to the non-graded coatings ones.[3] The grading in Ni–P coatings is developed based on percentage composition of nickel and phosphorous.

3.3.4.4 Duplex Coatings

Since many of the wear-resistant PVD and CVD coatings are relatively brittle, they can only be successfully applied to hard and stiff substrate materials such as hardened steel, CC, or structural ceramics. On softer substrates an intermediate layer acting as a mechanical support for the coating is usually required. For steel and titanium alloys, this support is preferably achieved by nitriding.[4] This combination of nitriding and PVD coating of steel is denoted as duplex coating. Duplex coating of electroless Ni–P/Ni–B are also formed and the compatibility between the layers are found to be good. It is also found that when Ni–P is the outer layer, the corrosion performance of the coating is better while wear resistance is better when Ni–B is the outer layer.

3.3.4.5 Multilayered Coatings

Multilayered coatings are different from sandwich layers by their periodically repeated structure of lamellae of two or more materials. The lamella thickness can vary between a few nanometers to a few tenths of a micrometer. Coatings made of multilayered structures have proved to be harder and significantly tougher than homogeneous coatings of the same materials since the lamellae structure obstructs dislocation and crack propagation.

3.3.4.6 Superlattice Coatings

Multilayered coatings of materials with similar crystal structures tend to form columnar crystals which extend through the whole coating, provided that the thickness of the individual lamellae is sufficiently thin (typically 5–25 nm). Such coatings are referred to as superlattice coatings. One of the first examples of superlattice coatings was obtained by combining TiN/VN and TiN/NbN.[5] Multilayered coating structure can also improve the hardness as well as the toughness, compared to single layers of the same materials.

By selecting a suitable combination of materials for the multilayered structure it is possible to improve the resistance against wear, corrosion, oxidation, high friction, etc. For example, superlattice coatings with thin lamellae of TiN and TaN have shown very good results in cutting of stainless steel. This is believed to be a result of a very good toughness combined with a low affinity of TaN to the work material.[6]

3.3.4.7 Multicomponent Coatings

Additional particles, grains or fibers are present in this type of coating. These additional elements may supplement some of the functionalities of the coatings. They may add to the strength of the coating by reinforcing action or by inherent hardness of the particles. In electroless nickel coatings, composite particles of SiC, B_4C, etc., help in making the coating hard and wear resistant. In contrast, soft particles like polytetrafluoroethylene (PTFE) help in reducing the coefficient of friction of electroless nickel coating. Different coating structures are illustrated in Figure 4.

3.3.5 Coating As a Method of Surface Finishing

Coatings are categorized as adding and altering techniques of surface finishing. They can be developed over the surface of compatible base materials (substrates) using suitable coating

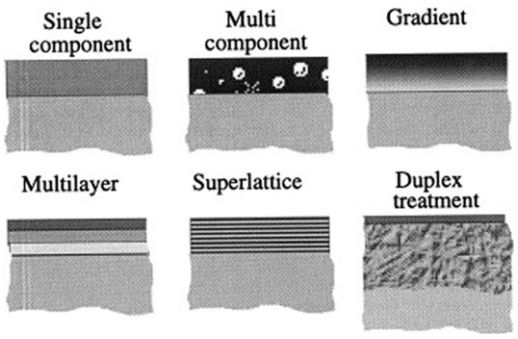

Figure 4 Structures of surface finish coatings. Adapted with permission from Ref. [2]. © Elsevier 2000.

methods. The substrate can be a metal or alloy, plastic, ceramic, i.e., any engineering material based on the application for which it is intended to be used. Depending on the demand of application, surface coatings can improve the esthetic appeal of a material, make the surface smoother and provide resistance against degrading phenomena, viz., corrosion and wear. Improving the esthetic appeal makes the product attractive and increases its marketability while covering the burrs and pits helps in reducing the surface roughness of the product which in turn lowers the frictional resistance. Prevention of corrosion and wear maintains the device performance as well as increases its service life. Moreover, this also eliminates the possibility of accidental hazards and enhances safety. Several types of coating methods exist each having its own set of advantages and limitations. However, with the advancement of technology, several novel coating methods are conceived from time to time which addresses the issues of the previous generation techniques.

Coating is more popular than other surface fishing techniques due to the following reasons:

- The procedure is simple and easy to carry out.
- Many materials and their combinations can be deposited.
- Wide varieties of coating processes exist. The one suitable can be selected.

3.3.5.1 Surface Finishing Facets of Coating

3.3.5.1.1 Improving esthetic appeal

Early applications of coatings within surface finish entity were mainly to improve the appearance of a particular object. Although the focus in the present times has shifted toward obtaining functional coatings, the decorative applications are befitting even today. The decorative applications are motivated by the following factors:

- The ability to compete favorably on an economic basis with decorative electroplating processes, keeping in mind the environmental considerations.
- The ability to provide a broad range of colors.
- Obtain corrosion resistance equivalent to or better than that of the coating process being replaced.
- Use of less expensive substrates.

Electrolytic coatings have for a long while served as a benchmark for decorative applications. Electrolytic coatings have often been used to produce gold plated jewelry and other decorative fittings. However, with passage of time several other coating methods have shown potential to serve in decorative applications. PVD, electroless nickel, chromium, etc., are commonly used for decorative purposes. Chromium plating is commercially used to produce wear-resistant and decorative coatings, but the plating bath contains hexavalent chromium, which has adverse health and environmental effects. Metal or ceramic coatings deposited by PVD are equivalent or superior in performance and are a cost effective alternative to chrome plating in case of decorative applications. Deposited PVD coatings can have a wide range of color. PVD coatings are used to plate watch components including bands, jewelry, eyeglass frames, pen parts (barrels, clips), cigarette lighter cases, knives, and other accessories. In case of jewelry, PVD coating is used to plate TiN which has a typical gold-like appearance. It has the further advantage of abrasion resistance. Now, stainless steel has high hardness and excellent corrosion resistance. TiN coated stainless steel jewelry provides the desired color and durability which has the potential to substitute gold as a cheaper alternative. Another interesting and widespread application of PVD is brass hardware, particularly door and window knobs and faucet parts. While brass hardware is attractive, the corrosion resistance of brass is somewhat limited. Unlike copper, which develops an attractive and uniform green patina on weathering, brass turns a dull dark brown. In order to maintain the attractive finish of highly polished brass hardware, it requires periodical polishing. The recent introduction of zirconium nitride (ZrN) PVD coating onto brass hardware has allowed suppliers of these components to offer 'lifetime' guarantee on surface finish. When deposited to the appropriate stoichiometry, ZrN has a finish that perfectly matches that of brass. It has excellent corrosion resistance, and therefore performs well in applications.

Most PVD is black in color; however, the underlying finish of the metal can affect the reflective properties. Thus, a bead blasted finish will produce a dull deep black appearance, whereas a rough brushed finish may produce a semi glossy finish. This adds a unique professional appearance to the timepiece and virtually eliminates reflective glare.

3.3.5.1.2 Protection against corrosion

Corrosion is a natural phenomenon that involves destructive attack of a metal by its environment so as to cause deterioration in the properties of the metal. Rusting of iron is the most common example of corrosion. Corrosion consumes about 3–5% of the Gross National Product of a nation. Corrosion science is an interdisciplinary area embracing chemistry, materials science, and mechanics. The study of aqueous corrosion processes involves the intersection of chemistry and materials science. But the science of mechanics must be incorporated to understand mechanically assisted corrosion processes, such as stress-corrosion cracking and corrosion fatigue.

Most of the things we encounter in day to day life is either made of metal or has metallic parts, which can get affected by corrosion. Besides, non-metals are also not entirely immune to corrosion. Hence, control of corrosion is vital so that the device service life can be extended. Corrosion protection is one of the primary aspects of surface finishing and coatings are widely used for the same. Electroless nickel, galvanizing, anodizing, etc., are popular for providing good corrosion resistance.

The protection mechanism of coatings against corrosion is normally twofold.

3.3.5.1.2.1 Barrier protection

As the name suggests, barrier protection acts by isolating the base metal from the environment. Barrier protection is perhaps the oldest and most widely used method of corrosion protection. All coatings provide barrier protection to some extent. As long as the barrier remains intact, the base material is protected against corrosion. However, if the barrier is breached, corrosion will begin. To keep the barrier intact, the coating should be strongly adhered to the substrate and also have good abrasion resistance. Hot-dip galvanized coating is widely employed for providing barrier protection to steel. The tightly bonded, impervious nature of zinc makes galvanizing a very good barrier coating. Furthermore, zinc corrodes approximately 1/10–1/40 the rate of steel depending on the environment, making the corrosion rate of a thin zinc coating equivalent to a much thicker steel piece.

3.3.5.1.2.2 Cathodic protection

Barrier protection is the first phase of protection offered by coatings. However, porosity is an issue in almost all the coatings. Presence of pores aids the corrosion products to reach the substrate surface easily. Moreover, coatings may get damaged or delaminated during handling and over a period of time. For these cases galvanic action at the region of contact of the corrosion product with the coating and the substrate determines the protection offered by the coating which is also termed as cathodic protection.

Cathodic protection is a more effective method of resisting corrosion. The cathodic protection depends on whether the coating material is higher than the substrate material in the galvanic series. The galvanic series of metals lists (**Table 3**) metals and alloys in decreasing order of electrical activity in seawater. This arrangement of metals determines what metal will be the anode and cathode when the two are put in an electrolytic cell. Metals higher on the list are anodic to the metals below meaning they provide cathodic or sacrificial protection when the two are connected. Cathodic protection requires changing an element in the corrosion circuit by introducing a new element, thus ensuring that the base metal becomes the cathodic element of the circuit. Hence, the new metal which is anodic corrodes in place of the base metal.

Table 3 Galvanic series of metals

Magnesium	Active (anode)
Zinc	↑
Aluminum	
Cadmium	
Steel/iron	
Lead	
Tin	
Nickel	
Brass	
Bronze	
Copper	
Stainless steel	
Silver	
Graphite	
Titanium	
Gold	
Platinum	Noble (cathode)

Galvanized steel is widely used in applications such as building, automotive body parts, and water distribution systems because of its good resistance to environmental corrosion. It is found that unprotected steel will normally corrode 10–40 times faster than hot-dip galvanized articles; the higher ratios usually being in high-chloride environments. Due to its inertness to high levels UV, hot-dip galvanization is the most popular coating for protecting steel in Australian continent as recommended by 'Galvanizers Association of Australia.'

Hot-dip galvanizing protects steel cathodically which is similar to the sacrificial anode method. From **Table 3**, it is apparent that in the case of hot-dip galvanizing, zinc will preferentially corrode to protect the underlying base steel. In fact, the cathodic protection of hot-dip galvanizing ensures that even if the coating is damaged to the point that bare steel is exposed, no corrosion will begin until all the surrounding zinc is consumed. Cadmium is also used to protect steel by this method.

Corrosion resistance of zinc coating is further improved when the zinc is alloyed with other metal (e.g., Co, Ni, Mn, Al). Some researchers have suggested that the higher protective ability of these systems is due to the corrosion products, zinc hydroxide salts ($Zn(OH)_2$), that formed as a result of interaction with the corrosion medium. Moreover, during the corrosion of zinc in an aerated, neutral solution (0.5 M Na_2SO_4), a passivation layer, which is composed of ZnO in association with $Zn(OH)_2$ is formed on the surface of zinc,[7] which further aids in its anti-corrosion behavior. The effect of pH over the corrosion rate of zinc is depicted in **Figure 5**.

Electroless Ni–P coatings are also widely used for corrosion protection application in a variety of environments. They act as barrier coatings, protecting the substrate by sealing it off from the corrosive environments, rather than by sacrificial action. However, in this respect, only electroless Ni–high P coating is effective in offering an excellent protection, whereas electroless Ni–low P and Ni–medium P coatings are not recommended for severe environments.[8] In general, the corrosion resistance of any alloy depends on the ability to form a surface protective film. Phosphorus can make the corrosion potential increase and the corrosion current decrease, and it promotes the anodic and cathodic reactions during the corrosion process, thereby increasing the anodic dissolution of nickel. Accelerated corrosion of nickel provides prerequisites for concentrating P and thereby for the formation of Ni_3P and Ni_xP_y stable intermediate compounds on the surface, which acts as barrier passive film.

The corrosion behavior of electroless Ni–P coatings is governed by three principal factors, viz., the degree of amorphous state, extent of internal stress, and the percentage of phosphorus content. The combined effect of all of these factors or dominance of any one of these factors is responsible for the observed corrosion behavior. The difference in corrosion resistance between electroless Ni–low P and Ni–high P coatings is in particular due to the difference in structure – a crystalline, inhomogeneous structure for the low P materials, and an amorphous, homogeneous one for the high P materials. Incorporation of specific elements in the electroless Ni–P coatings is found to increase its corrosion protectability. Copper element significantly improved

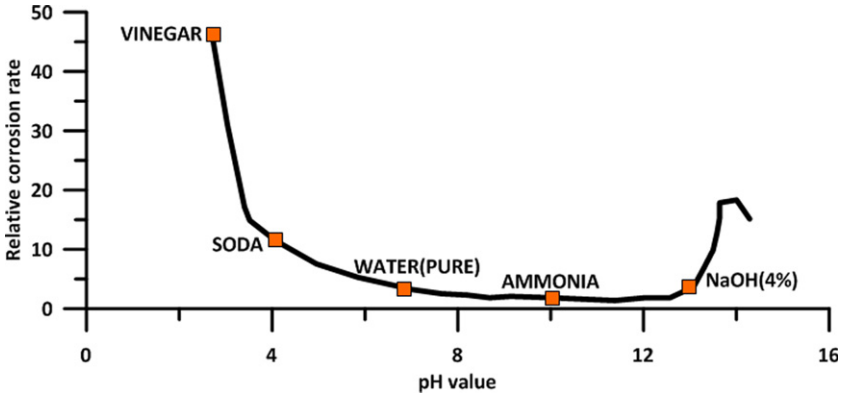

Figure 5 Effect of pH on the corrosion of zinc. Adapted from American Galvanizers Association. Available from: http://www.galvanizeit.org/ (accessed 29 February 2016).

the corrosion resistance of Ni–P coatings. Presence of copper in Ni–W–P deposit also improved its corrosion performance in both brine and acidic environments. Small amount of tin addition can improve the formability of the amorphous phase in Ni–P coating.[9]

Electroless nickel phosphorous coatings have been successfully applied on glass fiber reinforced plastic (GFRP) substrate for making blades of offshore wind turbine installations.[10] An offshore wind turbine should be designed so as to be able to withstand fatigue loads and a hostile environment at all times. Depositing Ni–P coatings on GFRP substrate increase its wear corrosion resistance besides imparting conductivity to resist against damage by lightning strikes. Electroless nickel coating has also been used to improve the wear and wear corrosion properties of carbon fiber reinforced plastic materials, which are frequently utilized in the aerospace, aviation, and automobile industries due to their light weight.[11]

Polyurethane (PU) coatings are employed for different structures today, such as storage tanks, oil and gas pipeline, water and wastewater pipes, bridges and ships to protect them against corrosion and abrasive wear. Chromium, aluminum, and silicon materials can be deposited with the help of diffusion coatings. This in turn makes the base metal develop extreme resistance to corrosion, oxidation, and erosion in its severe working conditions. This proves that the process is highly reliable, enhancing the manufacture of critical components. Diffusion coating is normally used to process gas turbine engine components (vanes, blades, and cases), pump impellers, gate valves, and power generation components.

The electric arc thermal spray technology has been used to coat large objects such as bridges, where aluminum and zinc are deposited to provide corrosion resistance. Flame spray and fuse coatings are produced in these industries to provide wear resistance along with excellent impact resistance.

3.3.5.1.3 Resistance to wear

Wear is a mechanical phenomenon which involves progressive loss of material when two bodies in contact move relative to each other. Mechanical devices suffer wear in operation which also limits their service life. Surface coatings are a way to tackle these deteriorating phenomena. Softer materials, viz., aluminum, magnesium, etc., can be made durable and wear resistant by putting suitable coatings on top. A preferred wear-resistant coating should have a high hardness combined with a relatively low modulus. This is because a high modulus limits the coating's flexibility and overall wear performance. Zeolite materials, with their unique crystalline porous framework, possess this demanding balance. Zeolites' crystallinity offers an exceptional hardness while their porosity provides a relatively low elastic modulus.[12] Zeolite coatings are demonstrated to outperform hard chrome and cadmium coatings in wear and corrosion resistance.

PVD is employed to prevent premature tool failure in cold forging. The wear volume of the coatings TiAlCN, TiC, and Si_3N_4/AlTiN is lower than for the coatings TiAlN and AlCrN.[13] A multilayered structure seems to act beneficially on the mechanical properties and the abrasive wear resistance of thin hard PVD coatings. The overall performance of the multilayered TiN/CrN coating indicates that this coating has a high potential as a tribological coating material. A multilayered coating of TiN/TaN seems to be the best choice for applications where abrasive wear is the predominant wear mechanism.[14]

Polycrystalline diamond coatings can be produced by CVD by using hydrocarbon gas (typically methane) in an excess of hydrogen. The resulting coating shows excellent wear and abrasion resistance. PVD is successfully used on transmission gears and engine parts of racing cars to help those 10 000 + RPM engines increase reliability. Because PVD reduces friction between metal parts less lubrication is necessary and temperatures are generally lower than without coatings. Though PVD coatings are typically only a few microns thick the molecules bond to the surface of the metal in such a way that they are very difficult to remove once applied. This long lasting resilience is what makes PVD so attractive for thousands of mechanical applications.

Tungsten carbide coatings can be put on top of materials like titanium and then subjected to finish grinding to increase its life span multifold. This type of parts can then be employed in landing gears of aero planes and automotive parts. Flame spray and fuse coatings are produced in these industries to provide wear resistance along with excellent impact resistance.

TiNrMoN have proved to be the most interesting multilayer coating, with exceptional tribological properties, when tested against alumina. The low friction properties of MoO_3 indicate

that it would provide good tribological properties also against other counter materials. Again Sn–Ni coatings electrodeposited from a chloride–fluoride-based solution present a somewhat better adhesion and wear resistance, in comparison with the coatings obtained from a pyrophosphate bath.[15]

The results showed that the wear resistance of the nanocomposites was increased by approximately 2–3.5 times compared with unreinforced Ni deposited material.[16] Chromium coatings prepared from a standard electrolyte are widely used in industry to restore parts of machines operating under various conditions and improve their wear resistance. Despite the advantages of these coatings over other materials, their use is limited by the aggressivity of the electrolyte.

Upon a thermal treatment of an electrolytic nickel–boron alloy coating at temperatures of 350–450 °C, the microhardness of the coating increases from 780–830 to 1300–1450 MPa.[17] Similar observations have been made in case of electroless nickel coatings. Electroless Ni–B in particular is found to be suitable for wear-resistant applications. The Taber wear index of Ni–B coating is found to reduce to an astonishing value of 13 after subjected to heat treatment at 400 °C in an atmosphere containing 95% Ar and 5% H_2.[18] Several other soft and hard particulates improve the wear performance of electroless nickel coating which include: alumina, boron carbide, silicon carbide, silicon nitride, silicon oxide, PTFE, and molybdenum sulfide.[9]

Dip coating of silica sol–gel coating reinforced with carbon nano tubes (CNTs) on magnesium alloys substrates displayed good wear resistance behavior.[19] Hard chrome (Cr) coatings are known for their excellent abrasion resistance, low friction coefficient, and their capability to produce thick layers for rebuilding worn parts back to specification. Cadmium (Cd) coatings are critical to aircraft fasteners as a sacrificial wear layer and to provide mild corrosion protection. Ceramic coatings, which are mainly composed of silicon carbide and polymer, showed excellent slurry-resisting performance, and the slurry-resistance is better than that of stainless steel 304, cast iron JM3 and high chrome alloy steel Cr30A. In case of cavitation erosion, a good coating is the one that is able to withstand the load and not flake off, consequently protecting the base material until the next maintenance. PU coatings are found to exhibit low cavitation erosion.[20] Plasma anodizing of aluminum offered a high abrasive wear resistance compared to coatings produced by thermal spray.[21] In case of injection molding of glass reinforced plastic parts for automotive industry, Stellite coatings deposited by cold spray process is found to be sufficiently wear resistant.

Besides possessing corrosion resistant properties, galvanized coatings also offer wear resistance up to some extent. Although the outer layer of galvanized coatings is soft and lacks abrasion resistance, the middle and inners layers are harder and more abrasion resistant than the steel. If the outer layer is removed in operation, the inner harder layers are exposed which give the coating outstanding abrasion resistance so that mechanical damage to galvanized coatings is minimized.

3.3.5.1.4 Generating smooth and lubricious surface

Any part can be made smoother by subjecting it to finer machining processes, viz., grinding, honing, and lapping. The use of these processes implies huge escalation in the production cost of the part. Coating is a method in which these cost can be avoided. Coating when applied on the surface of a part fills the gaps and other discontinuities making the surface smooth. Now, the general objective of applying coating to a surface for any tribology-based application is to impart both smoothness and hardness to the surface so that friction and wear are reduced. Among the two degrading phenomena, friction is a critical factor dictating the efficiency of mechanical assemblies that involve sliding surface contact. It is also partly responsible for wear, which is often the limiting mechanism of device service life. Thus, minimization of the friction of the coating is a vital need. For reduction in friction, sharper peaks, and lower contact condition is desired.

Electrodeposited cobalt coating reinforced by CNTs exhibited lower coefficient of friction than cobalt film at room temperature. However, the coefficient of friction of the composite films increased due to the formation of a significant amount of cobalt oxides on the surface and the dissipation of CNTs at 500 °C.[22] Electroless nickel coatings are inherently smooth and lubricious in nature due to their cauliflower-like microstructure. Addition of certain soft particles, viz., PTFE, graphite and MoS_2 is found to reduce the friction coefficient of electroless nickel coatings further. Introduction of CNTs in nickel matrix showed a very good lubrication property due the self-lubricating property of CNTs.[23]

With the development of low friction coatings such as DLC, smoothness of the substrate surface is now guaranteed. Tungsten disulfide (WS_2) offers low lubricity, with coefficient of friction around 0.03, under extreme load and temperature conditions. SiC–Ni coating produced by pack cementation was found to exhibit self-lubrication properties only at a temperature of 800 °C owing to dense tribo-film which spreads on the wear track.[24] Chrome oxide layer can be corrosion resistant, wear resistant and extremely lubricious. T800 is an alloy of cobalt and is deposited with the help of thermal spraying. It is used to prevent galling between sliding surfaces where lubrication is arduous and to prevent wear and corrosion.

3.3.5.2 Miscellaneous Surface Finish Applications

3.3.5.2.1 Hydrophobic coatings

Making various materials hydrophobic has been a popular topic of research in recent years. A high hydrophobicity is useful for a variety of products and industrial uses, such as self-cleaning fabrics and windows, friction reduction in microfluidic devices, glass wind-shields (that quickly evacuate the water for better visibility in adverse weather conditions) and solar panels.

There have been efforts to develop hydrophobic coatings which can be used in ultra-dry surface applications. Coatings can be sprayed onto objects to make them waterproof. PTFE and fluorinated ethylene propylene are hydrophobic coatings that increase lubricity, desirable in medical applications where devices need to slide easily within the body.

3.3.5.2.2 Conformal coatings

Conformal coatings can change their geometry according to the applied load and pressure. This may be helpful in certain application where undue stresses can be avoided. Moreover,

for fluid sealing applications, a conformal coating will be very helpful as it will maintain the leak-proof joint. Fluoro-polymer rubber coating are developed specifically to seal rougher surface finishes while withstanding high temperatures, long-term coolant and oil exposure, and joint shearing forces.[25]

3.3.5.2.3 Electrical and magnetic properties

CVD is widely used in the semiconductor industry, as part of the semiconductor device fabrication process, to deposit various films including: polycrystalline, amorphous, and epitaxial silicon, SiO_2, silicon germanium, tungsten, silicon nitride, silicon oxynitride, titanium nitride, and various high-k dielectrics. The CVD process is also used to produce synthetic diamonds. Electroless nickel coatings are used to plate printed circuit boards. They also help in metallization of plastic for electrical applications.

3.3.5.2.4 Thermal coatings

Thermal stability is another feature provided by some of the coatings. Thermal endurance may be required in industries, viz., steel industries, power plants, etc. For applications like in turbine blades which are subjected to very high temperatures, thermal barrier coatings like zirconia will enhance its high temperature properties and also extend the life of the blade.

3.3.5.2.5 Rough coatings

For paper industries the drum which needs to grip the paper part can be coated with a tungsten carbide-based coating which is extremely rough. In fact the roughness is so high that the drum can be held by a piece of Velcro.

3.3.5.2.6 Biomedical applications

Titanium and titanium-based coatings show potential for biomedical applications. Coatings of N–TiO_2 showed high corrosion resistance in simulated body fluid in protecting stainless steel.[26]

3.3.5.2.7 Optical coatings

Optical coatings are materials deposited on an optical element, viz., lens or mirror to modify the way in which the element transmits or reflects light. One type of optical coating is an antireflection coating, which reduces unwanted reflections from surfaces, and is commonly used on spectacle and photographic lenses. Another type is the high-reflector coating which can be used to produce mirrors which reflect more than 99.99% of the light which falls on them. Aluminum is used to make mirror surfaces. Silver has higher reflectivity compared to aluminum coatings. UV absorbent coatings are important for protection of human eyes and also increasing the life of the product. Hundreds of alternating layers of a high-mass metal such as molybdenum or tungsten is employed for this purpose. Coatings are also available in some colored lighting, tinted glazing, or sunglasses.

3.3.6 Eco-Friendly Coatings (Green Coating)

With advancement of science and technology, various new coating techniques have emerged. At the same time, the processes which are harmful to humans and pose a threat to the environment have also been identified and continuous effort for searching suitable replacements is on. Hard chrome coating is such a coating which was inevitable in industry even a few years back due to their high resistance against both corrosion and wear. But with time, the high toxicity of the chrome baths and its detrimental effects on environment was realized. With awareness growing this coating is presently in the process of being phased out. Similarly cadmium plating is another such coating for which technologists are in the search for replacement.

Standard chromium plating electrolytes based on chromic acid are among the most dangerous electrolytes in modern industry. Replacement of these electrolytes with those based on trivalent chromium salts is not a solution because the latter are also toxic, and, moreover, coatings formed from these electrolytes developed so far cannot replace coatings deposited from standard chromium plating electrolytes primarily in those cases when the functional properties of chromium coatings are required, for example, their high wear resistance. In recent times due to development of newer coatings, viz., electroless nickel the solution to this problem may be on the horizon. Electroless Ni–B coatings after suitable heat treatment attain hardness values in the vicinity of chrome hardness.

PVD is found to be a suitable alternative to electroplating and other metal finishing processes that use large quantities of toxic and hazardous materials. PVD is a desirable alternative to electroplating and possibly some painting applications because it generates less hazardous waste and uses less hazardous materials (i.e., no plating baths). PVD processes as a substitute for chromium plating in decorative applications represents a development toward an environmentally clean technology.

There are several other environment friendly coating techniques in existence today. It is found that 100% solid PU coatings can comply with the regulations on volatile organic compound emissions. Being virtually non-toxic, zeolites have found potential in medical applications such as in magnetic resonance imaging contrast agents and biocompatible coatings for implants where they produce no hazards to human health. Additionally, zeolites are generally accepted as eco-friendly alternatives in catalysis and in many other applications. Zeolites in thin film or coating form have been shown to have many applications including membranes, sensors, and insulators in computer chips. Electroplated zeolites (ZSM-5) are found to possess more wear resistance than cadmium and chromium coatings. Moreover, the coefficient of friction is also found to be superior.[12] Several research and development labs have also come up with different eco-friendly coatings of their own.

3.3.7 Influence of Coating Parameters and Process Optimization

Present day applications demand greater value and benefit but for a lesser cost. Moreover, due to constant scarcity of resources, it is important that the same product may be used with minimum wastage. This demand for value has kept the focus on getting improved system performance and that too to meet

environmental demand. Coating process optimization seems to be a step toward achieving this goal.

Optimization of the coating process at first involves knowing the different parameters that affect the deposit quality. Then the extent to which a parameter is influential needs to be determined. Finally, the optimization of the process can be carried out with a suitable mathematical- or statistical-based technique. Several studies in this regard have already been undertaken. It is observed that in general for electrolytic Sn–Ni coating, increase in current density during deposition increases the adhesion, wear resistance and absolute hardness of the coating.[15]

Ni matrix reinforced with nano-Al_2O_3 (80 nm in size) MMC coatings with 50–200 μm in thickness were successfully produced by DC electroplating using a modified Watt's type electrolyte. It is found that increasing the surfactant (hexadecylpyridinium bromide) content resulted in increase of Al_2O up to 11.74 vol.% in Ni matrix providing segregation free dispersion of nano-particles. The hardness values of the nano-Al_2O_3 reinforced electrodeposited coatings yielded as high as 641 Hv because of unique dispersion effect.[16] Parametric optimization of the deposition conditions is carried out to improve the hardness of Ni–B coatings and the maximum hardness is found to be about 1400 HV0.1.[27] Optimization of coating parameters is also done for electroless Ni–P coatings which reveal that heat treatment temperature and bath temperature have the most significant influence in controlling wear characteristics of the coating.[28]

It is found that the parameters of the induction-capacitance device have a significant effect on the deposition of chromium coatings from a tetrachromate electrolyte and on the physical and mechanical properties of the coatings. Both the wear resistance and microhardness can be doubles by suitably optimizing the inductance and capacitance values.[29]

3.3.8 Surface Finish Measurements of Coatings

Once a coating is developed, it is necessary to carry out a full-fledged evaluation of the coating so that desired qualities from the coating can be ensured. A coating supposed to provide a certain degree of wear or corrosion resistance should be checked whether it can meet the deliverables. Following are the properties which are normally evaluated for surface finish coatings.

3.3.8.1 Coating Thickness

Thickness is the most basic parameter of a coating. Thickness is very important in terms of corrosion protection. Higher thickness ensures good barrier protection for the coating subjected to corrosive environments. Besides, thickness is also important from wear point of view.

Thickness can be measured by a number of techniques, viz., direct displacement measurement, microscopy, profilometry, gravimetric analysis, electromagnetic methods, etc. Displacement measurement is the most simple thickness measuring technique. In this method the linear distance of blank sample is subtracted from the coated sample to obtain the thickness of the coating. However, this method is highly dependent on the resolution of the measuring instrument. Microscopy method observes the cross cut section of the sample and measures the thickness. The cut section must be evenly ground and polished to get a good view in the microscope. Profilometry measures the step height of a coated and non-coated region to obtain the thickness of the coating. Best results are obtained if the step is abrupt and if surface roughness does not make it too difficult to define the surface planes at the top and bottom of the step. Gravimetric method is a widely used technique to obtain the thickness of the coating. Here, measurements are made of the sample dimensions and the weight of the sample with and without the coating is noted. These measurements are then combined with the knowledge (or assumption) of the coating density to derive an average coating thickness.

Electromagnetic methods exist, which rely on a calibration of magnetic field strength or capacitance with distance. The substrate should be a conductor and should also be ferromagnetic or can be made to generate magnetic fields via induction of eddy currents or, for capacitance methods. Usually a calibration of the electromagnetic sensor response on an uncoated portion of the substrate is required. X-ray fluorescence method relies on calibration of the X-ray absorption of the material to be measured.

3.3.8.2 Adhesion Testing

Adhesion testing of the coating checks the adherence of the coating to the substrate. The simplest test is the straightforward pull-off test. This test uses a stud which is fixed with adhesive on to the coating, which is pulled off using a force-recording mechanical testing system. The force at which the coating gets separated from the substrate is the peel-off force. The maximum strength of the external adhesive poses a limitation to the system. Hence, coatings obtained through PVD and CVD, which in general possess a high degree of adhesion, cannot be measured by this technique.

Higher adhesion strength coatings can be tested by mandrel test or four point bend tests. These test methods apply a stress to the coating-substrate interface by means of a deformation to the entire substrate/coating composite structure. In mandrel testing (Figure 6(a)), a coated test sample is bent over a cylindrical mandrel to a preset angle. If cracking or spalling of the coating occurs before this preset angle, the coating is said to have failed by either cohesive or adhesive failure. In four point bend test, the coating is loaded in four point configuration (Figure 6(b)) so that the coating experiences tensile

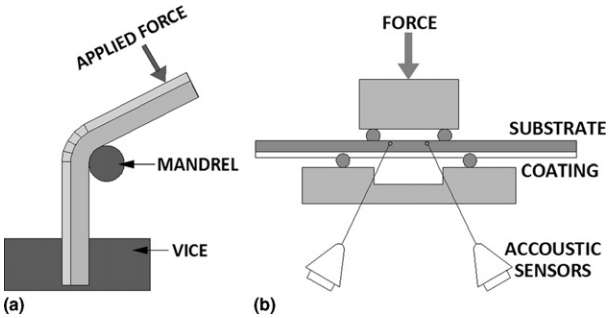

Figure 6 Adhesion tests for coatings (a) Mandrel test and (b) four point bend test.

stress. With increase of applied force, the stress increases and at a certain load (fracture strength of the coating), the coating fails by cracking through its thickness. With further increase in load, more cracks are formed and the strain at which some portion of the coating delaminates and spalls off is known as the adhesion strength of the coating. Rockwell indentation may also be used to evaluate coating adhesion.

3.3.8.3 Indentation Testing

Indentation tests have been popularly employed for measuring the hardness of a material. The basic goal of hardness testing is to quantifiably measure the resistance of a material to plastic deformation. Hardness values offer a comparative measurement of a material's resistance to plastic deformation from a standard source, as different hardness techniques have different scales. For coatings, the thickness plays a decisive part in indentation testing. Higher thickness coatings can be tested with the same instrumentation as for the bulk materials, however, with a lower load. For thin coatings, microhardness testers and nano hardness testers based on Vickers principle is available nowadays. These instruments have very small indenters which are pushed into the coating with very low loads so that effect of substrate hardness does not pollute the results. The indentation thus produced is measured by microscope attached to the system.

3.3.8.4 Surface Roughness

The geometrical parameter of a coating, that is its surface roughness, exerts a fundamental influence on the mechanical integrity of the coating. Accurate measurement of roughness is therefore critical to the evaluation of any coating. The common contact type instrument is the stylus and skid type device. The stylus, often with a diamond probe, is made to traverse the coated surface. The vertical movement of the stylus is recorded and plotted which is then statistically analyzed for obtaining the common roughness parameters. Contact type instrument has the limitation that physical contact with the sample has to be made in order to measure the surface roughness of the coating which is not always feasible. In order to address this issue, non-contact type instruments are available nowadays. These instruments are optically based and normally make use of lasers to capture the surface profile.

3.3.8.5 Measurement of Friction and Wear

As tribological studies are now part and parcel of surface engineering, coatings are subjected to friction and wear tests under near service conditions. Tribo-testing apparatus called tribometers or tribotesters are available which enable one to apply the predetermined load and lubrication if any and obtain the friction and wear behavior from the sample. In most tribometers used in the laboratory, test specimens of simple geometry are utilized in order to start the tests with test conditions as well defined as possible. Usually one of the moving specimens consists of a rotating cylinder or disk against which another solid specimen of different curvature is pressed thus leading to nominal point, line, or flat contact. The operating variables of a tribometer are broadly given by the following quantities: type of motion, load applied, velocity, ambient temperature, and test duration.

- Type of motion: the type of motion is connected with the geometry of the test system and is given by one of the four basic motion types, viz., sliding, rolling, spin, and impact or by a superposition of these basic types.
- Load: the load can be applied by various means to the test system, for example, as a mass (dead load), by a spring, by hydraulic means or by electromagnetic means. For the measurement of the load, force transducers based on strain gauges, inductive elements or pressure-sensitive detectors evaporated on the surface of the specimen in the contact zone are available. The measurement of the load by means of an electro-mechanical force transducer has the great advantage that the normal load signal together with the signal of the friction force can be fed to an electronic divider and the actual value of the friction coefficient (μ = friction force/normal load) can be calculated directly during the test and on real time basis.
- Velocity: for the control of velocity, electronic, or optoelectronic transducers are commercially available. The velocity is an important parameter in tribo testing as much as it determines the lubrication regime within the Stribeck curve. It is also the independent variable in the product of friction force and sliding velocity which gives the friction-induced power loss of a tribo-testing system.
- Temperature: the ambient temperature of the test system is another important operating variable since it determines the thermal state of the system – at least at the initial stage of the test. For the control of the temperature, the following two techniques are utilized most often: thermocouple techniques and infrared-pyrometer techniques.
- Test duration: the set of the operating variables (load, velocity, and temperature) acts on the tribo-testing system as function of time or duration. The test duration also should be selected to be consistent with the nature of the investigation. Attempts are frequently made to shorten the test duration in so-called 'accelerated tests' by increasing the severity of the operating conditions. This procedure, however, is only permissible if the nature of the tribological processes is not changed.

A typical tribotester setup is shown in Figure 7. Here the stationary rectangular specimen is made to slide against a rotating hardened steel roller. Load is applied by a leverage arrangement. The wear is directly measured in terms of depth by a LVDT sensor which is placed just above the specimen. Friction force is captured by a load cell as shown in the Figure. The coefficient of friction is then calculated by the ratio of the friction force and normal load.

3.3.8.6 Measurement of Corrosion

Protection against corrosion is one of the vital objectives of applying any coating. Now, corrosion is a natural process which occurs over a period of time. However, for laboratory-based measurements, the corrosion process is accelerated so that the effects of corrosion could be studied efficiently and in a timely

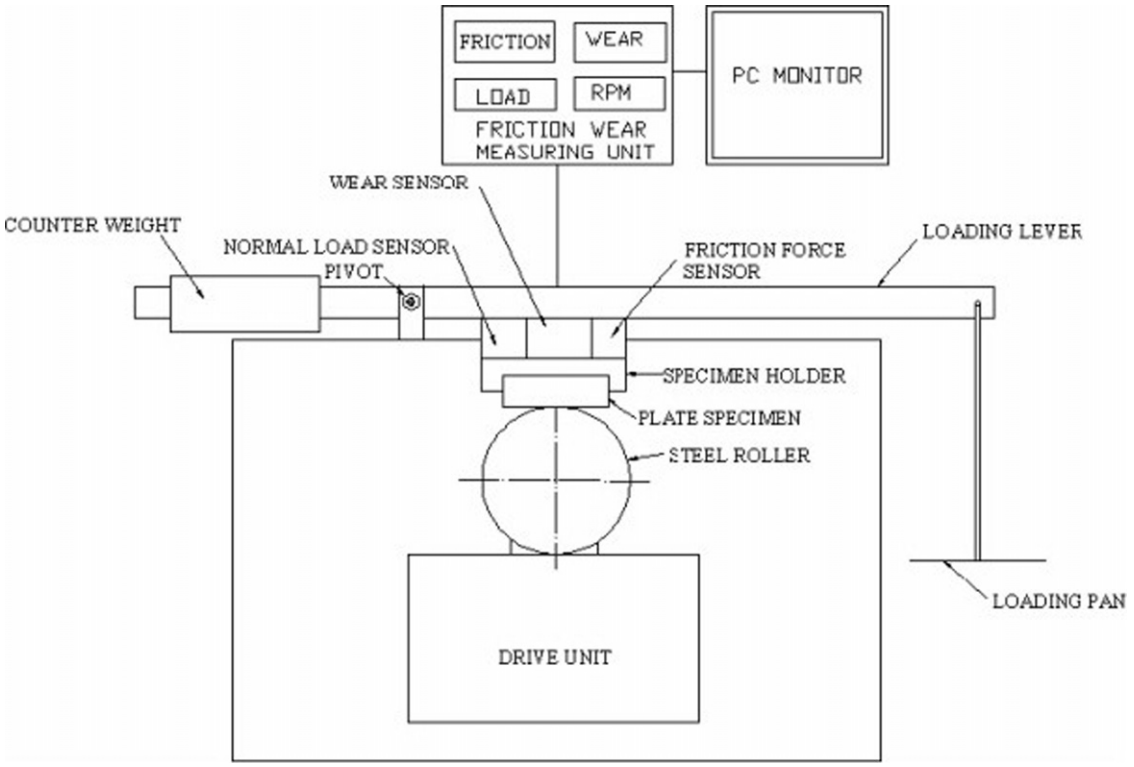

Figure 7 A typical tribotester setup. Adapted with permission from Ref. [30]. © Elsevier 2011.

manner. Corrosion rates for metals undergoing uniform corrosion can be determined by any of the following methods:

- Weight loss
- Weight gain
- Chemical analysis of solution
- Gasometric techniques (when one of the reaction products is a gas)
- Thickness measurements
- Electrical resistance probes
- Inert marker method
- Electrochemical techniques.

Each of the methods mentioned above has an application in either the laboratory or the field. But none of the methods above can provide insights into the underlying mechanism of corrosion-like electrochemical techniques. In addition, electrochemical techniques offer the possibility of mitigating corrosion by controlling the electrode potential. There are many methods of determining the corrosion rate by electrochemical techniques but the DC polarization method and the electrical impedance spectroscopy (EIS) methods using alternating current are the most popular. An instrument known as a potentiostat has control of the voltage across the working electrode-counter electrode pair, and it adjusts this voltage to maintain the potential difference between the working and reference electrodes (which it senses through a high-impedance feedback loop) in accord with the program defined by a function generator. One can view the potentiostat alternatively as an active element whose job is to force through the working electrode whatever current is required to achieve the desired potential at any time.

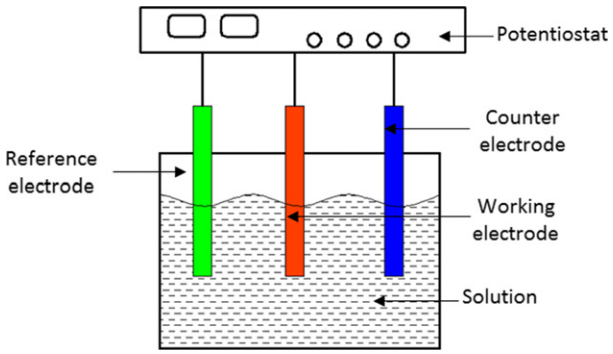

Figure 8 Potentiodynamic polarization setup.

In potentiodynamic polarization tests, the electrochemical cell consists of three electrodes (Figure 8). The coated specimen forms the working electrode which is actually the sample being interrogated. A saturated calomel electrode forms the reference electrode which provides a stable 'reference' against which the applied potential may be accurately measured. A platinum electrode serves as the counter electrode which provides the path for the applied current into the solution. The design of the cell is such that only a known standard area of the specimen is exposed to the electrolyte. The potentiostat is generally controlled via a computer which also captures the polarization data. Through dedicated software it is possible to manually extrapolate the values of E_{corr} (corrosion potential) and I_{corr} (corrosion current density) from the plot.

For EIS tests, the test setup is similar to that of polarization experiments. Electrochemical impedance spectroscopy is

a technique where the cell or electrode impedance is plotted vs. frequency. In case of corrosion studies, EIS is the response of an electrochemical system to AC excitations at frequencies from 100 μm to 100 kHz. In this method, voltage is applied and the current is measured as the response of the system or the vice versa. EIS is a very useful tool to characterize the corrosion properties of various coatings. It estimates with considerable accuracy the corroded area especially during the initial stages of corrosion when this area may not be visible. Hence, EIS allows the early detection and quantification of corrosion that leads to predictions of the useful life of the coating. Moreover, since small amplitude of AC signal is applied to the system, it is virtually a non-destructive method.

3.3.9 Effect of Pre-Treatment Processes

Every successful coating requires a good surface preparation. If the preparation remains incorrect or even inadequate the coating may suffer failure well before the end of its expected service life. In case of galvanizing process, the steel surface has to be thoroughly cleaned as zinc will not metallurgically react with an unclean steel surface. Any failures or inadequacies in surface preparation will immediately be apparent when the steel is withdrawn from the molten zinc, because the unclean areas will remain uncoated and immediate corrective action must be taken. Surface preparation for galvanizing consists of three steps: degreasing, acid pickling, and fluxing. In anodizing, oils and greases are removed in weak alkali solutions and the surface is etched to remove heavy oxides. After rinsing, the aluminum is dipped into a desmut solution to remove the insoluble components of the aluminum which remain on the surface after etching. Finally, the aluminum is rinsed and presented for anodizing. For electroplating, oils and greases are removed in weak to strong alkali solutions (depending on the metal being cleaned and the soils being removed). The surface oxides are removed in acids (strong pickles are used to remove heavy oxides and rust from steel). After rinsing, the parts are presented for electroplating. The vast majority of powder coating failures can be traced to a lack of a suitable surface preparation.

3.3.10 Selection of Coating for Surface Finish Applications

It is very critical to select a coating for a particular surface finish application. Selection of wrong or incompatible coatings could lead to its premature failure due to detachment, delamination, cracking and/or spalling. The selection of a particular surface coating broadly depends on the requirements to be satisfied by the particular component. In any component, the following basic requirements need to be satisfied.[31]

- Mechanical and tribological properties must be sufficient to withstand loads and have a satisfactory working life.
- The process of fabrication should be economic.
- The material should withstand the environmental conditions during its lifetime.

Now typical tribological mechanisms remain same for coatings as for any homogeneous material. The coating shall be selected to match the tribological situation and the life limiting surface damage mechanisms of the intended application. A classification of these mechanisms into three categories is convenient.[32]

- Damage without exchange of material: it involves permanent changes in the component geometry and/or surface topography. Significant parameters include Young's modulus and hardness of coating and substrate. Besides, thickness of the coating is also very important. Coating hardness is the crucial parameter for scratch resistance, while coating toughness or fracture resistance is crucial to resist surface cracking.
- Damage with loss of material (wear): the coating acts as a protective covering on a component. Hence, its wear resistance is of primary concern. If somehow a coating gets damaged and the substrate material is exposed, the service life depends on the wear resistance of the latter. Although a large number of wear mechanisms are described in the literature, the two main categories can be distinguished: wear dominated by coating detachment and wear caused by gradual removal of coating material. The former involves major damage to the coating while the latter often involves mild wear due to abrasion, erosion, chemical dissolution, etc., and does not deviate from the mechanisms causing wear of homogeneous materials.
- Damage with material pick up: work material locally adhered to, for example, the surface of a sheet forming tool used in the automotive industry will inevitably produce indentations or scratches in the surface of the product. Material transfer between the contact surfaces of sliding machine elements is a similar problem often named galling, scuffing, or seizure.

3.3.11 Closure

Coatings are well recognized and widely accepted method of surface finishing. Coatings incorporate different materials together on the substrate surface to have enhanced properties at the surface, which the bulk of the material may not possess. Several methods of coatings are in existence each having its distinct set of advantages and limitations. Among the processes, electrodeposition, electroless deposition, vapor deposition, powder coating, and conversion coatings are a few to be mentioned. Coatings can be applied over any material be it metal or non-metal, conductor or non-conductor, etc., depending on the process. Although previous generation coatings were mainly devoted toward enhancing the esthetic appeal of a component the present coatings primarily address the functional aspect. Depending on the coating material and the process, they can increase the corrosion and wear resistance of a part. Coatings can also make the surface smoother lowering its coefficient of friction. Apart from these there are a host of other applications which coatings can address. The selection of a particular coating for a surface finishing need depends on the requirements to be satisfied for the particular component keeping in mind the ecological concern. Moreover, once

installed, periodic monitoring of the coating health and its maintenance is important to obtain optimum performance from the component.

3.4.1 Introduction

Thermal spray coating techniques are very versatile, with different available methods that can be used for a wide range of engineering applications. Thermal spray coating involves a wide range of different techniques such as wire-arc, high velocity oxy-fuel (HVOF), plasma spraying, etc., that are used in many applications (Figure 1). One of the major issues concerning the coating performance is the effect of the residual stresses developed during the coating process on the life and behavior of the coating layer. Measuring these stresses could be very crucial to the evaluation process. Therefore, a lot of research has been done focusing on measuring and calculating the residual stresses quantitatively and qualitatively. Most of the work done was focused on pure experimental techniques to measure the residual stresses during the coating process. Others use a hybrid experimental and analytical procedure to get the stress values. Recently, there has been a lot of work that evolves the use of numerical techniques such as finite element (FE) analysis to calculate the stresses, with the use of experiments for calibrations.

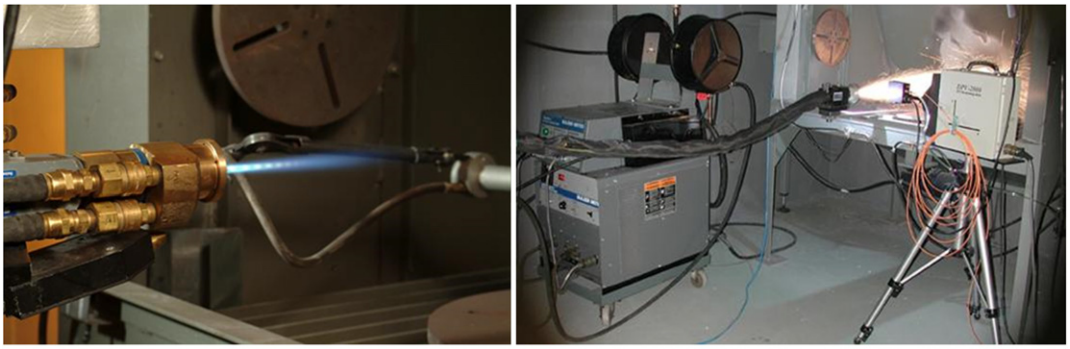

Figure 1 Examples of thermal spray coating techniques, (a) High velocity oxy-fuel spray (left) and (b) wire-arc spray (right). © Centre for Advanced Coating Technologies, University of Toronto.

3.4.1.1 Sources of Residual Stresses

There are two main sources of residual stresses in thermally sprayed coatings. The first is the rapid cooling that happens when the temperature of the sprayed particles drops from the melting temperature to the substrate temperature during the deposition process. This type of stresses is called 'intrinsic,' 'quenching,' or deposition stresses, and has a tensile nature. The second source, and possibly the most contributing, is due to the difference in coefficient of thermal expansion (CTE) between the coating and the substrate. This happens when the coating system temperature starts to drop from the average temperature reached after the deposition process to the room temperature, which is called secondary cooling. The residual stresses are then induced by the mismatch in the thermal shrinkage of the substrate and the coating. In general, if the CTE of the coating is smaller than that of the substrate, compressive residual stresses are likely to form, and vice versa. Aside from the two main reasons, other factors may contribute to the formation of residual stress indirectly. For example, kinetic energy of the coating particles affects the level of the residual stresses formed during deposition. This is related to the coating velocity and particles size.[1,2] Literature shows that the sources of residual stresses in thermal spray coating systems include:

1. Coating deposition process
   - Particles on impact, freeze and contract creating tensile stresses.
   - Largely relieved by the formation of micro-cracks in coatings.
2. Material mismatch stress
   - Generated when coated components cool down to room temperature.
   - Differences in thermal expansion coefficients of coating and underlying substrates.
3. Growth of the Thermally Grown Oxides (TGO)
   - Specially important for thermal barrier coatings (TBCs).
4. Transformation induced stresses
   - Hot corrosion of TBCs.

3.4.1.2 Quality Issues

Many of the process parameters such as the deposition speed, velocity of the spray gun, coating temperature, coating thickness, etc., play an important role in the formation of residual stresses. On the other hand, these parameters cannot be optimized solely based on residual stresses, and the quality of final coating has to be considered as well. The spray parameters must be selected carefully to obtain good quality coatings. A general flow of the coating process steps that affects the quality of the coating can be summarized through the following[3]:

Flow of spray particles → particle impact and deformation → coating formation → splat interactions → formation of pores → coating build up → final coating layer.

Having a clear understanding of the complete process can help in predicting the residual stresses and linking them with the process parameters, microstructure, coating quality, and surface quality.

3.4.1.3 Importance of Residual Stress Estimation

Compressive residual stresses are generally more favorable and their presence may cause no harm to the coating system in many cases, unless they exist in relatively large values. Tensile residual stresses are usually more harmful and raise many coating problems such as:

- initiation and propagation of cracks, which may lead to interface delamination,
- loss in adhesion, and
- fatigue failure.

For example, in TBCs, which are one of the main applications utilizing thermal spray coating, the effect of residual stresses plays a very important role in evaluating the life of the TBC. As shown in **Figure 2**, these cracks could propagate to the stage where complete failure of the coating could occur.[4,5] One of the most common techniques in measuring the residual stresses is by using hole drilling.[2,6,7] Usually in this process, the drilling is carried out gradually at the micro level until the substrate is reached. Since this process involves slow feed rates, high cutting rates, and low drilling depth for every step, it is quite accurate to assume the process generates no stresses. In addition, to ensure no thermally-induced stresses due to the drilling process, a cooling period is applied between every other drilling increment.[7] Then, due to the removal of the material, the residual stresses are released causing deformations to the area surrounding it. Finally, these deformations can be used to measure the strains using strain gages and calculate the stresses knowing the material properties of coating material.

Another experimental technique is the curvature measurements.[8,9] The basic principle in this approach is that after each coating deposition, the thermal mismatch between the coating and the substrate and the rapid cooling of the coating material deposited onto the surface will cause the free contraction of

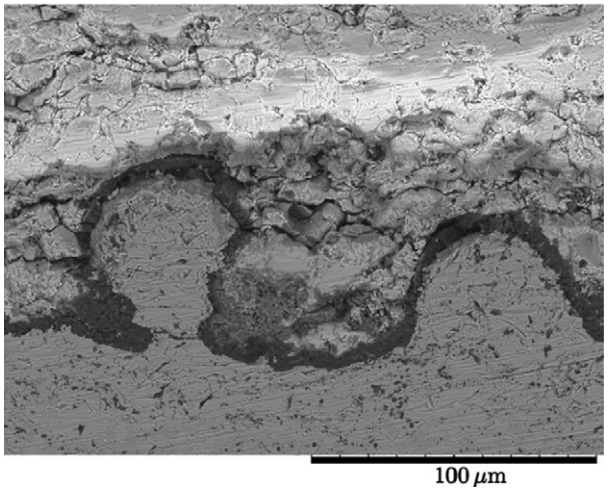

Figure 2 Scanning electron micrograph showing a magnified view of an oxidized thermal barrier coatings showing micro cracking in the vicinity of the thermally grown oxide layer between the top-coat and the bond-coat. The trajectory of the local delamination resides primarily within the top-coat and connects the peaks of the undulations.

the coating to be restricted by the substrate material. This generates internal forces acting between the coating and the substrate that leads to a bending moment causing the material to bend due to the stresses developed within the layers. With more coating layers, more coating thickness will build up and hence an increase in the bending curvature. By correlating the coating thickness and the curvature, the forces and moment balance can be used to calculate the residual stresses developed during the coating process.[10–13]

The curvature measurement method has some variations and can be extended and used along with Raman spectroscopy (RS) to measure the residual stresses.[14] A similar approach can be utilized by chemical substrate removal process[15] where the residual stresses can be calculated from the deflection and curvature of the free standing coating layer alone. The curvature of the coating layer can be evaluated using the same approach using the curvature measurement method, which is based on the classic Stoney equation.[16]

With the advancements in numerical techniques and simulations, new methods have emerged that combines experimental techniques along with numerical analysis. In most of the computational work done in calculating the residual stresses, experiments are used merely to capture the roughness of the coating and substrate interface in addition to the temperature profile. Then, it would be implemented into a FE model where the temperature profile is imposed into the model and the residual stresses are calculated.[2,17,18] The use of finite element methods (FEMs) can be beneficial since only one model needs to be calibrated, and then a variety of analyses can be performed for various coating thicknesses, cooling rates, etc., to calculate the residual stresses.

Other techniques and methods are available that involve a combined experimental and computational approach.[19] Scanning electron microscopy (SEM) can be used to observe the coating profile for any coating process, then object oriented finite element (OOF) is used to calculate the residual stresses.[3,19] This is done by discretizing the coating microstructure into a FE mesh and imposing the temperature profile of the coated sample into the FE model. The model can then be used to calculate the thermal residual stresses developed during the coating process.

3.4.2 Experimental Measurement

Residual stress is an important factor influencing the integrity and performance of thermal spray coatings. Residual stress in thermally sprayed deposits originates from the high-temperature excursions experienced by the material during the process. Residual stress can affect the integrity of the deposit–substrate system as well as its performance and reliability of the entire part. Hence, until now considerable efforts have been made to understand and predict the residual stresses that are generated during the production of thermal spray coatings.[20,21] Different types of techniques were developed for the measurement of residual stresses in thermal spray coatings and all are commonly characterized by two major categories named as destructive method and nondestructive method. The widespread use of each of these methods are fairly restricted because of problems associated with measurement accuracy, spatial resolution, ease of measurement, applicability to a broad range of materials and geometries, feasibility for use as a quality control device in mass production or during service, and flexibility for scaling up from small to large components.[22–24]

3.4.2.1 Destructive Methods

3.4.2.1.1 Hole-drilling method and layer removal

Destructive methods are based on material removal by drilling a hole in the coating/substrate or by grinding off a coating layer. The strain changes are monitored with strain gauges attached to the coating or the substrate, respectively, as shown in **Figure 3**. These methods are capable of determining depth profiling of residual strain. The destructive nature of these conventional techniques limits their use in finished components (e.g., in aerospace applications) and also causes uncertainty in the coating mechanical properties during hole drilling and layer removal (LR).[25] Furthermore, the removal of a layer with uniform thickness is physically very difficult and analyzing the strain gage data is not a simple task. Hence, a numerical method is necessary to validate the experimental results of stress measurement through this method. While the method has been used to evaluate the levels of stress in coatings, it is not really practical for thin or for brittle coatings.

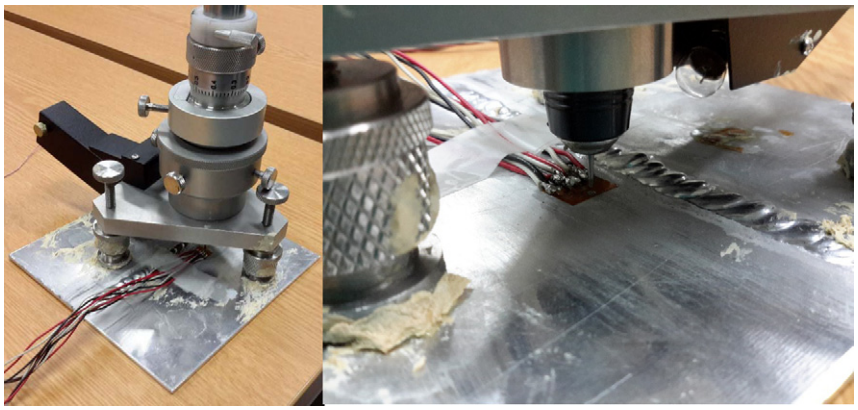

Figure 3 Hole-drilling setup for residual stress measurements.

Numerous researchers have conducted studies based on this approach and have calculated the residual stress of thermal spray coatings.[26–28] For example, Montay *et al.*[29] measured the residual stress gradient in depth of the coating by hole-drilling method (HDM). They calculated the stress by using strain gage rosette.

Greving *et al.*[30] developed a modified LR method for evaluating through-thickness residual stress distributions in thermal spray coatings. The method was experimentally applied to several typical industrial thermal spray coatings. Their results show that the modified LR method is better suited for calculating residual stresses in thermal spray coatings than the conventional LR method. Suresh and Giannakopoulos[31] proposed a general methodology for the determination of surface residual stresses and residual plastic strains using instrumented sharp indentation. This technique can be directly used for residual stress measurements in applications such as thin films, structural coatings, and engineered surfaces whose properties are altered by methods such as mechanical working, etching, ion implantation, case hardening, laser treatments, shot peening, or laser shock peening. Residual stress determination by this continuous load-displacement monitoring during indentation represents a promising alternative and also offers several potential advantages as a possible tool for the mechanical probing of materials. Recently, Sebastiani *et al.*[32] proposed a novel procedure for local residual stress measurement in plasma-sprayed single splats, based on focused ion beam micron-scale ring-core milling and digital image correlation (DIC) for relaxation strain mapping approach. This methodology can give sub-micrometer spatial resolution and it is independent of the splat microstructure. Further, this approach could be applied even to completely amorphous materials.

3.4.2.1.2 Material removal by chemical etching

In 1988, Hobbs and Reiter[33] modified the Hendricks approach[34] and proposed a simple bending theory for determination of residual strain at both the exposed and the interface surfaces in the plasma-sprayed zirconia layer. For this measurement, they prepared individual coating layer by chemical etching. This technique provides a clear insight into the residual stress state of ceramic TBCs. Using the same theory, Yung-Chin Yang[35] measured the residual strain and stress formed in the plasma-sprayed hydroxyapatite coatings. In order to obtain the complete and accurate value and state of the residual stress, the non-stressed free coating layers were produced from the substrate. For this purpose, he used particular types of the substrate and different directions of cooling jets.

3.4.2.2 Nondestructive Methods

3.4.2.2.1 Curvature method (in situ)

Curvature method is a part of nondestructive methods and also the most informative method of residual stress evaluation in thermal spray coatings. In 1909, Stoney derived the formula for this method[36] and it was further developed by Brenner and Senderoff.[37] In 1988, Kuroda *et al.*[38] developed a practical method for *in situ* measurement of both coating thickness and deposition stress during thermal spraying by using this approach. Meantime, Gill and Clyne[39] also measured the residual stress of thermal spray coating by *in situ* curvature approach. Since, numerous curvature measurement methods have been developed and are frequently used to determine the stresses within thermally sprayed coatings and layers.[38–42] This method works based on force and moment balance between the substrate and the coating. During the spray process, the deposition of a layer can induce stresses, which cause the substrate to curve. The resulting changes in curvature during deposition make it possible to calculate the corresponding variations in stress as a function of deposit thickness. Curvature can be measured by contact methods (e.g., profilometry and strain gages) or noncontact methods (e.g., video, laser scanning, grids, and double crystal diffraction topology).[24]

Matejicek and Sampath[43] developed a novel approach based on *in situ* thermoelastic curvature method for determination of stresses and moduli in thermal spray coating with a newly designed instrument and improved the analysis. This approach was based on Kuroda and Clyne's[40] experimental and theoretical treatment with appropriate modifications and improvements. Here the residual stress distribution in the entire sample was determined by superposition of the quenching and thermal stress distributions. For this purpose, the temperature and curvature of the substrate was recorded during the entire deposition process. Quenching stress was determined from the deposition period and thermal stress and coating modulus was determined from the cooling period. Jianguo Zhu *et al.*[44] utilized the three-dimensional digital image correlation (3D DIC) technique to measure the curvature of a thermally sprayed coating sample (**Figure 4**). Then they adopted elastic–plastic FEM to interpret the cross-sectional stress distribution. Their findings predict that the system has several advantages such as a noncontact and full-field optical displacement measurement with high accuracy. The setup is simple and easy to operate with little sample preparation. In addition, the authors believe that 3D DIC has a very high potential and broad application prospects for monitoring of curvature *in situ* by using high-temperature speckles fabrication techniques.

3.4.2.2.2 Curvature method (ex situ)

This is one of the simplest methods to determine the average stress values of thermal sprayed coatings by means of sample preparation, curvature measurement, and the analysis. However, this approach has some limitations and it cannot distinguish a stress gradient and stresses on different phases in coatings. For this measurement, substrate and the coating have to be planar and measurable curvature should be induced without changing the substrate elasticity. The coating and substrate are detached and their respective curvatures are measured. From the difference between the original and final curvatures, the stresses can be calculated.[45–47] This linear approximation stress profile of the coating microstructure was sufficient for certain practical commitments. In 1996, Kesler *et al.*[48] used this *ex situ* curvature measurement method to determine the residual stresses at room temperature. Their result found residual stresses as large as 200 MPa in plasma-sprayed thick Ni–Al_2O_3 composite coatings at room temperature. In principle, this method can be used to determine

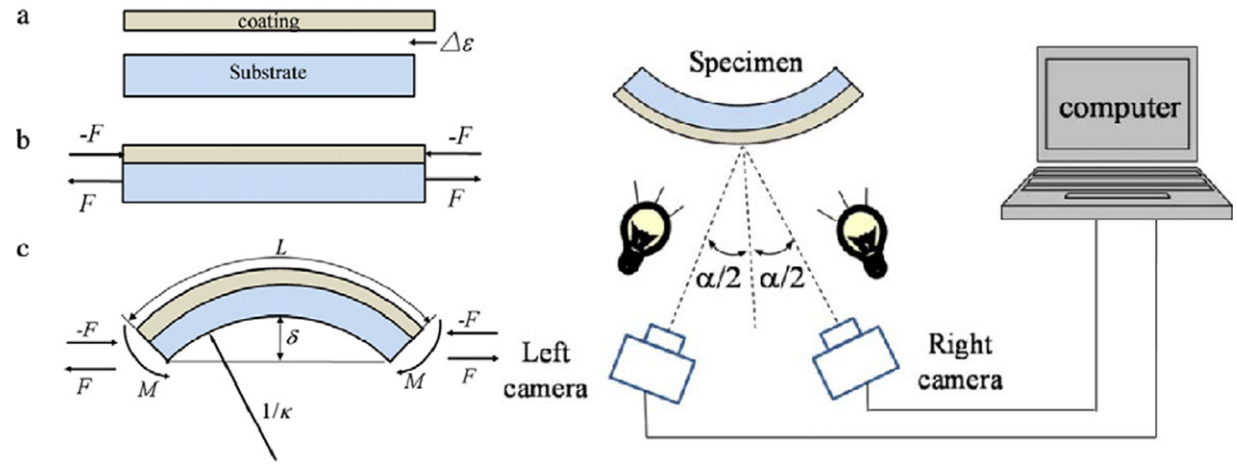

Figure 4 Schematic of the generation of thermal residual stress in a strip coating as a result of the misfit strain, $\Delta\varepsilon$: (a) unconstrained strains due to temperature difference; (b) strain compatibility at interfaces; and (c) bending and balance of bending moment, and the three-dimensional digital image correlation setup.[44]

physical and mechanical properties of layered and graded coatings produced by a number of different processing methods, including physical vapor deposition (PVD).

3.4.2.2.3 Diffraction method

The diffraction method of stress determination is based on the measurement of changes in crystal plane spacing in different directions with respect to the specimen surface, which exhibit themselves as shifts in angular positions of respective diffraction peaks. From this strain determination, stress can be calculated with the use of appropriate elastic constants.[22,49] This nondestructive nature method has plenty of advantages such as phase selectiveness and moderate restrictions on specimen dimensions and repeated measurements on the same specimen. Further, this method has a capability to determine the stresses in each individual phases in composites microstructures by varying the nature of diffraction.[50] Currently different diffraction methods are available and are distinguished by the types of beam source and its power such as X-ray, neutron, electron, and synchrotron X-ray.

3.4.2.2.3.1 X-ray diffraction

This is most the popular method for direct measurement of residual stresses in coating microstructure by observing the shift of selected X-ray diffraction (XRD) peaks. The 'sin2ψ' is the commonly used method to calculate residual stress[51] and numerous investigations have been carried out on row.[20–22,49,50] Low penetration ranges of X-rays (in the order of few ten microns) limit the investigation to a thin surface layer, which may be impractical for coatings with higher thickness and roughness. However, with a modified experimental procedure, the same feature can be used to determine through-thickness stress profiles.

3.4.2.2.3.2 Synchrotron XRD

Synchrotron (or hard) X-rays are alternative for conventional X-rays to measure the residual stress in coating microstructure. Synchrotron sources can be as much as a million times more intense than conventional sources and can provide high energy photons (20–300 keV) that are over a 1000 times more penetrating than conventional X-rays. More penetration depth means this technique is capable of providing high spatial resolution and 3D maps of the strain distribution in coating. Another great advantage that synchrotrons have is that intense narrow beams of 1 mm–10 μm in size are possible. Using this source many attempts have been made to determine the residual stress near the coating surface.[52] Stoica *et al.*[53] applied the X-ray synchrotron radiations to measure the residual stress distribution within the as-sprayed and hot isostatically pressed thermal spray cermet (WC–12Co) coatings. The sin2ψ method was applied with three ψ angles between 7° and 9° at 25 keV and between 12° and 14° at 15 keV.

3.4.2.2.3.3 Neutron diffraction

Neutron diffraction is an alternative to XRD and most of the drawbacks to the use of X-rays have been resolved. The penetrating power of neutrons enables through-thickness stress profiling without any material removal up to several millimeter based on materials. The stress determination in neutron diffraction is based on the same principle as XRD. Lower spatial resolution and challenging experimental procedure limits its usage. However, researchers widely used this method to determine the residual stress of thermal sprayed coatings.[54–57] Ahmed *et al.*[58] successfully applied vertical scanning technique in neutron diffraction experiment and measured the residual strain in 400 μm thick WC–Co thermal spray coatings.

3.4.2.2.4 Micro-RS

Micro-RS is a powerful technique to study the structural changes in the coatings because Raman scattering depends on electron–phonon interactions that are very sensitive to local environments. Due to its sensitivity, it is a suitable technique to identify and study small changes in the stress states of the coatings. This is nondestructive and noninvasive technique and has a high spatial resolution (1 μm or less).[59] This

technique allows measurements in very small areas (micrometer range) for the assessment of the residual stresses in the thermal sprayed coatings cross-section as well in the thin interlayer such as the thermal growth oxides in TBCs.[60,61] Tanaka *et al.*[62,63] measured the residual stress in air plasma-sprayed Y_2O_3 stabilized ZrO_2 TBC by using micro-RS. They used the frequency shift of Raman peak from tetragonal phase ($\approx 640\ cm^{-1}$) for determination of local stress in TBC system. Teixeira *et al.*[64] measured the residual stresses within the PVD bond coating and oxide interlayer by the micro-RS technique in cross-sectioned samples. Further, they introduced micro-displacement laser transducer technique to measure the residual stress within the single as-deposited PVD bond coatings.

3.4.2.2.5 Photoluminescence piezo-spectroscopy

Photoluminescence piezo-spectroscopy (PLPS) is a technique that can be conveniently used to determine the stress in alumina-containing material with high resolution, particularly it is a very useful technique to measure residual stress on TGO layers.[65,66] Zhao and Xiao[67] measured the residual stresses in TBCs by PLPS and compared with indentation technique. Similarly, Dong Liu *et al.*[42] measured the residual stresses of EB-PVD deposited TBC and the TGO layers by RS and PLPS, respectively. However, the direct usage of PLPS has been restricted by the absence of alumina in TBC system.

3.4.2.3 Other Methods

In 1967, Crecraft[68] showed that the acoustoelastic law could be employed for stress measurement of engineering materials. This method provides a macro residual stress over a large volume of engineering material. It also has the advantage of being able to be measured in the bulk area of the material and are therefore well suited to routine inspection operations.[69] However, this method cannot be used in thermal sprayed coating system due to the presence of porosity. Similarly, other existing methods such as magnetic and electrical techniques, thermoelastic and photoelastic methods have certain limitations which restrict their complete utilization for measuring the residual stress in thermal sprayed coatings.[24]

3.4.2.4 Residual Stress Measurement Work Done at Centre for Advanced Coatings Technologies

In 2009, *in situ* curvature measurement device was developed by using a linear variable differential transformer (LVDT) to the measurement of residual stress in single and multilayer coating formations. Further, a new numerical model was developed, employing a commercially available FEM software package, which addressed the shortcomings of the existing models. The numerical model was used to predict the development of internal stresses during deposition of the coatings and their subsequent cooling to room temperature. Resultant predictions were compared with experimental measurements of the curvature of test specimens during deposition to validate the numerical model. Finally, the numerical model was employed to predict the stresses expected under service conditions, incorporating the preexisting internal stresses arising from the deposition process. The multilayer coating developed in this study was predicted to exhibit significantly lower stresses than a conventional coating system.[70]

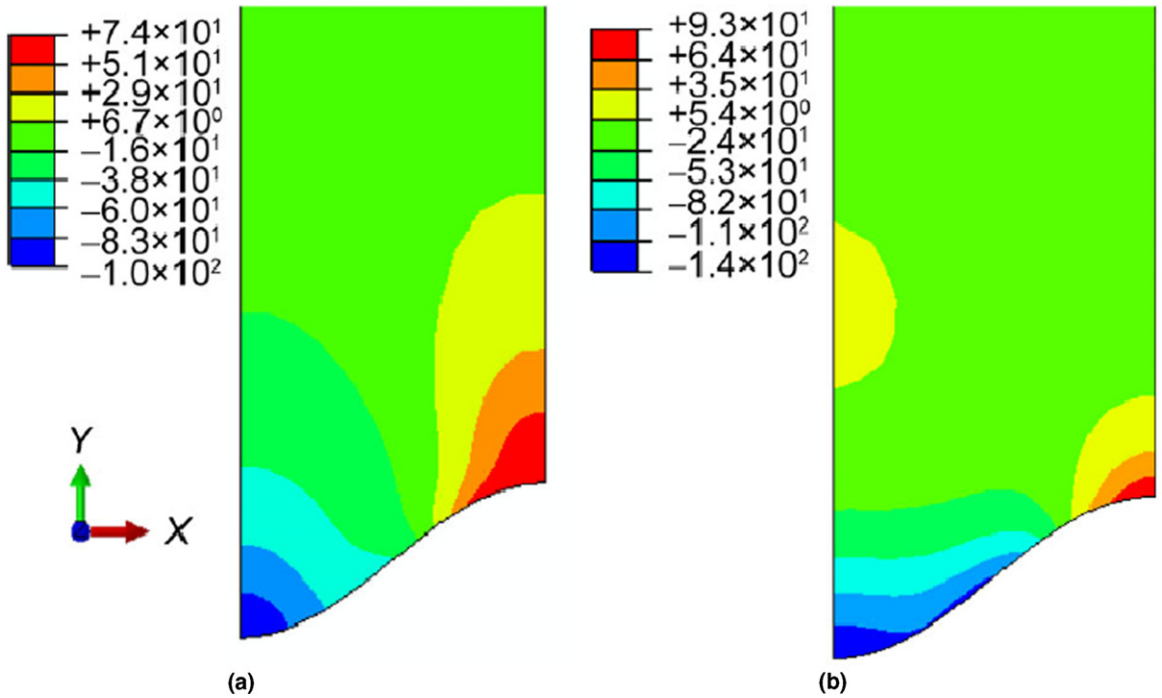

Figure 5 Residual stress σ_{yy} (MPa) in thermal barrier coatings after cooling with thermally grown oxide growth for amplitude A = 20 μm: (a) 3 μm TGO thickness and (b) 5 μm TGO thickness.[72]

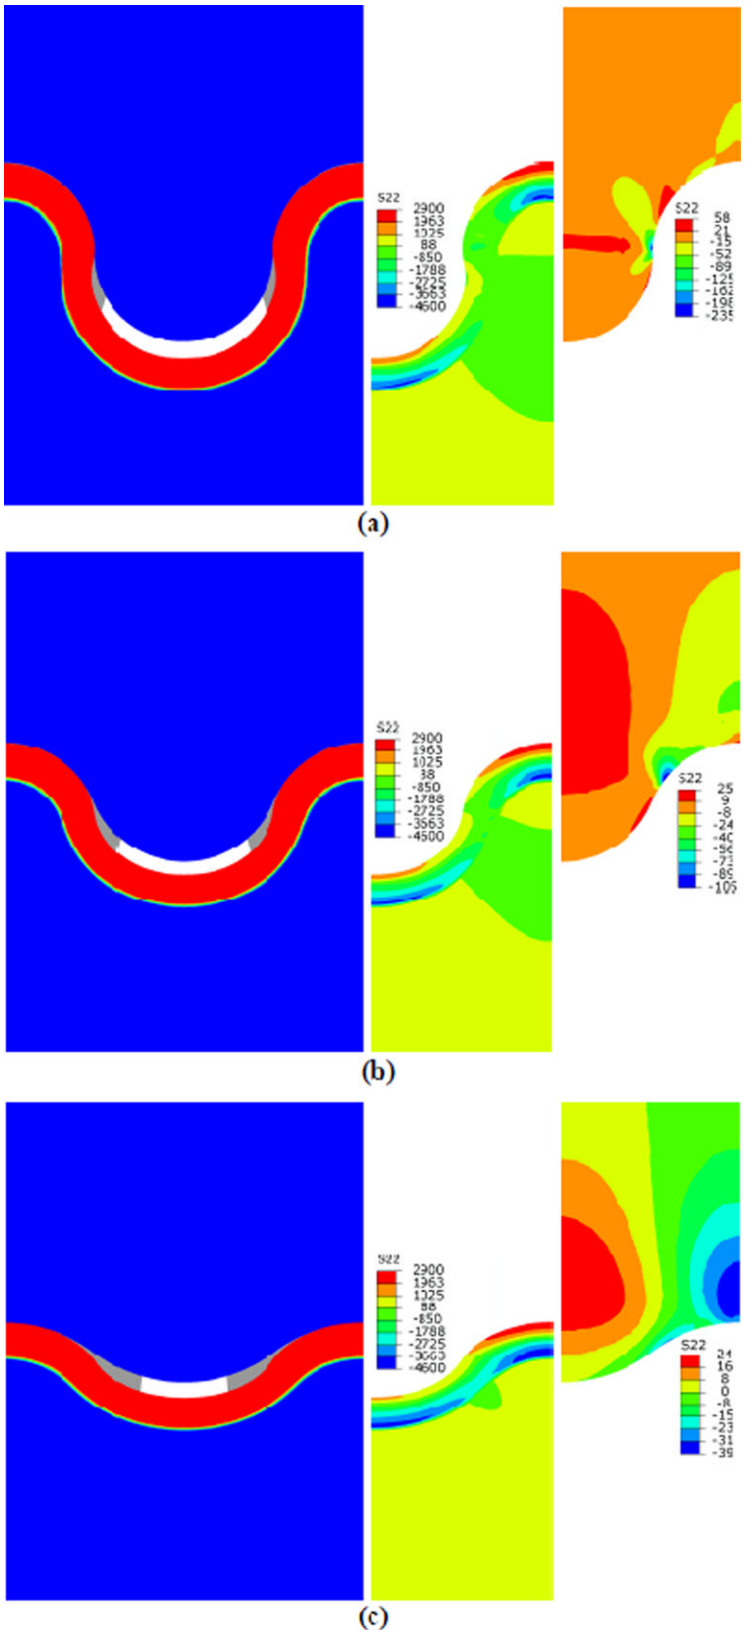

Figure 6 Simulation results and contours of the stress component S_{22} (MPa) in the top-coat and the bond-coat near the thermally grown oxide after 400 h of oxidation at 1050 °C and cool-down to room temperature for undulations with different initial amplitudes of (a) 15 μm, (b) 10 μm, and (c) 5 μm. The cohesive elements that have not yet failed completely are colored gray.[4]

3.4.3 Numerical Estimation

Even though few analytical models have been developed,[71] the prediction of residual stresses in thermal spray coatings was mainly carried out using the FEM. This is not surprising as FEM is more popular than other numerical schemes due its flexibility and suitability for modeling complex geometries. For the last few decades,[39] the residual stresses developed in thermal spray coatings has been widely attributed to the mismatch in the CTE between the various layers of the coating system. However, it can be argued that other phenomena such as TGO growth, phase transformations at various interfaces, inhomogeneity of respective layers, surface roughness of the substrate, deposition process parameters, etc., all contribute to the residual stresses even though their contribution is negligible.[72] Therefore, most of the research work carried out considered only the thermal residual stresses which mainly results from the thermal-mismatch stresses developed during cooling of the coating system to room temperature.

Coupled thermal stress analysis with conventional FE formulation is more popular in this field. However, a few modified numerical schemes such as the death and birth scheme, image-based FEM, etc., have recently been used to accurately predict the residual stresses as discussed below.

Starting with computation that was carried out using conventional FE schemes, Limarga *et al.*[73] evaluated the residual stresses induced during the thermal cycling of air plasma-sprayed zirconia TBC using one-dimensional FE model. Coupled thermal–structural elements with creep/plasticity capability and calibrated properties/boundary conditions were used for computation. All the interfaces between the respective layers were assumed to be flat and perfectly bonded. The FE result was validated using RS measurements. The results indicated that large in-plane stresses, which are dependent on cooling rates, are developed at the surface of the coating due to thermal cycling. Consequently, numerous cracks were initiated which result in the failure of the coated samples. The observed discrepancies between the experimental and numerical values were attributed to the use of homogenous, crack-free, and isotropic material model. Similar analysis was carried out by Ng and Gan.[74]

Jianguo Zhu *et al.*[44] investigated the residual stress field and failure mechanism of plasma-sprayed TBC using a two-dimensional plane strain formulation. In addition to the thermal-mismatch stresses, the stresses induced due to sintering/creep, stress relaxation, TGO growth, and surface roughness were included in the calculated residual stresses. A thin section which contains half-amplitude of the sinusoidally-represented surface roughness was used for the computation. The results show that

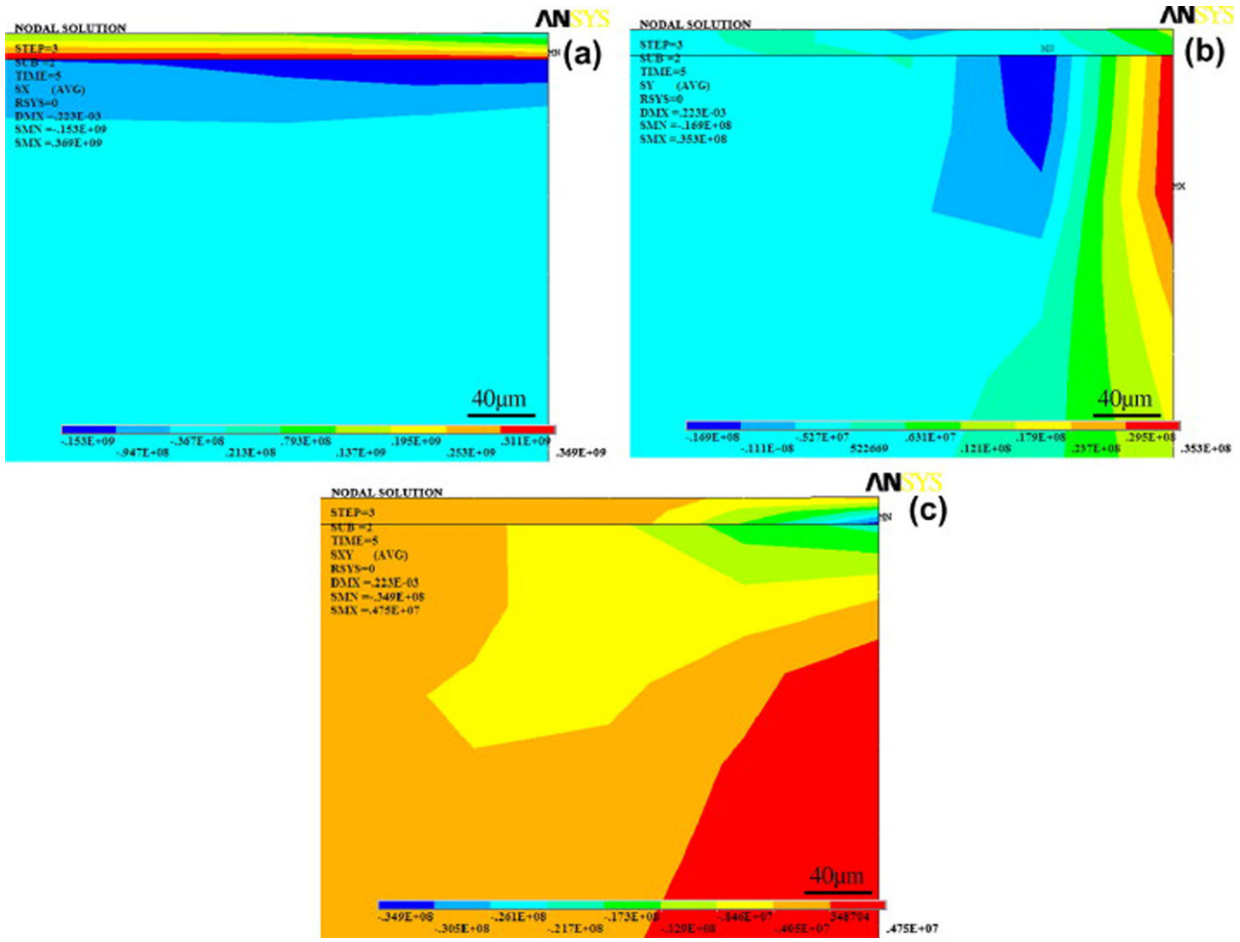

Figure 8 Typical contour plot of stress (MPa) distribution of (a) σ_{xx}, (b) σ_{yy}, and (c) σ_{xy} after the first layer deposition being finished for the LZ/8YSZ thermal barrier coatings (the above layer indicate one layer of the bond-coat).[83]

maximum tensile stress which increases with thermal cycling is developed in a direction perpendicular to the interface (Figure 5). Consequently, the cracks initialize in the high stress regions and propagate along the TBC/bond-coat (BC) interface resulting in the spallation failure of the coating. Therefore, the model has captured the experimentally observed failure mechanism of TBCs qualitatively. However, quantitative comparison of the numerical stress values with experimental values was not made. Similar analysis was carried out by Ranjbar-Far *et al.*[17] and Al-Athel *et al.*[4] (Figure 6).

Zimmerman[75] and Zimmerman *et al.*[76] developed a FE model for the prediction of residual stresses formed from the start of deposition of Ti coating onto Al_2O_3 substrate to when it is cooled to room temperature. The computation was carried out in two stages using a cylindrical sample (geometry). The first stage was a model for the computation of the stress state and temperature distribution induced during the impact of the coating onto the substrate and the layer-by-layer growth of the thickness. The data from the first stage were then transferred to the second stage for the computation of the residual stresses using a thermos-mechanical model. The numerical model was validated by comparing the deflections of the Ti/Al_2O_3 system produced by the detonation method. The results show that the radial residual stresses are higher at the coating/substrate interface and do not depend on the thickness of the sample. Similar analysis was carried out HVOF coatings by Lyphout *et al.*[77] and Bansal *et al.*[78]

Jiang *et al.*[79] carried out a thermo-mechanical analysis of the residual stresses developed in zirconia-based TBC on hollow cylindrical substrate using FEM. Axisymmetric elements with homogenous and isotropic material constitutive model were used for the computation. The FE analysis results the main origin of residual stress in TBC is thermal mismatch between the various layers of the system. Specimen dimension, spray process, coating thickness, and hole radius were also found to have effect on the stress field distribution (Figure 7).

Zhao *et al.*[80] developed a 3D nonlinear thermo-structural model for the multiple layer-by-layer deposition of Al_2O_3–13 wt.%TiO_2/NiCrAl coating on a flat low-carbon steel substrate. A sequentially-coupled approach where thermal analysis results were applied as loads for the computation of residual stresses using the structural model was used. Birth and death element technique was used for simulation of the coating deposition and layer growth. The results show that radial and axial compressive stresses were developed at the interface and BC while tensile stresses were developed at the free edges. They also reported a zig-zag variation of the residual stresses along the depth of the coating. Due to edge effect,

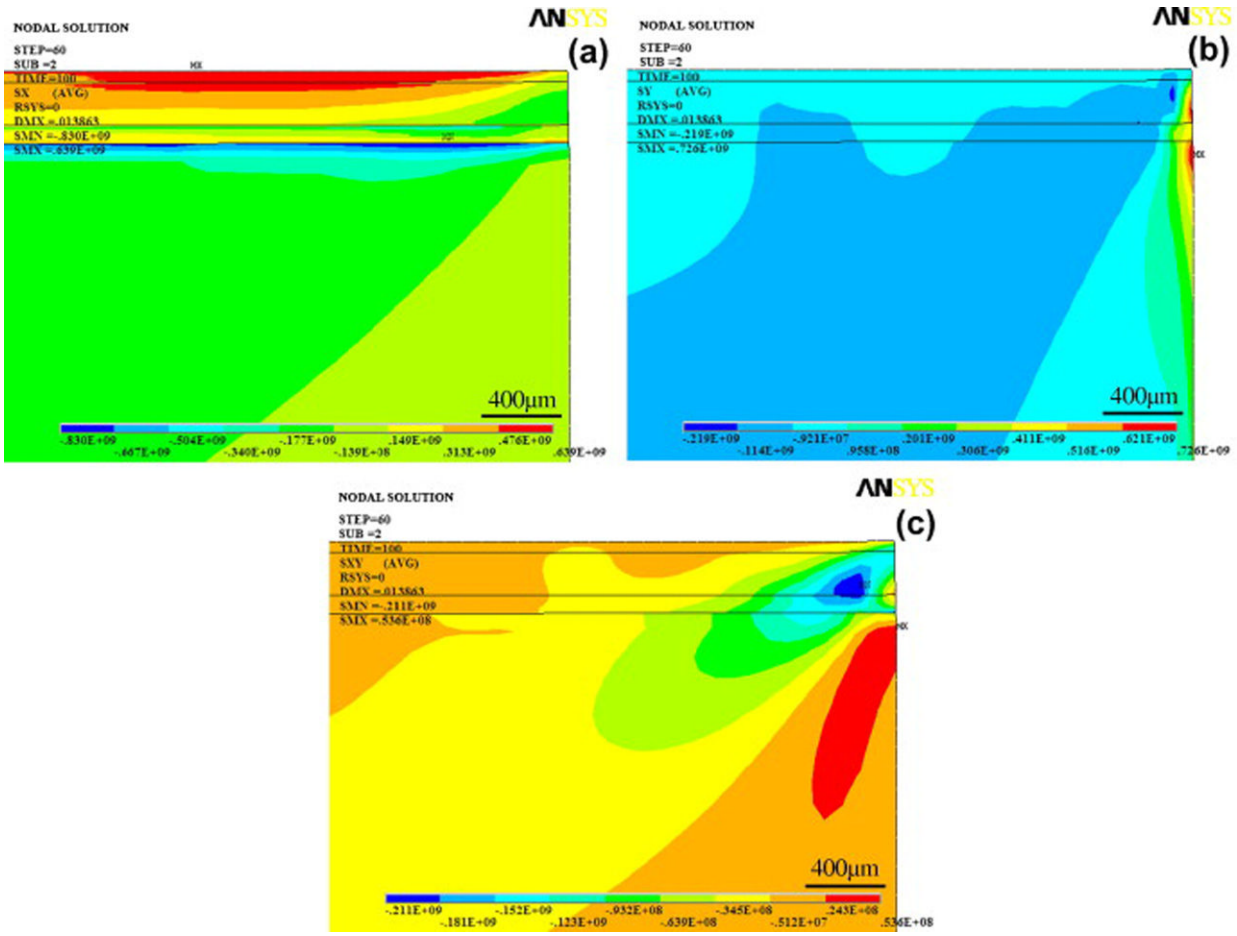

Figure 9 Typical contour plot of stress (MPa) distribution of (a) σ_{xx}, (b) σ_{yy}, and (c) σ_{xy} after the 20 layer deposition being finished for the LZ/8YSZ thermal barrier coatings (100 μm NiCoCrAlY bond-coat, 240 μm 8YSZ ceramic-coat, and 60 μm LZ top-layer).[83]

the model results show the residual stress is compressive with values ranging from 96–296 MPa, which is reasonably comparable with the average experimental (compressive) residual stress of 198 MPa given by XRD.

Liu *et al.*[81] developed a 3D multilayer thermo-mechanical model for the evolution of temperature and residual stress field during the thermal spray of alumina on stainless steel substrate. The influence of the sprayed particles on the substrate and pre-coated ceramic layer temperature was incorporated with the use of the birth and death element technique. The effects of porosities and micro-cracks on the effective properties of the coating were taken account. A tensile stress with small magnitude was obtained within the alumina coating at the end of the process. However, the residual stress became compressive after cooling of the coating to room temperature. Contrary to what was reported by Limarga *et al.*,[73] they observed that a higher cooling rate results in a lower temperature magnitude and lower residual stress within the coating. They validated the model by comparing the simulated deflection of the specimen with experimental measurements. Consequently, the model predicted a residual stress value of -422 MPa which is reasonable comparable to the experimental value of -365 MPa. Furthermore, a similar good comparison was previously obtained by Gan *et al.*[82] for the deposition of nickel–cobalt (NiCoCrAlY) alloy on an aluminum disk (AA1100) substrate. They found that the displacements obtained by the thermo-mechanical FE model compares with the measured one from experiments.

Furthermore, Wang *et al.*[83] predicted the residual stresses developed after deposition of double-ceramic-layer (DCL) $La_2Zr_2O_7$/8YSZ TBCs using birth and death element technique. They found that residual stress was due to quenching and thermal mismatch. The FE results show that the surface and the edge of interface are often the positions of high stress concentration. Their investigations reveal that DCL coating has lower residual stress as compared with the conventional single-layer 8YSZ coating. They further investigated the effect of defects on the residual stresses using a novel method, which uses actual image, i.e., the computational micro-mechanics (CMM) approach. They suggested that DCL coating be used as an ideal coating material in future due to its better thermal insulation effect, sintering resistance ability, and lower residual stress as compared with that of the conventional 8YSZ coating. **Figures 8–10** show the residual stresses after one layer of deposition, 20 layers of deposition, and after cooling.

Wu *et al.*[84] conducted a 2D axisymmetric thermo-structural analysis of the residual stresses developed after the deposition of air plasma spray TBC using the 'modified element birth–death

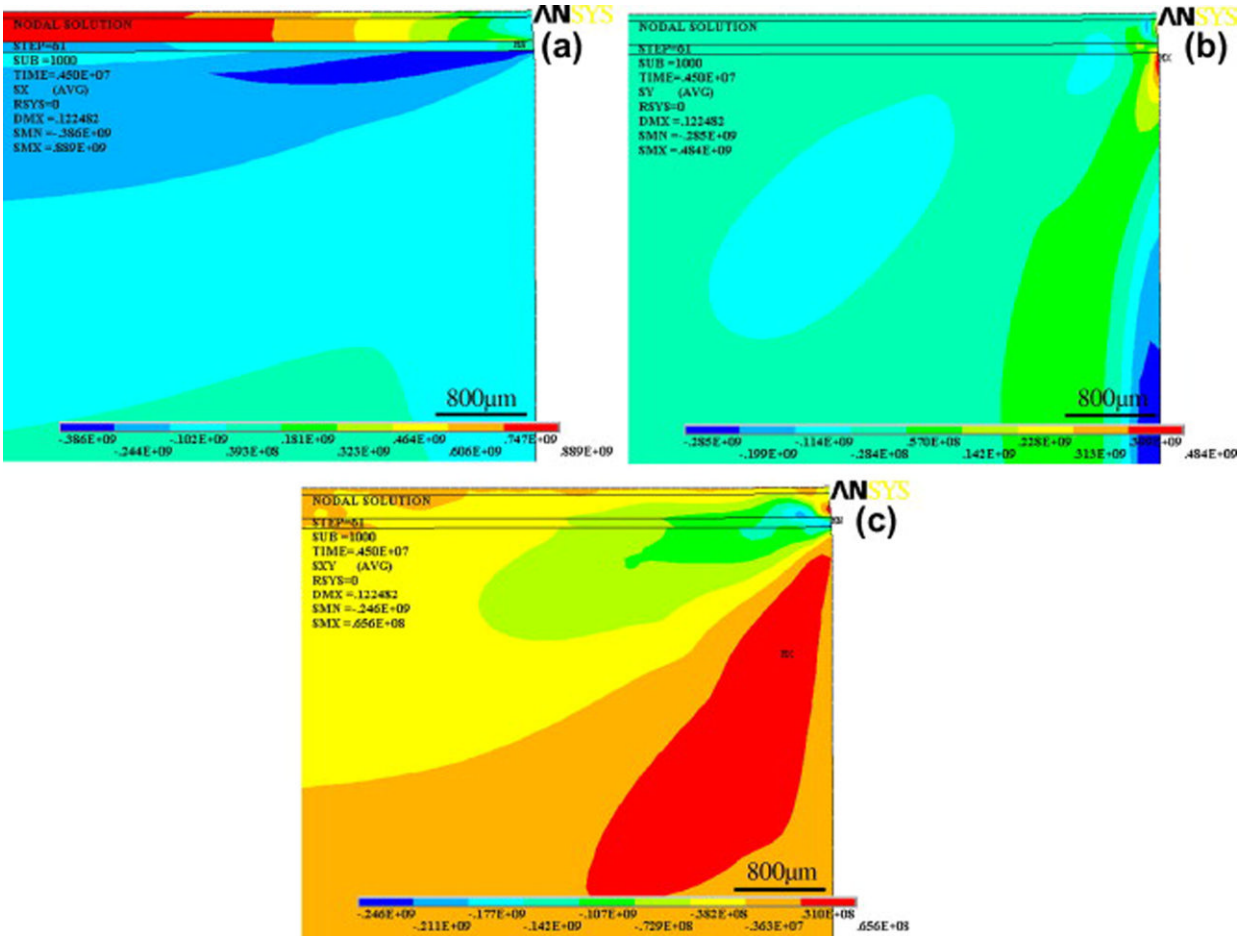

Figure 10 Typical contour plot of stress (MPa) distribution of residual stress of (a) σ_{xx}, (b) σ_{yy}, and (c) σ_{xy} after the LZ/8YSZ thermal barrier coatings being cooled to the ambient temperature (100 μm NiCoCrAlY bond-coat, 240 μm 8YSZ ceramic-coat, and 60 μm LZ top-layer).[83]

technique.' In conventional birth–death element technique, the nodes of the dead elements will not take part in calculation as long as they are inactive. However, nodes of death elements, which are located at the boundaries that are common to both activated and inactivated elements, will move thereby resulting in severe distortion of the inactive elements. To avoid this severe distortion, a 'modified element birth–death technique' was used. Before the computation was done, a group of 'soft/hypothetical elements' with suitable properties were added to appropriate locations within the model. Therefore, these elements could undergo large deformation at low stress levels with little influence on other active elements. The FE results show that the radial residual stress was almost uniform in top-coat layer due to the weakening of the material strength and opening of microcracks under tensile load. Axial residual stresses were found to be higher at the edge of the specimen and the maximum value was found at the BC/substrate interface which might lead to the delamination of the coating. Figure 11 shows the residual stress distribution after the first and the fifth spraying step. The residual displacements obtained using the FEM were found to accurately agree with experimental results obtained by HDM.

Finally, we discuss the papers that used an image-based FE model for the computation. Ghafouri-Azar *et al.*[19] developed 3D stochastic model the deposition of WC–Co coating onto stainless steel substrate using HVOF torch. The model was found to accurately capture the thermal spray process. The simulated microstructure, coating thickness, and percentage porosity were very comparable to experimentally observed ones. The experimental micrograph as well as the simulated microstructure were used with an OOF code developed at the National Institute of Standards and Technology to calculate the residual stresses in the coating. The FE model uses an adaptive meshing technique to discretize the coating microstructure into a mesh suitable for FE analysis. The residual stress values obtained with both the real and computationally generated microstructure were found to be very close. High stresses were found at the substrate/coating interface. The residual stresses were found to increase with coating thickness and coating temperature, and decrease with substrate temperature.

Similarly, Klusemann *et al.*[85] numerically predicted the residual stresses developed in thermal sprayed WC–Co coating that has been subjected to roller burnishing process. They first

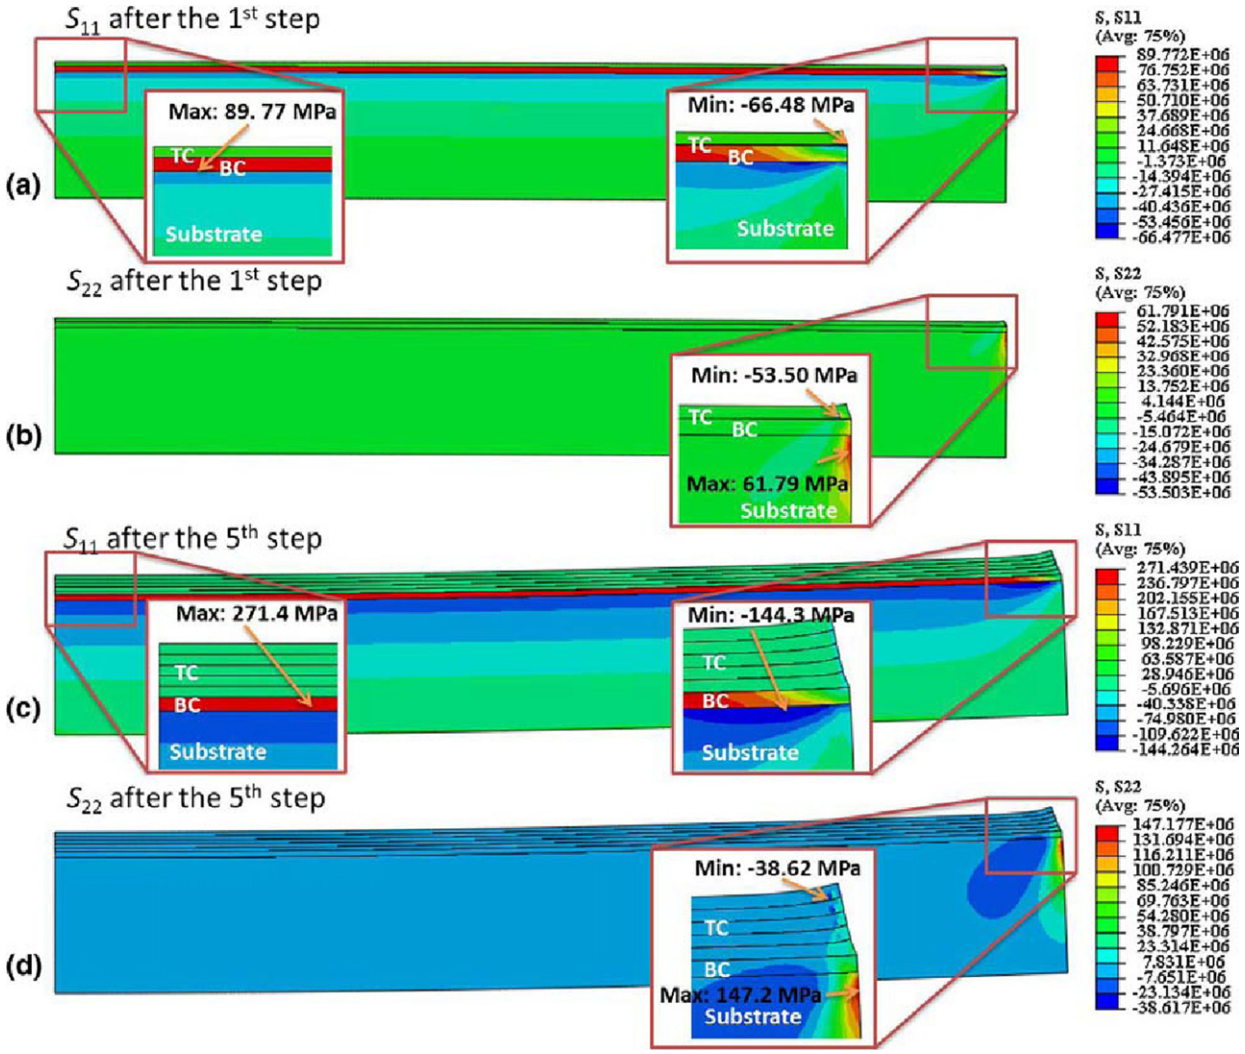

Figure 11 Distributions of residual stress components S_{11} and S_{22} in MPa after the 1st (a and b), and the 5th (c and d) spray steps.[84]

used SEM images to first estimate the effective material properties of the coating before performing a thermo-structural analysis using an optical micrograph for the computation of thermally-induced and rolling-induced residual stresses. The FE results show that compressive residual stresses were developed in the thickness direction after the rolling process, which agrees very well with experiment qualitatively. However, the model shows the development of a layer of tensile stresses the surface of the coating which could not be captured experimentally by HDM. They suggested that computations should be repeated with a 3D image-based model that is coupled with some damage models in order to improve the quality of the results.

3.4.4 Summary and Outlook

It can be seen that the FEM has been successfully used in estimating the residual stresses developed in thermal spray coatings. The FEM has been widely used as compared to other numerical techniques. This is due to its flexibility and suitability for complex or multilayer materials. The residual stresses have been found to be mainly due to thermal mismatch between the various layers of the coating system. However, other phenomenon such as TGO growth, phase transformations at various interfaces, inhomogeneity of respective layers, surface roughness of the substrate, and deposition process parameters; all contribute to the residual stresses even though their contribution is negligible. The results have been shown to be reasonably close to the experimentally measured residual stresses both quantitatively and qualitatively. Therefore, the FEM is a very powerful tool that can be used to predict residual stresses in coatings. But still the following issues need to be addressed in order to improve the effectiveness of FEM in predicting residual stresses:

1. In order to improve the accuracy of the results, a model that incorporates the effect of other processes (such as creep, TGO growth, process parameters, surface roughness, phase transformations, etc.) should be further exploited.
2. As aim of the residual stress prediction is to estimate the lifetime of the coating, future research should relate the developed residual stresses with the coating lifetime when used for specific applications.
3. Even though some image-based FE technique has been used, further investigation should be carried out in order to investigate more about the effect of materials inhomogeneity on the coating life.
4. No reliable coupling of the residual stress model with damage models has been found (to the best of our knowledge). Most of the researchers simply conclude that the high interfacial or residual stresses lead to the spallation or delamination failure of the coatings. Therefore, coupling a multi-scale damage model with the residual stress model may help in understanding more about the failure mechanism of thermal-spray coatings.

3.5.1 Introduction

The wetting characteristics of the solid surfaces play an important role in the practical applications. In metal cutting, friction, and bearing applications, the fluid wettability of the surface becomes important because of the requirement of the low friction between two contacted surfaces. The free energy of the solid surface and surface tension of the fluid are two important properties defining the wettability of the fluid on the solid surface; therefore, high surface energy of the solid and low surface tension of the fluid are required for the hydrophilic behavior. In general, the wetting state of the solid surface can be identified through surface hydrophilicity, which takes the form of hydrophilic for high wetting states and hydrophobic for low wetting states. However, hydrophobic surfaces are important when the surface self-cleaning characteristics are required. In this case, dust removal, condensation prevention, and stain-free surfaces can be generated. In nature, the hydrophobic surfaces give rise to a self-cleaning effect. One example of such surfaces is the lotus leaf, for which the surface wetting characteristics are significantly low.[1] A close examination of such surfaces reveals that surface texture and surface energy are two important properties that contribute significantly to the hydrophobicity. Solid surfaces can be textured while mimicking nature; in this case, the surface morphology consisting of micro-/nano-poles can be produced artificially at the solid substrate and modification of surface energy can create hydrophobic behavior of the textured surface. Many methods and processes were introduced to gain the hydrophobic characteristics of the solid surfaces.[2–10] Although the technology and techniques used for the surface texturing are available and, currently, they are part of the research activities in surface engineering, some of the processes are involved complicated steps with high costs. In addition, some of these multistep procedures require harsh conditions or specialized reagents and equipment. Some of these techniques include phase separation,[2] electrochemical deposition,[3] plasma treatment,[7] sol–gel processing,[8] electrospinning,[9] and solution immersion.[10] The surface free energy of solid materials can be modified through chemical and physical processes via altering chemical composition at the surface or coating or by introducing alloying elements. However, micro-/nano-texturing of surfaces have many challenges in terms of cost, processing time, equipment, and skilled manpower requirements. Laser processing of surfaces can be considered as one of the effective ways to texture solid surfaces. In addition, laser processing has several advantages over the other techniques. Some of these advantages include precision of operation, fast processing time, and low cost. High intensity beams are used in laser surface texturing, which triggers evaporation and melting at the surface simultaneously while forming small cavities at the irradiated surface. However, during the texturing process involved with the combination of evaporation and melting, process control is highly critical to achieve the desired texture and hydrophobic characteristics. Because the laser power intensity distribution is Gaussian, the peak power intensity takes place at the irradiated surface. Consequently, the region close to the irradiated spot center evaporates, whereas the region close to the edges of the irradiated spot undergoes melting because of the low incidence of laser power intensity in this region. During the simultaneous occurrence of the evaporation and melting processes, melt flow toward the cavity partially fills the cavity while causing reduction in the cavity size. However, this process can be used as one of the techniques to generate micro-/nano-poles and cavities at the surface. In addition, high-power laser irradiation at the solid surface causes the development of high temperature gradients in the irradiated region. This in turn, gives rise to the formation of high thermal strain in the shallow region of the irradiated surface. In some cases, thermal stress formed in the laser-treated region gives rise to the formation of asperities, such as cracks, voids, and metallurgical defect sites in the irradiated region. Consequently, laser texturing of the solid surfaces process involves with multiphysics and requires

further investigation to explore the physical insight into the processes.

The thermal and mechanical properties of the solid surface plays a vital role in the end product quality of the laser-textured surfaces. This is because of the fact that the absorption coefficient of the incident radiation, evaporation and melting temperatures, latent heat of melting, and thermal diffusivity significantly influence the cavity and melt sizes at the surface. In addition, thermal expansion coefficient, Poisson ratio, elastic modulus, and temperature gradients affect the thermal strain and stress levels in the heated region. Therefore, laser surface ablation characteristics and resulting texture change for different solid substrates; for example, because the thermal and mechanical properties of ceramic, metal, and polymers significantly differ, the resulting laser ablation-induced textures become different and stress levels in the treated layer also differ from each other. Consequently, in the present study, laser-induced texturing of three different materials is presented. These include polycarbonate (PC) sheet, which is widely used as a protective layer at photovoltaic (PV) cells; phosphorus bronze, which has antibacterial characteristics; and alumina, which is a ceramic that has a wide application in industry. The laser texturing process and texture analysis are provided in line with the previous studies.[11–13]

3.5.2 Background

In this section, the relevant literature surveys for the surface processing of the materials selected are provided under the appropriate subheadings.

3.5.2.1 PC Sheet

PC is a durable material. Although it has high impact resistance, it has low scratch resistance and in general, a hard coating is applied for the practical usage. The characteristics of PC are much like those of polymethyl methacrylate (PMMA, acrylic), but PC has superior mechanical properties and is usable over a greater temperature range. PC is highly transparent to visible light, with better light transmission than many kinds of glasses. PC has a high glass transition temperature (147 °C[14]), and it softens gradually above this point. Large plastic deformations can take place in PC sheets without cracking or breaking, thus enabling processing and formation at room temperature using sheet metal techniques, such as bending. This enables the use of PC in prototyping applications without losing its transparency or electrical properties. PC sheet can also be used as a protective cover on PV panels. However, due to dust accumulation over time, optical transmittance of PC sheet decreases and the efficiency of the PV panels is lowered. One method to avoid dust accumulation and to ease dust removal from the surface is to texture the PC surface while creating hydrophobic characteristics. Previously, surface texturing of PC sheet was performed via crystallization of the surface by using acetone.[15] Although the surface texture appears to generate hydrophobic characteristics, the optical transmittance is significantly reduced. However, laser texturing of PC surfaces offers advantages over other chemical methods. In the control gas-assisting environment, a combination of surface evaporation and melting results in micro-/nano-poles while demonstrating hydrophobic characteristics.[15]

Considerable research studies were performed to examine surface hydrophobicity of PC sheets. PC with hydrophilic/hydrophobic coatings for the fabrication of micro-devices was studied by Jang *et al.*[16] They showed that by using hydrophilic treatment of PC, they obtained microchannels that were resistant to organic solvents. Furthermore, by using subsequent hydrophobic treatment, multiple liquids were successfully injected into microchannels sequentially in a valve-free manner. A fabrication and characterization study for superhydrophobic surfaces of PC slab was performed by Zheng *et al.*[17] They indicated that the surface modification introduced the superhydrophobic property to the PC slab, and that abrasive polishing seriously damaged the superhydrophobicity, possibly because the mechanical abrasion removed much of the hydrophobic nano-layers and changed the microstructures in such a way that the surface roughness was considerably reduced and some small areas of bare PC surfaces were exposed. Superhydrophobic and superhydrophilic PC, by tailoring chemistry and nano-texture with plasma processing, was investigated by Palumbo *et al.*[18] They demonstrated that the etching process allowed for formation of nanopillars tens of nanometers wide and up to a micrometer high, which was responsible for the unique behavior. Wetting and other physical characteristics of PC surface textured using laser ablation were presented by Yilbas *et al.*[11] They showed that textured surfaces composed of micro-/nanopores with fine cavities increased the contact angle to hydrophobicity in such a way that contact angles in the range of 120° resulted. Superhydrophobic microtextured PC surfaces were studied by Bhagat and Gupta.[19] They indicated that the microtextured PC could be a perfect master for replication of micro-texture on other types of polymers such as polydimethylsiloxane (PDMS) in bulk and in thin film forms. Hierarchical polymeric textures via solvent-induced phase transformation were examined by Cui *et al.*[20] They demonstrated that the resulting surfaces exhibited high contact angles, low contact angle hysteresis, and complete de-wetting during droplet impact. In addition, theoretical analysis of the wetting and anti-wetting pressures showed that the nanoscale morphology was critical for achieving droplet impact resistance. Nano-texturing of nanocomposites by an innovative and advanced spray system was studied by Banerjee and Balasubramanian.[21] They indicated that the wettability and adhesive property of the nanocomposite resulted in a 131.7° contact angle for the centrifuged spray dryer technique. Stroke asymmetry of tilted superhydrophobic ion track textures was presented by Spohr *et al.*[22] They showed that the tilt orientation of a superhydrophobic surface led to the development of the advancing and receding contact angles, which were against the stroke direction.

3.5.2.2 Alumina Tiles

Alumina tiles are widely used in industry because of high resistance to corrosion, wear, and high temperature. In general, alumina tiles are produced from fine powders through hot

pressing or sintering. Because the powder size, in general, varies between 1 and 3 μm, some micro-/nano-voids are formed among the sintered particles. This limits the practical application of the tiles because of the presence of micro-/nano-pores in the tile structure. The pores can be eliminated through melting and solidification of tiles. However, the bulk melting is expensive because of the high melting temperature and the latent heat of alumina. One of the alternatives is to melt the surface locally using high intensity beams. Laser processing can possibly be used for this purpose; however, the proper settings of laser output power and frequency enable melting and evaporating at the irradiated spot locally at the surface. The combination of melting and ablation can cause texturing of the alumina tile surface. Consequently, laser-controlled processing could provide micro-/nano-textured surfaces and eliminate the localized pores in the vicinity of the tile surface.

Considerable research studies were performed to examine laser treatment of alumina surfaces. Crystallographic and morphological textures in laser surface-modified alumina were examined by Harimkar *et al.*[23] They discussed the interdependence of crystallographic and morphological textures of the surface grains within the framework of faceted growth model. They suggested that the formation of crystal shapes was governed by the relative velocities of certain crystallographic facets. Laser texturing of the alumina surface for improved hydrophobicity was studied by Yilbas *et al.*[12] They indicated that the presence of AlN contributed to hydrophobicity enhancement at the surface. In addition, Wenzel and Cassie–Baxter states were present at the treated surface due to the variation in the surface texture. The effects of laser surface texturing on friction properties of nickel-based composites were investigated by Li *et al.*[24] They demonstrated that the lubricious oxide particles stored in the dimples reduced friction coefficient at elevated temperatures and compensated for the extra lubricant due to the degradation of MoS_2 caused by its oxidation at high temperatures. Laser treatment of polycrystalline alumina and aluminum nitride was studied by Williams *et al.*[25] They indicated that the findings could assist in establishing optimum settings of processing parameters in association with the type, properties, and thickness of the substrates. Morphological modification in laser-dressed alumina grinding wheel material for microscale grinding was investigated by Khangar and Dahotre.[26] The findings revealed that the weight loss in the laser-dressed grinding wheels was lower than that of undressed wheel after grinding. The study of tribological behavior of alumina-doped zinc oxide films grown by pulsed laser deposition was performed by Prasad *et al.*[27] They showed that the presence of dark contrast regions in images of wear scars on $ZnO(Al_2O_3)$ films was due to the presence of a slippery phase. Laser synthesis of composite Al_2O_3–$Y_2Ti_2O_7$ ceramics powder mixtures was performed by Vlasova *et al.*[28] They demonstrated that increasing the alumina content in the initial mixtures increased the saturation of α-Al_2O_3 crystallites on the surface of the layers. Microfabrication of an anodic oxide film by anodizing laser-textured aluminum was studied by Jha *et al.*[29] They demonstrated that microstructures with a depth of a few to several tens of micrometers could be fabricated successfully on the anodic oxide film by using various combinations of laser power density and laser scanning speed. Improvement in the tribological characteristics of Si-DLC coating by laser surface texturing under oil-lubricated point contacts at various temperatures were examined by Amanov *et al.*[30] They indicated that the textured Si-DLC coating led to a lower friction coefficient and wear characteristics as compared to that of the untextured Si-DLC coating throughout the temperature range tested. This behavior could be attributed to the effects of dimples and microstructural alteration due to high-energy action of the pulsating laser beam. Pulsed fiber laser texturing of metals, silicon, and ceramics was performed by Hendow *et al.*[31] They showed that measured values for nanosecond-textured surfaces were in the range of 0.4–2.2 μm and 1.5–5 μm for monocrystalline Si and Al, respectively.

3.5.2.3 Phosphorous Bronze

Extensive research studies reported on laser treatment of bronze surfaces. Laser texturing of sliding surfaces of bearings and pump seals was examined by Antoszewski and Tarelnik.[32] They presented the selection of operating parameters of a picoseconds laser, which was used to produce texturing in elements made of steel, bronze, and silicon carbide. A study of microscopic inspection during laser treatments of artwork was performed by Cacciari *et al.*[33] They developed and tested a dedicated 3D digital microscope by implementing the shape from focus technique, which provided textural and chromatic information for the phenomenological characterization of black crust removal from stones. The tribological properties of the amphiphobic textured metal surface were investigated by Wang *et al.*[34] The findings revealed that a visible transition took place, from a high friction coefficient to low values, when the sliding speed increased. The laser ablation mechanism of bronze-bonded diamond wheels was studied by Chen *et al.*[35] They numerically predicted the average temperature and thickness of the melted layer, ablation velocity, and depth by using different laser power densities. A numerical study on laser ablation of quaternary bronze alloys was performed by Fornarini *et al.*[36] They indicated that the results supported the utilization of ultrafast laser sources for trace detection, despite the residual fractionation occurring in the examined range of fluences that affected the linearity of experimental calibration curves built for tin and lead after internal standardization on copper. The optimization study for the laser dressing of bronze-bonded diamond wheels was introduced by Deng *et al.*[37] The findings revealed that the normal and tangential grinding forces produced by the laser-dressed grinding wheel during grinding were smaller than those of grinding wheels dressed using the conventional mechanical method. Formation of periodic structures by laser ablation of metals in liquids was investigated by Kazakevich *et al.*[38] They showed that for a certain range of laser parameters (fluence and number of laser shots), the surface of the solid target was composed of microcones with a regular structure. The physics of selective evaporation of components during laser ablation of stainless steel was examined by Pershin *et al.*[39] Their findings demonstrated that the mechanism of selective evaporation allowed one to improve precision of the analysis for multicomponent alloys without reference calibration, which increased the practical

importance of the calibration-free laser-induced breakdown spectroscopy. Microstructure and performance of laser cladding on the surface of aluminum bronze was studied by Xu *et al.*[40] They indicated that the microstructure of the lower composite region was cellulated crystal and dendritic crystal. They demonstrated that the high rate of strain developed in the heated region, due to fast cooling rates, resulted in high von Mises stress in the surface region. Laser surface modification treatment of aluminum bronze with B_4C was performed by Yilbas *et al.*[41] They showed that the laser-treated surface produced was relatively free from defects and asperities, with a microhardness that was notably higher than that of the as-received bronze substrate. Laser surface alloying of a marine propeller bronze using aluminum powder was studied by Tang *et al.*[42] They indicated that the galvanic effect between the laser-treated and as-received samples was small, and this was a favorable factor for justifying the use of laser surface alloying with aluminum as a feasible method in the local surface treatment of manganese–nickel–aluminum bronze. Thermal–morphological analysis of laser-treated sintered bronze was performed by Gisario *et al.*[43] They proposed a model to approximate the real operational conditions and predict the most promising settings of the laser system aimed at improving the surface finishing of the metal substrates. Laser embedding of TiC particles into the surface of phosphor bronze-bearing material was presented by Yilbas *et al.*[44] They showed that the microhardness of the laser-treated surface increased almost three times as compared to the base material hardness. Electrochemical testing of the laser-treated bronze surface was studied by Yilbas *et al.*[45] The findings revealed that laser treatment improved the corrosion resistance of the treated surface. In addition, fine grains were formed in the surface region of the laser-treated layer, which were attributed to the long cooling rates at the surface.

3.5.3 Experimental Work

In this section, sets of experiments are provided in line with previous studies.[11–13] The experiments cover the morphological, metallurgical, mechanical, and hydrophobicity testing of the laser-treated surfaces.

The CO_2 laser (LC-ALPHAIII) delivering nominal output power of 2 kW was used to irradiate the workpiece surface. The nominal focal length of the focusing lens was 127 mm. The laser beam diameter focused at the workpiece surface was ~0.25 mm. Nitrogen assisting gas emerging from the conical nozzle and coaxially with the laser beam was used. Laser treatment tests were repeated several times by incorporating different laser parameters and laser parameters resulting in the minimum surface defects, such as small cavities with no cracks or crack networks.

A PC sheet with a thickness of 3 mm was used as the workpiece. The PC sheet was a PBA (*p*-hydroxypheyl) and had excellent optical clarity with high toughness. The PC samples were prepared at $30 \times 30 \times 3\ mm^3$ (width × length × thickness). They were cleaned with distilled water prior to laser treatment. The phosphor bronze with elemental composition (wt%) of 6% Sn, 0.1% P, and balance of Cu was used in the experiments. The samples were prepared from phosphor bronze sheet with a thickness of 3 mm and size of 20 mm × 20 mm (length × width). Alumina (Al_2O_3) tiles (Ceram Tec-ETEC, 2010) with a thickness of 3 mm were used as workpieces.

Material characterization of the laser-treated surfaces was performed using optical microscope, scanning electron microscope (SEM), energy dispersive X-ray spectroscopy (EDS), and X-ray diffraction (XRD). Jeol 6460 electron microscopy is used for SEM examinations and Bruker D8 Advanced with CuKα radiation is used for XRD analysis. Typical XRD settings are 40 kV and 30 mA, and scanning angle (2θ) ranged from 20° to 80°.

Microphotonics digital microhardness tester (MP-100TC) was used to obtain microhardness at the surface of the nitride layer. The standard test method for Vickers indentation hardness of advanced ceramics (ASTM C1327-99) was adopted. Microhardness was measured at the workpiece surface after the laser treatment process. The measurements were repeated five times at each location for consistency of the results.

The XRD technique is used to measure the residual stresses in the laser-treated surface region of phosphorous bronze and alumina tile. The XRD technique provides the data in the surface region of the specimens due to the penetration depth of CuKα radiation into the treated layer (i.e., the penetration depth is approximately 5 μm). The measurement relies on the stresses in the fine-grain polycrystalline structure. The position of the diffraction peak exhibits a shift as the specimen is rotated by an angle (ψ). The magnitude of the shift is related to the magnitude of the residual stress. The relationship between the peak shift and the residual stress (σ) is given by:[46]

$$\sigma = \frac{E}{(1+\upsilon)\sin^2\psi}\frac{(d_n - d_0)}{d_0} \quad [1]$$

where E is Young's modulus, υ is Poisson's ratio, ψ is the tilt angle, d_0 and d_n are the d spacing measured at each tilt angle. If there are no shear strains present in the specimen, then the d spacing changes linearly with $\sin^2\psi$. In the case of alumina, the γ-Al_2O_3 peak (ICDD 29-1486) takes place at 37.5°, which corresponds to the (311) plane with interplaner spacing of 0.239 nm. The linear dependence of d(311) results in a slope of -1.677×10^{-12} m per degree with an intercept of 0.239 nm. The residual stress determined from the XRD technique at the surface vicinity is approximately $-2.1(+0.06/-0.06)$ GPa. In the case of phosphorous bronze, the calculations were performed for $Cu_3N(100)$ planes ($2\theta = 23.44°$) with an interplaner spacing of 0.3844 nm. It should be noted that Cu_3N is identified in accordance with the ICDD 00-055-0308 card. The linear dependence of $d(100)$ results in a slope of $-1.9 \times 10^{-3} \pm 9.12 \times 10^{-5}$ nm and an intercept of $0.3844 \pm 4.75 \times 10^{-3}$ nm. The elastic modulus and Poisson's ratio of phosphor bronze are 96.5 GPa and 0.34,[26] respectively. The residual stress measured is approximately −350 MPa, which is compressive, and the estimated error is ±10 MPa, which is 2.4%. It should be noted that the error is estimated based on three repeats of the XRD measurements and the error related to the measurements is approximately 3%.

In the case of PC sheet, residual stress measurements were performed using the curvature method. The deflection of the workpiece during laser scanning was recorded and the final

deflection was measured using the optical imaging technique. The equation relating deflection Δx to curvature κ is obtained from the geometric relation, which yields:[47]

$$\kappa = \frac{1}{R} = \frac{L_{arc}}{\cos^{-1}\left(1 - \frac{\Delta x}{R}\right)} \quad [2]$$

where L_{arc} is the arc length of the specimen, R is the curvature radius, and Δx is the final deflection due to curvature. The Stony equation[47] is used to obtain the relationship between the residual stress (σ) and the curvature[47]:

$$\sigma = \frac{\kappa E_s t_s^2}{6(1 - \upsilon_s)t_c} \quad [3]$$

where E_s is the elastic modulus, t_s is workpiece thickness, v_s is the Poisson's ratio of the polycarbonate glass, and t_c is the laser-treated layer thickness, which is measured from SEM images.

Scratch resistance of the laser-treated and untreated surfaces was determined from the standard test method in line with the ASTM D7027-05 standard. The linear micro-scratch tester (MCTX-S/N: 01-04300[9]) and scratch hardness measurement data were incorporated in the calculations. According to ASTM D7027-05 standard, scratch hardness (H_s) can be defined as:

$$H_s = \frac{4qP}{\pi w^2} \quad [4]$$

where P is the normal load used in the scratch tests in Newtons, w is the scratch width in millimeters, and q is the dimensionless parameter, which depends on the extent of elastic recovery of the polymer during scratching. In this case, full elastic recovery implies $q=1$, whereas no recovery implies $q=2$.

The wetting experiment was performed using Kyowa (model DM 501) contact angle goniometer. A static sessile drop method was considered for the contact angle measurement. The water contact angle between the water droplet and the heat-treated surface was measured with a fluid medium such as deionized water. Droplet volume was controlled with an automatic dispensing system with a volume step resolution of 0.1 μl. Still images were captured, and contact angle measurements were performed after 1 s of deposition of water droplets on the surface. The contact angle measurements are performed to assess the hydrophobicity of the laser-ablated surface. Because the laser-ablated surface is chemically heterogeneous due to the local nitride formations and nitride dissolutions at the surface, the application of Young's equation[48] is limited in assessing the contact angle. Wenzel[49] and Cassie and Baxter[50] proposed a relationship between the contact angle of a liquid droplet and the surface roughness factor to overcome this limitation. The Wenzel formulation takes the liquid penetration into the rough grooves into account and expresses the contact angle as follows:[51]

$$\cos\theta_w = \frac{r(\gamma_{sv} - \gamma_{sl})}{\gamma_{lv}} \quad [5]$$

where θ_w is the rough surface contact angle, γ_{sv} is the interfacial tension of the solid–vapor interface, γ_{sl} is the interfacial tension of the solid–liquid interface, γ_{lv} is the interfacial tension of the liquid–vapor interface, and r is the surface roughness factor, which is defined as the ratio between the actual and projected surface areas, where $r=1$ for a perfectly smooth surface and $r>1$ for a rough surface. The contact angle equation is expressed as follows:[51]

$$\cos\theta_c = f_1\cos\theta_1 + f_2\cos\theta_2 \quad [6]$$

where θ_c is the apparent contact angle, f_1 is the surface fraction of the liquid–solid interface, f_2 is the surface fraction of the liquid–vapor interface, θ_1 is the contact angle of the liquid–solid interface, and θ_2 is the contact angle for the liquid–vapor interface. In the case of an air–liquid interface, f_1 is the solid–liquid fraction and air fraction (f_2) becomes $(1-f_1)$. For $f_1=0$, the liquid droplet is not in contact with the solid surface; for $f_1=1$, the droplet completely wets the surface.

3.5.4 Results and Discussion

Laser texturing of PC sheet, phosphorous bronze coupons, and alumina tiles are performed. Morphological, metallurgical, mechanical, and surface hydrophobicity are presented according to the materials used in the present study. The findings are in line with the findings of the previous studies.[11–13]

3.5.4.1 PC Sheet

The findings of mechanical, optical, hydrophobicity, and morphological properties are given here and are in line with those of the previous study.[11]

Figure 1 shows optical and SEM micrographs of the laser-treated surface. Laser-treated surface is free from large-scale asperities such as large cracks and voids. Although surface treatment takes place at a constant laser scanning speed, no regular textured patterns are observed at the surface, unlike laser ablation of ceramic surfaces. This is associated with the shallow cavity formation under the controlled ablation at the surface. It should be noted that repetitive pulses with 1500-Hz pulsing frequency are incorporated during the laser ablation process. In this case, overlapping of the irradiated spots due to laser repetitive pulses results in formation of continuous laser scanning tracks, which consist of fine cavities and resolidified sections at the surface. Because laser beam intensity is Gaussian at the workpiece surface, peak intensity occurs at the irradiated spot center. The cavity is formed at the central region of the irradiated spot and melting takes place in the cavity vicinity due to the low laser intensity in this region. However, repetitive laser pulses modify this structure at the surface because of the molten flow from the recently formed cavity near the previously formed cavity. Therefore, surface texture is modified and micro-/nano-pores are formed at the surface. It is evident from the optical image (**Figure 1(a)**) that crystal growth extends radially from the potential nucleation site; however, widespread branching is not visible in the frame of the radial growth. In addition, in some regions (**Figure 1(a)**), intermittent branching takes place, which can be considered as a hallmark of growth to form large spherules. The fine cavity

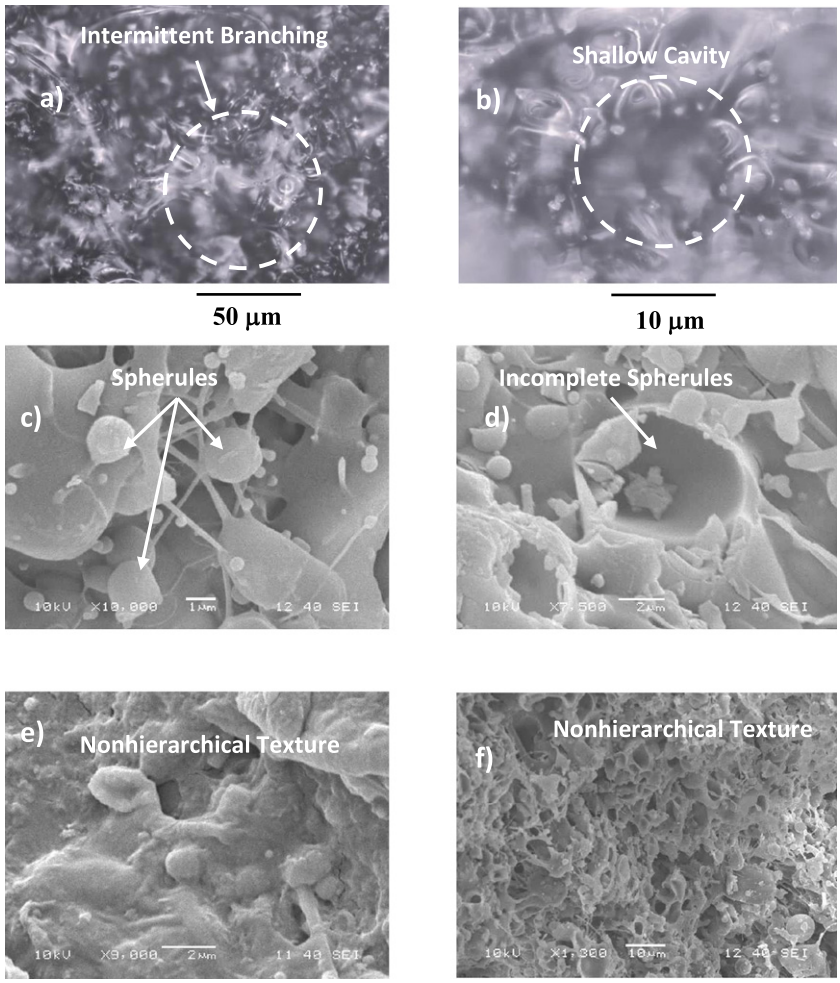

Figure 1 Optical images and scanning electron microscope micrographs of laser-treated surface[11]: (a) optical image demonstrating the crystals formed at the surface and radial growth of crystals and intermittent branching; (b) laser-produced fine shallow cavity and spherules; (c) spherules formed at the surface; (d) incomplete spherules; and (e) and (f) nonhierarchical texture.

formation is also observed in Figure 1(b). Because high-pressure argon is used as assisting gas, no sideways burn-through oxidation reactions are observed at the ablated surface. Surface texture composed of micro-/nano-features is evident from the high-magnification SEM micrograph (Figure 1(a)). Partially formed spherules with varying diameters are also observed from optical and SEM micrographs (Figure 1(b)); however, they do not form hierarchical structure at the surface (Figures 1(c) and 1(d)). This is associated with the varying nucleation density due to nonuniform cooling rates at the surface. Although crystal size varies at the surface, large crystals do not form due to the high cooling rates, unlike those reported for other crystallization processes.[52] Figure 2 shows SEM micrographs of the cross-section of the laser-textured layer. The laser-treated layer consists of fine structures emanating from the surface (Figure 2(b)) and crystal structures formed in the surface region during the solidification process (Figure 2(c)). The laser-treated layer extends almost uniformly along the workpiece surface with a thickness of approximately 2 μm. The fine cavities formed at the surface result in micro-/nano-level waviness contributing to the overall surface texture of the laser-treated layer.

Residual stress formed in the treated layer is determined from the curvature technique. Residual stress obtained from the curvature method is approximately -26 MPa, and the findings reveal that residual stress is compressive. The formation of residual stress is associated with the thermal effect due to high cooling rates and crystallization of the laser-treated surface; in which case, molecular structures are modified in the crystal structure while causing the stress formation after completion of the crystallization process.[53] It should be noted that the volume change due to hydrolysis has an effect on the residual stress formation in the surface region. However, the measurements are performed immediately after the completion of the laser treatment process; therefore, this affect is expected to be insignificant.

Figure 3 shows the friction coefficient of the laser-treated and untreated surfaces. Laser treatment lowers the friction coefficient at the surface, which is associated with enhancement of surface microhardness after the laser treatment process. Laser treatment increases the microhardness of the surface; in which case, microhardness of the untreated surface is 11.2 ± 0.2 HV and that of the laser-treated surface is 25.1 ± 0.9 HV. It should be noted that microhardness

measurements were repeated 10 times at different locations on the laser-treated surface and the error estimated from the hardness data is approximately 0.9 HV. Microhardness variation at the surface is associated with the nonuniform cooling rates and nonuniform distribution of crystal sizes at the surface. However, microhardness enhancement is associated with the crystal structures formed at the surface and high cooling rates that lower the crystal size in the surface region; consequently, a dense crystalline surface results after the laser treatment process. The scar sizes are almost uniform and the scar depth is shallower for the laser-treated and untreated surfaces. The laser-treated surface results in shallow scar depth, which is due to increased hardness at the surface, and no cracks are observed around the scar mark for the laser-treated and untreated surfaces. This demonstrates that the surface fracture toughness reduction due to surface hardness enhancement is not significant. The scratch hardness values of the laser-treated and untreated surfaces are 110 ± 11 MPa and 80 ± 3.2 MPa, respectively. The scratch tests were conducted at different regions of the laser-treated and untreated surfaces. Based on the repeatability of the data, the estimated error is approximately 6% for the laser-treated surface and 4% for the untreated surface.

In general, the laser-treated surface demonstrates the Cassie–Baxter state[50]; in which case, surface texture with low roughness results in air pockets occupying the texture gap while generating hydrophobic behavior at the surface. This situation can be observed from the small value of hysteresis ($\theta_{\text{Advancing}} - \theta_{\text{Receding}}$, where $\theta_{\text{Advancing}}$ is the advancing angle and θ_{Receding} is the receding angle) for the low roughness surface (Table 1). However, in some region at the laser-treated surface, texture changes and surface roughness increases, resulting in nonhydrophobic behavior of the surface, such as

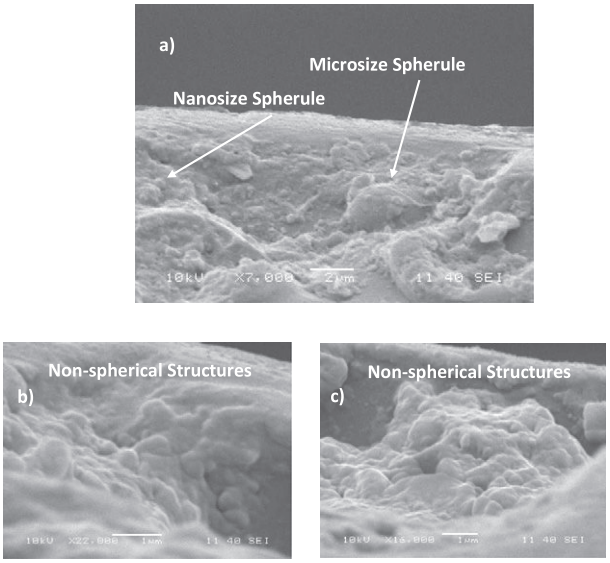

Figure 2 Scanning electron microscope micrographs of the cross-section of the laser-treated layer[11]: (a) spherules at different sizes; (b) nonspherical structures initiating the formation of spherules: and (c) nonspherical dense structure.

Table 1 Contact angles measurement results before and after the laser treatment of polycarbonate sheet[11]

		Contact angle (in degrees)	
		Low roughness	*High roughness*
Laser-treated surface	Advancing	128.2 (+5/−5)	92.3 (+5/−5)
	Receding	121.4 (+5/−5)	78.5 (+5/−5)
Untreated surface	Advancing	84.2 (+5/−5)	–
	Receding	56.6 (+5/−5)	–

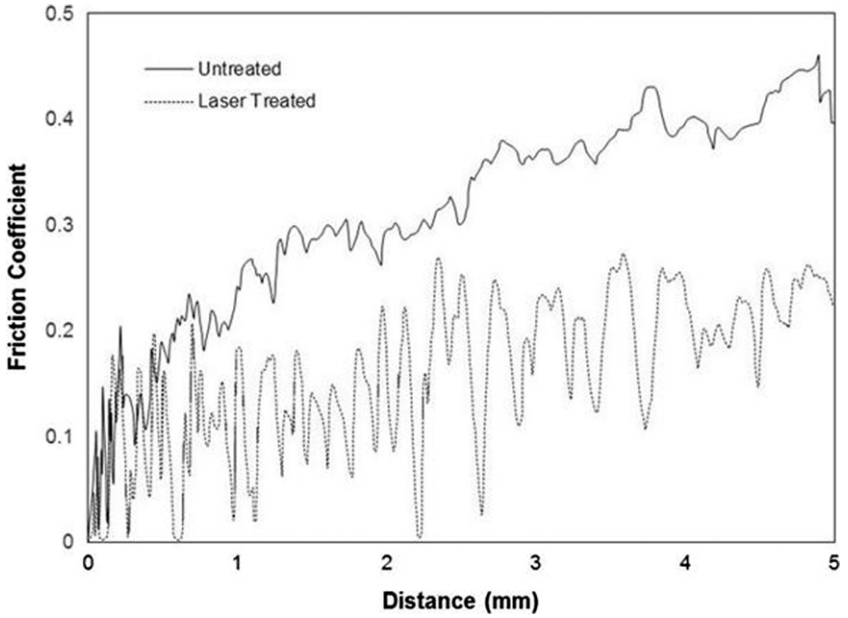

Figure 3 Friction coefficient along the laser-treated and untreated surfaces.[11]

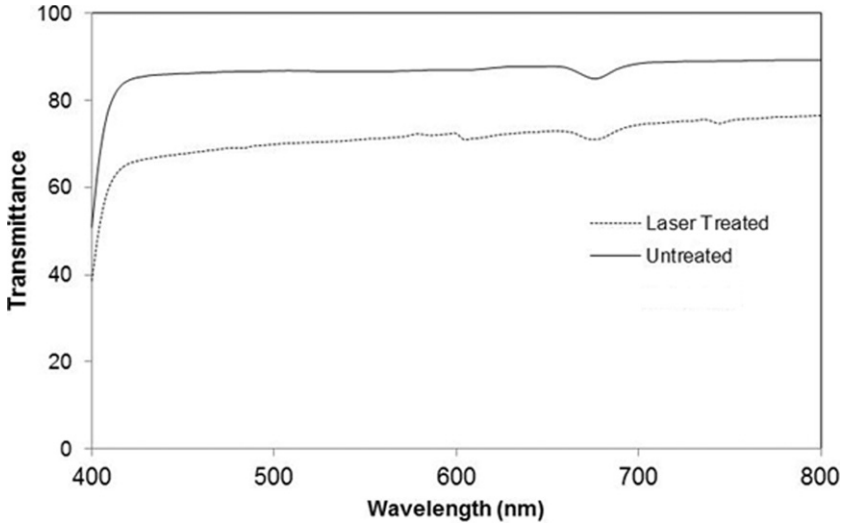

Figure 4 Transmittance data for laser-treated and untreated workpieces.[11]

attainment of a high value of hysteresis (Table 1). This occurs randomly and the total coverage area of this region is small at the laser surface. Consequently, the mixture of hydrophobic states consisting of the Cassie–Baxter and Wenzel states occur at the laser-treated surface. The contact angle measurements reveal that the laser-treated surface demonstrates hydrophobicity across a large area (Table 1, which provides the contact angle data). The roughness factor (f) should be within $0 \leq f \leq 1$ for the hydrophobic surfaces. However, superhydrophobicity is only possible for f values approaching zero. Therefore, f should approach zero for large contact angles in the Cassie and Baxter state. This situation is possible when the surface texture comprises a mixture of micro-/nano-size dimples and pillars, which in turn give rise to the Cassie and Baxter state with large contact angles. This situation is observed in a few locations at the laser-treated surface; in which case, contact angles well in excess of 140° resulted. Figure 4 shows the optical transmittance of the laser-treated and untreated surfaces. The laser-treated surface has less transmittance than that corresponding to the untreated surface. This is associated with the crystal formation at the surface, which alters the absorption characteristics of the incident radiation. Nevertheless, the maximum reduction in the transmittance is approximately 15%, which is significantly low compared to the crystallized surface by the chemical processes, such as immersion in acetone.[54]

3.5.4.2 Alumina Tile

The results obtained for alumina tiles due to mechanical, morphological, and hydrophobic properties are presented and are in line with those of previous study.[12]

Figure 5 shows an optical photograph of the laser-treated workpiece, whereas Figure 6 shows SEM micrographs of the laser-treated surface. The regular ablated tracks can be observed at the laser-treated surface. The tracks are formed during the repetition of the laser pulses at 1500 Hz. To avoid the large-scale cavities at the surface, the laser scanning speed and the laser power intensity are set accordingly after the several

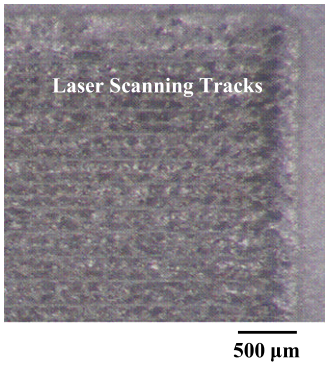

Figure 5 Optical photograph and atomic force microscope micrographs of laser-treated workpiece surfaces.[12]

experimental trials. The maximum depth of the micro-cavities, due to ablation, is approximately 1 µm. The pulse repetitions at the surface modify the micro-cavity shape because of the overlapping of the irradiated spot at the surface. The overlapping ratio of the spots is estimated as 72%, which provides continuous ablation without leaving an unablated gap at the surface. In addition, the overlapping of the irradiated spots modifies the cavity depth such that the initially ablated surface, due to the first pulse, is partially heated by the second consecutive pulse. Because the pulse intensity reduces radially due to Gaussian intensity distribution, the power absorbed by the initially ablated surface due to the second consecutive pulse becomes less because of the workpiece movement during the laser scanning. This, in turn, causes melting rather than ablation in this region; consequently, local flow of molten material fills some part of the previously formed cavity and modifies the geometric features of the cavity surface. Therefore, irregular surface textures with micro/nanoscale dimples are generated at the surface, which can also be seen in the SEM micrographs. The topologic irregularity shows the similarity of the geometric features of the lotus leaf surface.[1] The melting is localized across the small part of the ablated cavity, and no

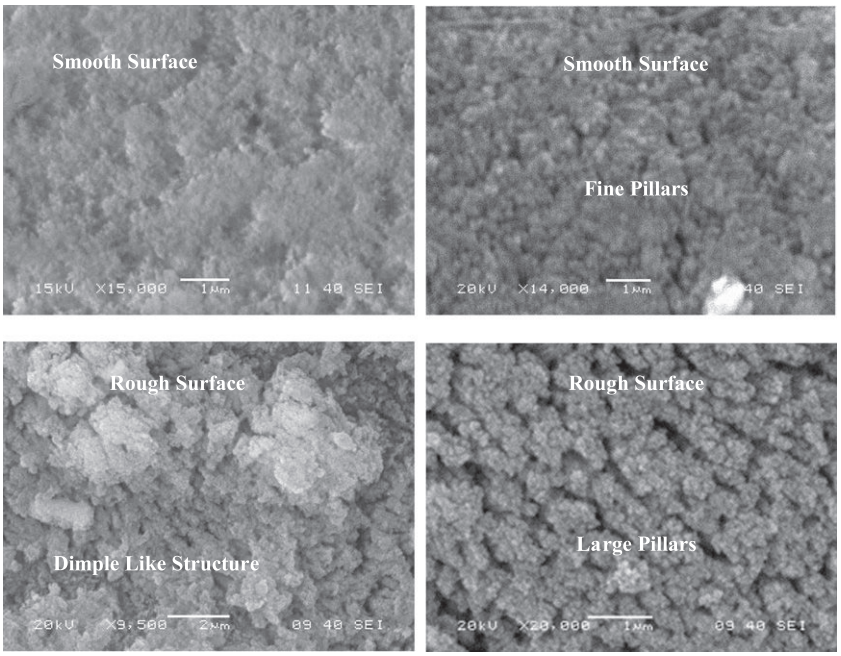

Figure 6 Scanning electron microscope micrographs of laser-treated surfaces.[12] Relatively smooth and rough surfaces.

overflow of molten material is observed across the laser scanning tracks. In addition, the molten flow does not have observable effects on the neighboring cavities. Therefore, the controlled ablation resulted in shallow cavities with dimple-like structures at the surface without large-scale or regular asperities at the surface. Although the cooling rate is high because of the short processing duration and the convection effect of the assisting gas, no crack or crack network is observed at the treated surface. The closed examination of the SEM micrograph reveals that the ablated surface has an irregular texture comprising nano-size grains. The grain refinement at the surface is associated with the high cooling rates and the formation of nitride species at the surface. It should be noted that the use of high-pressure nitrogen as an assisting gas causes the nitride species formation at high temperatures during the ablation process. Moreover, during the laser ablation, evaporated material forms small surface plasma because of the absorption of the incident beam by the vapor front. Because the surface plasma is transiently hot, it contributes to melting at the cavity surface. The surface plasma appears as a bright spot at the irradiated surface during the treatment process. Once the plasma temperature and pressure increase significantly, due to the absorption of the incident beam, the plasma expands rapidly and its thermal effect on the molten flow diminishes. However, the plasma residues appear to be fine dusts at the workpiece surface.

Figure 7 shows SEM micrographs of the cross-section of the laser-treated workpiece. The treated layer extends uniformly 15 μm below the surface because of the constant scanning speed and the steady laser power intensity. Laser ablation at the surface results in fine and dense structures in the surface vicinity, which are attributed to the high cooling rates and the formation of nitride species at the surface. It should be noted that the density of AlN is smaller than the density of Al_2O_3; the volume shrinkage takes place in this region through which the dense structures are formed. Although volume shrinkage results in micro-stress formation in the surface region, no micro-cracks are observed in this region. The overlapping of the laser spots creates a self-annealing effect; in which case, the lately formed cavity site acts like a heating source to the previously formed cavity sites while creating the self-annealing effect. The cooling rates remain high in the region next to the surface vicinity, resulting in small columnar structures. As the depth below the surface increases, the cooling rate becomes slower and relatively larger (as compared to that corresponding to the surface vicinity) columnar structures are formed. As the depth below the surface increases further, large columnar structures replace the grains. The low thermal diffusivity of the substrate material suppresses the extension of the heat-affected zone into the solid bulk. Consequently, the narrow heat-affected zone results between the treated layer and the base material.

Figure 8 shows an X-ray diffractogram for laser-treated and as-received surfaces. The formation of the AlN compound during the laser processing of the surface is evident. The formation of aluminum nitride may take place in two steps. $Al_2O_3 + Al_2O \rightarrow Al_2O + 2CO_2$ (in the first step) and the presence of high-pressure nitrogen as the assisting gas (in the second step) provide $Al_2O + CO + N_2 \rightarrow AlN + CO_2$. A carbonic gas (carbon dioxide) formed during the process escapes from the irradiated surface. AlON compound peak is also observed in the XRD diffractogram. The possible explanation for the formation of AlON is that when the temperature reaches the melting temperature, $Al_2O_3 \rightarrow 2AlO + ½O_2$ is formed. The oxygen atom remains in the alumina structure[55]; however, the presence of N_2 gives rise to $2AlO + N_2 \rightarrow 2AlON$ and formation of the AlON phase. The transformation of the γ-Al_2O_3 phase into thermodynamically stable α- Al_2O_3 is observed when comparing diffractograms of laser-treated and as-received workpiece surfaces. **Table 2** provides the EDS data at three locations on the laser-treated surface. The elemental

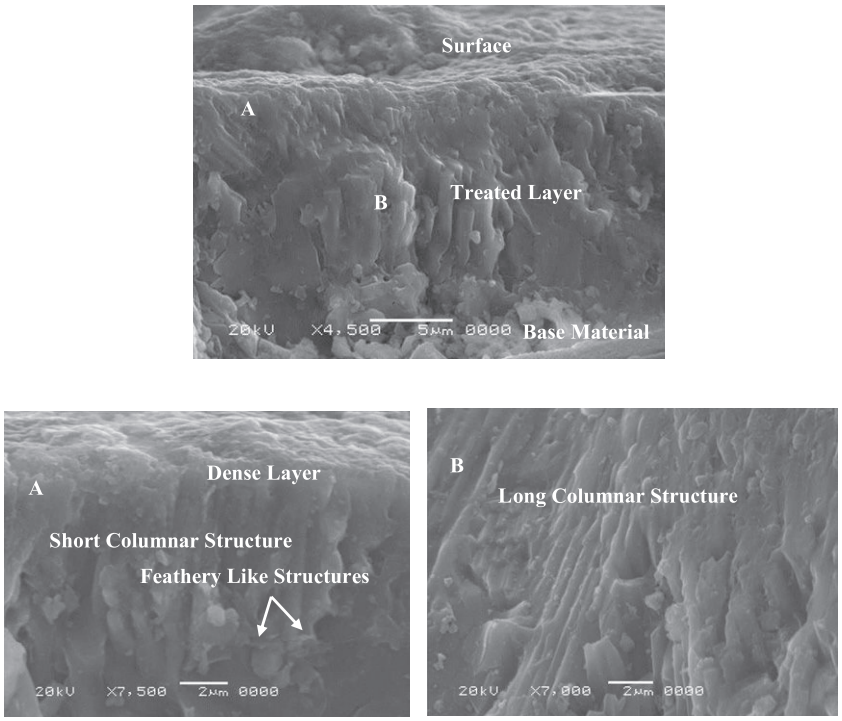

Figure 7 Scanning electron microscope micrographs of cross-section of laser-treated workpiece.[12]

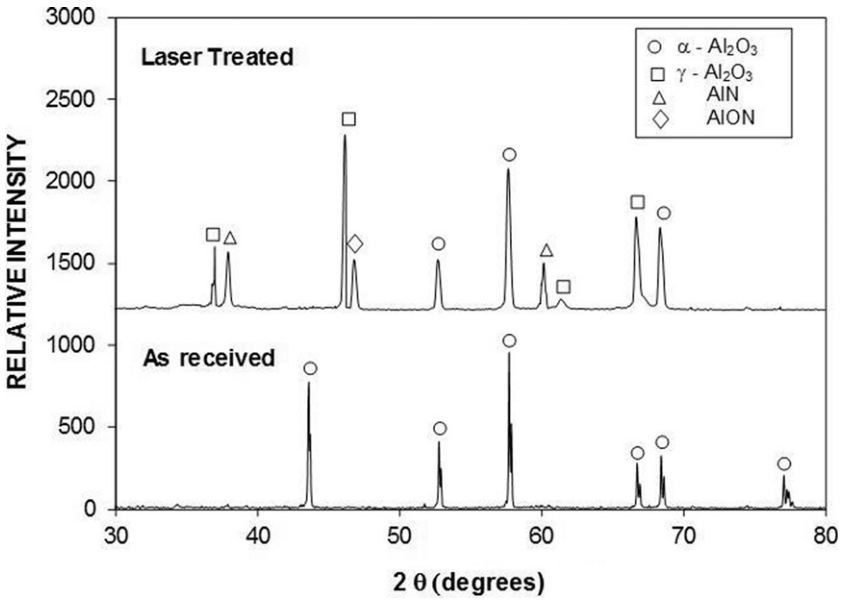

Figure 8 X-ray diffractogram as-received and laser-treated workpiece surfaces.[12]

composition remains uniform at the treated surface. Although the quantification of the light elements involves error in EDS data, the presence of nitrogen is evident, which is attributed to nitride species formation at the surface. **Table 3** gives the microhardness and the residual stress determined from the XRD technique for the laser-treated surfaces. The microhardness increases significantly at the surface, which is approximately 50% more than the base material hardness. The residual stress developed is approximately -2.1 GPa, which is compressive. The formation of a dense layer consisting of fine grains, due to high cooling rates, and nitride phases are responsible for the attainment of high hardness and high residual stress at the surface of the treated surface.

Figure 9 shows photographs obtained from the contact angle measurements, whereas **Table 4** gives the contact angles at different locations at the surface. Because the roughness and

surface energy alter the wetting properties,[35] the contact angle changes at different locations at the surface. It can be observed from the photographs that in the first case (rough surface), the Wenzel state takes place; therefore, the water droplet penetrates into the grooves and touches the surface without presence of the air gap. In this case, the contact angle attains a slightly low value. However, this behavior is only observed at two out of seven locations where the tests were performed. When comparing the laser-treated and untreated surfaces, it is evident that the contact angle reduces considerably for the untreated surface. The formation of nitride species (AlN) at the treated surface modifies the surface energy such that γ_{sl} reduces. It should be noted that the surface free energy of AlN is 38.3 mJ m^{-2}, whereas it is 68 mJ m^{-2} for Al_2O_3.[56] For the second case, the behavior of the water droplet demonstrates the Cassie and Baxter state; in which case, the fine roughness at the surface results in air pockets, which are captured in the grooves, forming a composite state. According to eqn [6], the f should be within $0 \leq f \leq 1$. Therefore, f should approach zero for large contact angles in the Cassie and Baxter state. This situation can be observed from **Table 4**. Consequently, composite surface texture with the combination of micro-/nano-dimples and pillars results in two states of hydrophobicity at the treated surface, provided that the Cassie and Baxter state dominates over the Wenzel state.

3.5.4.3 Phosphorous Bronze

The results of morphological and metallurgical changes, surface texture, hydrophobicity, and residual stress are discussed and are in line with those of a previous study.[13]

Figure 10 shows SEM micrographs of laser-ablated phosphor bronze surfaces. Laser ablation takes place during the irradiation of repetitive laser pulses along the laser scanning direction; in which case, the ablated surface forms regular laser scanning tracks. Because the laser pulse frequency is 1500 Hz and the laser scanning speed is 0.1 m s^{-1}, overlapping of irradiated spots occurs at the surface. The overlapping ratio is approximately 70% at the surface. Laser intensity distribution is Gaussian and the pulse intensity remains high at the irradiated

Untreated surface	63.2 (+5/−5)	

spot center. This, in turn, results in surface evaporation in the region limited to the irradiated spot center, and the melting takes place in the remaining region of the irradiated spot. The melt flow toward the cavity center from its neighborhood modifies the cavity shape and reduces the cavity depth. Therefore, surface texture consisting of micro-/nano-poles and cavities results at the treated surface. The mahogany color in **Figure 11** represents the presence of Cu_3N in the surface region, which is also observed in the X-ray diffractogram, for example, the presence of $Cu_3N(100)$ is associated with the high nitrogen pressure incorporated in the laser treatment process. The presence of a few scattered copper spots is due to the dissolution of Cu_3N at elevated temperatures. In this case, in the near region of the cavity, the surface melts and solidifies rapidly because of the convection cooling of the nitrogen assisting gas; therefore, the dissolution of Cu_3N does not cover the whole surface. Laser-treated surfaces are composed of submicron grains, which are attributed to the rapid solidification and formation of nitrides at the surface region. In addition, the submicron size of the packed particles indicates that each particle contains many single crystals of Cu_3N.[13] Although use of assisting gas increases cooling rates at the surface, no micro-cracks are observed between the packed grains.

Figure 12 shows optical images of the water droplet on the laser-ablated and untreated surfaces, whereas **Table 5** provides the data regarding the contact angle measurements at different

locations at the surfaces. The contact angle varies slightly with the location at the surface, which is attributed to the surface texture variation and the texture composition at the surface. In general, the laser-treated surface demonstrates superhydyrophobic behavior, and the average contact angle of the surface is approximately 142°. Consequently, the texture of the laser-ablated surface, consisting of fine pillars and poles at micro-/nano-scale, results in large contact angles of the water droplet.

Figure 13(a) shows SEM micrographs of the cross-section of the laser-ablated layer. A dense structure consisting of submicron packed particles and extremely fine grains is formed in the surface region (Figure 13(b)). Formation of Cu_3N in the surface region lowers the density and causes volume shrinkage in the dense layer. In addition, the high quench rates in the cooling cycle after laser ablation are responsible for the formation of fine grains in the dense layer. A dendritic structure with elongated grains is observed at some distance below the dense layer (Figure 13(c)). The formation of a dendritic structure indicates the high rate of solidification in this region, and the nonuniform cooling is responsible for the formation of the elongated grains. As the distance below the surface increases further, a cellular structure is formed (Figure 13(d)), which is associated with the relatively lower cooling rates as compared to that of the surface region. EDS data for the elemental composition of the laser-treated surface are given in Table 6. Although quantification of the light elements in EDS data involves error, the presence of nitrogen is evident, which

	Hardness (HV)	*Residual stress (MPa)*
Laser-ablated surface	580 (+30/−30)	−350 (+10/−10)
As-received surface	140 (+10/−10)	–

has a high concentration at the surface. The absence of Sn in some EDS spectrums indicates that Sn was evaporated in the surface region during the laser ablation process. The heat-affected zone is shallow without forming a demarcation line between the heat-affected zone and the base material, which is attributed to the high thermal conductivity of the bronze.

The microhardness and residual stress data for the laser-ablated surface are given in Table 7. The microhardness of the laser-ablated surface is high at 580 ± 30 HV, which is almost four-times the hardness of the base material (145 ± 10 HV). This is due to one or all of the following: the dense structure formed in the surface region and the formation of Cu_3N compounds in the surface region after the laser ablation process. The residual stress measured by the XRD technique is approximately −350 ± 10 MPa. Because ablation takes place along the laser scanning tracks, recently ablated regions create a self-annealing effect on the previously ablated regions. This in turn, modifies the cooling rates, particularly below the surface. However, the self-annealing effect created during the cooling period does not significantly alter the stress levels in the surface vicinity because of the convective cooling of the assisting gas at the surface; therefore, the residual stress remains high in the surface region. It should be noted that the residual stress measured is limited to the surface vicinity because the penetration depth of the X-ray radiation is approximately a few micrometers. Although the workpiece surface expands freely during the laser ablation process, the surface vicinity is not free to expand and compressive stresses are formed. This behavior is responsible for the attainment of high residual stress in the surface region. Figure 14 shows the scratch test results used to determine the friction coefficient of the laser-ablated and as-received surfaces.

3.5.5 Concluding Remarks

Laser gas-assisted surface texturing has several advantages over the conventional texturing methods. This is because of the precision of operation, low cost, local treatment, and

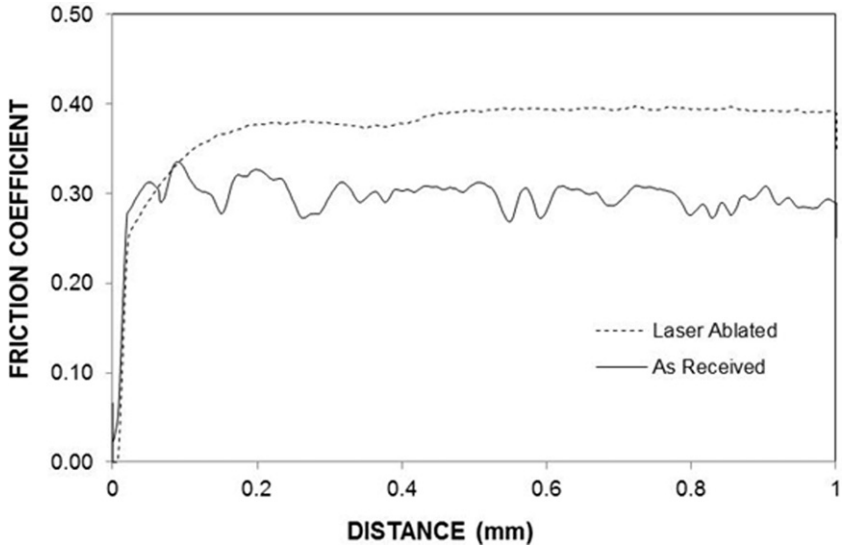

Figure 14 Friction coefficient for laser-ablated and as-received workpiece surfaces.[13]

high-speed processing. A high-intensity laser beam with fine focus spots with a high repetition rate (1500 Hz) is used to irradiate the workpiece surface under the high-pressure nitrogen gas environments. This results in the combination of melting and evaporation at the surface and modifies the cavity size formed at the surface. Therefore, laser surface treatment, which involves the combination and evaporation, gives rise to the surface texture having micro-/nano-poles at the treated surface. In addition, use of nitrogen assisting gas causes the formation of nitride species in the treated surface. In general, the nitride compounds formed at the surface allow the attainment of the low surface energy while improving the surface hydrophobicity. Consequently, the mutual presence of low surface energy and surface texture composed of micro/nano textures results in superhydrophobicity at the surface. However, the use of a high-intensity beam during the texturing of the surface causes formation of high thermal stresses in the surface of the laser-treated region. Therefore, thermally induced stresses become important for using the textured surface in practical applications. The close examination of the residual stress data reveals that the residual stress formed in the laser-treated region is smaller than the yielding limit of the materials, including PC, alumina, and phosphorous bronze. The specific findings are:

- Laser-textured surfaces composed of micro-/nano-texturing, which are due to the combined mode of evaporation and melting at the surface during the texturing. In general, the pole heights vary within the range of 30 nm–1.5 μm, which is true for all the substrate material textured by a laser beam.
- The use of high-pressure nitrogen assisting gas results in nitride compound formation in the surface vicinity of all the substrate materials used for texturing, except PC. The formation of nitride species reduces the surface energy of the textured surfaces.
- The laser-textured surfaces are free from asperities, including large cavities and the micro-cracks. This is associated with the proper selection of the laser texturing parameters.
- Microhardness of the laser-textured surface increases for all the substrate materials used in the study. The microhardness increase can be attributed to the fine grains, which are formed at the surface under the high cooling rates. In addition, formation of nitride species contributes to the microhardness enhancement at the surface.
- The residual stress formed in the laser-treated layer is compressive for all the substrate materials used in the study. This is attributed to the depth of the treated layer, which is shallow (i.e., approximately 20–40 μm).
- The surface hydrophobicity, in general, increases after the laser texturing. However, nonuniform behavior of the laser surface texturing and the mixture of Cassie–Baxter and Wenzel states are observed. Nevertheless, the Cassie–Baxter state covers almost 80% of the total textured surface.

3.6.1 Introduction

The formation of Co–Ni alloy coatings by plating methods has been strong for many years due to their excellent magnetic properties, hardness, light weight, wear, versatility, abrasion and corrosion resistance, and particularly its prominent catalytic activity.[1–9] The use of this technique to produce these alloys is attractive due to its low cost, flexibility (e.g., deposition as single layer or multi-layer coatings on planar and non-planar substrates), efficiency, and ease of high volume production in contrast with other methods such as sputtering and chemical vapor deposition.[4,10] A significant feature of Co–Ni plating is that alloy composition can be modulated since these metals form homogeneous phases over the whole concentration range.[11] Thus, multiple properties can be explored by only varying its composition. However, as occurs with other iron-group alloys (e.g., Fe–Ni, Fe–Co), the co-deposition is classified as anomalous since the mole fraction of the less noble component cobalt produced in the alloy becomes higher than the $[Co^{2+}]/([Co^{2+}]+[Ni^{2+}])$ ratio in the solution.[11,12]

An extensive amount of research has been intended to investigate this anomalous behavior, suggesting different proposals: faster adsorption rate of the less noble component (e.g., cobalt hydroxide $Co(OH)^{+}_{ads}$) in comparison with the more noble species (e.g., $Ni(OH)^{+}_{ads}$),[13–17] enhanced surface coverage of the less noble $Me(I)_{ads}$ intermediate,[18] formation of intermediate adsorbed species (i.e., $NiCo(III)_{ads}$) which increase the cobalt content in the alloy and release Ni(II) species,[19] differences in electronic structures and liabilities of Co(II) and Ni(II) species on the basis of ligand field theory,[20] and faster charge-transfer of single Co(II) reduction in comparison with Ni(II) reduction.[21–23] Accordingly, there is strong evidence to consider that the phenomena describing this anomaly are presumably arising from intrinsic changes in the electronic structure of the oxidized form of these metals, ion-solvent interactions, as well as transitions states emerging from molecular interactions on the electrode surface, since kinetically the single Co(II) deposition is considerably faster than the Ni(II) one. However, the use of typical quantitative analysis available for electrochemical methods (including mesoscopic to macroscopic scale modeling) is limited to capture the properties of the Co(II) and Ni(II) atomic structures, tracking fast intermediates in the reaction pathway, and collecting quantitative information of the molecular and electronic interactions responsible for such kinetics. Therefore, *Ab initio* methods (i.e., quantum mechanics) need to be used to account for the atomic interactions determining the anomalous behavior of the Co–Ni alloys. To our current state of knowledge, this topic has not been undertaken.

From a practical standpoint, it has been reported that the anomalous behavior of Co–Ni electrodeposition could be overcome through the use of cyclic voltammetry and Pulse Reverse (PR) plating in chloride-based solutions at pH 2 under potentiostatic conditions.[17,24] In these studies, alloy plating was conducted only in chloride electrolyte under stagnant conditions. A subsequent analysis[23] corroborated that the anomalous behavior can be removed with high current efficiencies but only under the above conditions. This effect is due to the high ionic conductivity of Cl^{-}, and the more labile kinetics for metal reduction in the presence of this anion, a requirement to alleviate the anomalous by hastening the dissolution of both metals, particularly Co. On the other hand, sulfate media was not effective to eliminate such behavior, and electrolyte agitation exacerbates anomalous deposition and reduces the current efficiency by enhancing mass transport of Co(II) and H^{+} to and from the cathode surface. These results demonstrate that the pulse plating and PR techniques are tractable to alleviate the anomalous behavior of Co–Ni alloys, regardless of the operation mode, namely potentiostatic or galvanostatic.[17,23,24] Note that galvanostatic operations

 doi:10.1016/B978-0-12-803581-8.09169-4

maintain a constant reaction rate and the potential varies with time; whereas in potentiostatic conditions, the driving force for the reaction (i.e., activity ratio of oxidized/reduced species) remains constant and the reaction rate changes as a function of time. Applied voltage enables a better control of current efficiency and alloy composition, although practical regulation of pulsed voltage is very challenging to attain unlike pulsed current.[25]

The main implications of the use of pulsed techniques in terms of mass transfer effects arises from the continuous depletion of electroactive species in the diffusion layer (outer layer) when subjected to dc operations. During pulse plating, a pulsating diffusion layer (inner) exists close to the electrode surface, as a result of the frequency of the current which generates a pulsating concentration.[25] This concentration profile relaxes when the current is turned off (off-time). If the length of the pulse is short, there is not sufficient time for the diffusion layer to grow into the solution. Metallic cations are furnished to the electrode surface through the outer diffusion layer during the off-time, and this supply enables the relaxation of the pulsating diffusion layer. Note that the concentration gradient is larger in the inner layer (transient) than in the outer one (stationary). Therefore, the depletion of cations in these layers limit the pulse and the average current densities, respectively. Limitations due to mass-transport effects in pulse plating are associated with the fact that the maximum average current density cannot exceed the dc limiting current density, and the length of pulse cannot be longer than the transition time.[25]

The incorporation of adatoms and adions into a crystal lattice (crystallization) has also been connected to the properties of alloy coatings, particularly the morphology and grain refinement. This phenomenon occurs either by the build-up of old crystals, which is enhanced by factors such as: low overpotentials, high surface diffusion rates, and low population of adatoms; or by the formation of new nuclei with demand opposite magnitude (i.e., high overpotentials, low surface diffusion).[25] Pulse current densities are typically higher than the corresponding dc densities, whence the number of surface adatoms during pulse plating is higher than under dc conditions, this leads to an enhancement of nucleation rate and refinement of the grained structure. Although surface diffusion is primarily affected by adsorbates on the cathode surface when additives are added to the plating bath, modulation of the current can also alter this factor. The use of high pulse current densities increases the population of adatoms on the surface so high that there is no enough time for assembling them into the crystal lattice, producing materials with similar properties to those obtained by rapid quenching.

In PR, the critical feature is that cathodic reduction is followed by a period of anodic polarization during each cycle. The purpose of this inversion is to preferentially dissolve the metal (i.e., Co) to lower down in the alloy content, when the anodic voltage or current density are applied.[26] Concerning the micro-structure, this second pulse (anodic) removes metal from areas that tend to overplate during cathodic deposition, which is beneficial to sluggish dendrite formation and improving the plating thickness distribution over complicated shapes. Likewise, PR forces nucleation to start off at each new cathodic pulse, which modifies the alloy structure and grain size. Multiple studies have described significant improvements (i.e., roughness) when compared to dc techniques. However, just a few studies have been intended to comprehensively analyze the structural variations undergone by these alloys when fabricated with the aforementioned techniques, and mainly to understand the influence of mass-transfer during plating. Thus, this cooperative effort is devoted to investigate the textural and structural changes when Co–Ni alloys are formed with dc and PR in chloride media. X-ray diffraction (XRD), scanning electron microscopy (SEM), atomic force microscopy (AFM) and X-ray photoelectron spectroscopy (XPS) are utilized to chemically characterize the texture and structure of the deposits. Additionally, electrochemical characterization is used to determine the influence of mass-transfer on such features.

3.6.2 Materials and Methods

3.6.2.1 Plating of Co–Ni Alloys

The alloys were plated at room temperature in solutions containing 1 M Na_2SO_4 (99.3% purity, Fisher) as supporting electrolyte, 0.1 M $NiCl_2$ (98.1% purity, J. T. Baker), and 0.1 M $CoSO_4$ (99.3% purity, Fisher). The pH in each bath was adjusted to 3. No additives were included in these plating baths to avoid misinterpretation of the effects of pulse plating. All solutions were freshly prepared in deionized water ($\sim$pH 6.8) and deoxygenated with N_2 (Praxair, grade 4.8) prior to experiments.

A 3-electrode cell was used to conduct the electrochemical experiments. The working electrode was a copper (99.999%) disk embedded in nylon with 1.26×10^{-5} m^2 of exposed area. This substrate is not catalytic for hydrogen evolution reaction (HER) unlike other surfaces such as Pt and provides a good conductive surface. No rotation was applied to the electrode to have a better control of the mass transfer of the electroactive species, in order to be able to suppress the anomalous behavior. A pure graphite rod (6.15 mm diameter $\times$ 152 mm long, Alfa AESAR, 99.999%) and Hg–Hg_2SO_4 electrode (Radiometer Analytical) were used as the counter and reference electrodes, respectively. All potentials reported herein correspond to the standard hydrogen electrode scale. Prior to each experiment, the working electrode surface was mechanically polished using SiC-type abrasive of different grades and polished to a mirror finish using Buehler alumina powder (final grain size $\leq$0.05 μm). The electrode was then rinsed with ultrapure water and placed in an ultrasonic bath for 5 min before carrying out the experiments. The three electrodes were connected to a Princeton Applied Research potentiostat/galvanostat model VMP3, interfaced with data acquisition EC-Lab software.

After experiments, samples were washed with deionized water, dried under exposure to N_2 flow, and kept under inert conditions in a desiccator until chemical and textural analyses were carried out.

3.6.2.2 Chemical and Textural Analyses

Plating was carried out using the Galvano static mode for a sufficient period to ensure that a total charge of 2 C was transferred during each experiment. After co-deposition, each working electrode was exposed to a concentrated HNO_3

solution in a vial to dissolve the coating. The solution was then analyzed using an atomic absorption spectrophotometer (Varian Model 220 FS) to obtain the cobalt and nickel composition in the coating.

XRD patterns for the plated samples were obtained using an advanced X-ray diffractometer (Bruker D-8 with geometry Bragg–Brentano) with Cu–Kα radiation ($\lambda = 1.5406$ Å), by performing sweeps from 5° to 70° of 2θ. The diffractometer was operated at 40 kV, 30 mA and the step size used was 0.02°. The XPS analyses were performed using a K-Alpha Thermo Scientific spectrometer with a monochromatized Al–Kα X-rays source (1487 eV), running at a power of 150 W. XPS narrow scans, using an X-ray spot size of 400 μm^2, were collected at 60 eV pass energy. XPS core level spectra were analyzed with Avantage v5.41 software from Thermo Scientific and fitted using a Gaussian–Lorentzian mix function and Shirley type background subtraction used to decompose spectral peaks.

SEM images were collected with a high-field emission microscope JMS-7600 F, using an accelerating voltage of 5.0 kV and equipped with energy dispersive X-ray spectroscopy (EDS) capabilities. The AFM analysis was performed with a Nanosurf easy scan 2 AFM digital system using tapping mode in air to visualize plated alloys (scan rate between 0.5 and 1 Hz). The silicon cantilever showed a free resonance frequency of 13 kHz and a constant of 0.2 N m^{-1} during these experiments. AFM analysis was performed to generate a complete description of the textural properties of Ni–Co alloys.

3.6.3 Results

3.6.3.1 Electrochemical Plating

In general it is recognized that during voltammetry conducted on multiple metallic substrates and electrolytes, H^+ reduction is the reaction occurring at more positive potentials, followed by Ni(II) and Co(II) reduction as thermodynamically predicted.[21–23,26,27] Although the onset of nickel deposition is located at more positive potentials, the kinetics of cobalt deposition is a way faster, whence the anomalous behavior is observed.[20] Once the above reactions become mass-transfer controlled, H_2O reduction proceeds without these limitations. Both H^+ and H_2O reduction contribute as parasitic reactions to the well-known HER. As a result of the occurrence of these processes, one of the following choices needs to be followed in order to suppress the anomalous behavior: (1) an additive has to be added to the electrolyte to form a stable complex with Co(II) or blocking its adsorption, (2) cobalt deposition needs to be forced to occur under mass-transfer control, or (3) the deposit of cobalt needs to overcome dissolution as in pulse-reverse. In this work, the two previous features are combined to control the composition of Co–Ni alloys, namely the use of PR. This approach has been selected since it is a tractable and flexible route unlike the addition of chemical agents.

Table 1 presents the experimental conditions used to form the alloys with dc (M1–M2) and bipolar (M3–M10) techniques. As observed in the pulse plating experiments, the nickel content in the alloy increases as the current density becomes more cathodic, which has been consistently reported for other electrolytes.[21] This behavior results from the faster kinetics of Co(II) deposition which generates a mass-transfer control at lower current densities if compared to nickel deposition. In general, it has been described that the composition of the more noble metal is augmented as the current is made more negative in anomalous deposition, unlike what happens in regular plating.[11] This phenomenon can be confirmed if the partial current densities of the Ni(II), Co(II), and H^+ reduction are plotted as a function of current density (Figure 1). These values can be readily calculated using Faraday's law:

$$j_{Ni} = \frac{z_{Ni}\, m_{Ni}\, F}{M_{Ni}\, t} \quad [1]$$

$$j_{Co} = \frac{z_{Co}\, m_{Co}\, F}{M_{Co}\, t} \quad [2]$$

$$j_{H_2} = j - j_{Ni} - j_{Co} \quad [3]$$

where z_i is the number of electrons transferred [2] to metal i (Ni, Co) during plating, m_i is the mass of species i deposited determined from atomic absorption, F is the Faraday constant (96485.5 C mol^{-1}), M_i is the molecular weight of metal i and t is the electrolysis time. Note that j_{H_2} (partial current density associated to HER, H^+, and H_2O reduction) is obtained from the difference between the total current density and the sum of j_{Ni} and j_{Co}. As observed, j_{Co} (5.28 A m^{-2}) is lower than j_{Co} (34.72 A m^{-2}) and j_{H_2} (10 A m^{-2}) at the lowest current density used in this study (-50 A m^{-2}). Not surprisingly, this behavior results from the faster kinetics of cobalt deposition and a more noble H^+ reduction, respectively. Once that Co(II) concentration becomes rapidly depleted around -250 A m^{-2}, the nickel content surpasses cobalt in the alloy, and the slope of j_{H_2} turns out to be steeper as a result of the onset of H_2O reduction. However, this increase of the nickel composition with more cathodic current densities is not accurately the removal of the anomalous behavior since most likely the deposit is made up of nickel oxides due to a significant occurrence of the HER.[21,23,26] Evidence of such behavior is observed in the lowest current efficiencies obtained under dc conditions for samples M1d–M2 in Table 1, although chemical and textural characterizations should be more conclusive (refer to Sections 3.6.3.2 and 3.6.3.3). Thus, pulsed techniques are utilized below to suppress the anomalous behavior of the Co–Ni alloy without compromising the current efficiency and textural properties of the films. PR (bipolar) is preferred over pulse plating (unipolar) since it has been confirmed that it is the only way (and cyclic voltammetry) to achieve high nickel contents in the deposited alloy.[17,23,24]

The experimental conditions used in the PR are shown in Table 1. The cathodic and anodic amplitudes were selected using cyclic voltammetry (not shown) to favor the nickel deposition at high current efficiencies, and preferentially enhance the dissolution of deposited cobalt, respectively. Typical frequency (t^{-1}) values in pulse plating were evaluated for short (500 Hz) and long cycles (5 Hz), and duty cycles

Table 1 Experimental parameters of the dc and pulse plating experiments conducted in electrolytes containing 0.1 M $NiCl_2$, 0.1 M $CoSO_4$ and 1 M Na_2SO_4 at pH 3

Experiment	*Cathodic amplitude (A m^{-2})*	*Anodic amplitude (A m^{-2})*	*Frequency (Hz)*	*Duty cycle*	*Ni content (wt%)*	*Current efficiency (%)*

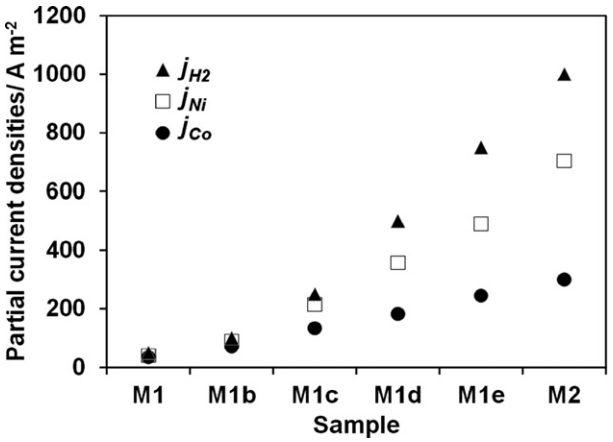

Figure 1 Partial current densities of Ni(II), Co(II), and H^+ reduction calculated for the plating experiments as a function of dc current density.

(i.e., fraction of a cycle elapsed for the cathodic pulse) of 50 and 80%. Note that duty cycles lower than 50% yield very little deposit, regardless of the cathodic current imposed on the electrode, presumably due to a large amount of HER and too much metal dissolved during the anodic pulse. A comparison of the dc and PR conditions reveal that in general, higher nickel contents are obtained for the alloys formed using the anodic pulse, and similar current efficiencies are obtained if considered that the deposits formed with PR undergo oxidation. A trend is observed in current efficiency, the higher the anodic amplitude is, the lower the current efficiency will be. In spite of this trend, the current efficiencies are relatively high for the PR technique. Another important finding described in Table 1 is that the current efficiency decreases as the frequency is raised. This effect benefits the HER since less time is enabled to elapse during each cathodic cycle and less depletion of Co (II) and Ni(II) species will occur close to the electrode surface, whence H^+ and H_2O reduction effectively competes with the alloy formation. A similar effect occurs with the nickel content, which decreases as the frequency is raised. This results from the same point discussed above, Co(II) reduction is considerably faster, thus, if less depletion of this species takes place during the cathodic pulse, the nickel content will not augment in the alloy, unless the duty cycle is increased up to 80% (refer to M7–M10 samples in Table 1), where the nickel composition virtually becomes constant. Using these long duty cycles, the depletion of Co(II) is ensured by using a cathodic pulse lasting 4/5 of the total cycle. However, it should be bear in mind that high frequencies around 500 Hz compromise the current efficiency due to the competitive reduction between Ni(II) and H^+ species.

PR has been used to alleviate the anomalous behavior of Co–Ni alloys at relatively high current efficiencies; however, systematic information of the textural and morphological properties is scarce in the literature. Below, XRD and XPS analysis are conducted to accurately determine the alloy composition and structure, while AFM and SEM are utilized to study the morphological features of the deposits.

3.6.3.2 XRD and XPS

Figure 2 shows XRD patterns (XRD) obtained for the Co–Ni alloys plated using direct current (M1–M2) and PR (M3–M10) at the experimental conditions shown in Table 1. In general, all XRD patterns exhibit two intense peaks at ~43.4° and ~50.6° of 2θ values that correspond to (111) and (200) planes of elemental FCC copper crystalline phase, which has been as used as substrate to conduct the deposits. These peaks were determined using the standard powder diffraction card PDF, copper file 04–009–2090.[28] No oxide copper crystalline species were observed. The XRD patterns contain no evidence of the presence of either pure nickel or cobalt phases, suggesting the formation of a solid solution. Likewise, no oxide metals were indexed, most likely due to their low content to be detected by the technique. Figure 2 displays two more peaks at ~ 44.36° and ~51.6°, corresponding to Co–Ni alloys, and their concentration rely on the experimental conditions as formerly determined with atomic absorption (refer to Table 1). Sample M1 formed at the lowest current density of the dc conditions presents peaks with low intensity in comparison

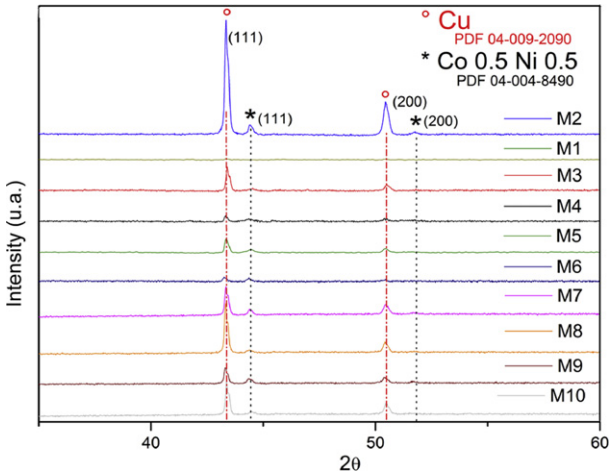

Figure 2 X-ray diffraction spectra obtained for Co–Ni alloys deposited at different experimental conditions shown in **Table 1**.

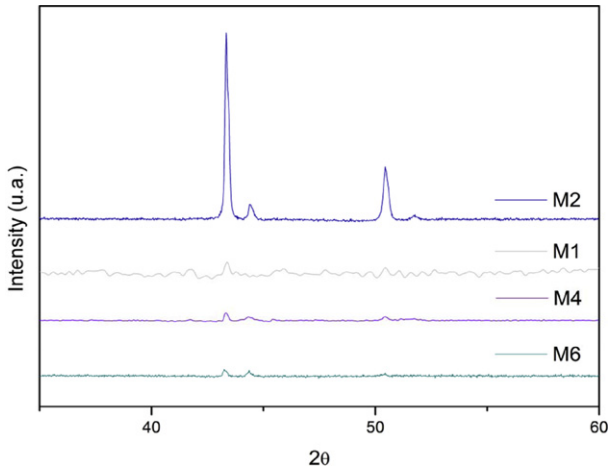

Figure 3 X-ray diffraction spectra obtained for Co–Ni alloys deposited at different experimental conditions shown in **Table 1** (M1, M2, M4, and M6).

with other samples. Presumably, this behavior results from a low amount of deposit as a result of a significant occurrence of a more noble H^+ reduction, and overcoming activation energies for metal reduction (i.e., overpotential). Note that the detection limit of atomic absorption is lower compared to XRD. On the other hand, M2 is a more crystalline material since it was formed at the most cathodic current density ($-1000\,A\,m^{-2}$), whereby a thick deposit was achieved, regardless of the existence of H_2O reduction. All samples show two peaks related to the Co–Ni alloy, that approximately match the nickel composition presented in **Table 1**. Samples M2, M3, and M5 were indexed to PDF 04–004–8490 that is associated to the ~0.5 nickel and ~0.5 cobalt alloy concentration.

Figure 3 shows a comparison of Co–Ni alloys formed by dc current and PR with different Ni wt% and 50% of duty cycles. According to the chemical analysis performed with the atomic absorption, sample M1 contains 13.14 wt% of nickel, M2 contains 57.31 wt% of nickel, while M4 28.08 wt% and M6 27.09 wt%. These analyses are representative of the nickel content obtained with XRD.

Table 2 Weight percentages determined using X-ray photoelectron spectroscopy for the Co–Ni alloys plated with dc and pulse plating experiments conducted according to the conditions shown in **Table 1**. XPS data were fitted to core Ni 2p3, Co 2p, O 1s, and C 1s level spectra

Experiment	*Ni 2p3 (wt%)*	*Co 2p (wt%)*	*O 1s (wt%)*	*C 1s (wt%)*
M1	14.9	81.1	2.2	1.8
M3	51.0	48.5	0.2	0.3
M4	15.5	78.8	4.1	1.6
M6	24.3	73.2	1.3	1.3

Further chemical analysis for the Co–Ni alloys (M1, M4, and M6) with a different Ni wt% was performed using XPS to corroborate the alloy composition. **Table 2** shows the wt% obtained for these samples by fitting the XPS experimental data to core Ni 2p3, Co 2p, O 1s, and C 1s level spectra. As observed, M1, M4, and M6, respectively, contain 14.9, 15.5, and 24.3 wt% Ni (refer to Section 3.6.2.2 for further details of calculations), while the same alloys analyzed with atomic absorption presented 13.14, 28.08, and 27.09 wt% Ni, confirming that the Co–Ni composition can be determined with atomic absorption, XRD and XPS. Likewise, the alloys exhibiting around 50 wt% Ni can be accurately determined with these techniques (i.e., M3). Note that C and O atoms are detected in very low concentrations for all samples. This analysis does not provide details whether the oxygen belongs to oxides/hydroxides formed in the electrolyte or in contact with air, but it provides sufficient experimental evidence to consider that an important contribution (C, O) arises from CO adsorption on the samples surfaces. It is worth mentioning that slight changes in composition are observed among different techniques. This is due to the variation in composition of the samples with depth, which is sensitive to the surface irradiation of the material with the beam of the technique (e.g., XPS, XRD), and only atomic absorption is able to determine the overall composition by dissolving the entire deposit.

3.6.3.3 AFM and SEM

AFM technique was used in an attempt to assess the influence of plating conditions, such as duty cycle, frequency, cathodic and anodic amplitudes, on the textural properties of Co–Ni alloys formed under dc and PR conditions. **Figure 4** shows AFM images collected on M1–M6 alloys formed under the experimental conditions shown in **Table 1**. The morphology of M1, M3, and M5 alloys exhibits sub-micron grains that are homogenously distributed and appear fairly similar to each other. Note that M1 grains are larger compared to M3 and M5, presumably, due to the influence of H^+ reduction in the formation of M1 and also its lower nickel content. On the other hand, the textural features of M2, M4, and M6 (refer to **Table 1**) alloys differ from the characteristics of the

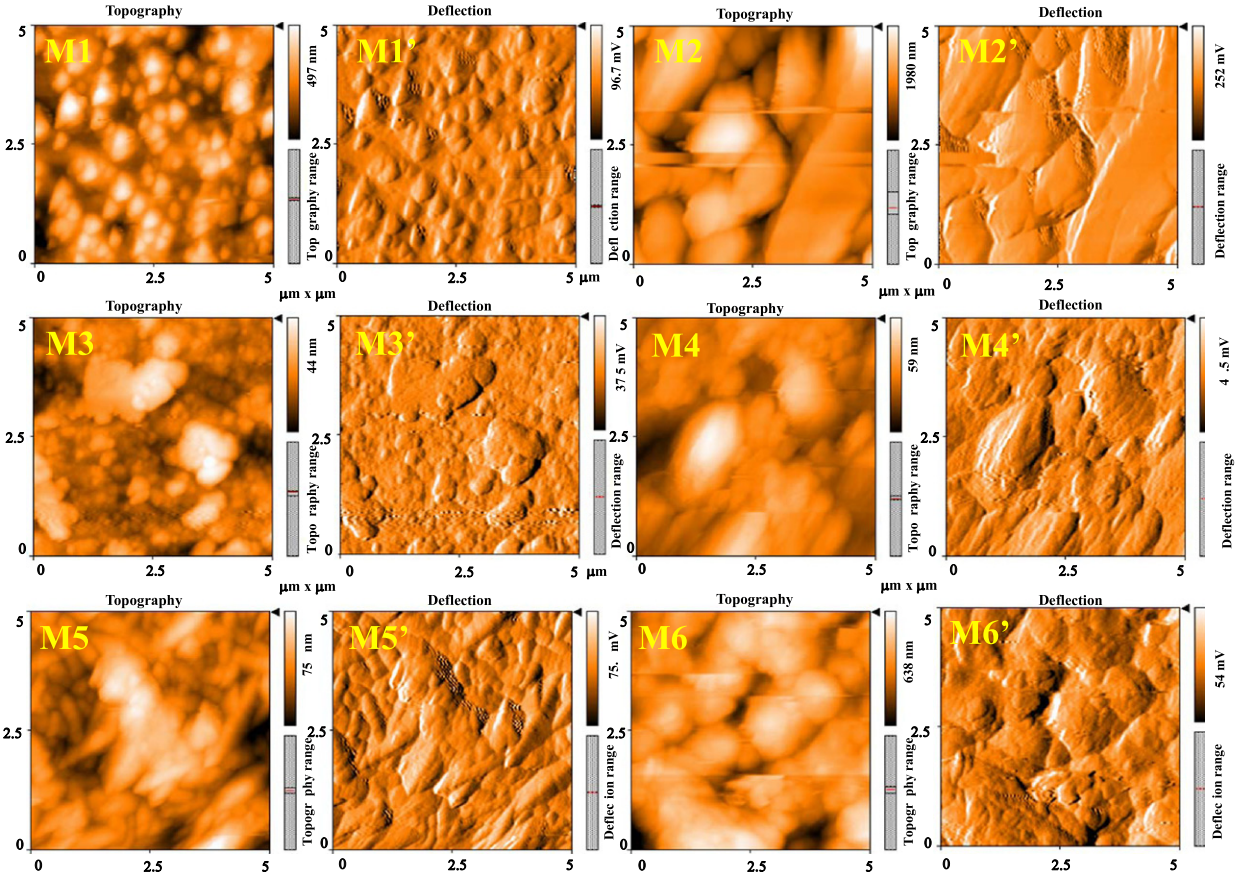

Figure 4 AFM images (topography and deflection modes) collected for plated Co–Ni alloys at different experimental conditions shown in **Table 1** (M1–M6). Scan rate used between 0.5 and 1 Hz.

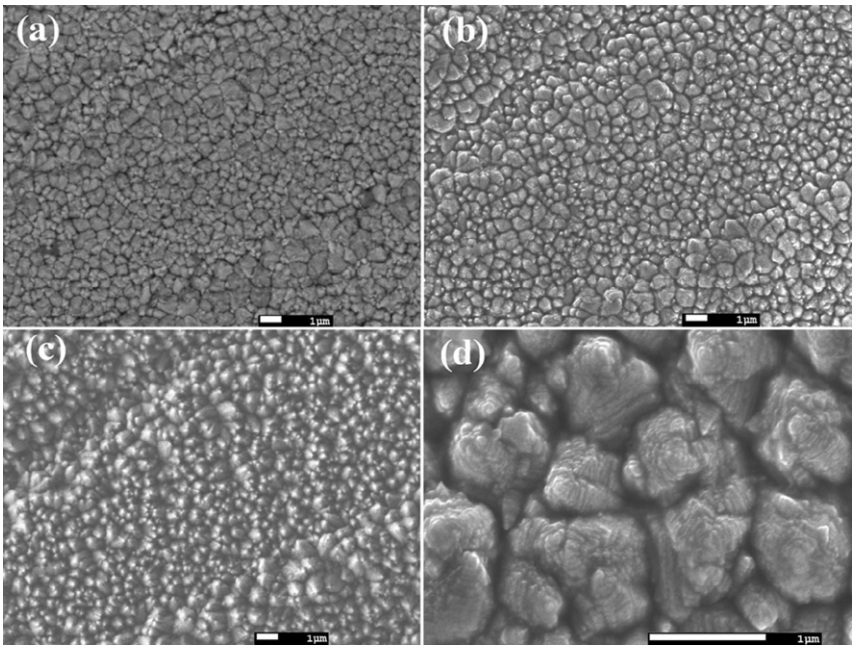

Figure 5 SEM images of Co–Ni alloys deposited under dc conditions using a cathodic amplitude of -50 A m^{-2} (M1), and acquired with different detectors: (a) A low angle backscatter detector (LABe), (b) an upper detector (SEI), (c) a lower detector (LEI), and (d) magnification of (c).

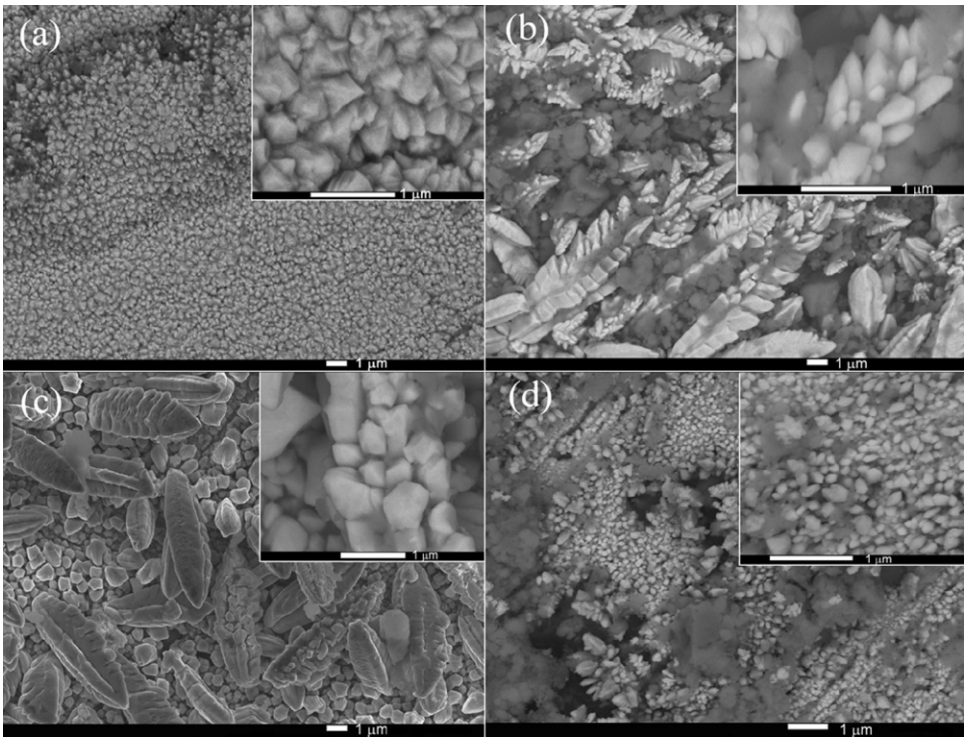

Figure 6 SEM micrographs of Co–Ni alloys deposited at different experimental conditions shown in Table 1. The cathodic amplitudes used to conduct the plating are: (a) -50 (M1), (b) -500 (M1d), (c) -750 (M1e) and (d) -1000 A m^{-2} (M2).

aforementioned systems, but are similar each other (Figure 5). M2 is a particular case since it is formed with an important input of the H_2O reduction, thus, similar to M1 sample is difficult to draw its morphology only on the basis of the nickel content. For M4 and M6 alloys, the sub-micron grains are stretched out, and they appear to be well interconnected each other. Surprisingly, the similarity of the textural properties could result from the same nickel content and current efficiency obtained for both alloys, unlike the more agglomerated flattened shapes collected for M2, resulting from a considerable gas evolution on the electrode surface, and most likely involving metal oxides/hydroxides.

The microstructure of the Co–Ni alloys (M1–M6) was also analyzed with SEM, in order to draw the influence of the plating parameters on this property. Figure 5 shows SEM micrographs of the M1 alloy (Table 1) acquired with different detectors: (a) at low angle backscatter detector (LABe), (b) secondary electron imaging, an upper detector (SEI), (c) secondary electron a lower detector (LEI) and (d) a magnification of the sample obtained. As observed in Figure 5(a), the LABe detector enables observing particles with high spatial resolution and the absence of contrast clearly shows a homogeneous surface sample. The morphology of the sample is uniform and a difference in contrast due to differences in the chemical composition of the sample is not observed. Figure 5(b) shows the SEI mode image. Edges and contours of the particles are defined and the sample reveals roughness and relief. Figure 5(c) shows the LEI mode that provides topological information. The surface of the sample is uniform without defects, holes, and impurities incorporation during plating due to a low input of H^+ reduction (refer to current efficiency in Table 1), although the grains are large. Figure 5(d) reveals the magnification of the pyramidal-like particles deposited over copper. Co and Ni are miscible and form stable alloys at room temperature. The pyramidal-shaped grain size is around 1 μm. The crystal structure, particle shape, and size of the electrochemically obtained Co–Ni alloy deposits considerably depend on current density. According to the nickel content, the alloy showed uniformity and homogeneity of the surface chemical composition at this cathodic amplitude (-50 A m^{-2}). These images are consistent with the AFM analysis conducted for the same sample (Figure 4), which concludes that submicron sized grains have a homogeneous distribution.

Figure 6 shows SEM images of Co–Ni alloys formed under the following dc cathodic amplitudes: (a) -50 (M1), (b) -500 (M1d), (c) -750 (M1e), and (d) -1000 A m^{-2} (M2). The morphologies of the deposited particles are significantly different, depending on the imposed current density. At -50 A m^{-2} (Figure 6(a)), the surface is homogeneous and the crystal size is less than 0.5 μm (sub-micron order). Crystals display sharp edges and pyramidal-like morphology. When the cathodic amplitudes are increased to -500 and -750 A m^{-2} (Figures 6(b) and 6(c), respectively), a bimodal particle morphology is observed. The bimodal particle morphology consists in semi-spherical grains size less than $\sim$0.5 μm and there are elongated particles around $\sim$10 μm. In particular, the elongated particles obtained at -750 A m^{-2} exhibit a smooth surface. Larger grains are obtained in both conditions, and the edges are smoothed in comparison

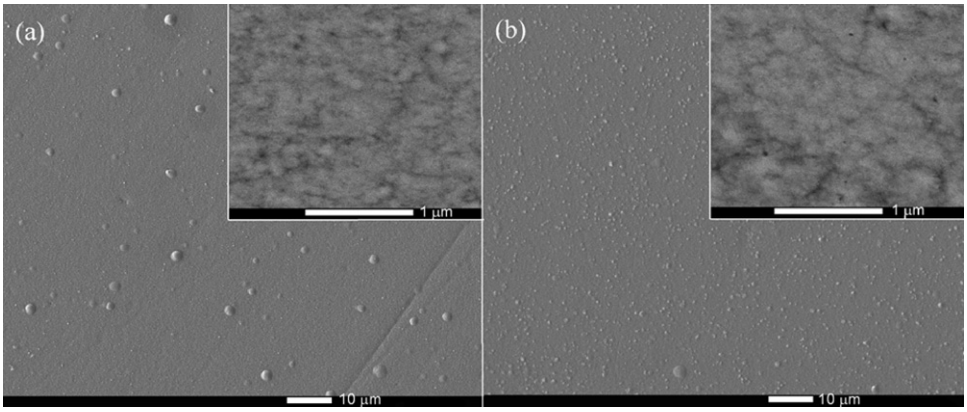

Figure 7 SEM micrographs of Co–Ni alloys deposited using pulse reverse at 5 Hz and 5% of duty cycle (Table 1): (a) sample M3 and (b) sample M4.

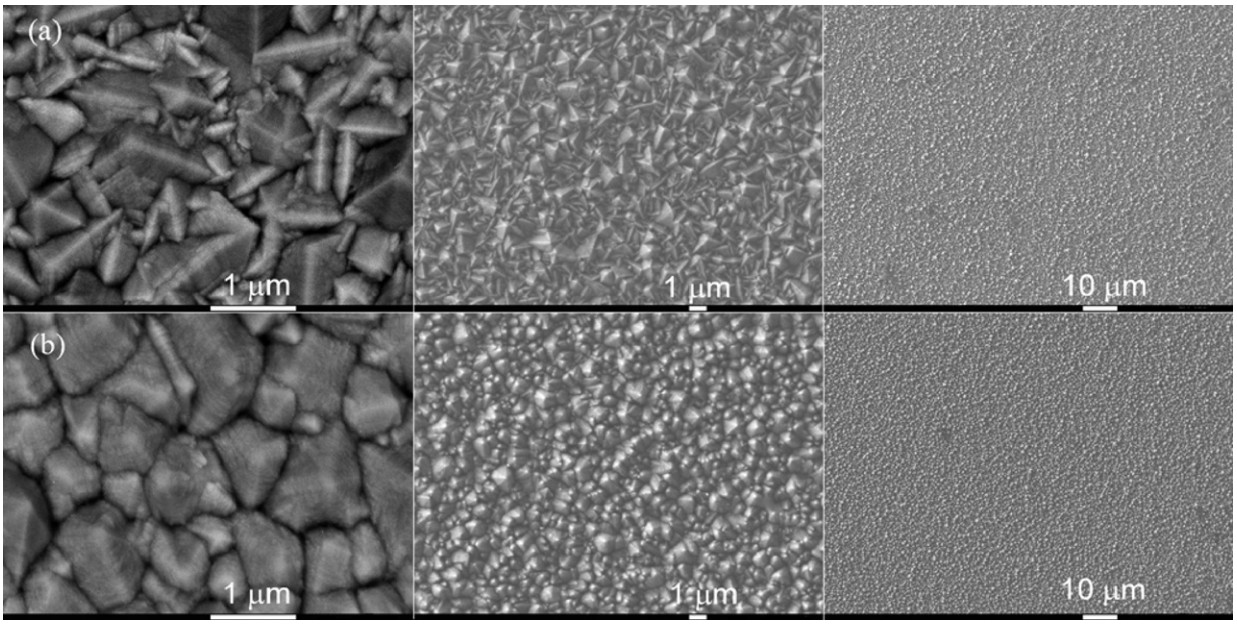

Figure 8 SEM micrographs of Co–Ni alloys deposited using pulse reverse at 500 Hz and 50% of duty cycle: (a) sample M5 and (b) sample M6.

with the dc operation condition obtained at $-50\ A\ m^{-2}$ (M1). The appearances of pyramidal-shaped grains are not observed under these conditions. At $-1000\ A\ m^{-2}$ (M2, Figure 5(d)), the grains formed are coarser, spherical, denser, and more pack together to yield a more compact structure, although some holes appear all over its surface. The bimodal particle morphology loss the elongated shape. High deposit rate promotes high defect densities and impurity incorporation, which can be the cause of decreasing alloy grain size. Although the nickel content in the alloy plays an important role to refine the grain size (e.g., sample M2), the parasitic reaction (HER) also exerts some influence in the morphology of the alloy as noted in Figure 6, where H_2O reduction becomes dominant and H^+ reduction enters the mass-transport control as the current density becomes $-1000\ A\ m^{-2}$.

When PR conditions are imposed on the electrode surface, different microstructures are obtained in comparison with dc plating. Figure 7 shows SEM micrographs collected for M3 (a) and M4 (b) samples and 5% of duty cycle. As observed, smooth surfaces are observed for both alloys, suggesting that the anodic pulse favorably modifies the alloy structure and grain size, and improves the roughness. The morphology exhibits a more compact surface aggregation instead of the rocky-rod or bimodal particle shape. These results agree with the AFM images (Figure 4).

Figure 8 shows SEM images of samples M5 (a) and M6 (b), prepared at 500 Hz and 50% of duty cycles at different magnifications. Once again, smooth and homogeneous surfaces are observed at lower magnifications for both samples. At $-600\ A\ m^{-2}$ (M5, Figure 8(a)) a pyramidal morphology with shape edges is observed, and particles size distribution is broad. Also, the grains are more stretched out and flattened compared to M6. At $-400\ A\ m^{-2}$, the particle size distribution is narrower and the grains are coarser than

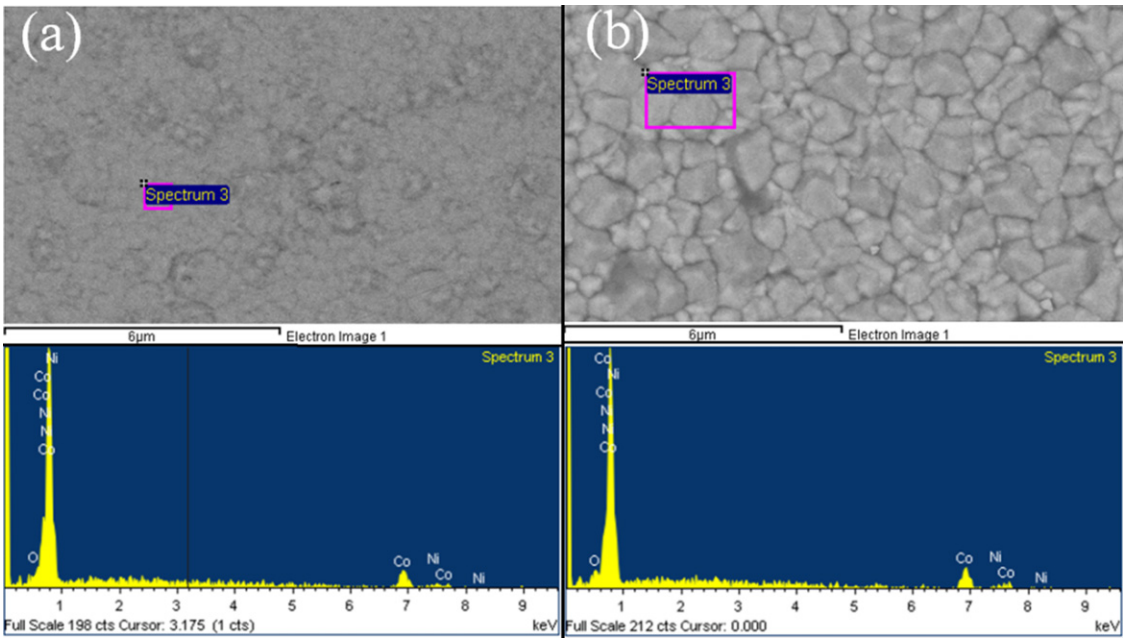

Figure 9 Energy Dispersive Spectroscopy measured for Co–Ni alloys: (a) sample M4 and (b) sample M6.

the sample M5. The morphology reveals sub-micron grains homogeneously distributed. The nickel content could modify the grain size and the particle size distribution. Results are in accordance with **Figure 4**, showing AFM images for these samples.

Figure 9 shows EDS spectra of samples M4 and M6. At lower frequencies (sample M4, **Figure 7(a)**), the Ni concentration is 28 wt%, while with the increase of frequency (sample M6, **Figure 8(b)**) the Ni content decrease to 27.7 wt%. All nickel concentrations in the samples were estimated with the EDS and the results were similar to XPS measurements. Also, these results agree with the atomic adsorption measurements shown in **Table 1**. Overall, the morphology of electrodeposited alloy depends strongly of the deposit parameters. The surface morphology of the deposits is determined by the nature of the electrochemically active ions or complexes and kinetics of the electrocrystallization processes.

3.6.4 Conclusions

Co–Ni alloy formed with plating methods is classified as anomalous behavior, where the less noble component (Co) experiences a kinetically faster kinetics in comparison with the nobler component (Ni), whereby way larger contents of Co in the alloy are typically obtained during deposition. Although such behavior is displayed in most electrolytes, it has been observed that electrolytes containing chloride mitigates this effect. Therefore, mixed sulfate–chloride electrolytes (0.1 M $NiCl_2$, 0.1 M $CoSO_4$ and 1 M Na_2SO_4 at pH 3) have been used to fabricate Co–Ni alloys, along with PR techniques which have assisted the removal of the anomalous behavior. Likewise, analysis conducted with pulse plating have been devoted to determine the influence of mass transfer modulated with plating parameters (cathodic and anodic amplitudes, frequency, duty cycle) on the nickel content, current efficiency and textural properties of the alloys. Using only dc plating, the nickel content in the alloy increased as the dc current density becomes more cathodic, since Co(II) deposition entered the mass-transfer region; and current efficiencies dropped at low and high cathodic current densities due to H^+ and H_2O reduction, respectively.

Higher nickel contents and similar current efficiencies were obtained in the alloys when they were subjected to anodic amplitudes like in PR. Duty cycles lower than 50% yielded very little deposit, regardless of the cathodic current imposed on the electrode, presumably due to a large amount of HER and too much metal dissolved during the anodic pulse. Plating proceeded under lower current efficiencies when the anodic amplitude was increased, and both efficiency and nickel content decayed as the frequency was raised, since less time was enabled to elapse during each cathodic cycle whence less depletion of Co(II) and Ni(II) species occurred close to the electrode surface. In summary, better results in terms of nickel composition and current efficiency were obtained using duty cycles of 80% with a frequency of 5 Hz, and anodic amplitudes of 120 A m^{-2}. This behavior resulted from a prolonged depletion of Co(II) and H^+, which forced these species to become mass-transport controlled without experiencing a significant nickel dissolution.

Chemical analysis revealed that the techniques of atomic absorption, XRD and XPS were able to determine an accurate alloy composition, producing the same results. XRD patterns collected for the alloys provided no evidence of the presence of either pure nickel or cobalt phases. Likewise, no oxide metals related to variation of the surface pH due to HER were found, presumably as a result of their low content. Adsorption of CO on the sample surfaces was determined using XPS.

Textural properties (micro-structure, morphology) were evaluated with AFM and SEM. These techniques showed that

larger grains with a more significant roughness are obtained when dc conditions are used to form the alloys. At low currents ($-50\ A\ m^{-2}$), crystals displayed sharp edges and pyramidal-like morphology and the surface was relatively homogeneous, while at intermediate currents (-500 to $-750\ A\ m^{-2}$) a bimodal particle morphology was observed, consisting of semi-spherical grains size lower than $\sim 0.5\ \mu m$ combined with elongated particles around $\sim 10\ \mu m$. At $-1000\ A\ m^{-2}$, the grains formed were coarser, spherical, denser, and more packed together to yield a more compact structure, although some holes appeared all over its surface. PR generated finer grains and way more smooth surfaces if compared to dc plating. Although, the parasitic reactions (current efficiency) and the nickel content exert some influence in the morphology and micro-structure of the Co–Ni alloys. It was determined that the plating mode is more determining than the aforementioned parameters due to a better control of the mass-transport of the electroactive species and their electrocrystallization phenomena. Although, different morphologies (i.e., pyramidal) can be deposited using PR. It was found that frequency is a crucial plating parameter to control in order to fabricate Co–Ni alloys with enhanced features, since it more frequently removes unstable regions of the deposit (e.g., dendrites) and create more nuclei.

3.7.1 Introduction

Surface finishing of thermal spraying is interesting because of the rough surface texture generated during the spraying process. High velocity oxygen-fuel coating (HVOF) is one of the coating techniques, which is widely used in industry because of its ease of operation, low cost, and efficient processing. In addition, HVOF coatings can protect the underlying surface from the harsh environments such as high temperature, corrosion, and abrasion. The coating can be resistive to erosion, corrosion, and wear depending on the powder properties used for spraying such as Diamalloy 4010 (iron/chrome blend) is widely used for corrosion and wear applications. The combination of these powders in layered structure form is preferable, since it offers advantages over the coating produced by one powders type. The multilayer coating can improve the mechanical properties of the resulting layered structure. The coating can be designed for corrosion or wear protections, which depends on the required functions of the coating. However, multilayer coating can serve for both purposes at the same time. In this case, top coating can be wear resistance and the bottom coating serves for corrosion protection. However, in multilayer coating the coating thickness becomes large and it may not suit in some applications such as the requirements of tight fitting of the surfaces. In addition, the high temperature gradients developed in the coating gives rise to thermal stresses, which limits the practical application of the coatings.

Although considerable research studies were carried out previously to explore the HVOF coating, the challenges for achieving the coating quality and the expected surface finish are still are still in progress. In this chapter, HVOF coating of nickel-based alloys is presented in the light of the previous studies.[1–6] The studies related to spraying, modeling, corrosion assessment and further processing will be given under the appropriate sub-headings.

3.7.2 Literature Review and Background

The progresses made toward achieving the quality of coating are significant over the years. However, some of the selective literature and background work will be provided in the light of the previous studies.[1–6]

The thermal process pertinent to the formation of a WC–Ni coating on low alloy steel by HVOF spraying was studied by Sobolev *et al.*[7] They indicated that the second and subsequent layers of the coating did not have practical influence on the thermal state of the substrate-coating interface. Moreover, the substrate coatings thermal interactions were completely determined by interactions between substrate and the first layer of the coatings. The influence WC–Cr was examined by

 doi:10.1016/B978-0-12-803581-8.09170-0

Zhao *et al.*[8] They indicated that the spray distance had less influence on the wear resistance of coating as compared to those corresponding to the total gas flow rate and the powder feed rate. The mechanical and tribological properties of HVOF thermal sprayed WC–Co coating were investigated by Qiao *et al.*[9] They showed that coatings produced by near nanostructured powders (containing an additive) presented high sliding wear resistance. Investigation into bond strength of Ni and Co composite powders blended with carbides and sprayed by HVOF process onto mild steel surfaces was carried out by Wang *et al.*[10] They found that the bond strength of HVOF coating was correlated well with the spraying parameters, except temperature and particle velocity.

The microstructure of multilayer coatings produced by thermal spray process was examined by Fagoaga *et al.*[11] They showed that the multilayer coatings presented a microstructure composed of alternate phases of chromium carbide cermet and oxides, which were resulted from preferential oxidation of chromium compounds. The mechanical properties of mono and multilayered coatings were examined by David *et al.*[12] They observed that WC–CoCr deposited by HVOF spraying onto P91 steel presented on high fatigue resistance. The bond strength and thermal shock behavior of HVOF sprayed multilayered coating was examined by Wilden *et al.*[13] They showed that HVOF coatings had higher contact of oxygen and higher density than that produced by plasma-sprayed coatings. The mechanical properties of single layer coatings of WC–Co produced by HVOF were examined by Wang *et al.*[14] They indicated that multilayered coatings exhibited better wear resistance under the high load conditions as compared to that corresponding to the single layered coatings. The microstructure and wear resistance of WC–Co coatings thermally sprayed onto tool steel were studied by Pepe *et al.*[15] They introduced the neural network to classify the wear performance of the coatings and indicated that the neural network would be used as an effective tool to classify the wear behavior of the resulting coatings.

The influence of process parameters on molten particle speed and surface temperature and properties of HVOF coatings were investigated by Lih *et al.*[16] They indicated that standoff distance, gun barrel length, and gas flow rate were the most influencing parameters on the coating wear properties. The component repair using HVOF thermal spray was studied by Tan *et al.*[17] They showed that a longer spraying time was required to accomplish repair work on the nitrided components compared to other coatings due to hardened nitrided surfaces resulted in defect sites at the surface during the spraying process. The properties of HVOF NiAl nanostructured coatings were investigated by Hu *et al.*[18] They indicated that spraying was possible to form high quality NiAl nanostructured intermetallic compounds in the coating. Microstructural characteristics of cold-sprayed nanostructured WC–Co coatings was examined by Lima *et al.*[19] The results revealed that there was no degradation of the WC–Co powder during the cold-spray process and uniform WC coating could be produced by the cold-spraying process. The parametric studies on HVOF spraying of MCrAlY coatings were carried out by Lungscheider *et al.*[20] They showed that spray distance, fuel/oxygen ratio and powder feed rate exerted a major influence on microstructure and oxygen content, whereas powder feed gas rate was not significant. The evaluation of through-porosity of HVOF sprayed coatings was carried out by Kowaskita *et al.*[21] The method introduced enabled them to calculate corrosion resistance due to the presence of through-porosity.

The decarburization of WC–Co coating deposited by HVOF process was investigated by Chivavibul *et al.*[22] They showed that the warm spray process did not produced detrimental phases such as W2C and W, which was usually developed due to decarburization of WC. The influence of substrate hardness on decarburization of porous WC-12% Co particles in cold-spraying was investigated by Gao *et al.*[23] They indicated that the properly designs porous cermet powder with certain hardness was a necessary condition to produce hard WC–Co cermet coating. The residual stress formation in the HVOF coating of WC–Co powders onto stainless steel substrate was investigated by Kuroda *et al.*[24] They showed that the residual stress on the surface of the HVOF coating was low and often in tension, but the stress inside the coating was high level of compression. The Young's modulus and fracture toughness of HVOF sprayed bioceramic coatings were examined by Li *et al.*[25] They indicated that the four-point bending test was not suitable for the determination of fracture energy at the coating/substrate interface due to the poor cohesion of the bioceramic coatings. The influences of heat treatment on the abrasion wear behavior of HVOF sprayed WC–Co coatings was examined by Stewart *et al.*[26] They correlated the abrasive wear behavior with the residual stress state, coating integrity, and microstructure.

The residual stress measurement using the curvature method was carried out by Liao *et al.*[27] They showed that temperature history of a part was of paramount importance in stress generation and distribution. The residual stress in HVOF thermally sprayed thick deposits was investigated by Stokes and Looney.[28] They analyzed the change in the stress state from tensile to compressive stress with deposit thickness in terms of quenching and cooling rates. The residual stress generation during thermal spraying was examined by Gill *et al.*[29] They showed that the continuous curvature measurement technique was potentially a reliable and accurate method with a minimum measurement error. The measurement of the residual stress in plasma-sprayed coatings was carried out by Kesler *et al.*[30] They indicated that the respective thermal expansion coefficients and the mechanical properties were the most important factors determining the stress level and the magnitude. The measurement of the residual stress in thermal spray coatings by the incremental hole drilling method was carried out by Santana *et al.*[31] They showed that the nature of the residual stress is tensile and their values were in between 150 and 300 MPa; however, the residual stress was depended on the substrate material, and the process parameters. The residual stress measurement using the curvature method and X-ray diffraction (XRD) technique was carried out by Totemeier and Wright.[32] They indicated that the magnitude of the stresses determined using the curvature method agreed with the XRD results for the coatings, which were sprayed at low particle velocities. However, the stress became compressive for the coatings, which were sprayed at high velocities. The residual stress development in thermal spray coatings was investigated by Ghafouri-Azar *et al.*[33] They indicated that the magnitude of residual stress increased significantly with

increasing the coating thickness. The residual stress development in the HVOF carbide coatings was studied by Pejryd *et al.*[34] They evaluated the coating crack resistance due to bending and low cycle fatigue loads. The residual stress distribution in thermally sprayed coatings was carried out by Otsubo *et al.*[35] They indicated that the residual stress remained almost the same in the coating, except at interface, which reduced from the mean value. The residual stress in HVOF tungsten carbide coating and its effect on the fatigue life were studied by McGrann *et al.*[36] They showed that the fatigue life of the tungsten carbide coating could be determined using the modified layer removal method. The fracture behavior of the brittle coatings was investigated by Bansal *et al.*[37] They showed that the development of the finite element code made it possible to study the effect of various coating parameters in isolation, which was difficult to achieve in an experimental study.

Influence of spraying parameters on electrochemical behavior of HVOF coating was investigated by Planche *et al.*[38] They introduced spraying parameters maximizing the electrochemical resistance of the coating surface. The properties of HVOF sprayed Ni-based alloys with presence of carbides were examined by Hamatani *et al.*[39] They indicated that the inclusion of tungsten carbide in the coating powder improved the corrosion resistance notably. The corrosion behavior of HVOF sprayed steel in sea water was investigated Kawakita *et al.*[40] Their findings revealed that the corrosion took place around the small pore located at the boundary between the splats at the surface. The corrosion behavior of HVOF sprayed and Nd-YAG laser-remelted chromium, nickel chromium coatings were examined by Tuominer *et al.*[41] They showed that laser remelting resulted in the formation of dense oxide layer at the top of the coating as well as full homogenization of the sprayed structure occurred, which in turn improved the corrosion resistance of the surface. The corrosion behavior of HVOF sprayed Inconnel 625 coatings were studied by Zhang *et al.*[42] They indicated that passive current density obtained from the potentiodynamic tests were 10–20 times lower in the liquid fuel coatings than in those sprayed with the gas fuel gun. The corrosion resistance of superheated tubes coated by HVOF thermal spray was investigated by Fukuda and Kawahara.[43] They showed that HVOF coating resulted in high corrosion resistance of the super-heater tubes operating at high temperatures. The corrosion resistance of the HVOF coating was studied by Bolelli *et al.*[44] Their findings revealed that Inconel 625 coating failed to protect the substrate material after 20 h of testing due to inadequate coating conditions.

3.7.3 Experimental

A HVOF coating unit was employed to spray the powders. The spraying parameters selected based on the optimum coating conditions are given in **Table 1**.

Iron/molybdenum blend (Diamalloy 4010) and tungsten carbide cobalt/nickel alloy (Diamalloy 2002) blend powders were used during the coating process. The powder had a particle distribution between 25 and 45 μm with spherical morphology with some small and local satellite attachments.

JEOL JDX-3530 scanning electron microscope (SEM) and EDS are accommodated to obtain photomicrographs of the cross-section and surface of the workpieces after the tests. Microphotonics digital microhardness tester (MP-100TC) was used to obtain microhardness across the depth of the nitride layer. The standard test method for Vickers indentation hardness of advanced ceramics (ASTM C1327–99) was adopted. Microhardness at the surface was measured at the free surface of the workpiece after metallurgical preparation. The workpiece cross-section was also prepared for the microhardness measurements. The measurements were repeated three times at each location.

Table 1 Process parameters of HVOF thermal spray

Oxygen pressure (kPa)	*Fuel pressure (kPa)*	*Air pressure (kPa)*	*Powder feed rate ($m^3\ h^{-1}$)*	*Spray rate ($kg\ h^{-1}$)*	*Spray distance (m)*
1023	590	720	0.85	6.5	0.31

3.7.3.1 Fracture Toughness by Indentation Tests

The indenter test data and crack inhibiting can be used to measure the fracture toughness of the surface. The cracks length (l) covered the distance between the crack tip to the intend. The crack lengths were individually summed to obtain $\sum l$ as described in the previous study.[45] The crack length 'c' from the center of the indent is the sum of individual crack lengths '$\sum l$' and half the indent diagonal length '$2a$.' Therefore, $c = a + \sum l$.[45] However, depending upon the ratio of $\frac{c}{a}$, various equations were developed to estimate the fracture toughness (K). The equation proposed by Evans and Charles[45] was incorporated to estimate the fracture toughness (K) of the surface, which was applicable for $\left(0.6 \le \frac{c}{a} \le 4.5\right)$; therefore,

$$K_c = 0.079\left(\frac{P}{a}\right)^{3/2} \times \log\left(4.5P\frac{a}{c}\right) \quad [1]$$

where P is the applied load on indenter, c is the crack length, and a is the half indent diagonal length.

3.7.3.2 Residual Stress Measurements by Curvature Method

The deflection of the specimen during the coating was recorded and the final deflection was measured using the optical imaging technique.[32] The equation relating deflection Δx to curvature κ is obtained from the geometric relation, which yields:

$$\kappa = \frac{1}{R} = \frac{L_{arc}}{Cos^{-1}\left(1 - \frac{\Delta x}{R}\right)} \quad [2]$$

where L_{arc} is the arc length of the specimen and R is the curvature radius. The Stony equation[32] is used to obtain the relationship the residual stress and the curvature:[32]

$$\sigma = \frac{\kappa E_s t_s^2}{6(1 - \upsilon_s)t_c} \quad [3]$$

where E_s and v_s are the elastic modulus and the Poison's coefficient of the base material, t_s and t_c are the thicknesses of

the base material and the coating, respectively. However, the equation is only applicable for $t_s \gg t_c$.

The measured L_{arc} and Δx, and calculated R values as well as other parameters are used to determine the residual stress.

3.7.3.3 Analytical Expression for Residual Stress

The analytical expression for the residual stress was developed previously is used.[28] The previous expression is based on the thermal expansion mismatched between the coating and the base material. Therefore, the residual stress is:

$$\sigma = \frac{[E_c(T_f - T_R)(\alpha_c - \alpha_s)]}{1 + 2\left(\frac{E_c t_c}{E_s t_s}\right)} \quad [4]$$

where E_c and E_s are the elastic modules of the coating and the base material, t_c and t_s are the coating and base material thicknesses, T_f is the maximum temperature during laser heating, and T_R is the room temperature after the cooling period is over, α_c and α_s are the thermal expansion coefficient of the coating and the base material, respectively.

3.7.3.4 Electro Chemical Tests

Corrosion tests (potentiodynamic polarization and Tafel analysis) on the laser-treated and untreated surfaces were carried out in a three electrode cell, which composed of a specimen as a working electrode, a Platinum wire as a counter electrode, and a saturated calomel reference electrode (SCE). The specimens were degreased in benzene, cleaned ultrasonically, and subsequently washed with distilled water prior to electrochemical tests. The investigations were carried out with an exposed working electrode area of 0.3 cm^2 in 0.5 M NaCl solution at room temperature. The experiments were performed using PCI4/750 Gamry potentiostat and repeated several times to ensure the reproducibility of the data. DC105 corrosion software was used to analyze the Tafel region, while Potentiodynamic polarization experiments were performed at the same scan rate of 0.5mV s^{-1}.

3.7.4 Mathematical Modeling

The mathematical analysis is presented in the light of the previous study.[4] The mathematical analysis covers the formulation of the laser heating of HVOF coating located onto the steel substrate. However, the laser heating analysis is involved with the phase change in the irradiated region. In the analysis, the solid body heat conduction and phase change with temperature-dependent conductivity, internal energy (including latent heat effects), and convection and radiation boundary conditions are considered.

In the case of a moving heat source along the x-axis with a constant velocity U (Figure 1), the energy gain of the substrate material in accordance to Fourier heat transfer equation yields:

$$\rho \frac{\partial(CpT)}{\partial t} = (\nabla(k\nabla T)) + \rho U \frac{\partial(CpT)}{\partial x} + S_o \quad [5]$$

where

$$S_o = I_o \delta (1 - r_f) e^{\left(-\frac{x^2+y^2}{a^2}\right)} \quad [6]$$

I_o is laser power peak density, δ is the absorption coefficient, a is the Gaussian parameter, r_f is the surface reflectivity, ρ is the density, and x and y are the axes while the laser beam scans the surface along the x-axis. The laser beam axis is the z-axis (Figure 1). It should be noted that the laser beam intensity distribution is assumed to be Gaussian at the irradiated surface.

The convective and radiation boundary conditions are considered at the free surface of the workpiece. Therefore, the corresponding boundary condition is:

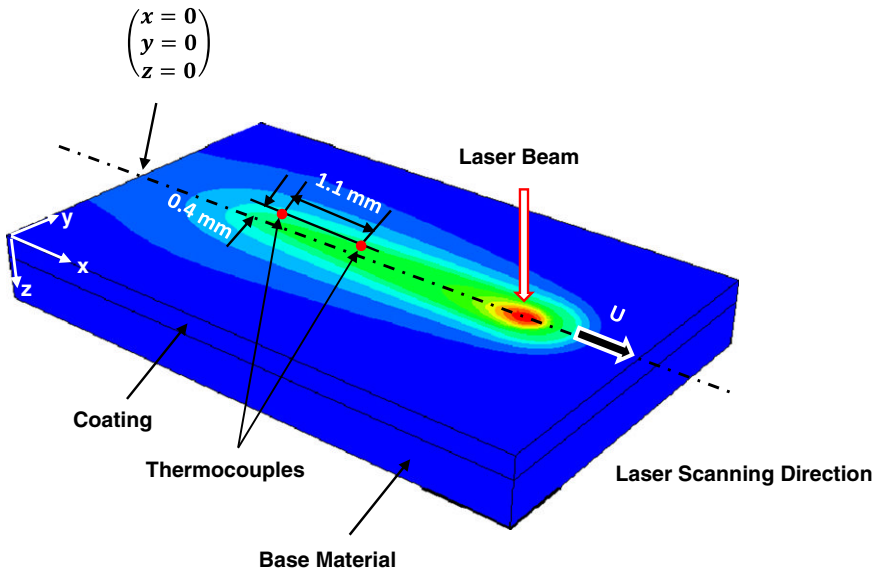

Figure 1 Schematic view of laser scanning of coating and the coordinate system.[4]

At the irradiated surface (top surface):

$$\frac{\partial T}{\partial z} = \frac{h_f}{k}(T_s - T_{amb}) + \frac{\varepsilon\sigma}{k}(T_s^4 - T_{amb}^4) \quad [7]$$

where h_f ($=3000\ \mathrm{W\,(m^2\,K)^{-1}}$) is the forced convection heat transfer coefficient due to the assisting gas.

At the bottom surface:

$$\frac{\partial T}{\partial \gamma} = \frac{h}{k}(T_s - T_{amb}) + \frac{\varepsilon\sigma}{k}(T_s^4 - T_{amb}^4) \quad [8]$$

and

$$\frac{\partial T}{\partial z} = \frac{h}{k}(T_s - T_{amb}) + \frac{\varepsilon\sigma}{k}(T_s^4 - T_{amb}^4) \quad [9]$$

where h ($=20\ \mathrm{W\,(m^2\,K)^{-1}}$) is the heat transfer coefficient due to natural convection, and T_s and T_{amb} are the surface and ambient temperatures, respectively, ε is the emissivity ($\varepsilon=0.9$ is considered), σ is the Stefan–Boltzmann constant ($\sigma=5.67\times10^{-8}\ \mathrm{W\,(m^2\,K^4)^{-1}}$). At far away boundary (at edges of the solution domain) constant temperature boundary is assumed (T=293 K), i.e.,

$$x=\infty\ ;\ \ y=\infty\ ;\ z=t_h \rightarrow T=293\,K \quad [10]$$

where t_h is the thickness of the workpiece. Initially (prior to laser treatment), the substrate material is assumed to be at constant ambient temperature, i.e., $T=T_{\mathrm{amb}}$, which is considered as constant ($T_{\mathrm{amb}}=293$ K).

Equation [1] is solved numerically with the appropriate boundary conditions to predict the temperature field in the substrate material. However, to analyze the phase change problem, the enthalpy method is used.[46] The specific heat capacity is associated with the internal energy gain of the substrate material, i.e., $Cp(T)=\frac{\partial U}{\partial T}$. However, the internal energy gain during the phase change is associated with the latent heat of fusion, which is given separately in terms of solidus and liquidus temperatures (the lower and upper temperature bounds of the phase change range) and the total internal energy associated with the phase change, called the latent heat. Since the primary interest is the stress field developed in the laser irradiated section, the flow field generated in the liquid phase in the surface vicinity during the laser melting process is omitted. It should be noted that the thermal stress field is considered to be almost zero in the melt pool, since only negligibly small hydrodynamic pressures are present in the melt pool.

Solidification involves small strain, so the assumption of small strain is adopted in this work. The thermal strains which dominate thermo-mechanical behavior during solidification are on the order of only a few percent. Several previous solidification models[46] confirm that the solidified metal part indeed undergoes only small deformation during solidification. The displacement spatial gradient is small $\nabla\mathbf{u}=\partial\mathbf{u}/\partial\mathbf{x}$ so $\nabla u{:}\nabla\mathbf{u}\approx1$ and the linearized strain tensor becomes:[47]

$$\varepsilon=\frac{1}{2}\left[\nabla u+(\nabla\mathbf{u})^T\right] \quad [11]$$

The small strain formulation can be used, where Cauchy stress tensor is identified with the nominal stress tensor $\boldsymbol{\sigma}$, and $\mathbf{b}$ is the body force density with respect to initial configuration.

$$\nabla\cdot\boldsymbol{\sigma}(\mathbf{x})+\mathbf{b}=0 \quad [12]$$

The rate representation of total strain in this elastic-viscoplastic model is given by:

$$\dot{\varepsilon}=\dot{\boldsymbol{\varepsilon}}_{e1}+\dot{\varepsilon}_{\mathrm{ie}}+\dot{\varepsilon}_{\mathrm{th}} \quad [13]$$

where $\dot{\boldsymbol{\varepsilon}}_{e1}$, $\dot{\varepsilon}_{\mathrm{ie}}$, $\dot{\varepsilon}_{\mathrm{th}}$ are the elastic, inelastic (plastic + creep), and thermal strain-rate tensors, respectively.

Stress rate $\dot{\sigma}$ depends on elastic strain-rate, and in this case of linear isotropic material and negligible large rotations, it is given by eqn [9] in which ':' represents inner tensor product.

$$\dot{\sigma}=\underline{\underline{\mathbf{D}}}:(\dot{\varepsilon}-\dot{\varepsilon}_{ie}-\dot{\varepsilon}_{th}) \quad [14]$$

$\underline{\underline{\mathbf{D}}}$ is the fourth order isotropic elasticity tensor given by eqn [9]

$$\underline{\underline{\mathbf{D}}}=2\mu\underline{\underline{\mathbf{I}}}+\left(K_B-\frac{2}{3}\mu\right)\mathbf{I}\otimes\mathbf{I} \quad [15]$$

Here μ, K_B are the shear modulus and bulk modulus, respectively, and are in general functions of temperature, while $\underline{\underline{\mathbf{I}}}$, $\mathbf{I}$ are fourth and second order identity tensors and '$\otimes$' is the notation for outer tensor product.

Inelastic strain includes both strain-rate independent plasticity and time-dependent creep. Creep is significant at the high temperatures of the solidification processes and is indistinguishable from plastic strain. The inelastic strain-rate is defined here with a unified formulation using a single internal variable, equivalent inelastic strain $\bar{\varepsilon}_{el}$ characterize the microstructure. The equivalent inelastic strain-rate $\dot{\bar{\varepsilon}}_{el}$ is a function of equivalent stress $\bar{\sigma}$, temperature T, equivalent inelastic strain $\bar{\varepsilon}_{el}$

$$\dot{\bar{\varepsilon}}_{el}=f(\bar{\sigma},T,\bar{\varepsilon}_{el}) \quad [16]$$

$$\bar{\sigma}=\sqrt{\frac{2}{3}\sigma'_{ij}\sigma'_{ij}} \quad [17]$$

where σ' is a deviatoric stress tensor defined in eqn [17].

$$\sigma'_{ij}=\sigma_{ij}-\frac{1}{3}\sigma_{kk}\delta_{ij} \quad [18]$$

The workpiece is assumed to harden isotropically, so the von Mises loading surface, associated plasticity and normality hypothesis in the Prandtl–Reuss flow law is applied:[48]

$$(\dot{\varepsilon}_{ie})_{ij}=\frac{2}{3}\dot{\bar{\varepsilon}}_{el}\frac{\sigma'_{ij}}{\bar{\sigma}} \quad [19]$$

Thermal strains arise due to volume changes caused by both temperature differences and phase transformations, including solidification and solid-state phase changes, i.e.,

$$(\varepsilon_{th})_{ij}=\int_{T_o}^{T}\alpha(T)\,dT\delta_{ij} \quad [20]$$

where α is temperature-dependent coefficient of thermal expansion, and T_o is the reference temperature and δ_{ij} is Kronecker's delta. It is normally accounted for in stress analyses through a temperature-dependent differential thermal expansion coefficient, $\alpha(T)$. ABAQUS/Standard analysis a

spatially varying thermal expansion can be defined for homogeneous solid continuum elements by using a distribution, which includes the tabulated values for the thermal expansion.[46] ABAQUS uses an implicit backward-difference scheme for time integration of both temperature and displacements at every material integration point.[46]

3.7.4.1 Numerical Solution

Finite element discretization was carried out using the ABAQUS software.[46] The fixed boundary conditions are applied on the both ends of the workpiece resembling the experimental laser heating situation. Laser heat flux with Gauss distribution and prescribed velocity of 10 cm s^{-1} along the x-axis through user subroutine DFLUX is applied to the thermal model. The Gauss parameter 'a' is $a = 0.000333$ m, in accordance with the experimental power intensity distribution. The thermal model consisted of two steps. The first step, which lasts 0.05 s, simulates the response of plate under moving laser heat flux. The second step, which lasts for 1000 s, simulated the continued cooling in the model. Cooling was allowed to continue until all of the plate reaches initial temperature (room temperature). The temperature–time history resulted from the thermal analysis is used as input to the thermal stress analysis. The workpiece is considered as an elastic body, which is modeled as von Mises elastic-plastic material with isotropic hardening and with a yield stress that changes with temperature.

3.7.5 Findings and Discussions

The findings of HVOF coating on metallic substrates are presented according to the appropriate sub heading in the light of the previous studies:

3.7.5.1 Coating Morphology and Metallurgical Changes

3.7.5.1.1 Single layer coating

Morphological and metallurgical changes of HVOF coating blended with WC particles and sprayed onto steel 304 surfaces is presented here in. The influence of WC content on the fracture toughness of the resulting coating is discussed in details. Indentation tests and the fracture toughness of the coating surfaces are also included. This section is presented in the light of the previous study.[1]

Figure 2 shows SEM micrographs of the top surface of the coating while Figure 3 shows SEM micrographs of coating cross-section. It is evident from SEM micrograph (Figure 2) that coating is free from cracks and irregularities like voids and large gaps between the splats.

Moreover, addition of WC particles is also partially evident and appeared as dark spots at the surface. In some regions at the surface some loose splats are observed. This situation may occur because of the improper spraying parameters or the powder mixture with non-metallic powders. Nevertheless, this situation is limited with only two samples, which are not considered in the fracture toughness measurements. In the case of cross-sectional view of SEM micrograph (Figure 3), it is evident that splats are bounded through mechanical anchoring. However, some small cavitations and voids are observed at coating-base material interface, which form the irregular patterns in this region. The porosity of the coating changes between 2 and 3%. It is noted that the porosity increases slightly with increasing WC content in the coating, for example, the porosity increase is in the order of 5%. The increase in the porosity is associated with the presence of hard particles in the coating. In this case, during the spraying, splat forms a shape not occupying all the space in the coating once it interacts with the un-deformable hard carbide particle. This situation is also evident from the SEM micrograph that microvoids are formed around the carbide particles. Although the Inconel powder was mixed with carbide particles prior to coating, agglomeration of WC particles occurs in the coating. This forms almost locally scattered small size WC lands in the coating. This situation is more pronounced when WC content is increased in the coating, which may occur because of the spraying process. In this case, small WC particles (2–5 μm) have small mass and during the spraying their momentum becomes less than the Inconel splats. This, in turn, results in early arrival of Inconel splats at the coating and carbide particles arrived at the top of the Inconel splats in a group. This appears as small WC islands in the coating. It should be noted that the melting temperatures of WC particles is much higher

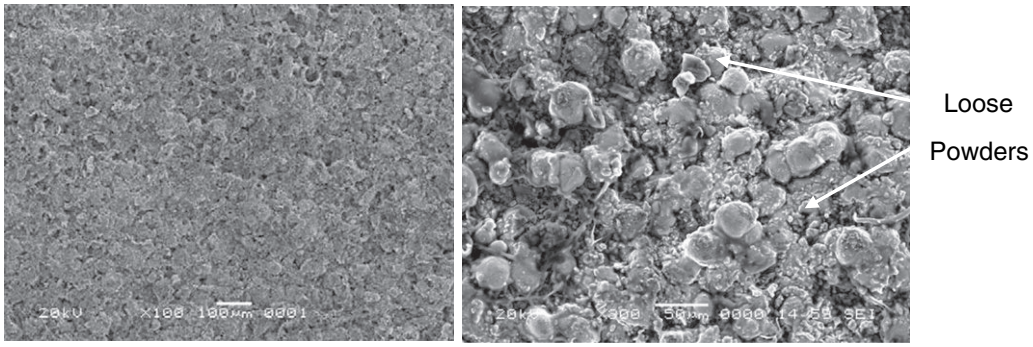

Figure 2 Scanning electron microscope micrographs of top surface of high velocity oxy-fuel coatings.[1]

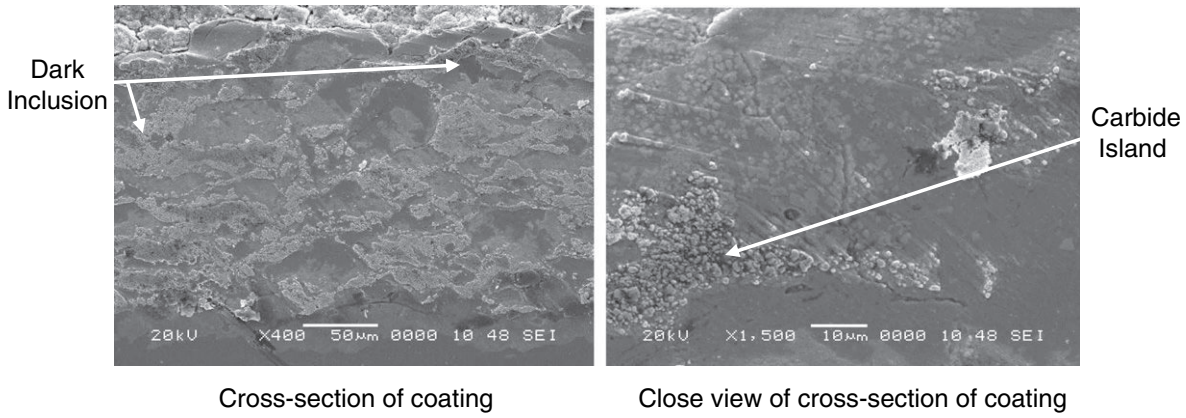

Figure 3 Scanning electron microscope micrographs of cross-section of high velocity oxy-fuel coating.[1]

than that corresponding to Inconel powder; hence, WC particles remain in solid phase during the spraying and remains the same in the coating. The presence of dark inclusion in the coating is the oxides formed during the spraying process. This can also be seen from the EDS line scan, which is shown in Figure 3. It is possible that oxide formation is due to presence of chromium in the Inconel powder. Consequently, high temperature Inconel powders onset of leaving the spraying gun undergo oxidation reactions during the in-flight time. However, depending on the location of the particle in the jet, the splat may undergo severe oxidation reactions. It should be noted that enough oxygen molecules in contact with the powder surface are needed for the oxidation reactions to take place.

Table 2 shows that fracture toughness of the coating surface produced at different WC content. It is evident that increasing WC content in the coating enhances the surface hardness of the resulting coating. This is attributed to the contribution of WC to the overall hardness, since WC hardness is considerably higher than that of Inconel 625. In addition, presence of WC modifies the structure of coating; in which case, rather compact coating is resulted. The fracture toughness of the surface varies with the WC content. Increasing WC in the coating enhances the fracture toughness slightly. This is because of one or all of the following reasons: (1) elastic modules of the coating increases, which is directly proportional to the fracture toughness, (2) increasing hardness, which contributes positively to the fracture toughness, and (3) small voids developed around the carbide particles, which acts as a micro-stress relaxation centers preventing the crack propagation in the surface region. Moreover, improvement in the fracture toughness is considerable despite the fact that the rate of oxide formation is higher due to open atmosphere. In addition, attainment of low fracture toughness for Inconel 625 coating without WC blending is because of the brittle structure formation in the free surface region. The oxide compounds in the surface region are responsible for brittle structure formation in the surface region.

3.7.5.1.2 Two layer coatings

HVOF coating of two-layers consisting of Diamalloy 4010 and 2002 powders onto carbon steel is presented here in. The surface morphology and microstructure of the coating are included in the discussions. This section is presented in the light of the previous study.[2,3]

Table 2 Fracture toughness and elastic modulus obtained from the indentation tests. The error estimated based on the repeats of the indentation test is 5%

	Fracture toughness (MN m$^{-3/2}$)	*E* (GPa)
0% WC	7.4	215
9.3% WC	8.52	240
47% WC	13.3	420

Figure 4 shows SEM micrographs of the top view of the coatings produced by Diamalloy 4010 and 2002 powders it is evident that no loose splats and surface irregularities including voids, cracks, and cavities are observed. However, surface roughness is high because of the presence of the partially molten powders. This is true for the surfaces resulted from both powders. It should be noted that Diamalloy 2002 contains WC, which has a high melting temperature. Consequently, the molten state of the powders requires excessive temperature rise during the spraying process. This can also be observed from the SEM micrographs, i.e., some protruded particles are observed. Moreover, high spraying velocity increases the momentum of the particles and, upon impacting, some particles penetrated into the coating surface. Consequently, the protruded particle distribution is random and they are cover a small area at the coating surface.

Figure 5 shows SEM micrographs for the cross-section of the coatings including single layer coatings produced from Diamalloy 2002 and 4010 powders as well as the two layered coating. It should be noted that the top layer is produced by using Diamalloy 2002 in two layered coating. It is evident that the coating consists of lamellar structure, which is produced during the multi-pass spraying process. Moreover, the porosity in the coating is measured and it is found that the porosity is in the order of 3%. The possible cause of the porosity is due to the presence of the semi-molten and molten splats during the spraying process as well as uneven shapes of the powders. The presence of semi-molten and hard splats is evident and they appear as rounded shapes in the coating; however, this is

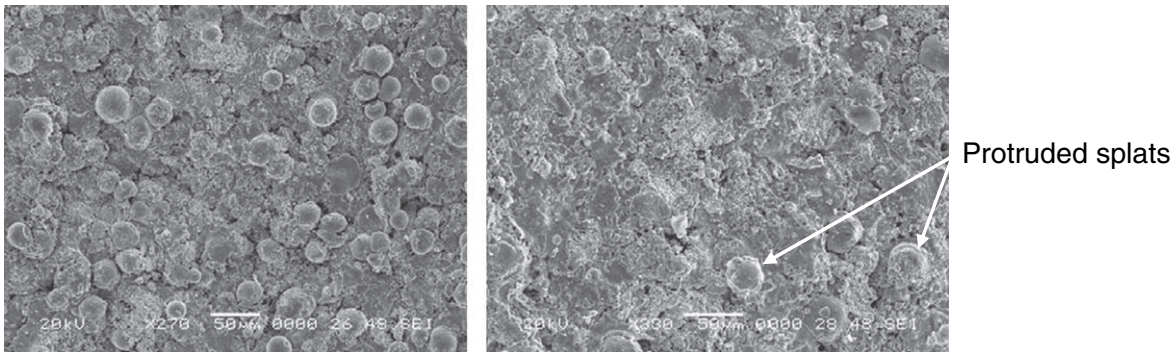

Figure 4 Scanning electron microscope micrographs of top view of coatings produced from Diamalloy 2002 and Diamalloy 4010 powders.[2,3]

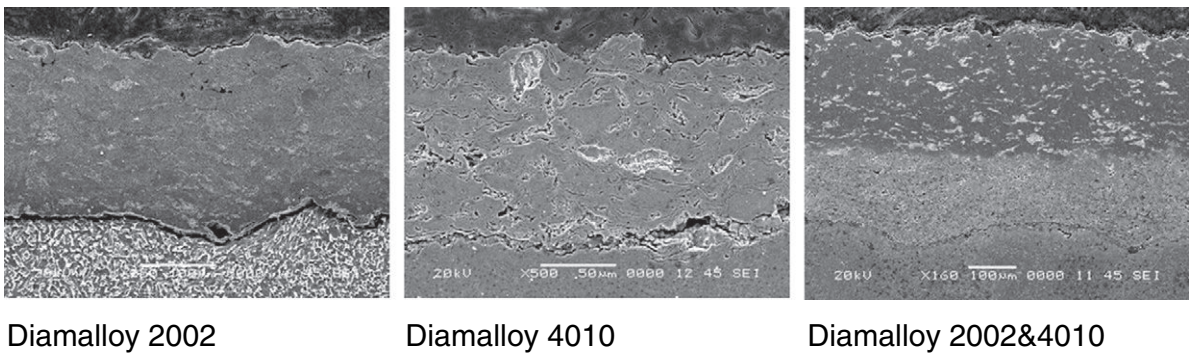

Figure 5 Scanning electron microscope micrographs of cross-sections of single and two layered coatings with two different powders.[2,3]

mainly observed in the surface region of the coatings, particularly for 2002 Diamalloy coating. This is because of the presence of WC in the powders, which requires high temperature for melting. Moreover, some stringers like inclusions are also observed in both coatings. This may be attributed to the oxide formation during the spraying process, i.e., high temperature oxidation occurs around the splats during the spraying process. This situation can also be seen from the EDS line scan. The presence of O_2 shows that oxidation takes place around the splat surface, provided that the oxide layer may not cover the whole surface. This situation is true for both coating produced form Diamalloy 2002 and 4010 powders. The splats are well integrated into the base material at the coating-base material interface. No large cavity or other irregular structure is observed. This indicates that the high velocity of the molten splats were widen over the surface upon high velocity impact. This is particularly true for the coating produced from Diamalloy 4010. In the case of Diamalloy 2002 coating, a small gap of discontinuity is observed at the interface between the coating and the base material, provided the gab is not extended to large area at the interface. This may be because of the presence of WC, which remains at solid phase during the spraying process due to its high melting temperature.

Figure 6 shows indentation marks produced at the surface of Diamalloy 2002 and 4010 coatings as well as in the cross-sections. It is evident the marks produced in Diamalloy 2002 coating is smaller in size than that corresponding to Diamalloy 4010. This is because of the hardness of the Diamalloy 2002 coating due to the presence of WC powders. Moreover, only small cracks are observed around the indentation marks. This is true for all the coatings. The formation of the small size cracks around the indentation marks is unable to determine the surface fracture toughness. However, the fracture toughness may vary over the coating surface despite the fact that the measurement covers the layer area at the surface. Moreover, the cracks produced around the indentation marks are mainly along the direction of lamella structure, which is parallel to the coating surface. This is because of the direction, which is most prone to de-cohesion (easiness of delamination). This is situation is observed from the indentation marks produced at the coating cross-sections. It should be noted that the absence of reasonably large radial cracks does not show the low fracture toughness; however, low tensile strength of the coating. In this case, sharp edge of indenter results in large tensile stresses around the indentation marks.

3.7.5.2 Laser-Treated Coatings

Laser controlled re-melting of HVOF coating diamalloy ((WC-12) Co, Ni, Cr, Fe, Si) particles are presented. Metallurgical changes in the coating prior and after the laser re-melting are included in the discussions. This section is given in the light of the previous study.[4]

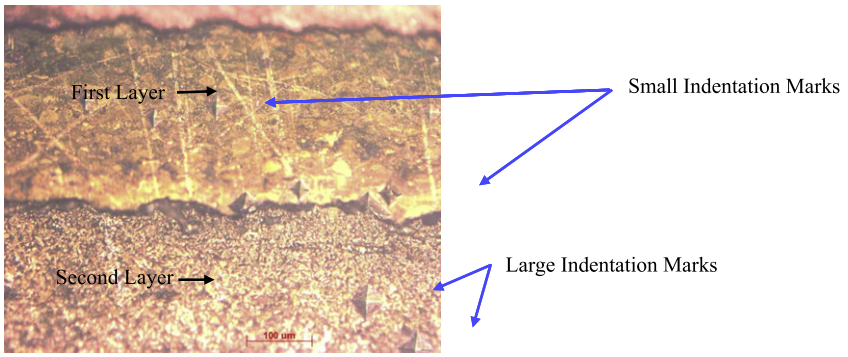

Figure 6 Optical photograph of indentation marks across the two layered coating.[2,3]

Figure 7 shows SEM micrographs of top views of surfaces of as-sprayed coatings and laser-treated coatings. As-sprayed coating surface resembles partially attached splats, which are randomly distributed at the surface. This is associated with the relatively high cooling rates at the surface for the last sprayed powders. In this case, last sprayed powders anchor the free surface of the coating and convection heat transfer from the surface changes the state of the splat from molten to solid at a fast rate. However, the laser treatment re-melts these splats at the surface together with remaining splats in the coating. This, in turn, results in thermal integration of the partially attached splats with the coating. The laser-treated surface is smoother than as-sprayed and it is also free from cracks. Although the cooling rates at the surface are high, initially spayed splats in the coating decrease the cooling rates while generating self-annealing effect at the surface region of the coating. This reduces the stress levels and microcrack formation at the treated surface. Since the laser power intensity is set below the evaporation limit at the coating surface, no cavities are observed at the surface due to avoiding the surface evaporation. The laser scanning tracks are visible at the surface, however, no molten flow between these tracks is observed. The sprayed powder contains WC blend which undergoes oxidation reaction with air at high temperatures releasing the carbonic gas. This, in turn, generates micro-sized gasification holes at the laser-treated surface. The close examination of the treated surface reveals that no micro-sized hole is observable at the surface. Consequently, carbonic gas released from the splats takes place during the in-flight time rather than at the coating surface.

Figure 8 shows SEM micrographs of the cross-section of as-received and laser-treated coatings. As-received coating cross-section consists of molten and partially molten states splats. In addition, locally distributed dark inclusions are also evident indicating oxide particles in the coating. The size of dark inclusions is small, which is associated with the small size powders. In this case, small powder undergoes oxidation reaction during in-flight and form stringers like dark inclusions in the coating. The oxide formation in the coatings is evident from the EDS data, which is given in Table 3. Locally scattered few voids are observed in the coating. However, no major or minor cracks are observed in the coating cross-section. Although thermal expansion coefficients of WC particles and splats are different, thermal strain developed during the cooling period does not cause formation of excessive micro-

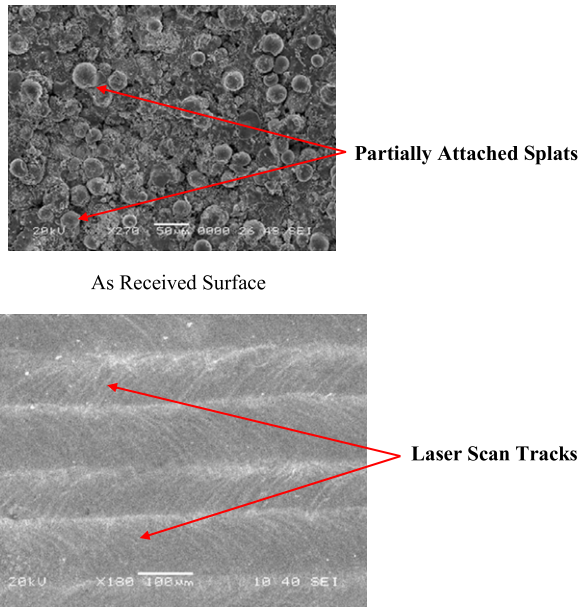

Figure 7 Top view of as-received and laser-treated coating surfaces.[4]

stress around WC blends. Consequently, no micro-cracks network is observed in the coating cross-section. The slow cooling rates in the coating release the thermal strain and lower micro-stress levels around the WC blends. In the case of laser remelted coating, uniform melting along the coating thickness is evident. Laser controlled melting resulted in cellular structure in the coating. Since the cooling rate is non-uniform in the coating, the cell size and their orientation differ in the coating. The differences in thermal conductivity of WC and coating alloy result in non-equilibrium solidification causing the growth of plaques in the liquid layer. This initiates the formation of small cells through a polyphase solidification. The close examination of the coating cross-section also reveals the presence of partially melting of WC blends in the coating. At the interface between the coating and the base material, no boundary defects, such as cracks and separation, or large cavitation are observed. This indicates that no volume shrinkage of the coating occurs in the interface region of the coating.

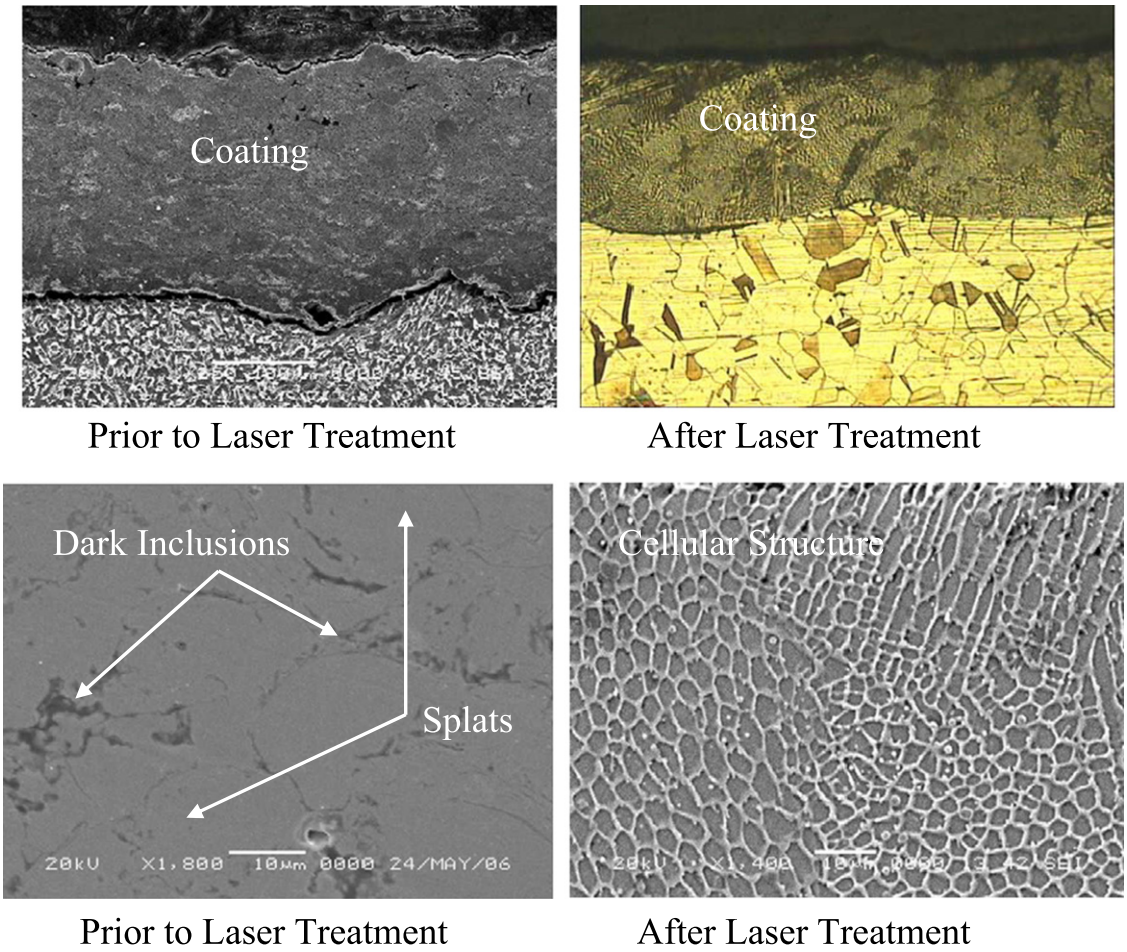

Figure 8 Cross-section of laser coating prior and after the laser treatment process.[4]

Table 3 Elemental composition of diamalloy coating after laser treatment (wt%)

Spectrum	*Si*	*Cr*	*Fe*	*Co*	*O*	*W*	*Ni*
Spectrum 1	1.1	11.5	6.5	1.5	3.5	10.4	Balance
Spectrum 2	1.2	12.2	7.5	1.5	3.4	12.3	Balance
Spectrum 3	2.1	14.0	6.5	2.3	2.8	12.1	Balance

Table 4 gives the residual stress predicted from the simulations and obtained from the measurements using the curvature method. It is evident that the residual stress is lower for as-sprayed coating as compared to that of the laser-treated coating. The self-annealing effect in the coating reduces the residual stress levels in the as-sprayed coatings. In addition, cooling rates after the laser treatment process contributes to attainment of high residual stress in the laser-treated coating. Table 5 gives microhardness test results in the coating prior and after the laser treatment process. Microhardness of the laser-treated coating increases significantly, provided that microhardness in the region of the coating-base material interface is lower than that at the surface region. This is associated with the slow cooling rate in this region, which in turn results in low stress levels in consistent with the stress predictions in this region.

Table 4 The residual stress predicted from the simulations and measured from the curvature technique

	Experiment (MPa)	*Predictions (MPa)*
Laser treated	730	770

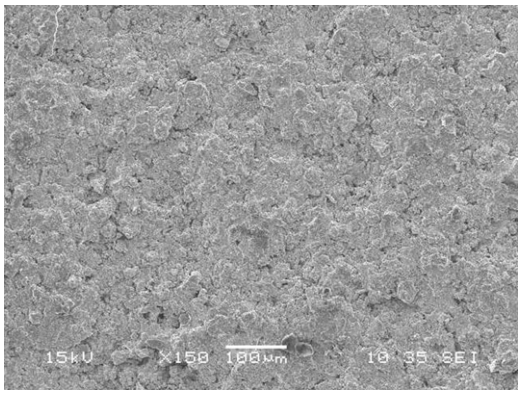

Figure 9 Scanning electron microscope micrograph of the top view of HVOF coated surface.[5]

3.7.5.3 Electro Chemical Testing

HVOF coating of diamalloy on steel substrate and the corrosion resistance of the surface due to 0.5 M NaCl solution is presented in the light of the previous study.[5]

Figure 9 shows SEM micrographs of top view of the coated samples prior to potentiodynamic tests. The coated surface is free from cracks, delimitation, and large size voids. However, partially bonded splats appearing like satellites at the surface are visible from the SEM micrographs. These splats are the last sprayed splats reaching at the surface. Consequently, they are exposed to atmospheric ambient and cools down at a fast rate due to convection heat transfer effects at the free surface. Although high cooling rates results in high temperature gradient at the vicinity of the coated surface, the self-annealing effects of the initially sprayed splats below the coating surface reduces temperature gradient in this region with progressing time. This suppresses the development of thermally induced high stress levels at the surface region. However, presence of the compressive residual stress is evident since the coating and steel substrate slightly bends outwards.

Figure 10 shows SEM micrographs of the cross-section of the coating prior to potentiodynamic tests. It is evident that coating extends uniformly at the steel surface with a thickness of 300 nm are observed in the coating. The coating comprises of lamellar-like structures due to the presence of different sizes of splats in the coating. However, the close examination of SEM micrographs reveals that dark inclusions are present in the coating, which are scattered locally around the splat boundaries. Since the sizes of the dark inclusions are small they appear on boundary separator between the splats. The presence of dark inclusions is attributed to the oxidation of small powders during in-flight. Moreover, small size semi-molten splats at the surface undergo oxidation reactions contributing to stringers like structure at the surface vicinity. The powders sprayed contain 12% WC and melting temperature of WC is high; therefore, these particles remain in solid phase during the spraying process. This increases porosity in the coating. Since the thermal expansion coefficients of WC and the remaining alloying elements are different, stresses are expected to develop around WC particles. This is attributed to the stress development in the coating due to mismatching of thermophysical properties. Nevertheless,

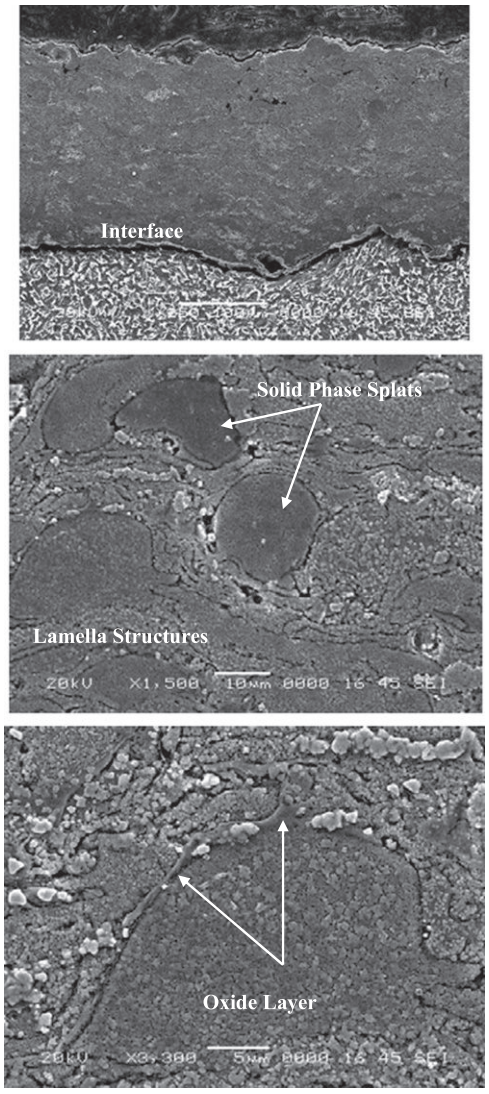

Figure 10 Scanning electron microscope micrograph of cross-section of HVOF coating.[5]

micro-stress developed around WC particles is not large enough to form micro-cracks around the splats, which is also revealed from close examination of SEM micrograph. The dark inclusions and WC particles are hard and brittle and act as the stress centers in the coating. In this case, under the external loads, inclusions break while form large cracks in the coating. Locally scattered few cavities are observed at coating-base material interface, which are attributed to improper anchoring of the splats during the spraying process.

Figure 11 shows the potentiodynamic polarization response of bare carbon steel together with two different kind of HVOF coating using commercial powders, Diamalloy in 0.5 M NaCl solution at room temperature (25 °C). It can be noted by Tafel data as showed in Figure 11 and Table 6 that corrosion rate of 2002 coating was decreased as compared to bare metal. Also the corrosion potentials of 2002 coating was –0.69 V_{SCE} as compare to bare metal, which was –0.53 V_{SCE}. Figure 12 shows SEM micrographs of HVOF coated surfaces after the potentiodynamic tests. The small pit and deep sites

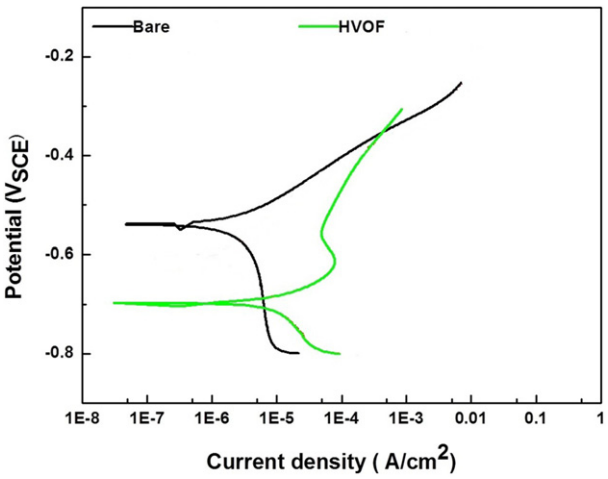

Figure 11 Potentiodynamic polarization response of HVOF coating and base material in 0.5 M NaCl solution at room temperature.[5]

Table 6 Electrochemical test results in 0.5 M NaCl solution at room temperature

	I_{corr} ($10^{-9} \times$ A)	E_{corr} ($10^{-3} \times V_{SCE}$)	*Corrosion rate (mpy)*
Base material	47.9	−538	7.1
HVOF coat surface	30.5	−697	4.5

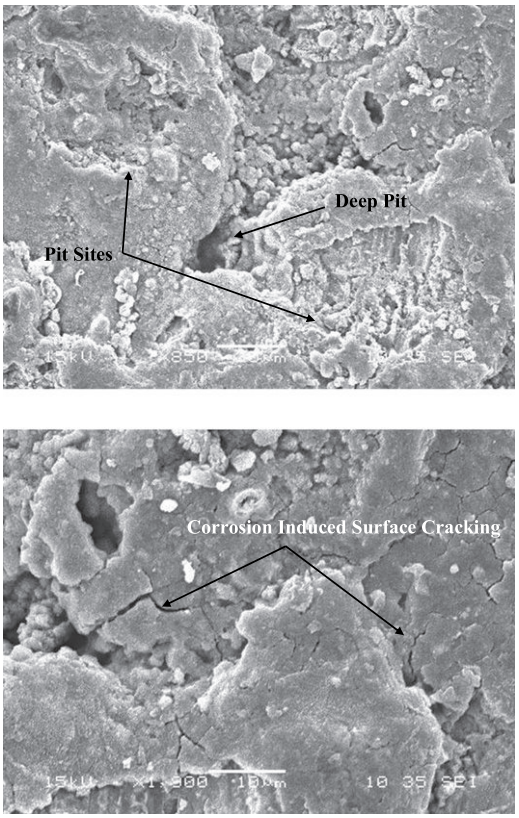

Figure 12 Scanning electron microscope micrographs of pit sites at HVOF coating.[5]

are evident. The presence of deep pit sites is attributed to pores network within the coating, which provides passage to the electrolyte in the coating. This, in turn, causes preferential corrosion around the splat boundaries; consequently corroded splats have higher oxide content. Moreover, a lateral cracking is not observed at the coating surface. This indicates that oxidation induced expansion takes place in the surface region of the coating than at the coating-base material interface. It should be noted that geometrically non-ordered surface texture formed at the coating surface influence the size and depth of the pit sites. The small spacing between the large surface peaks accelerates crevice corrosion while forming the deep pit sites.

3.7.5.4 Modeling of Laser Treatment of Coating

The findings of the model study for laser re-melting of HVOF coating diamalloy (WC-12) Co, Ni, Cr, Fe, Si) is presented in the light of the previous study.[4]

Figure 13 shows temperature distribution along the laser scanning line in the x-axis for different cooling periods. The cooling period starts after $t = 0.05$ s at which the laser power is switched off. Temperature attains high values in the region where the laser power is ceased In this case, temperature exceeds the liquidus temperature of the coating material in the irradiated region while indicating the liquid phase heating in this region. Temperature decays sharply in the neighborhood of the high temperature region, which is more pronounced along $0.005\ \text{m} \le x \le 0.0055$ m. The sharp decay of temperature results in high temperature gradients in this region. Moreover,

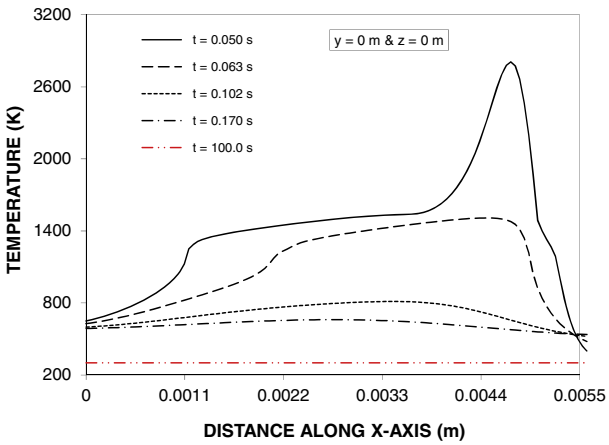

Figure 13 Temperature distribution along the x-axis for different cooling periods.

temperature decay along $0.0011\ \text{m} \le x \le 0.0035$ m is gradual. This is associated with the cooling rate of the initially laser heated region along the x-axis. However, as the cooling period progresses, temperature along the x-axis reduces and almost room temperature is reached at $t = 100$ s of the cooling period. The convection and conduction heat transfer from the laser heated region is responsible for the high cooling rates.

Figure 14 shows von Mises stress variation along the laser scanning line in the x-axis for different cooling periods, which

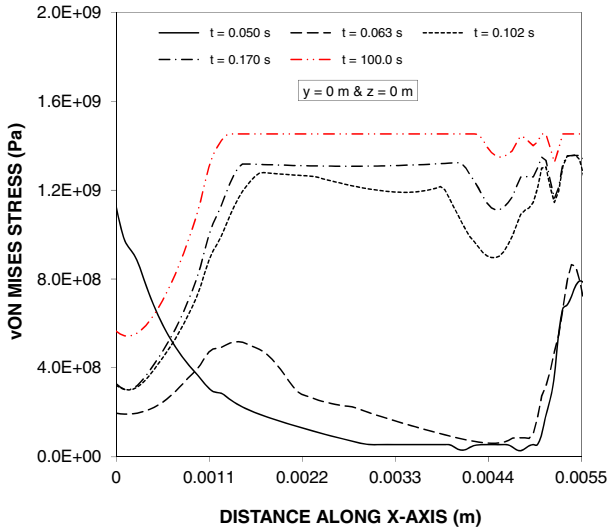

Figure 14 von Mises stress distribution along the *x*-axis for different cooling periods.

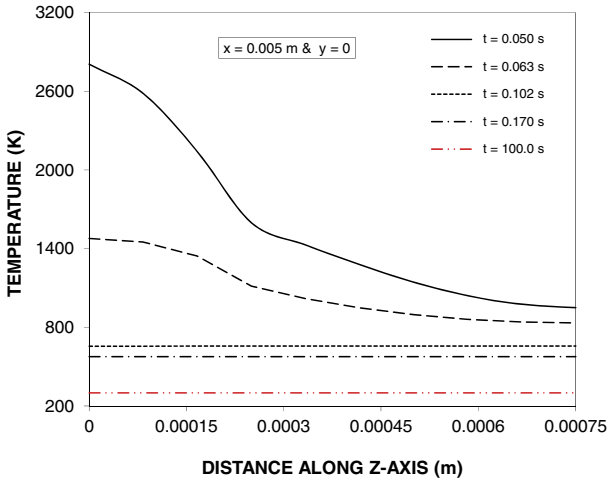

Figure 15 Temperature distribution along the *z*-axis for different cooling periods.

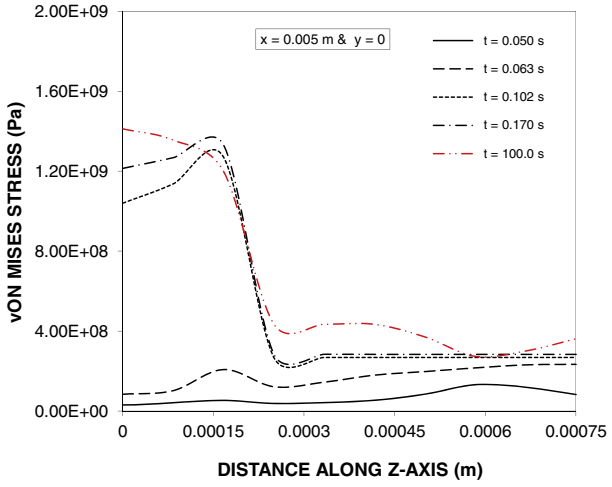

Figure 16 von Mises stress distribution along the *z*-axis for different cooling periods.

are similar to those shown in Figure 13. von Mises stress is low in the region where temperature is high and stress becomes high in the region where temperature decay is sharp. This is attributed to temperature-dependent elastic modulus, which reduces with increasing temperature. In addition, high temperature gradient gives rise to formation of high thermal strain leading to high stress levels in the workpiece. As the cooling period progresses, temperature reduces so that von Mises stress increases. In addition, von Mises stress reduces slightly at the end of cooling period in the region where temperature is initially the highest. This corresponds to the location where the laser beam is switched off. In this case, self-annealing effect of the heated zone in this region is responsible for the stress relaxation. This situation is also observed at different cooling periods toward the end of the cooling cycle.

Figure 15 shows temperature distribution along the *z*-axis in the coating and in the substrate material for different cooling periods. Temperature decay is gradual in the cooling cycle particularly in the surface region of the coating ($z=0$) at the onset of cooling cycle initiation. This is attributed to internal energy gain of the substrate material from the irradiated field just before the laser beam is ceased. Consequently, high rate of energy deposition results in excessive liquid depth and temperature variation in the melt zone becomes small. However, in the interface region between the coating and the base material ($200\ \mu m \leq z = \leq 250\ \mu m$), temperature decays sharply particularly in the cooling period while temperature decay in the base material is gradual. This is attributed to thermal properties of the coating and base material, which are different. Temperature reduces in the coating and the base material as the cooling period progresses; in which case, temperature in the coating and the base material becomes almost the same.

Figure 16 shows von Mises stress distribution along the *z*-axis for different cooling periods. von Mises stress remains low in the coating and base material in the early cooling period due to attainment of low elastic modulus at high temperatures. As the cooling period progresses, von Mises stress attains low values in the surface region. This is associated with high thermal strain developed in the surface region and increasing elastic modulus with reducing temperature. Von Mises stress reduces sharply between the coating and the base material, which is attributed to differences in mechanical properties and thermal expansion coefficients of the coating and the base material. However, high stress field remains almost the same in the coating except the interface region. The attainment of almost uniform stress levels across the coating thickness suggests that no large stress gradients are formed in the coating, except in the interface region. The maximum von Mises stress is on the order of 1.4 GPa.

3.7.6 Concluding Remarks

HVOF coating is established technology for protection of surface from high temperature, corrosion, and wear environments.

However, the research into the improvement of coating quality and the surface finish is still in progress. The important factors affecting the coating quality and the surface finish are large in numbers; however, two of the important factors are the spraying process and the powder quality used during the spraying. Although post-treatment of coating surface improves the coating quality in terms of mechanical properties, the studies on the improvement of surface finish is one of the research areas of the surface finish.

3.7.6.1 Single Layer Coating

The coating surface is free from defects, such as cracks and large size voids. However, irregular pattern of locally scattered contours are observed across the coating and base material interface. WC particles agglomerate in the coating while forming the small carbide islands. This can be attributed to the momentum difference between the carbide particles and the Inconel splats during the spraying process. This situation is more pronounced as the WC content increases in the coating. Oxide compound formation is evident from XRD diffractograms, which also appears as black inclusions around the splats in the coating. The carbonic gas formation during the spraying process alters the carbon content in WC; in which case W_2C is formed in the coating. Elastic modules and microhardness of the coating increases with addition of WC in the coating. The fracture toughness of the surface also increases with increasing WC content in the coating. This is attributed to increase in the elastic modules and microhardness in the surface region. In addition, micro-cavities around the WC particles act like the stress relaxation centers. This, in turn, prevents crack propagation in the surface region.

3.7.6.2 Two Laser Coating

Coatings produced from the Diamalloy 2002 and Diamalloy 4010 give similar surface textures, provided that some scattered protruded splats are observed at the surface for Diamalloy 2002 coating. This can be related to the presence of contains WC, which has a high melting temperature. Coatings produced from both powders formed lamellar structures with the porosity of the order of 3%. No large cavities or irregularities are observed at the coating-base material interface, except Diamalloy 2002 coating. In this case, a locally extended line of discontinuous gab is observed. Oxidation of the some splat surface appears as black inclusions in the coatings; however, the oxide layer does not cover all the surface of the splats. The microhardness measurement reveals that the coating formed by using Diamalloy 2002 has higher hardness than that corresponding to Diamalloy 4010. This is attributed to the presence of WC in the splats. The elastic modulus determined from the indentation tests shows that the elastic modulus of the coating formed form Diamalloy 2002 is higher than that of Diamalloy 4010.

3.7.6.3 Laser Treatment of Coating and Numerical Study

Laser scanning of the coating surface resulted in scanning tracks at the surface and no molten flow across the laser scanning tracks is observed. Uniform melting along the coating thickness is achieved. Although thermal expansion coefficients of WC and neighboring alloying elements in the coating are different, no micro-cracks, or crack network is observed in the laser-treated coating. Due to non-uniform cooling in the coating, cellular structures are observed in different sizes and orientations. The residual stress predicted agrees well with the experimental data. Laser treatment enhances the residual stress levels in the coating as compared to as-sprayed coating. In addition, microhardness of the laser-treated coating increases significantly, particularly in the surface region. Temperature predictions reveal that temperature gradient in the region close to the laser irradiated spot is high. This, in turn, increases von Mises stress in this region. Due to the self-annealing effect of the splats in the coating, von Mises attains slightly lower values in the region where the laser beam is switched off. von Mises stress remains high in the coating, except in the region close to the coating-base material interface; in this case, it reduces notably in this region.

3.7.6.4 Corrosion Testing of Coating

The corrosion resistance of the coating is estimated through potentiodynamic tests in 0.5 M NaCl solution. The findings revealed that the coating consists of a lamella-like structure with the presence of few semi-molten splats. No minor or major cracks observed at the coating surface and the cross-sections. Dark inclusions are observed between the splats due oxidation of small powders during in-flight. In addition, few semi-molten splats are partially attached to the coating surface, which is attributed to the high coating rates at the surface. The residual stress predicted agrees well with its counterpart obtained from the analytical formulation. The residual stress is compressive in nature. The presence of dark inclusions and WC content in the splats contributed to residual stress formation. In this case, mismatch of thermal expansion coefficients between WC and alloying element is responsible for the formation of the micro-stresses around WC. Fracture toughness and microhardness of the coating varies slightly at the surface, which is associated with the WC distribution at the surface; in which case, WC increases microhardness and lowers fracture toughness through enhancing the crack lengths around the indentation mark. HVOF coating improves the corrosion resistance of the base material. However, presence of deep pit sites at the surface suggests the occurrence of preferential corrosion around the splat boundaries. In addition, closely spaced surface texture peaks act as crevice corrosion centers at the surface while initiating the formation of deep pit sites.

3.8.1 Introduction

3D printing or additive manufacturing (AM) is described as the process of making a three-dimensional solid object from a digital file using additive processes. A 3D object is created by depositing successive layers of a material according to a computer design.

To print a 3D object, first one needs to have the design. A completely new object can be made in CAD (computer-aided design) file using a 3D-modeling program, such as SolidWorks® or AutoCad®. Alternatively, the copy of an existing object can be made by scanning it using a 3D scanner. Using appropriate software, the 3D model is sliced into horizontal layers, and loaded onto a 3D printer. The 3D printer builds the final object one layer at a time.

A large number of 3D printing techniques is now available, the main differences between them being the way layers are deposited and the materials used. Amongst them, laser-based techniques are very popular, as the laser beam can be focused and directed very accurately.

In this chapter we will detail and compare the most popular laser-based 3D printing techniques. In Sections 3.8.2 and 3.8.3 and we will describe Stereolithography (SLA) and Selective Laser Sintering (SLS), the most industrial of the laser-based 3D printing techniques. In Section 3.8.4 we will concentrate on microscale 3D printing techniques: projection stereolithography (PSL, Section 3.8.4.1) and multiphoton lithography (MPL, Section 3.8.4.2); We will describe extensively the principles and applications of the latter, the most popular and widely used of all microscale 3D printing techniques. Finally, in Section 3.8.5, we will describe how lasers are used to structure the surface of polymers, glasses, semiconductors, and metals.

3.8.2 SLA

SLA is an AM technology for producing 3D objects in a layer-by-layer fashion, by photopolymerizing a photosensitive material with an ultraviolet (UV) laser. The father of SLA is Charles (Chuck) W. Hull; he first coined the term 'stereolithography' and described the apparatus in the 1986 patent "Apparatus for production of three-dimensional objects by stereolithography."[1] There, it is described as "a new and improved system for generating a three-dimensional object by forming successive, adjacent, cross-sectional laminae of that object at the surface of a fluid medium capable of altering its physical state in response to appropriate synergistic stimulation, the successive laminae being automatically integrated as they are formed to define the desired three-dimensional object." It is basically describing a system for making solid objects by successively curing thin layers of a photopolymer using UV light. The patent described a focused UV light beam drawing each layer of the object onto the surface of a vat filled with liquid resin, as shown in **Figure 1**. Also in 1986, C.W. Hull founded 3D Systems Inc.,[2] the first company to develop a commercial SLA system.

In a commercial SLA machine, a focused UV laser beam – nowadays usually the 3rd harmonic of an yttrium aluminum garnet (YAG) laser – is used to photopolymerize an acrylate or epoxy liquid resin.[3] The first (usually sacrificial) layer of the component is built on an elevator platform. At every layer and

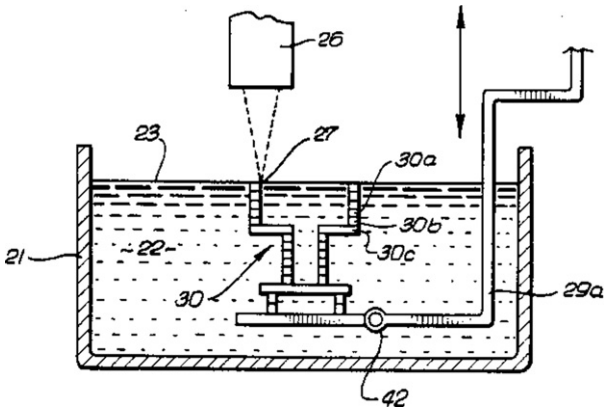

Figure 1 SLA design, as described in the original C.W. Hull patent. Hull, C. W. Apparatus for Production of Three-Dimensional Objects by Stereolithography. U.S. Patent 4,575,330, 1986.

always according to a CAD design, the beam draws a pattern on the surface of the liquid resin, selectively solidifying it and making it adhere to the layer below. After each layer has been 'written,' the elevator platform lowers by a single layer, the built section is re-coated with liquid resin (made flat by employing a re-coating blade), and another layer is 'written.' After the completion of the laser writing, the unexposed photopolymer is removed by immersing the structure in a solvent that dissolves the liquid monomer, and not the polymerized material. To save time, each layer is not fully photopolymerized, but instead the laser traces its exterior, and crosshatches in between. This results in a slice with a honeycomb interior and solid skins on top and bottom, encapsulating liquid resin. After removing the unexposed resin, the 3D object is 'baked' in a UV 'oven,' to solidify the encapsulated liquid resin. Very often the objects made by SLA need to have supporting structures, to avoid deformation due to the piston movement, gravity, and the re-coating blade. These supports need to be removed manually after the completion of the building process.

SLA can produce almost infinitely complex functional prototypes in a time length from a few hours to more than a day. The resolution can be down to 5 μm, while the overall size depends on the type of the machine and the size of the elevator platform. Typically, an SLA machine will be capable of producing components of maximum size $50 \times 50 \times 60\ cm^3$. However, nowadays there are SLA machines, such as the Mammoth,[4] that can produce sizes up to 2 m. On the downside, both photosensitive resins and SLA machines can be very expensive.

The main application of SLA is prototyping; as such, it has been employed by a variety of industries, from medical prototyping to the car industry, where it is routinely used to make polymer prototypes of car engines.

However, the use of SLA models is not limited to prototypes; modern SLA resins provide strong enough models to be machined and make functional synthetic parts, but they are mostly used as master patterns for injection molding and metal casting.

SLA has also been applied in medicine, to fabricate guides for tumor identification and surgery guidance,[5,6] but also for the fabrication of implants and scaffolds for bone and cartilage tissue engineering.[6–10] The materials used in this case can be pure photopolymers, or custom materials such as resins mixed with hydroxyapatite.

3.8.3 SLS

The SLS technique employs a high-power laser to sinter layers of material in powder form, in order to build 3D structures. A typical experimental setup is shown in **Figure 2**. A layer of powder is first deposited on a fabrication piston substrate. The laser beam is scanned over the powder surface following a CAD design. The laser beam heats the powder to melting point and causes the powder particles to melt together to form a solid mass. Subsequent layers are built directly on top of the earlier layers, with new layers of powder deposited on the top of the already sintered layers using a roller.

The materials used for building components in SLS machines can be single component powders (such as metal powders produced by ball milling) or, more commonly two-component powders, coated powders or powder mixtures. Compared to other 3D laser printing techniques, SLS can build components from a wide variety of materials. These can be polymers such as nylon and nylon-coated metal particles,[11–17] polystyrene,[15,18–26] metals such as titanium,[27–35] steel,[36–44] alloys,[32,45–49] and several biomaterials such as hydroxyapatite, polycaprolactone, polylactide, and mixtures of those with other biopolymers.[50–77] Depending on the material, up to 100% density can be achieved with material properties comparable to those from conventional milling methods.

Due to its material versatility and its potential to make very complex geometries directly from computer models, SLS is widely used nowadays. While its original use was in prototyping, it is now used also in custom or limited-run manufacturing to produce end-use parts. One such area is dental implants **Figure 3**[34] and scaffolds for hard and soft tissue engineering. SLS has been extensively used to create hard scaffolds for bone and cartilage tissue engineering,[62,78,79] often employing mixtures of poly-*e*-caprolactone with calcium phosphates as a scaffold material.[80] In soft tissue engineering its use has been more limited; it has been used to melt together poly-*e*-caprolactone layers for cardiac regeneration[81,82]; biodegradable polycaprolactone was also structured in order to grow avidin–biotin human hepatoma Hep G2 cells, for liver tissue engineering. SLS has also been used to make replication masters for biomedical implants.[83]

3.8.4 Microscale 3D Printing Techniques

Progress in technologies such as MEMS and microfluidics has increased the requirement for 3D printing technologies with micro and nano features resolution, using diverse materials, such as ceramics and polymers. In the following paragraphs we describe two laser-based 3D microfabrication techniques: Projection micro-steleolithography and multiphoton lithography.

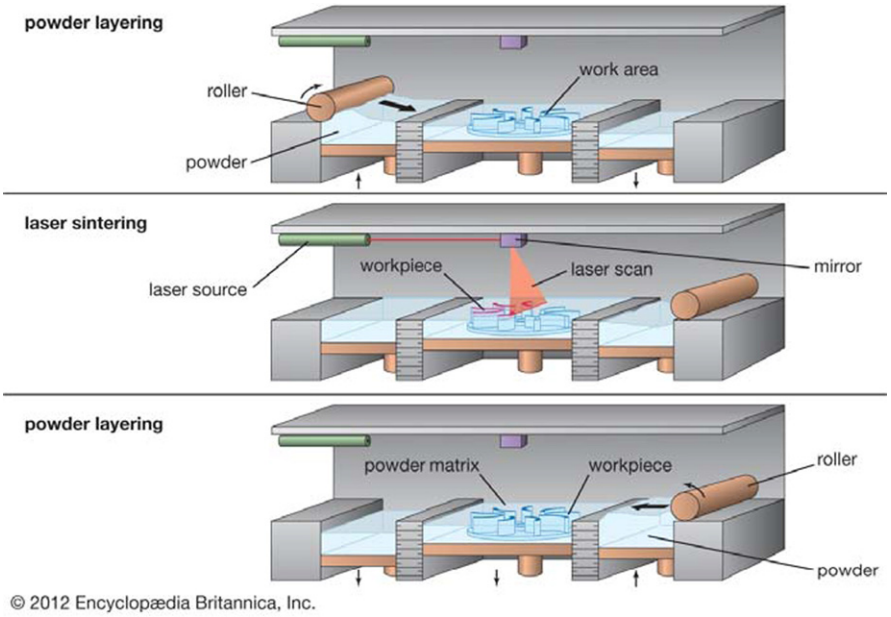

Figure 2 The SLS process, showing (top) the rolling of a thin layer of powder over the work area, (middle) the sintering of powder by a laser beam to build up the workpiece, and (bottom) the rolling of fresh powder over the workpiece to begin a new layer (http://www.britannica.com/technology/3D-printing/images-videos – Encyclopedia Britannica).

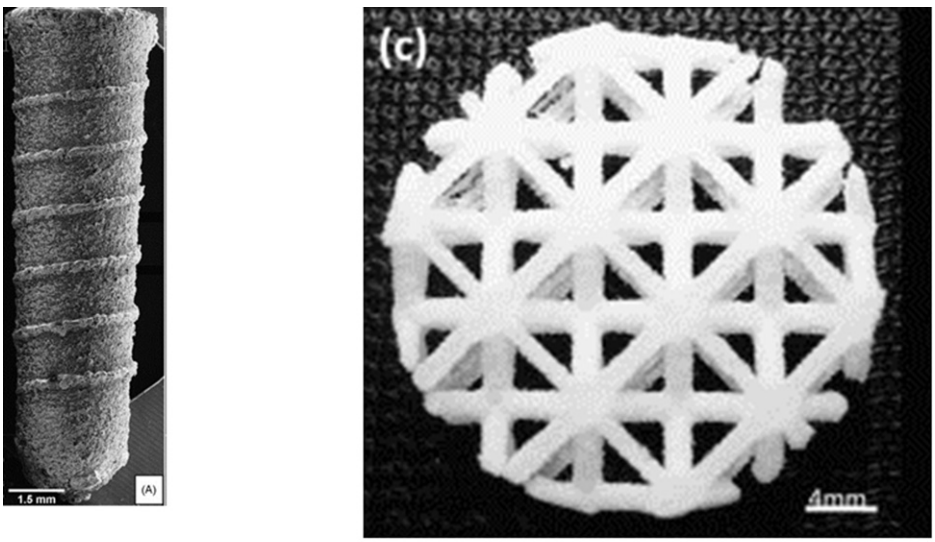

Figure 3 (a) A dental implant made using SLS[34] and (b) poly-*e*-caprolactone scaffolds made using SLS for cardiac regeneration.[82]

3.8.4.1 Projection Micro-Stereolithography

In Section 3.8.2 we described SLA as a technique for fabricating large-scale components and prototypes. The same technique was miniaturized to produce micron scale components,[84] and is now called micro-stereolithography (μSLA). The procedure is exactly the same as in classic SLA, except the beam is focused very tightly, to enable high resolution.

While μSLA worked well, it never became popular for mass production as it was very slow. To overcome this problem, Alain Bertsch and co-workers proposed a new system based on a dynamic mask pattern being projected on the liquid resin surface, therefore photopolymerizing each layer of the pattern in one shot.[85,86] The experimental setup is shown in **Figure 4**. There, the beam of a green laser (515 nm) was modulated by a liquid crystal display (LCD), to project an image on a platform

immersed into the photosensitive resin. As each component layer is made using a single light exposure, the only moving part in the system is the *z*-axis of the component platform.

As the Bertsch system was designed to operate with green light (a wavelength of transparency of the LCD display), it could not use any of the commercially available photosensitive resins designed for classic SLA. This was accomplished by the Chatwin group (Sussex University, UK), who replaced the LCD with a custom-made spatial light modulator (SLM), transparent to the UV.[87–89] Several materials composed for SLA and high-resolution structures were made using this technique (**Figure 5**).[87–90]

Replacing LCDs with SLMs solved the material availability problem but generated others: the low switching speed and low optical density of the refractive elements of the SLM during the *OFF* mode reduce the contrast of the transmitted pattern. In addition, the SLM UV transparency is limited, resulting in energy wastage and overheating (therefore limited lifetime) of the device itself.

At the same time as the Chatwin team developed SLM-based μSLA, digital micromirror devices (DMDs) became available by Texas Instruments.[91] DMD is a reflective array of fast, digital light switches that are monolithically integrated onto a silicon address chip. Used as a projection system, a DMD replaced the SLM in a system implemented by Sun *et al.*,[92] providing high-quality, seamless, all-digital images with exceptional stability and minimal power loss. The quality and resolution of the structures fabricated using this technique was superior to anything presented before (**Figure 6**).

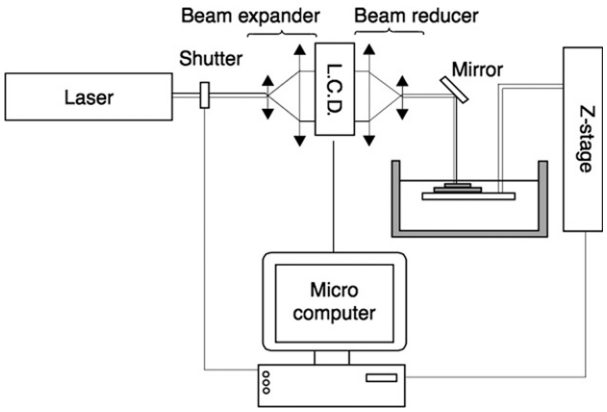

Figure 4 The first projection μSLA set-up using an liquid crystal display as a dynamic mask.[85,86]

The application of DMDs in μSLA is still fairly limited, and most research has focused on improving the process rather than developing applications.[93–96] Again, however, the main area of research applications has been developing microenvironments for cell growth.[97–100]

3.8.4.2 Multiphoton Lithography

Multiphoton Lithography based on the Multiphoton Polymerization of photosensitive materials is a direct laser writing technique that allows the fabrication of three-dimensional structures with submicron resolution.[101–105] The polymerization is based on two-photon absorption (TPA); when the beam of an ultrafast laser is tightly focused into the volume of a transparent, photosensitive material, the polymerization process can be initiated by nonlinear absorption within the focal volume. By moving the laser focus three-dimensionally through the material, 3D structures can be fabricated. The technique has been implemented with a variety of acrylate and epoxy materials and several components and devices have been fabricated such as photonic crystal templates,[106] mechanical devices,[107] and microscopic models.[108] Resolution below 100 nm has been achieved using this technique.[109]

The unique capability of MPL lies in that it allows the fabrication of computer-designed fully 3D structures with resolution beyond the diffraction limit. No other competing technology offers these advantages. Classic 3D prototyping techniques such as UV laser SLA, 3D inkjet printing, and laser sintering can also produce fully three-dimensional structures; however, they cannot provide resolution better than a few microns. On the other hand, lithographic techniques with superior resolution, such as e-beam lithography, cannot produce anything more complicated than high-aspect ratio two-dimensional structures.

In this section we summarize the principles of microfabrication by MPL. We discuss the fundamental principles of multiphoton absorption (MPA) and describe a typical MPL experimental setup. Then we concentrate on materials used for MPL microfabrication, on recent progress in the functionalization of the surface and the bulk of the 3D-fabricated structures, while at the same time discussing applications of the technology.

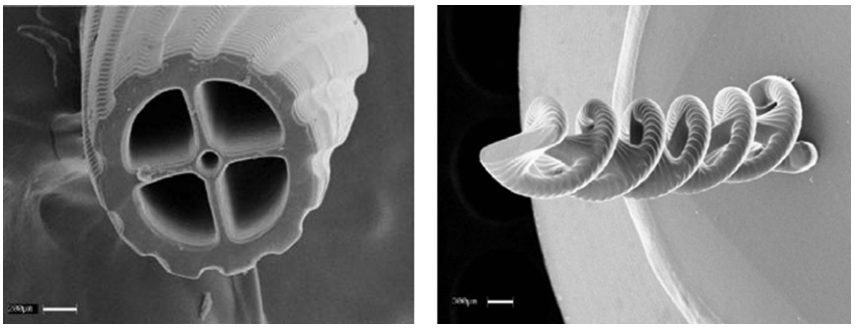

Figure 5 3D structures fabricated using an spatial light modulator as a dynamic mask.[89]

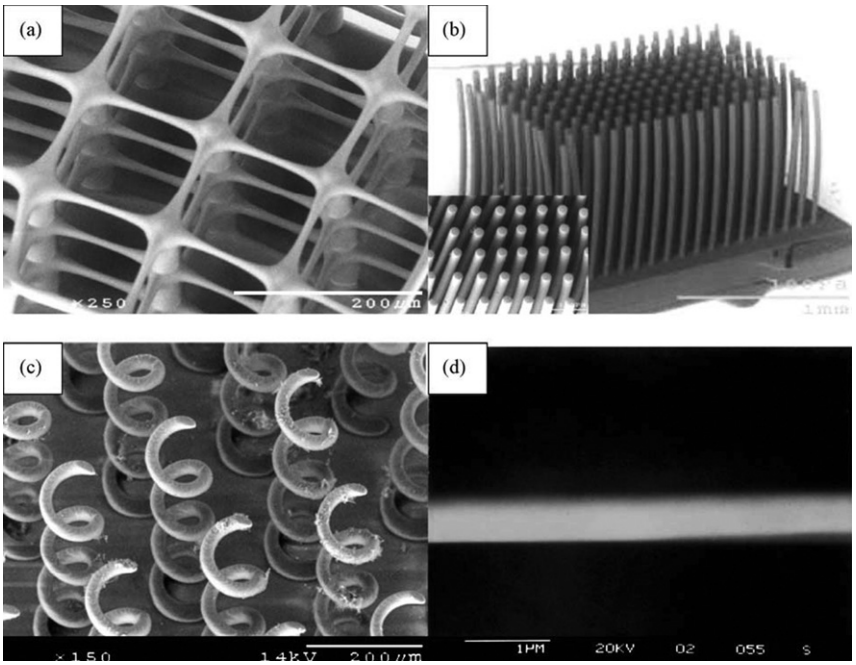

Figure 6 3D complex microstructures fabricated employing a DMD as a dynamic mask. (a) Micro matrix with suspended beam diameter of 5 μm; (b) high aspect-ratio micro rod array consists of 21 × 11 rods with the overall size of 2 mm × 1 mm. The rod diameter and height is of 30 μm and 1 mm, respectively; (c) micro coil array with the coil diameter of 100 m and the wire diameter of 25 μm; and (d) suspended ultra fine line with the diameter of 0.6 μm.[92]

3.8.4.2.1 Multiphoton polymerization

The basis of MPL is the phenomenon of MPA. For simplicity, we will discuss TPA and two-photon polymerization (TPP) – the same rules apply to more than two photons.

There are two types of TPA: sequential and simultaneous. In sequential, the absorbing species is excited to a real intermediate state, then, a second photon is absorbed. The presence of the intermediate energy state implies that the material absorbs at this specific wavelength; it will therefore be a surface effect and will follow the Beer–Lambert law.[3] The simultaneous absorption, on which the MPL technique is based, was originally predicted by Maria Göppert-Mayer in 1931 in her doctoral dissertation.[110] It is defined as "an absorption event caused by the collective action of two or more photons, all of which must be present simultaneously to impart enough energy to drive a transition." This prediction was not experimentally verified until over 30 years later by Werner Kaiser, when the invention of the laser permitted the first experimental verification of the TPA through the two-photon excited fluorescence detection in a europium-doped crystal.[111] In simultaneous absorption, there is no real intermediate energy state, i.e., the material is transparent at that wavelength. Instead, there is a virtual intermediate energy state and TPA happens only if another photon arrives within the virtual state lifetime.[112] For this to occur high intensities are required, which can only be provided by a tightly focused femtosecond (fs) laser beam. This is illustrated in Figure 7; as it can be seen, the electron transition in this case is caused by two photons of energy $h\nu/2$ rather than one of energy $h\nu$.

Ti:Sapphire and near-infrared lasers are widely used for this purpose. They have two main advantages; firstly they have very

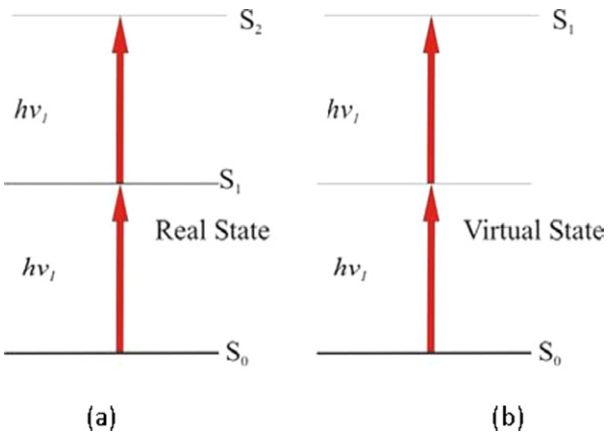

Figure 7 Sequential (a) and simultaneous absorption (b). In the first case the intermediate energy level is an actual energy level, while in the second case it is virtual.

short pulses, in the order of a few tens of femtoseconds, so they do not cause thermal damage. Secondly, their standard wavelength is 780–820 nm, which is twice the wavelength of polymerization of a wide range of photopolymers. In addition, most photopolymers are transparent at around 800 nm, which allows in-volume focusing of the laser beam with minimal scattering.

When the laser is focused tightly into the material, the photoinitiator used to initiate the polymerization will absorb two or more photons and produce radicals. As the material response is proportional to the square of the intensity, this will only happen at the focal point, which, combined with the fact

that the two-photon transition rate is very small, will provide very high-spatial resolution.

Photopolymerization is a light-induced reaction, which converts a liquid or gel monomer into a solid polymer. These reactions require the use of an appropriate photoinitiator, which is a light sensitive molecule that produces an active species upon irradiation with UV, visible, or infrared light. The photoinitiators that have been most extensively used so far are divided into two main categories depending on the nature of generated active species (radicals or cations). An effective initiator has a high-quantum yield in the generation of the active moieties, high-thermal stability and stability in darkness, and is highly soluble in the polymerization medium.

Free-radical polymerizations are chain reactions in which the addition of a monomer molecule to an active chain-end regenerates the active site at the chain-end.

The free-radical photopolymerization mechanism involves at least three different kinds of reactions (Eqn [1a]–[1b]):[113–115]

- The first step is the initiation during which the free-radical initiator is decomposed with light in the presence of monomer to form an active species (Step 1a).
- In the next step, known as the propagation, the initiator fragment reacts with a monomer molecule to form the first active adduct that is capable of being polymerized. Monomers continue to add in the same manner resulting in the formation of macroradicals which are end-active polymers (Step 1b).
- The final step is the termination during which the growth center is deactivated and the final polymer molecules are formed. This step normally involves the reaction between two polymers bearing active centers and can proceed by two different mechanisms, combination or disproportionation, leading to the formation of one or two polymers chains, respectively (Step 1c).

Equations [1a]–[1b] show the TPP process

$$\text{Initiation} \quad I \xrightarrow{h\nu,\, h\nu} I^{*} \longrightarrow R^{\bullet} \qquad [1a]$$

$$\text{Propagation} \quad R^{\bullet} + M \longrightarrow RM^{\bullet} \xrightarrow{M} RMM\cdots \longrightarrow RM_n^{\bullet} \qquad [1b]$$

$$\text{Termination} \quad RM_n^{\bullet} + RM_m^{\bullet} \longrightarrow RM_{n+m}R \qquad [1c]$$

Besides the above, other reactions, such as chain transfer and chain inhibition, often take place and complicate the mechanism of free-radical polymerization.

Photopolymerizations follow the general scheme for any polymerization, however, the use of light, rather than heat, to drive the reaction has certain advantages, such as the elimination of solvent, the high-reaction rates at room temperature, and the spatial control of the polymerization.

3.8.4.2.2 The diffraction limit

Theoretically, the highest resolution that can be achieved by a focused laser beam is given by Abbe's diffraction limit (eqn [2]).[116]

$$\text{Diffraction limit} = \frac{0.5\lambda}{\text{N.A.}} \qquad [2]$$

where λ is the laser wavelength and N.A. is the numerical aperture of the focusing objective; this has fueled the race for ever decreasing wavelengths, such as electron wavelengths and for alternative, non-light patterning techniques such as atomic force microscopy[117–121] and near-field scanning optical microscopy,[122–124] however, these techniques only allow surface and not in-volume patterning. To produce 3D structures with in-volume patterning, and produce photopolymerized voxels smaller than that defined by the diffraction limit, materials with well-defined photopolymerization threshold need to be used.

As the photoinitiator is excited by the laser process, it produces radicals; these radicals are quenched by oxygen and other quenchers in the system. Quenching is a competing effect to photopolymerization and is usually considered detrimental to the process. In MPL, however, it can be used to circumvent the diffraction limit and produce structures of very high resolution. This can be done by modifying the light intensity at the focal volume, in a manner so that the light-produced radicals exceed the quenchers and initiate polymerization only at a region where exposure energy is larger than the threshold. In this case the diffraction limit becomes just a measure of the focal spot size and it does not really determine the voxel size.

3.8.4.2.3 Experimental set-up

A typical experimental setup for the fabrication of three-dimensional microstructures by MPL is shown in **Figure 8**. The laser source typically is a Ti:Sapphire femtosecond oscillator operating at 800 nm; there are also examples in literature where an Optical Parametric Oscillator is used with a Ti:Sapphire laser, to reduce the laser wavelength to visible wavelengths.[109,125] The laser will typically have a pulse length of less than 200 fs and a repetition rate of 50–80 MHz. The energy required for the polymerization process will depend on the material, the photoinitiator and the focusing, but is usually in the order of a few nanojoules per pulse.

The photopolymerized structure is usually generated in a layer-by-layer format. Each layer is formed either using an x–y galvanometric mirror scanner or x–y piezoelectric stages. The main difference between the two cases being that in the former case, the structure remains immobile and the structure is generated by the laser beam moving, while in the latter case the x–y stages move the structure and the laser beam remains immobile. Movement on the z-axis can be achieved using a piezoelectric or a high resolution linear stage.

To achieve the tight focusing conditions required for TPP to occur, a microscope objective needs to be used; when the numerical aperture of the objective is higher than 1, immersion oil is used for index matching. Galvo scanners have to be adapted to accommodate microscope objectives, as usually they are designed to take lenses with long focal lengths.

Beam control can be achieved by either using a fast mechanical shutter or an acousto-optic modulator, while beam intensity control can be achieved using neutral-density filters, a variable attenuator, or a combination of a polarizer and a waveplate.

For the online monitoring of the photopolymerization process a charge-coupled device camera can be mounted behind a dichroic mirror, as shown in **Figure 8**. This is possible

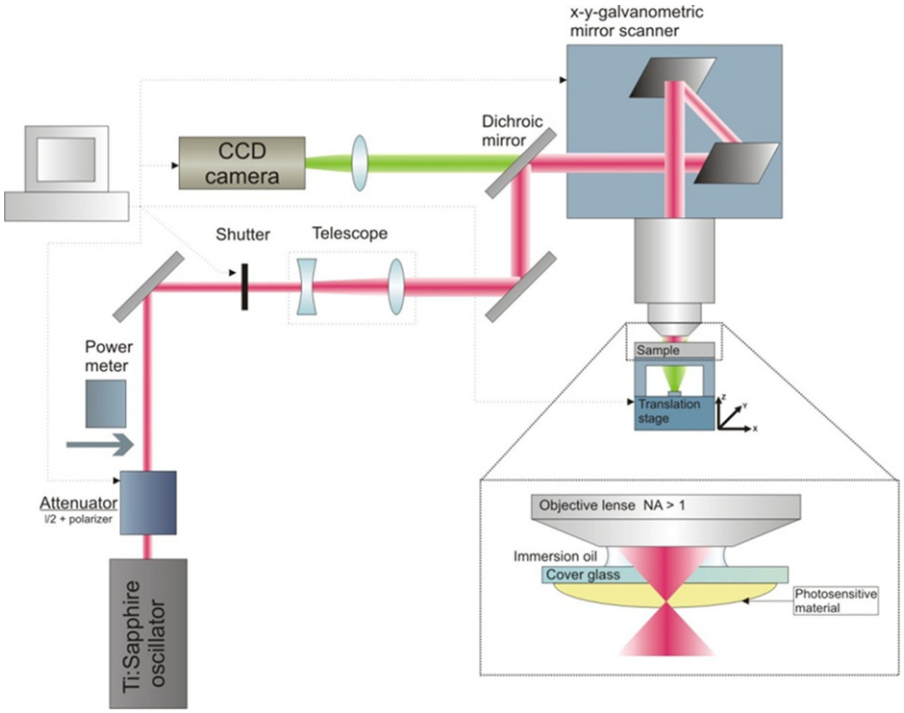

Figure 8 A typical setup for multiphoton polymerization, consisting of a fs laser, a galvanometric mirror scanner, moving stages, directional and focusing optics, and a monitoring camera.

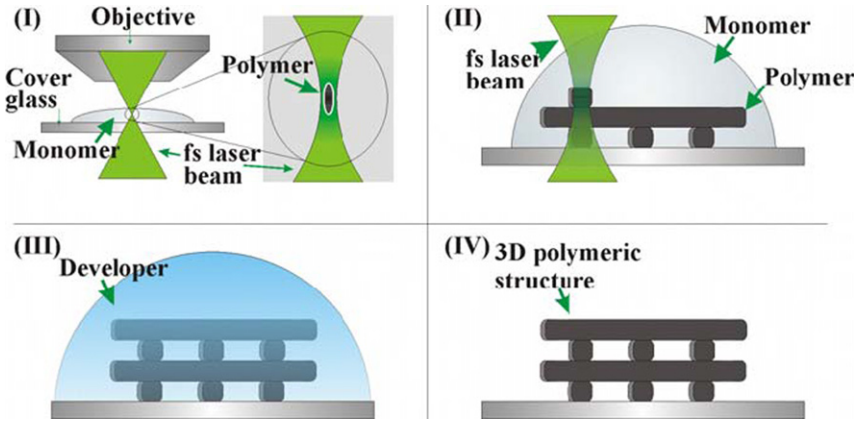

Figure 9 MPL experimental procedure (I) beam focusing, (II) laser writing, (III) development, and (IV) completed structure.

as the refractive index of most photopolymers changes during polymerization, so that the illuminated structures become visible during the building process.

When the photosensitive polymer is in a liquid form, in order to avoid liquid movement as the samples moves, the samples are prepared in a sandwich format between two thin glass coverslips; a spacer needs to be used to maintain sample uniformity. When the sample is a solid or a gel, then there is no need for the sandwich format. To avoid the distortion of the focused laser beam by the built structures, they are fabricated layer-by-layer bottom up with the last layer attached to the glass coverslip.

After the completion of the photopolymerization process and in order to remove the unphotopolymerized resin, the samples need to be developed like in any lithographic process. The developer used and the time for development will depend on the material.

The experimental procedure for fabricating a 3D structure by MPL is shown in Figure 9: (1) The laser beam is tightly focused into the volume of the material. (2) Either the focused beam or the sample move following a computer-generated pattern. (3) After the laser writing of the structure, the sample is immersed into an appropriate developer. (4) The freestanding structure is revealed.

3.8.4.3 Materials for Laser Polymerization

3.8.4.3.1 Introduction

In general, a material suitable for structuring with MPL includes at least two components: (1) a monomer, or a mixture of monomers/oligomers, which will provide the final polymer and (2) a photoinitiator, which will absorb the laser light and provide the active species that will cause this polymerization. Several monomer/oligomer and photoinitiator combinations have been used for this purpose. These are mostly negative photoresists such as hydrogels, acrylate materials,[126,127] the epoxy-based photoresist SU-8,[102] and hybrid materials.[103,128] Recently, redox and Diels–Alder photopolymerization have been also been reported.[129,130] In the following sections, we will discuss briefly these photoinitiators and materials.

3.8.4.3.2 Photoinitiators

During polymerization, a monomer is converted into polymer and this transformation can be induced by light. In classic photolithography, a photoinitiator absorbs the light and produces an active species which causes the photopolymerization. In TPP, however, things are more complicated, and these extra requirements must be fulfilled:[101,126]

- Both the photoinitiator and the monomer/oligomer are transparent at the laser wavelength used, so that the laser beam can be focused inside the volume of the material without being absorbed at the surface.
- The monomer/oligomer needs to be transparent at the TPA wavelength ($\lambda/2$); if it is not, then the photopolymer is likely to be burnt or ablated.
- The photoinitiator needs not only to absorb at the two-photon wavelength, but also to have a high two-photon cross-section, a high radical quantum yield and highly-active radical species generated; typically, if any two of these three are large enough, the initiator will normally be efficient for TPP.

In classic lithography, there are two types of photoinitiators: radical photoinitiators and cationic photoinitators. All the materials developed to date for MPL employ radical photoinitiators; these, upon light irradiation, generate free radicals, which initiate a polymerization process of acrylates or vinyl ethers. Cationic initiators are photo-acid generators that produce cations upon light irradiation and are used for the polymerization of epoxides or vinyl ethers;[113–115] to the best of our knowledge, there are no materials to date, specifically developed for MPL employing cationic polymerization, however, it is employed in the most commonly used photolithography resist, SU-8.

An effective MPL photoinitiator has a high quantum yield in the generation of the active moieties, high thermal stability and stability in darkness, and is highly soluble in the polymerization medium.[131] The most commonly used free-radical photoinitiator is benzophenone and its derivatives.[132,133]

Nowadays, there is a lot of concentrated effort to synthesize fast and efficient photoinitiators specifically for multiphoton applications.[134] In addition, there is a lot of work toward biocompatible photoinitiators, specifically for bio-applications. To this end, classic dyes such as Bengal Rose, Eosin, Nile Red, biomolecules such as flavin mononucleotide, but also novel, synthetic photoinitiators have been used.[127,131,135–141]

3.8.4.3.3 Organic photopolymers

The first materials used for MPL were acrylate photopolymers[142] (Figure 10). These materials have several properties which make them attractive for MPL applications: a wide variety of the full composites or their monomers are commercially available; they are transparent at visible and near-infrared wavelengths, and can therefore be processed by IR and green ultrafast lasers; they can be developed in common, nonaggressive solvents such as isopropanol; they can be polymerized fast and with low shrinkage and, after polymerization, they are mechanically and chemically stable.

Due to their versatile chemistry, acrylate photopolymers have been used in their pure form but also doped with other materials to add them functionality. They have been doped with TiO_2 nanoparticles to increase their refractive index for photonic crystal applications;[143] with CdS nanoparticles for the fabrication of light-emitting 3D structures (Figure 11);[144,145] with metal-binding materials to cover them with metals

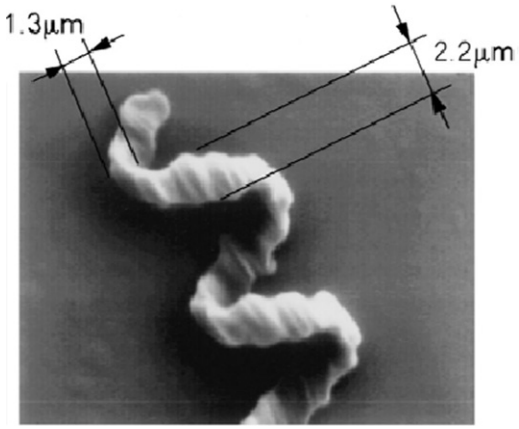

Figure 10 The first 3D structure fabricated by MPL.[142]

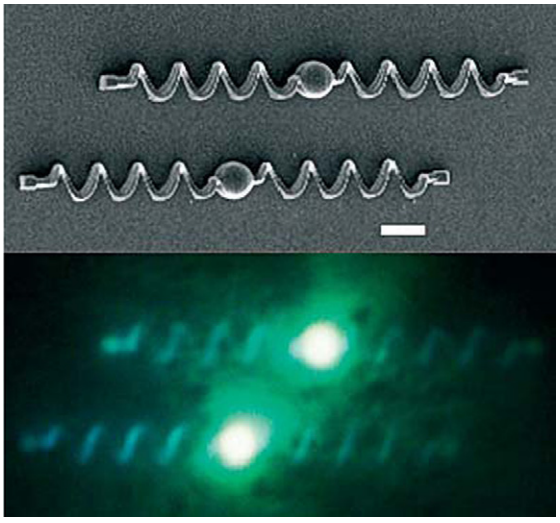

Figure 11 A 3D light-emitting structure.[144]

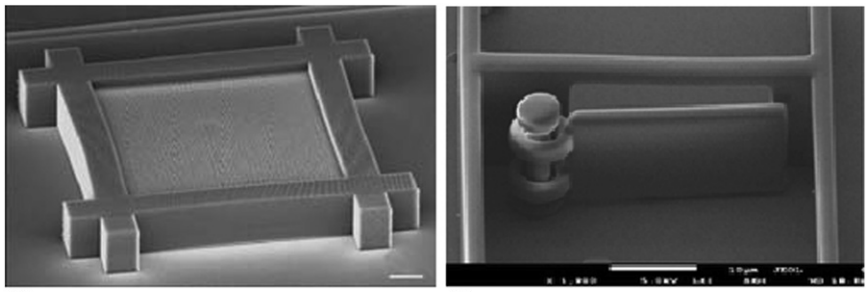

Figure 12 Microstructures fabricated using SU-8. (a) A photonic woodpile structure[108] and (b) A movable microfluidic structure.[158]

using electroless plating;[146,147] with chitosan to make them suitable for bio-applications;[148] with Poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV) to make them electroluminescent.[149]

3.8.4.3.3.1 SU-8

SU-8 is a negative, epoxy-based photo-resist commonly used for the fabrication of high-aspect ratio structures, using standard contact lithography. Its absorption maximum is at 365 nm. When exposed to the appropriate light, SU-8's long molecular chains cross-link, causing the material to become insoluble to most common solvents. For this to happen, the SU-8 films require postexposure heat treatment.

The possibility to structure SU-8 by MPL polymerization was first demonstrated by Witzgall *et al.*, who employed single shots from Ti:Sapphire femtosecond amplifier to fabricate small dots.[150] More complex 2D and 3D structures were built by Belfield *et al.* and Kuebler *et al.*, respectively, who worked on the development of novel, efficient photoinitiators for cationic polymerization.[151,152] Since then, SU-8 has been used by a large of the research teams involved in MPL fabrication have used SU-8.[153–157]

SU-8 is thermally stable, transparent in the visible and highly resistant to solvents, acids, and bases. These properties make it suitable for permanent use application; by itself, SU-8 has been employed for the fabrication of photonic (**Figure 12(a)**),[108] microfluidic (**Figure 12(b)**),[158–160] and biomedical structures,[161] while it has also been covered with metal for metamaterial fabrication.

3.8.4.3.3.2 Hybrid materials

Over the last few years, MPL materials research has focused on the development of photosensitive hybrid composites. Especially silicate-only based photopolymers have proved to be a very popular choice, as they can be commercially available and they combine properties of silicate glasses such as hardness, chemical and thermal stability, and optical transparency with the laser processing at low temperatures of organic polymers; properties impossible to achieve with just inorganic or polymeric materials.[125,162–178] The most widely used and studied silicate material is the photopolymer ORMOCER®, commercially available from Microresist Technologies, Germany, and it has been used for a variety of mostly photonic applications, like the optically active polymer microdisk of **Figure 13**.

ORMOCER® and other silicate-only based hybrid materials have provided the possibility to fabricate high-resolution

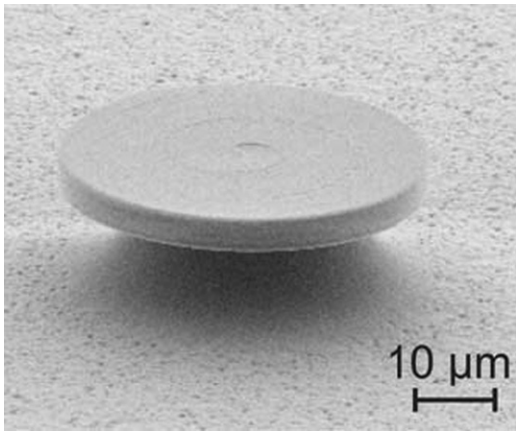

Figure 13 A microdisk fabricated using ORMOCER®.[173]

3D structures. They do not allow, however, the optimization and 'fine-tuning' of the materials properties for specific applications. The versatile chemistry of hybrid composites allows the copolymerization of more than one metal alkoxides; this has been shown to enhance the material's mechanical stability and allows the modification of its optical properties. There are a few examples of composite photosensitive hybrid materials used in MPL applications;[103,133,179,180] Ovsianikov *et al.* showed that under specific fluence conditions, specific material combinations can be structured into complex 3D structures without shrinkage.[181,182] In addition to metal alkoxides, hybrid materials chemistry provides the possibility of the inclusion of functional groups, such as nonlinear optical molecules,[183,184] quantum dots,[185] and metal-binding materials.[186] Zirconium silicates doped with a monomer containing amine moieties were used for the fabrication, for the first time using MPL, of 3D structures selectively metalized with silver (**Figure 14**).[187,188]

3.8.4.4 Applications

3.8.4.4.1 Metamaterials

Metamaterials are artificial materials with properties that do not exist in nature; these properties are due to structure and not material composition. Their name derives from the greek word 'meta,' which means beyond, because these materials have properties that extend beyond materials found naturally. In metamaterials, an assembly of structures can replace the role that atoms and molecules have in conventional materials, resulting in a composite structure with electromagnetic properties beyond

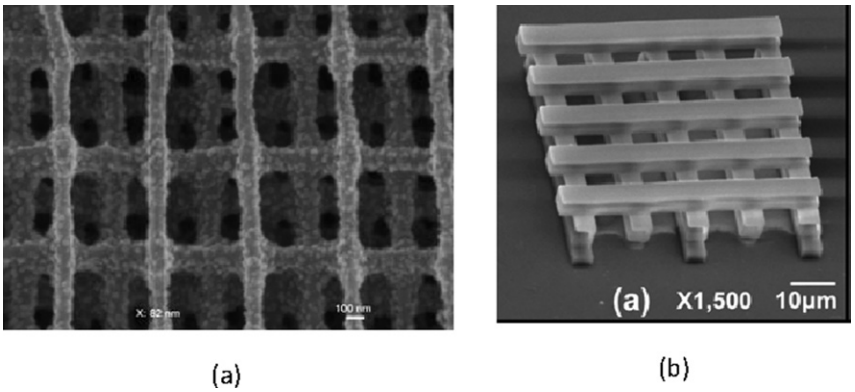

Figure 14 (a) A three-dimensional photonic crystal with sub-100 nm features[187] and (b) an IR polarizer.[188]

anything that can be found naturally, or chemically synthesized. An excellent tutorial on metamaterials can be found in the website of Prof. David R. Smith (Duke University).[189]

Photonic metamaterials consist of nanostructured metalo-dielectric subwavelength building components, and allow the realization of many new and unusual optical properties, such as negative refractive index, magnetism at optical frequencies, perfect absorption, and enhanced optical nonlinearities. Several applications of metamaterials have been proposed, including ultrahigh-resolution imaging systems, compact polarization optics, and cloaking devices.[190] The realization of these applications requires the fabrication of large-scale metallo-dielectric structures, a very challenging task. There has been some limited research into the direct fabrication of metallic 3D structures using multiphoton reduction of metal ions. The quality of the structures, however, has been compromised by the reduced transparency of the metal ion solutions at the laser wavelengths used (500–800 nm).[191,192] Metallic woodpile structures have also been realized experimentally at micron wavelengths using traditional lithographic techniques.[193–195] However, lithographic techniques can accommodate only a very limited number of layers, and aligning each layer with the previous one is difficult.

MPL is the only inherently 3D fabrication technique, with the potential to fabricate 3D structures, but the majority of the materials structurable by MPL are dielectrics. A popular approach is to use MPL to make dielectric structures, and subsequently metallize them. The most successful approaches and their advantages and disadvantages are listed in below:

1. MPL of positive photoresists and filling with gold using electroplating.[196,197] Here, voids are created in a positive tone photoresist using MPL; these are subsequently filled with gold using classic electroplating (**Figure 15**). The main advantage of this technique is that there is no need to remove the photoresist as the refractive index contrast between the gold and the dielectric material is very high. The main disadvantage is that the number of designs that can be structured is limited, as the right apertures of the material removal and gold filling have to be allowed; therefore, this is fundamentally a 2.5D structuring technique.
2. MPL of dielectric structures and nonselective metallization with electroless plating. Here, a standard photolithographic material is used, such as SU-8, for the fabrication of the structures, and subsequently their surface is covered with silver using classic electroless plating.[198–201] Additional processing, to enable the metal adhesion on the surface, is required and the quality, structural integrity, and resolution of the structures depend on the building material and the surface-processing step. The advantage of this technique is that any photopolymer can be used; the disadvantages are that, as the density of the metal-binding sites on the structure cannot be controlled, the metallization quality can vary. In addition, along with the surface of the structures, the substrate is also activated; the metallization is therefore not selective, often requiring an extra step to remove the structures from the metalized substrate.[199]
3. MPL of dielectric structures and selective metallization with electroless plating. Here, a composite doped with the metal-binding sites is employed for the structure fabrication.[147,186,187] The main advantages in this case are that the metallization is selective, and the density and distribution

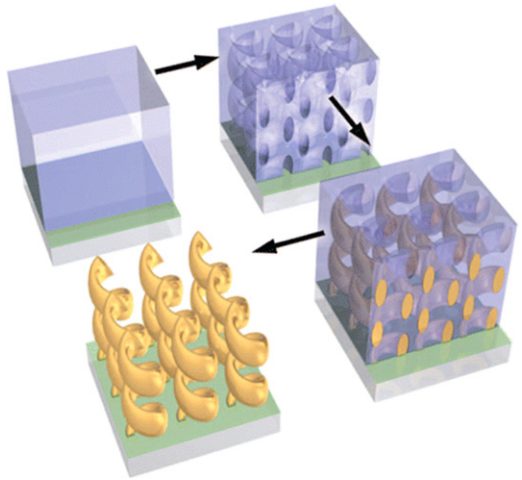

Figure 15 MPL of positive photoresists and filling with gold using electroplating. A positive photoresist is spun onto a glass substrate covered with a 25-nm thin film of conductive indium-tin oxide (ITO) shown in green. After MPL and development, an array of air helices in a block of polymer is fabricated. After electroplating the polymer is removed by plasma etching, leading to an array of freestanding 3D gold helices.[197]

of the metal-binding sites can be controlled. The main disadvantages are that specific metal-binding materials need to be used, and in most cases these were not able to provide the required resolution and structural integrity required for optical metamaterials. Only very recently it was shown that it is possible to use this method for the fabrication of optical nanophotonic devices.[187]

4. MPL of dielectric structures and metallization with chemical vapor deposition (CVD). Here MPL is used to fabricate 3D structures by any material, typically SU-8.[202] The surface of the structures is subsequently activated using plasma etch. Finally, they are covered with silver using CVD. The main advantage of this technique is that any photopolymer can be used, and the resolution and final quality of the structures will depend on that. The main disadvantages are firstly, CVD can only penetrate a small number of structure layers, allowing only a small number of unit cells, and secondly, there is no selectivity; as with the plasma etch, the substrate is activated as well as the structure.

It should also be noted that, recently, there has been reported some work concerning structuring by MPL of transparent conducting materials, such as ionogels.[203,204] However, neither the conductivity nor the resolution of these materials are sufficient for applications in optical metamaterials.

3.8.4.4.2 Biomedical applications

The biomedical applications of MPL can be broadly divided into two categories: biomedical microdevices and scaffolds for cell culture.

The first category, biomedical microdevices, includes devices such as micro-needles for drug delivery, and micromechanic, microfluidic, or optofluidic functional devices.[205,206] Despite the enormous potential of 3D nanostructuring in this field, there are only few examples to date, mostly because there has not been much research into the integration of MPL-made structure into existing micromechanical systems. Only recently, Amato *et al.* employed MPL to build a cell sorter inside a commercial microfluidic chip.[207,208] Most other structures reported are freestanding and have not been integrated into a functional device.[209–216] Special mention should be made to some recent research introducing magnetic materials into the photopolymerizable resin, making possible the contact-free controlled movement to the fabricated devices.[217,218]

The second category, MPL scaffolds for cell culture studies and tissue engineering, has seen an enormous growth over the last few years (Figures 16 and 17). Tissue engineering is the discipline applying the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function or a whole organ.[219] An important part of the development of artificial tissue is the choice of scaffold, as it can influence the attachment, migration, and proliferation of cells. 3D cell cultures offer a realistic environment where the functional properties of cells can be observed and manipulated.[220–222] Although producing scaffolds using laser-based, user controlled manufacturing techniques such as MPL or classic SLA is time consuming and therefore costly, recent studies have shown that they can provide tissue engineering solutions for aligned and complex tissue growth. An important advantage is that a controlled topological environment for cell growth can be achieved (Figure 18). In addition, ordered 3D scaffolds are ideally suited for exploring the relationship between 3D topology and cell proliferation. The possibility to manipulate particles in an aqueous solution in order to produce composite material scaffolds with different biological properties selectively localized in space is another advantage of MPL.[223]

Recent reviews by Raimondi *et al.*,[224] Ovsianikov *et al.*,[225] and Selimis *et al.*[104] describe in great detail the use of lasers in tissue engineering applications. In this field, most groups have used permanent scaffolds for hard tissue engineering or investigating cell (including stem cell) growth.[148,161,226–237] More recently, there has been a lot of active research into

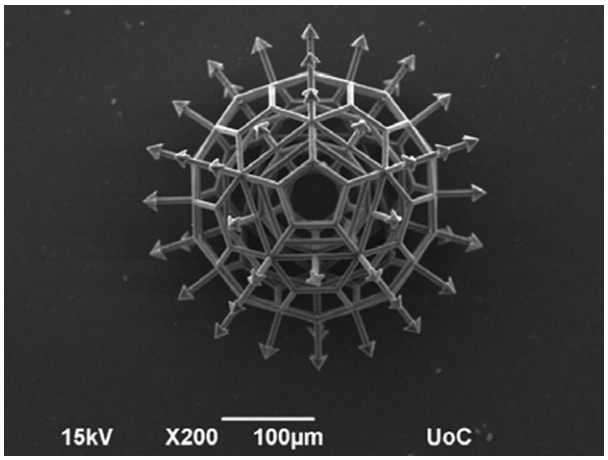

Figure 17 A freestanding micro-scaffold.[227]

the synthesis of new, biocompatible and biodegradable materials.[132,238,239]

3.8.5 Laser-Based Surface Texturing Techniques

In general, the assortment of the laser materials processing comprises cutting, drilling, welding, surface hardening, alloying, cladding, rapid prototyping, laser-assisted forming, ablation, and shot peening. In our days, the available laser units can deliver beam with wavelength ranging from the UV to the infrared (IR) spectral region owning continuous or pulsed power density – the laser power may extend from low values (~mW) to extremely high ones as 1–100 W – exhibiting not only both spatial and temporal coherence but low divergence as well.[240,241] Upon the laser materials processing, a portion of an either pulsed or continuous wave laser beam – which incidents on the material surface – is absorbed, while the greater one is reflected. The absorbed photon energy may lead to excitation of valence and/or conduction band electrons, excited electron–phonon interaction within 10^{-11}–10^{-12} s, electron–electron or electron–plasma interaction and electron–hole recombination in a 10^{-9}–10^{-10} s timescale.[242,243] That is to say, extreme heating and cooling rates (typically 10^{3}–10^{10} K s^{-1}) are achieved within the laser-treated region and, most importantly, besides the high total deposited energy density (10^{3}–10^{4} J cm^{-2}), the bulk material temperature is not significantly affected[242,244,245] allowing, thus, the high controlled and precise processing of the material. In any case, toward the achievement of the desired and effective degree of heating and phase transition for the laser surface-processing gamut, the amount of the deposited laser energy density as well as the laser pulse duration should accordingly be picked out. The laser surface processing can be accomplished, *grosso modo*, either without melting (hardening, bending) requiring low power density, with melting (cladding, welding, cutting) necessitating high power density, or, with vaporization (cutting, drilling, ablation) calling for significantly high power density being deposited at ultrashort pulse duration.

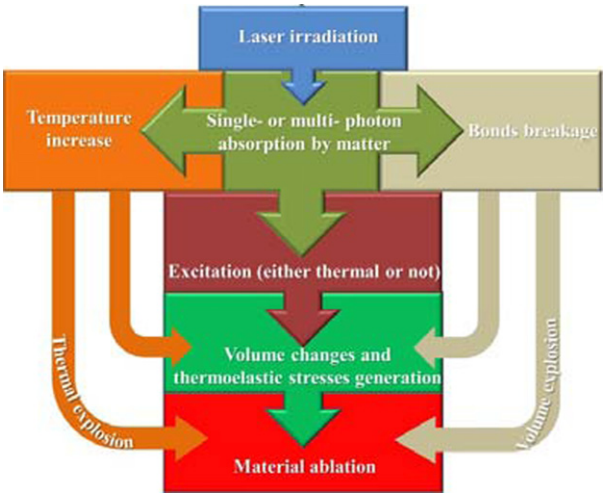

Figure 19 Spectrum of laser-matter interactions leading to material ablation.

In the present section, we shall focus on techniques aiming to the surface roughness modification relying indicatively on laser ablation and laser texturing. The tailoring of surface roughness and topography is very promising for a plethora of applications and the various results found at the literature for metals, ceramics, glasses, and polymers are presented. In general, the formation mechanism(s) underlying the laser-induced topographies remain under study because of the laser machining (LM) process complexity. They are interpreted in terms of material laser ablation (**Figure 19**) based on physical models of molecular dynamic simulations,[246–248] but they do not account for the poorly understood laser-generated effects of plasma plume formation and expansion, oxide formation, optical property changes, nanoparticle shielding, incubation, self-organization as well as for the medium in which the laser processing takes place.[249]

Recently, a detailed theoretical approach concerning the development of various types of self-assembled morphologies, ranging from nano-ripples to periodic microgrooves and quasi-periodic micro-spikes has been reported.[250]

For more than 20 years, laser surface texturing (LST) has proven an efficient and controllable method for producing the texture of micropores on magnetic disk drives[251] and ceramics.[252] LST is, nowadays, an efficient and clean to the environment technique which enables the precise shape and dimension control of induced micro-patterns. It is considered to be the most precocious technique for polymer, metal, ceramic, glass, and semiconductor surface engineering toward the control of wettability,[253–261] the color marking for counterfeit protection,[262,263] the control and improvement of wear resistance and friction coefficient in tribological contact,[264–268] biomimetic,[269–272] and microfluidics[273–275] purposes. LST, relying on material ablation, induces a regular array of a great number of micro-dimples on a surface which meets many challenges in various lubricated applications by friction reduction in conformal lubricated contacts.[273] Indeed, these dimples serve either as traps for wear debris, as reservoir for lubricant under starved lubrication, or, they may enhance the hydrodynamic lubrication mechanism.[274] There have been performed many theoretical and experimental studies concerning the LST contribution to increase the surface adhesion for bonding[275] and to the tribological performance of: (1) lubricating sliding contacts pinpointing at first place the fluid film lubrication – e.g., oil, water, aqueous bovine serum albumin solution[264,265,274,276–286] but, the solid film lubrication[287,288] and, the dry one[289,290] as well, (2) reciprocating automotive components,[291,292] and (3) diamond-like carbon coatings.[293,294] The UV lasers, offering the advantage of reduced surrounding surface overheating over the IR ones, they have been adopted in the surface topography modification of ceramic and hard coatings.[295,296] In advance, LST has also been applied in the fiber laser microgrooves and micro-holes fabrication on the surface of polycrystalline diamond tools,[297] in the tribological properties improvement of Al_2O_3/Mo laminated composites at room and high temperatures,[298] of gray cast iron,[299] of titanium alloy combined with diamond-like carbon films coating technology[300] and of hard TiAlSiN coatings combined with high-energy ion implantation.[301]

Besides the many advantages that LST offers, such as non-contact, good flexibility, and high spatial resolution, its broader application is hindered due to the residual stress and the shrinkage cavity generated by thermal effects during LST process. A surface treatment process for improving several mechanical properties, for example, fatigue, durability, corrosion resistance, and wear performance, of metals is the laser shock peening (LSP) one.[302] It is a cold machining process which relies on the laser-generated shock waves able to induce severe plastic deformation of materials surface: a section of the material to be peened is paint coated and a thin film of water runs over the surface, while, a laser beam passes through the water layer being focused onto a particular target location causing the paint layer to vaporize into plasma.[303] Upon plasma expansion, high pressure (GPa-TPa), short duration (ns), shock waves propagate into the water layer, which confines the energy and increases the pressure pulse intensity within the base material under texturing (**Figure 20**).

It is the amplitude of the laser-induced shock waves that causes the plastic deformation at the surface.[304–306] LSP has been proposed for the fabrication of micro-dimple arrays on copper surface[307] and, it can be applied as a post-processing method for the improvement of surface layers mechanical properties since it induces a compressive residual stress within a depth of more than 1 mm. LSP subsequently to LST has been applied in the case of bionic non-smooth 0Cr18Ni9 stainless steel surfaces fabrication[308] and the effects of LSP and groove spacing on the their wear behavior have been investigated.[302]

The range and variety of the laser-induced microstructures on the surfaces of titanium, stainless steel, aluminum, molybdenum, and copper substrates comprise holes,[253,309–313] bumps or spikes,[254,270,309,314–321] bulges,[322] undulating grooves,[323–325] dimples,[322,326,327] honeycombs,[328] linked nanostructure-textured mound-shaped microstructures,[329] melt-like[312,330] and

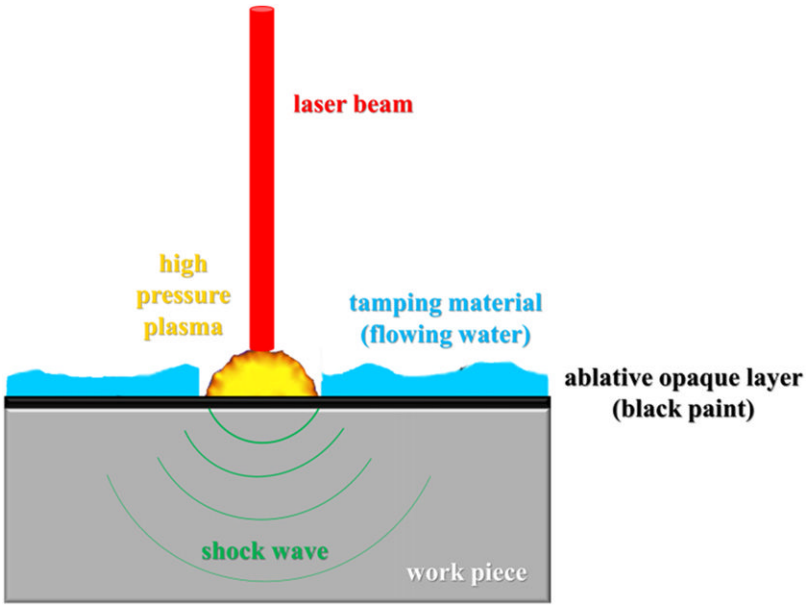

Figure 20 Laser shock peening principle.

cauliflower-like[331] structures. In addition, the formation of laser-induced periodic surface structures, nano-pillars, and micro-columns has also been reported.[332] Other than that, there has been observed the formation of nano-ripples on TiO_2 surface following UV femtosecond laser irradiation,[333] the fs laser nanostructuring of nitrided alloy steels containing Cr,[334] the LST of plasma electrolytically oxidized aluminum 6061 alloy for improved hydrophobicity[335] and the IR fs laser nano- and micro-texturing of a stainless steel surface combined with chemisorption of an hydrophobic agent.[336] In general, the optimization of the laser settings toward a desired surface texture consists a tediously long procedure given the large breadth of the experimental parameters space:[249] laser fluence value, number of applied laser pulses, pulse duration, repetition rate, scanning speed, and number of scans – varying, at the same time, from metal to metal.[337]

In several applications (cutting tools, wearing parts, heat engines, medical implants, construction) for which exceptional physical and mechanical properties are required – such as high hardness, advanced thermal resistance, and chemical stability – the ceramics have established a strong foothold.[338,339] LM has proven a promising tool for their texturing, especially if one takes into account the fact that conventional techniques can hardly face the issue of their machining due to the brittle and hard nature the ceramic materials exhibit.[339–341] There are mainly three ceramic LM techniques: the laser-assisted chemical etching, the LM and the laser-assisted machining (LAM) one.[339,342] In any case, the challenge in the laser micromachining of ceramics lies in the great scattering of common laser wavelengths from their surface restricting, thus, the localized energy absorption.[343]

According to the laser-assisted chemical etching, laser radiation excites the material surface and/or the molecules of an employed appropriate etchant acting, thus, upon the reaction between the material and the etchant. In such a way, the etching rate is mostly affected by the laser fluence value.[344,345]

In LM, the absorbed high-energy density of the incident laser photons causes the breakage of the chemical bonds leading to the material ejection from the irradiated area inducing grooves formation on the ceramic surface.[346,347] The mechanism underlying the material removal deals with material melting, decomposition, and evaporation. The crucial parameter for the process effectiveness employs different properties of the ceramic under treatment each time, such as, reflectivity – especially the multiple reflections in the laser-induced grooves[348] thermal conductivity, specific heat, and latent heats of melting and evaporation.[339,349–351] Alumina owing excellent dielectric strength, thermal stability, and conductivity[352] has been laser textured by CO_2 laser,[353–356] YAG lasers,[357–360] copper vapor laser,[343] KrF laser,[357,361] and near infrared[352] femtosecond laser. In addition, alumina has been laser machined in three dimensions (3D) by 3D laser carving; an industrial technique for ceramic manufacturing of complex shapes based on 3D CAD model slices[362] and by the laser milling technique.[363] In advance, it has been proposed, that, after a focused laser beam scribes two groove-cracks at two intersecting surfaces of a rectangular alumina substrate, a defocused one is applied throughout the length of the groove-cracks, generating, thus, great thermal stress leading to the two groove-cracks link together, requiring much lower energy power compared to the conventional LM technique.[364,365] Several research publications[366,367] report on the use of two laser beams for laser alumina texturing toward the fracture control upon the procedure. Recently, a new methodology has been mentioned for the fabrication of complex-shaped Al_2O_3 ceramic parts by combining LM and gelcasting technique.[368] According to this technique, the unwanted ceramic powders parts are selectively removed by LM specified by a computer program, and the gelcast Al_2O_3 green bodies were machined to a designed shape by a CO_2 laser. Bearings, rocker arms, piston rings, and cams can be made by LM of silicon nitride for automotive, semiconductor, and aerospace industries purposes. CO_2 laser in air[369–371] or under N_2, O_2 gas atmospheres,[372] Nd:YAG laser[373] and excimer laser systems[374] have been employed in the LM of silicon nitride aiming to the micro-cracks minimization. 3D structuring of silicon nitride by employing a relatively new machining process, namely, the laser milling technique relying on CAD data has also been reported,[375] based on an ablation operation leading to the material removal in a layer-by-layer fashion. Another broadly laser-machined ceramic is the silicon carbide. It has been treated by CO_2 laser [70,376,377] in air[373,378,379] or in N_2, O_2 gas atmosphere[372] by Nd:YAG laser[360,378–381] and by KrF laser beam[361] leading to the fabrication of controlled wettability textures.[382,383] The high thermal conductivity and small thermal expansion mismatch with silicon of aluminum nitride justify its widely use in microelectronic substrates and packages[384] and has been laser machined with near-IR and excimer lasers.[359,384,385] The fabrication of pH meters, fuel cells, IR radiators, pressure, and oxygen sensors employs the use of zirconia due to is unique characteristics: low thermal conductivity and friction coefficient, high fracture toughness, and good thermal shock resistance.[386] As the previously mentioned ceramics, it has been textured with Nd:YAG laser,[349,379] CO_2 laser,[370,387] and porous structures are induced upon its XeF laser[377] treatment.[74] LM of blind holes in glass-ceramic sheets have also been applied for inclusion of thermal sensors in the substrate and for fastening the glass-ceramic to other ceramic or metallic components.[388] The LM has also been applied to Al_2O_3–34 wt.% TiC -the induced textured ceramic can be used for high precision parts, such as magnetic head sliders[389,390] and to Si_3N_4/TiC ceramic for wavy grooves fabrication[391] using Nd:YAG laser.[392] As far as it concerns the recent developments in laser texturing of ceramics, there has been reported the formation of alumina precise micro-channels with surface micro-patterns[393] by using LM, imprinting, and a technique of interposing laser-formed sacrificial heat-removable sheets in between ceramic sheets; these features can be used under conditions where chemical and heat resistances are necessary.[394] In addition, it has been mentioned, that, when cutting hard-brittle ceramic biomaterials to prepare scaffold and implant, or, when sectioning them for porosity evaluation, it is better to choose KrF excimer LM.[395]

Unlike LM, in LAM the material removal occurs with no melting of the ceramic, but instead, with a conventional tool following the localized heating of the ceramic by the laser beam. The laser beam deforms the brittle behavior of the ceramic to a ductile one.[339,391] This technique has been applied for the laser texturing of silicon nitride,[391,393,396–403] zirconia,[404,405] magnesia-partially-stabilized zirconia,[406] Al_2O_3,[407–409] and

Inconel 718[410] with carbide and ceramic inserts. A recent publication[411] offers a comparison of LAM technique with conventional machining methods as well as the recent developments in the field.[412]

It seems that laser texturing of ceramics meets the increasing demand for the fabrication of parts owing microscale features for semiconductor, biomedical devices, and optics applications.[413] The rapid, noncontact, and highly flexible nature of the laser process leads to the accurate dimensional design of micro-featured products,[414] for example, of kerfs with depth and width smaller than 100 μm,[339] ensuring the employment of ceramics LM in a great variety of tremendous applications. The Nd:YAG lasers are broadly used compared to the CO_2 ones due to their high-energy density and small focused spot size.[341] However, in most cases, it is a combination of short pulse duration and short wavelength that guarantees best results in many ceramics, with no evidence of melting.[343] New innovations such as short pulsed or femtosecond lasers have drastically decreased the amount of unwanted damage associated with LM.[411] In any case, the conditions of the ceramics laser processing to be selected depend strongly on the material properties and the released constituents upon texturing in order the safety and health requirements to be fulfilled.

Other than that, surface structures can be produced traditionally using lithography with photoresist coating, exposure, and transfer processes[415] or printing, molding, and embossing methods.[416,417] Mask-less laser interference lithography (LIL) enables the large-area periodic structuring with simple equipment.[418,419] This technique relies on the interference of coherent light beams to form a horizontal standing wave for a grating pattern able to be recorded on a photoresist. The period of the structures depends on the laser wavelength and the angle(s)[420] between the -two or more[420–426] incident beams intersection, whereas the laser fluence,[427] the polarization[424,427] as well as the exposure time[428] strongly influence the procedure. By 90° rotation of the sample, and a second exposure, the grid pattern on the photoresist can be defined.[419] LIL has been applied in: the preparation of large-area, long-range ordered ZnO[429,430] and Si[431] nanowires arrays, the micro-lens array fabrication for super-resolution surface nanopatterning,[432] the production of magnetic nano-dot arrays[433,434] and AlGaAs microdisks,[435] the nanostructures fabrication for surface plasmon resonance tuning by gold and silver bimetallic dot arrays,[436] the GaAs solar cells improved efficiency by the induced nanopatterning,[437] and the Cr, Co, Ni, and Ge high-density dot arrays fabrication.[438] One should also mention that there have been textured sixfold symmetry structures on a two-dimensional polymer (SU-8),[439] periodic grating structures on poly(methyl-methacrylate) by soft X-ray laser beam,[440] and nanostructured holes of hexagonal symmetry on tungsten oxide surfaces,[441] via LIL.

LIL on photoresist or as photofluidization lithography has emerged as a technology capable to fabricate templates by irradiating an azo-polymer or a photoresist with interference patterns obtained by using two or more coherent – typically UV – laser beams, mostly operating in continuous wave mode.[442–444] In addition, the LIL-induced nano-patterning structure, following the pattern transfer, can be used in: optical devices,[445] surface plasmon resonance sensors,[446,447] metamaterials,[448] electrodes for cross-bar electronic devices like memories as well as transparent electrodes for light-emitting-diodes and photovoltaic cells,[449] large-area broadband photonic crystal membrane reflectors on glass substrates,[450] biomimetics,[451] micro-sieves for micro-filtration,[452–454] template for self-assembly,[455] field emission panel displays,[456] large-area photonic crystal slabs for visible light,[457] and micro- and nano- fluidics.[458,459] The potential of the LIL technique wider employment in industry has also been mentioned.[460]

Alternatively, the direct laser interference patterning (DLIP) technique enables a scalable process for polymer substrates structuring by direct substrate material ablation, requiring only a single processing step without solvents or heating.[461–463] In DLIP, similarly to LIL, two or more coherent laser beams are brought to interference with each other on a substrate and different one- and two-dimensional periodic patterns are induced by direct ablation of the substrate – with spatial periods ranging from some hundreds nanometers up to several micrometers – in the absence of any masks or templates. The produced patterns are attributed to the periodic light intensity variation and the high light absorption by the material.[464]

Silicon rewards a special dedication since it is an important semiconductor material with numerous applications of broad range, and has erstwhile till recently been laser surface textured for microelectronics, solar cells, or biomedical purposes.[465–472] In general, micro-, submicro-, and nano-periodic patterns[473] (e.g., grooves, pits, spikes) are induced on the Si surface depending on the laser irradiation parameters, the irradiation gas atmosphere or environment[474] affecting the melt material distribution following ablation. In advance, near-field enhanced laser irradiation with micro-nano-sized spheres[475,476] and near-field scanning optical microscope[477,478] have been used. On the contrary, a non-ablative laser surface structuring technique to form a regular array of micro-bumps on Si surface by a 1090 nm continuous wave fiber laser has been proposed,[479] besides the high transparency that Si exhibits at this wavelength. The non-ablative laser-induced micro-bumps formation was attributed to localized Si oxidation.[480] Recently, there has been reported that upon 1064 nm picosecond laser irradiation of Si, micro-nano hierarchical pore structures are formed on its surface, which are subsequently precisely chemically etched and, finally, light-trapping structures are fabricated.[481] LIL has also been applied for the fabrication of two-dimensional photonic crystals in silicon-on-insulator wafers[482] and for Si texturing with thoroughly investigated wetting properties of the induced periodical nano-patterns and hierarchical structures.[483] More recently, there has been reported the case of moth-like[422] as well as of grating, triangle, and square[423] surface structures induced on silicon by multi-beam LIL. Concerning the solar cells applications, sub-micrometer conical and pillar-shaped spikes have been fabricated by irradiating hydrogenated amorphous silicon thin films deposited on glass substrates with hundreds of 800 nm-wavelength, 130 fs-duration laser pulses in air and water environments, respectively.[484] Lately, there has been reported the laser-induced formation of 300 nm period pore arrays on Si combined with electrochemical etching.[485]

Concerning the LST of polymers, a key parameter of the procedure is the polymer molecular weight.[486–489] Low molecular weight polymers with short polymer chains are volatile, whereas, the longer ones of the high molecular weight

polymers melt. In this case, the material removal is due to evaporation from the polymer substrate – upon an explosive boiling procedure – in an ablation plume full of molecular fragments, ions, free electrons, neutral particles, and products from the chemical reactions between the plume components and the irradiation atmosphere. Among the laser textured polymers, poly(methyl-methacrylate) (PMMA) has received the lion's share of the universal applied research interest,[258,486,489–501] for example, for microfluidic devices fabrication, by using mainly UV laser radiation. However, from an application point of view, the thermal damage minimization of the surrounding (the laser irradiated area) material is crucial since it deteriorates both the spatial resolution and the ablation quality.[502] Consequently, the photochemical processes which lead to the so called 'cold' ablation are most preferable. In general, the energy of the UV lasers photons is high enough to induce the direct bond breakage in a strongly absorbing at the irradiation wavelength organic material. It is of great importance the fact that the bulk properties of the laser textured polymers remain intact and, thus, they can be employed in bioengineering applications since the microscale topography may influence several properties, such as wetting properties[260,503] and cell behavior.[504–508]

At the end, it is worth mentioning the recent laser texturing developments at the sake of tissue engineering applications, since they prove the potential spreading of the technique in this rapidly growing interdisciplinary field: the micro-channels on medical needles,[509] the osteoblastic commitment improvement of human mesenchymal stem cells on Ti alloys,[510] the neuronal cells cultivation on Si spikes[470] the fibroblasts cell culture on laser-made chitosan scaffolds[511] and the osteoblast proliferation and morphology on metallic alloys.[512]

3.8.6 Conclusions

This chapter has attempted to cover the laser-based 3D printing and surface texturing techniques which meet the ever increasing challenges and demands of either existing or emerging scientific fields. The superior precision and reproduction, the high working speed, the wide bandwidth of possible materials, and the exceptional degree of flexibility justify the laser fabrication techniques employment in a smorgasbord of human life domains in the industrialized countries: manufacturing, communication, military aspects, health technologies, metrology, reprography, and entertainment. The laser versatility in the ability to create structures of any desired dimension and geometry guarantees the progress of future structuring procedures. Yet, there is a long trail behind the Holy Grail of laser processing capabilities: the controllable fabrication at nanometer scale, which will provide a broad range of technical opportunities with frame and limits left to human imagination.

3.9.1 Introduction

A chemical approach is proposed to develop economically feasible hydrophobic surfaces with optimal optical properties. The work includes developing hierarchical superhydrophobic surfaces to significantly improve the hydrophobicity while maintaining the transparency of the solar panels cover, thereby conserving cleaning water and reducing the operational costs. Novel characterization methods are developed to comprehend these characteristics at nanoscale.

3.9.1.1 The Effect of Dust Accumulation on the PV Cell Efficiency

About 5% of the solar light is reflected at the interface between the photovoltaic panel's surface and the air owing to the refractive index difference. During the period of 8 months from the date of the PV cells installation in the desert, dust accumulation, furthermore, was found to reduce the efficiency of the cells' efficiency by 36% due to the surface-transmittance drop. This efficiency reduction extends to be about 72% after 15 years of exposure to the dusty and dry environment of the desert.[2] Therefore, for the PV panels installed in dry environments, the dust particles should not stick over the surfaces of the cells. This may be achievable by texturing the surface to have micro-/nano-patterns in order to mimic the lotus leaf phenomenon as observed from Figure 1.[1]

3.9.1.2 Historical Background

During the last decade, several studies have been performed in order to investigate and improve the different techniques which are used to design hydrophobic surfaces by controlling the surface topography and chemistry.[3] In fact, the idea of developing hydrophobic surfaces is inspired from nature.[4] Lotus leaf has gained the main the focus of the scientists who are interested in this field of research because its surface is rough and hydrophobic as well. Several crop plants also have the same characteristics like the lotus leaves, for example, *Brassica*, *Alchemellia*, and *Lupinus*.[5,6]

Figure 1 A hydrophobic plant leaf.[1]

3.9.1.3 Polycarbonates: Properties and Synthesis

Polycarbonates (PCs) are considered as an organic polymeric material with two subclasses; aliphatic and aromatic. The bisphenol A(2,2-bis(p-hydroxyphenyl) propane)-based PCs (Figure 2) has interesting characteristics like high toughness, high transparency, high heat capability, low water absorbability, low synthesis cost, and ease of decoration; therefore, industrially it is considered one of the most important polymers. Synthesis of PCs includes four different methods: (1) interfacial synthesis, (2) transesterification, (3) oxidative carboxylation, and (4) synthesis using CO_2.[7]

3.9.1.4 Crystallization Process of PCs

Surface texturing and modification of polymers toward achieving surface hydrophobicity and characterization have been of central interest to the researchers.[8–11] The interaction between the PC and acetone is spontaneous and induces crystallization and hence it is utilized to texture the PC surface and form hierarchical superhydrophobic structures.[12] During the crystallization reaction physical changes occur at the surface of the PC due to the phase–phase interaction between the PC surface and the acetone solvent. This physical change leads to create the hierarchical surface pattern with a certain roughness (Figure 3). The semicrystalline polymers have higher chemical resistance compared to the amorphous polymers. An additional important characteristic of the amorphous polymers is the high chain mobility which induces its crystallization.[13] The crystallization of PCs is a very slow process.[13,14] Polymer crystallization process can be induced either thermally or by using organic or inorganic solvents.[15,16] Liang *et al.*[17] used diallyl-orthophtalate as a solvent to induce the PC crystallization process, in the presence of plasticizers. Turska *et al.*[18] treated the PC samples thermally, by heating till 190 °C for about 7 days, in order to get a low degree of crystallization, which is 23% on average. Scientists found that the best organic solvent which can induce the PC crystallization process efficiently is acetone.[19,20]

3.9.2 Theoretical Models

3.9.2.1 Fundamentals

Surface tension (γ_{LV}) is defined as the force which is responsible for reducing the free liquid's surface area; the unit of this force is N m^{-1} or J m^{-2}.[21] Two forces affect the status of the water droplet over the solid surface, (1) gravitational force and (2) surface tension. The volume of the droplet is the main factor, by which the effecting force is determined. For a water droplet present over a solid surface, interfacial tension forces γ_{SL}, γ_{SV} and γ_{LV} are established, the status of the water droplet, either flattened over the surface or remaining as a sphere, depends upon the balance between these forces.[5]

$$S = \gamma_{SL} + \gamma_{LV} - \gamma_{SV} > 0 \quad [1]$$

Where S: the power of spreading, γ_{SL}: the solid–liquid surface tension, γ_{LV}: the liquid–vapor surface tension, and γ_{SV}: the solid–vapor surface tension.

3.9.2.2 Young's Equation (for Flat Surfaces)

The hydrophobicity of a surface can be identified as the incapability of the surface to interact with water, therefore leading to create a high contact angle (CA), θ (i.e., the angle between the surface and the tangent of the water droplet which is found over it) so as to minimize the contact area between the droplet and the surface. In contrast, if the hydrophilic surface likes water; it makes a small CA, θ, with the water droplet in order to maximize the contact area, thereby leading to droplet-flattening over the surface. The surface is described as hydrophilic if $\gamma_{(SV)} > \gamma_{(SL)}$, the CA is lower than 90°, while, the hydrophobic surface possesses a CA higher than 90° if $\gamma_{(SV)} < \gamma_{(SL)}$ (Figure 4).[5]

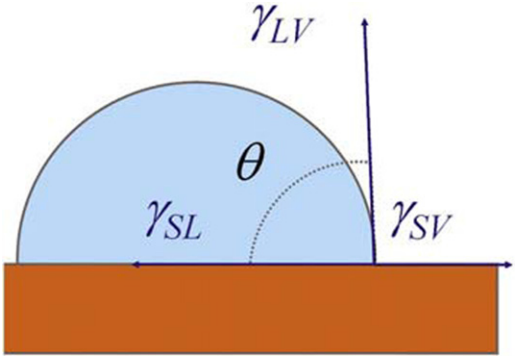

Figure 4 Three-phase contact line diagram of a water droplet on a solid surface.[53,54]

For flat surfaces, there is a mathematical model which illustrates the behavior of a water droplet on such surfaces. Young's equation shows the relation of the three-phase contact line between the droplet and the flat surface[22]:

$$\cos\theta_y = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \quad [2]$$

3.9.2.3 The Effect of the Chemical Treatment and the Roughness on the Surface Hydrophobicity

The surface roughness does not usually alter the nature of the surface significantly, in other words, it does not transform the hydrophobic surface to be a hydrophilic one or vice versa. The chemical structure and the terminal chemical groups at the materials' surfaces are the only factors that control if the material is hydrophobic or hydrophilic. Coating surfaces with a hydrophobic chemical material can only increase the smooth-surface CA with water up to 120° via lowering the surface energy, while using a hydrophilic chemical as a coating material increases the surface energy, however it can not achieve a CA between the smooth surface and the water droplet lower than 70°. The purpose of texturing the surface is to increase its hydrophobicity or hydrophilicity.[25] Thereby for the hydrophobic and rough surface, the CA can reach more than 160° and, in this case, the surface is called superhydrophobic, whereas for the hydrophilic rough surface, the CA can reach less than 5° and the surface is known as superhydrophilic surface. The contact angles for both the superhydrophobic and the superhydrophilic surfaces are apparent angles, and they are referred back to Cassie–Baxter (θ_{cb}) and Wenzel (θ_w) states, respectively (Figure 5).[26]

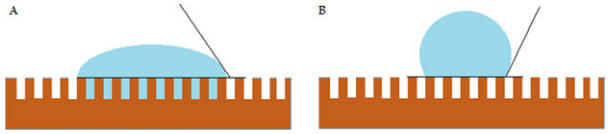

Figure 5 A: Wenzel state, or commonly known as Wenzel impregnated state. The water replaced the air in the gaps and the water droplet flattened, forming an acute angle between its tangent and the surface. B: Cassie–Baxter state. The water droplet is in a semi-sphere shape, forming an obtuse angle between its tangent and the surface.[53,54]

3.9.2.4 Wenzel and Cassie–Baxter States (for Rough Surfaces)

However, not all the surfaces are flat; there are rough surfaces (Figure 6). The water droplet behavior on the rough surface is totally different from the smooth one; in which case, surface texture plays a major role in (1) the degree of the hydrophilicity or the hydrophobicity of the surface and (2) the droplet mobility over the surface. In order to identify the rough surface, basically, it is the surface that has a lower surface energy than the corresponding flat surface of the same material. The energy of the rough surface is lower because if a square with a certain area is taken from a flat surface of a certain material and compared with another square with the same area, which is taken from a rough surface of the same material, more surface area can be found in the rough square because it is a three-dimensional one, while the flat square is only two-dimensional (Figure 6).

Two mathematical models are utilized to study the behavior of the water droplet on the rough surface, Wenzel model and Cassie–Baxter model. In Wenzel model, upon the landing of the water droplet over the rough surface, a water film is produced over the texture because water fills the pockets and therefore replaces the trapped air. According to this case, the water droplet sticks over the surface and does not move, even under the effect of the gravitational force. Wenzel's formula can be formulated as in eqns [3] and [4][23]:

$$\cos\theta_w = r\cos\theta_y \quad [3]$$

$$r = \frac{\text{actual surface}}{\text{geometric surface}} \quad [4]$$

where θ_w: apparent CA (i.e., CA over the rough surface or Wenzel's CA), θ_y: actual CA (i.e., CA over the corresponding smooth surface or Young's CA) and r: roughness factor. This state is non-favorable because it causes stickiness of the water droplet over the surface, so this is against the idea of water droplet rolling which is favorable for self-cleaning surfaces.

In Cassie–Baxter state, there is no water film formation because there is no water-diffusion in the air pockets. However, instead, the water droplet still touches only the

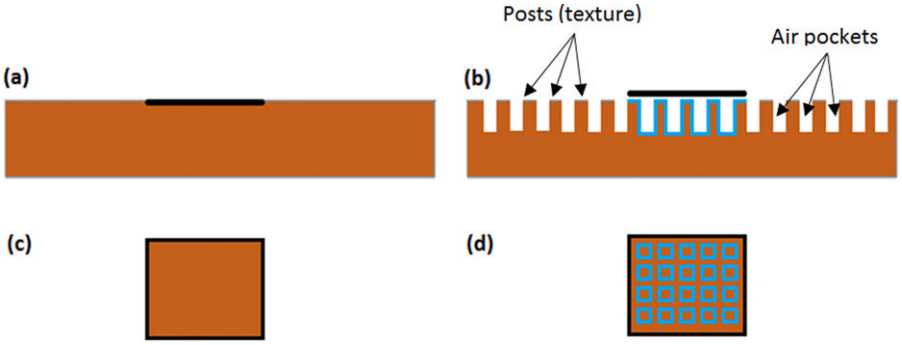

Figure 6 (a) and (b): diagrams illustrate the flat surface and a cross-section of it, and (c) and (d): diagrams illustrate the rough surface and a cross-section of it. From the diagrams, you can see that the rough square has a higher surface area, so a lower surface energy, than the flat square.[53]

tops of the surface-pillars, leaving the areas between them filled with air (eqn [5]). In Cassie–Baxter state, the droplet-curvature is smaller than the gaps due to the weight of the droplet.[5]

$$\cos\theta_{cb} = f_s(\cos\theta_\gamma + 1) - 1 \qquad [5]$$

where θ_{cb}: apparent CA (i.e., CA over the rough surface or Wenzel's CA), θ_γ: actual CA (i.e., CA over the corresponding smooth surface or Young's CA), f_s: the total area of the liquid–air interface.[24]

3.9.2.5 Classification of Rough Surfaces

Designation of rough surfaces can result in three forms of the surface texture: (1) regular, (2) hierarchical, and (3) random textured surface. For the regular rough surfaces, the etching can be done by using photolithography; and this type has a single-scaled roughness; and it is helpful in investigating the droplet behavior over the rough surfaces. The hierarchical rough surfaces, designed by chemical etching, possess complex structures and include roughness of two-scales. However, the random rough surfaces, fabricated by plasma etching, are of multi-scaled roughness.[1]

3.9.2.6 Self-Cleaning Surfaces

Acquiring the self-cleaning property is one of the surface characteristics that are favorable to be present. The self-cleaning feature requires uniform, smooth mobility of the water droplet over the hydrophobic surface. The regular rolling of the water droplet over the hydrophobic surface allows the removal of the accumulated dust particles and contaminants, like in the lotus leaves. The degree of ease and smoothness, with which the water droplet can move over the hydrophobic surface can be measured by measuring (1) the advancing CA (i.e., the CA at the front of the moving water droplet, θ_A; at this point, the volume of the water droplet increases with its motion) and (2) the receding CA (i.e., the CA at the back of the moving water droplet, θ_B; at this point, the volume of the water droplet shrinks with its motion).

The difference between the advancing and receding contact angles results in a new term, called contact angle hysteresis (CAH), θ_h, which is a measurement of the surface homogeneity (eqn [6]) (**Figure 7**). Both, the advancing and receding contact angles are measured at a surface-tilt angle of 1°–30°, for example.

$$\theta_h = \theta_A - \theta_B \qquad [6]$$

Three cases can be found in the values of the CAH: (1) zero or approaching zero value; in this case, the surface is homogeneous and the water droplet rolls smoothly over it, (2) positive value; in this case, the surface is heterogeneous and the water droplet rolls slowly or slides over it, and (3) negative value; in this case the water droplet sticks over the surface. CAH depends on the type of deposited liquid,[27] surface morphology and spaces between the generated textures,[28–31]

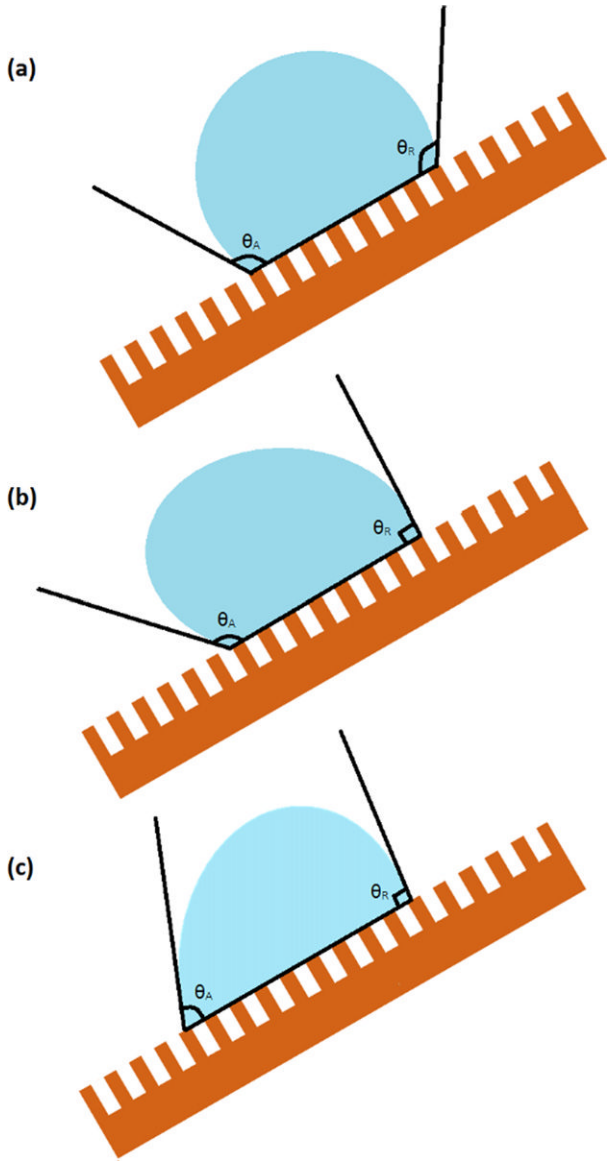

Figure 7 (a) Uniform (contact angle hysteresis (CAH) = zero), (b) nonuniform (CAH = positive value), and (c) nonuniform (CAH = negative value, theoretical case) water droplet movement over the rough hydrophobic surface.[53]

and the type of impregnated liquid in case of lubricant impregnated surfaces.[32,33]

3.9.3 Fabrication Methods and Technologies of Superhydrophobic Surfaces

The designation of a superhydrophobic surface requires the generation of a rough and low-energy surface. The critical problem of increasing roughness is the light reflectance from the rough surface and as a consequence, the decrease of the rough-surface light-transmittance; therefore controlling the surface roughening process should be taken into consideration.[34] Several types of superhydrophobic rough surfaces can

be designed by many techniques; every technique has its own characteristics, advantages, and disadvantages[35]:

1. Photolithography: it is highly controlled and favored in academic studies (to study the effect of varying r and f_s values), however it is very expensive.
2. Colloidal micro- and nano-particles: these types of particles accumulate by self-assembly, can pattern wide surface-areas with multiple scales, and the deposition process is controllable.
3. Template method: a rough surface can be utilized as a negative template and filled up with a material in the liquid state, wait for its hardening, and then get it out. The method is simple and the template can be used for several runs.
4. Etching: several methods of etching, for example, acid, laser, or plasma etching are investigated to create textured surfaces.

One of the crucial applications of the superhydrophobic surfaces is the self-cleaning surfaces. Scientists are spending significant efforts to design an optimized self-cleaning surface, which has the capability of repelling dust particles, by using a variety of methods.[36]

Mimicking the morphologies of natural superhydrophobic surfaces like the lotus leaf structure is the first step to come up with hydrophobicity properties. Template-based techniques, plasma treatment, self-assembly and self-organization, chemical deposition, layer-by-layer (LBL) deposition, colloidal assembly, phase separation, and electrospinning are some of the main methods to develop hydrophobic surfaces.[37–39]

Bruynooghe *et al.*[40] enhanced the light transmittance of the glass surface by coating it with an antireflective material which uses the light-destructive interference phenomenon to reduce the fraction of the scattered light. The coated substrate could be further coated with another coating material, which is hydrophobic (water repelling) and oleophobic (oil repelling) for making it durable and has a self-cleaning property. This top-layer coating included MgF2 (expensive material) in order to make the surface nonreflective. They achieved a CA of 110° after coating with 0.14% reflectance at incident angle of 78° in the spectral region 400–680 nm. Nakajima *et al.*[34] designed boehmite–TiO_2 films, with varied TiO_2 compositions, and a following (heptadecafluorodecyl) trimethoxysilane (FAS-17) coating to be used as superhydrophobic coating materials. Both roughness and CA were studied with different TiO_2 wt.% values. It was noticed that the roughness and CA increase with increasing the TiO_2 wt.%. However, TiO_2-based coatings were affected by UV light, especially at higher TiO_2 compositions, leading to hydrophobicity drop due to the photocatalytic effect (strong oxidation power under UV light) of the TiO_2. Ganbavle *et al.*[41] have used the sol–gel technique of a single step with a view to design a hydrophobic, self-cleaning silica coating material over a glass surface. The coating was tetraethoxysilane (TEOS) based with methyltrimethoxysilane (MTMS) as a co-precursor. The MTMS/TEOS ratio variation, by changing the MTMS concentration versus the hydrophobicity and self-cleaning property was studied; it was found that at the ratio between 0.78–1.57, the water droplet sticked over the surface due to the Cassie-impregnated state, in which a water film was formed on the pillars causing the strong adhesion of the water droplet to the surface; this phenomenon is illustrated in Figure 8. While at the ratio of 7.84, the coating showed a CA of 135°, but with a reduced light transmittance (80%). Lai *et al.*,[42] also designed TiO_2-fluoroalkylsilane thin films, using an electrophoretic deposition method, demonstrating both superhydrophobicity and good transparency (Figures 8 and 9). By Stober method, Chen *et al.*[43] grew hollow silica particles over carbon cores, using chemical vapor deposition (CVD), in order to synthesize a superhydrophobic coating. The achieved CA was 152° with transmittance of 90%, after one coating cycle and 75% after five coating cycles.

Park *et al.*[44] developed superhydrophobic surface with a CA higher than 150° and a hysteresis of lower than 20° by fabricating an ordered microshell array on transparent and flexible polydimethylsiloxane (PDMS) elastomer surface without a need for a low surface energy chemical coating. Verma *et al.*[2] created superhydrophilic nanostructured glass with a CA less than 5° by deposition of thin film of nickel on glass substrates, followed by annealing to create nickel nanoparticles. Their data showed an improvement in the solar cell performance, since net optical transmission increased and the surface was proven to be self-cleaning. Hee *et al.*[45] deposited different thicknesses of TiO_2 film on glass surface by using a simple method. They observed that dust accumulation decreased due to the deposition effect and this effect became more significant when increasing the film thickness.

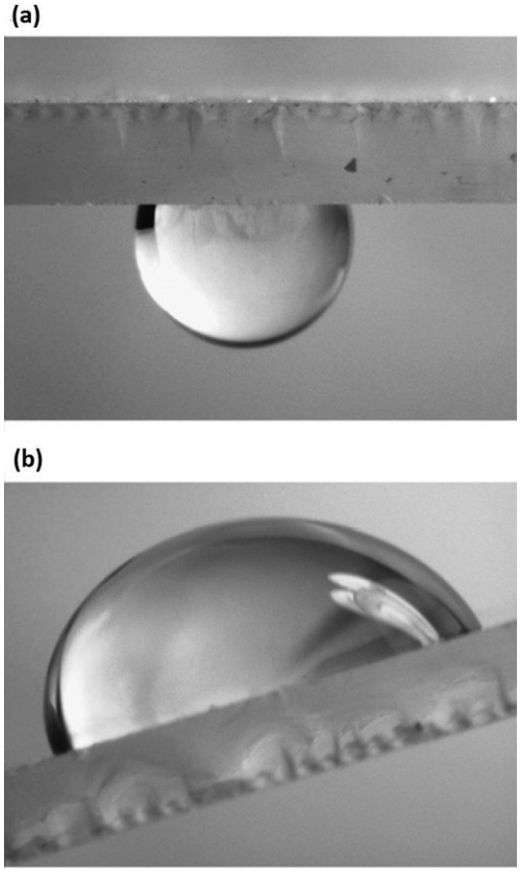

Figure 8 (a) Surface with ratio = 1.57 (Cassie-impregnated state), (b) surface with ratio = 7.84.[41]

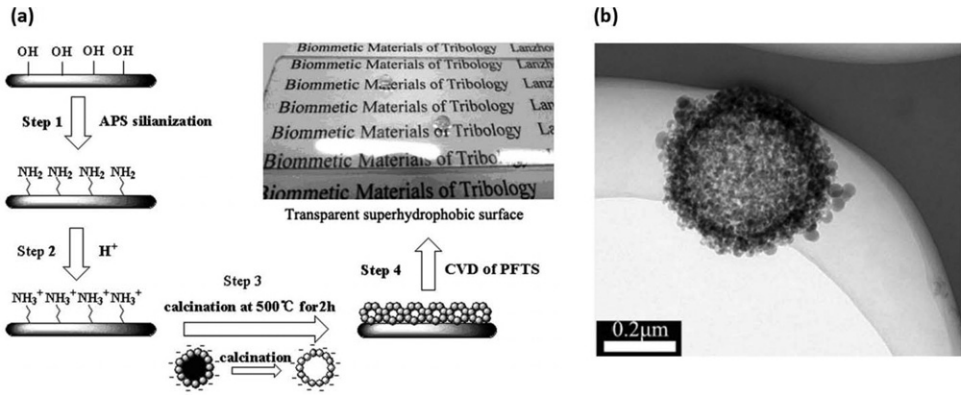

Figure 9 (a) Scheme for the preparation method and (b) hollow silica particles.[43]

However, such dry hydrophobic surfaces do have their limitations; for example, they cannot sustain high impact pressure. During the vapor condensation, surface loses its non-wetting properties. In addition micro-textures can enhance the light reflection. Lubricant impregnated surfaces do overcome limitations. In addition, wet hydrophobic surface exhibit extremely low CAH thus providing better self-cleaning and slippery properties.

Texturing the hydrophobic surfaces enhances the non-wetting properties by increasing the surface geometry while the trapped air between the surface texture posts leads to a superhydrophobic behavior, because the droplets sit partially on air.[31] However, there is a challenge in keeping the air pockets stable between the texture posts. But in case of humid conditions like Kingdom of Saudi Arabia environment, the air pockets can collapse due to dew condensation or evaporation. This occurs at a nanoscale throughout the texture and in turn leads to a highly wetted textured surface.[31] Such effect drew the attention to develop non-wetting surfaces with self-healing properties which are maintained by creating pockets of liquid instead of air by impregnating the texture with lubricant. The lubricant is stabilized by capillary wicking that arises from the micro- or nano-texture.[33] Lui *et al.*[46] fabricated lubricant impregnated surfaces (LIS) by filling organogel-based film on substrate with oil. The surface showed low CAH and self-cleaning efficiency. Wong *et al.*[27] prepared LIS through impregnating ordered epoxy-resin-based nanostructured surfaces and a random network of teflon nano fibrous membranes with lubricant perfluorinated fluids. It has been showed that LIS has the ability to repel different types of low and high surface tension liquids such as water, glycerol, and ethylene glycol. Furthermore, matching the refractive indexes of lubricant fluid and substrate leads to render the micro-texture highly transparent;[27,32] also LIS demonstrated self-healing properties . In case of any surface physical damage, the oil can flow and fill cracks and retain its surface properties.[27] On the other hand, LIS can sustain high drop impact pressure,[27] reduce ice accretion,[27,47,48] and enhances condensation and heat transfer dissipation.[49,50]

The lowest total interface energy state of water droplet represents the thermodynamics stable configuration. It depends on surface texture and impregnated liquid properties such as viscosity, spreading coefficient, and density.[51] Viscosity of oil plays a role in droplet sliding angle and velocity. High viscous oil leads to reduction of the droplet rolling speed and increases the sliding angle.[46,51,52] On the other hand, using high viscous oil can enhance the shearing sustainability of the surface.[49]

3.9.4 The Solid–Liquid Interface and PC-Liquid Acetone

The case study including surface crystallization of PC sheet is presented below toward the surface hydrophobicity assessment in line with the previous study.[53,54]

PC sheets are immersed in pure liquid acetone of different concentrations for different durations. Texture profile micrographs from atomic force microscope (AFM), give detailed images which illustrate the distances between the pillars within the textured surfaces. Roughness mean square and roughness average values, from AFM, are the parameters which give insight into the surface texture and provide information to enhance the hydrophobicity of the surface. All the former characterizations flew in the direction of measuring the contact angles of water droplets over the different textured surfaces as a tool for deducing the surface hydrophobicities.

3.9.4.1 AFM Micrographs

3.9.4.1.1 Surface topography

Several AFM scans are taken for different areas on the smooth PC surface, at different scales (500 nm, 1, 5, 10, 20, and 40 μm). The micrographs ascertain the absence of any kind of texture over the surface of the PC sheet as seen in **Figure 10(a)** with a scanning scale of 40 μm. The elevation that appears at the top-right of the micrograph is due to the sample's general surface morphology due to manufacturing process. **Figures 10(b)–10(f)**, at lower scales, further demonstrate the smoothness of the surface.

Several AFM scans are taken for different areas on the textured PC glass surface, at different scales (500 nm, 1, 5, 10, 20, and 40 μm). The micrographs illustrate clearly the appearance of a new surface texture after the immersion process. In **Figure 11(a)**, with a scanning scale of 40 μm, large spherules appear over the surface after immersing the sample for 10 min. The average size of the spherules, appearing in the figure, is

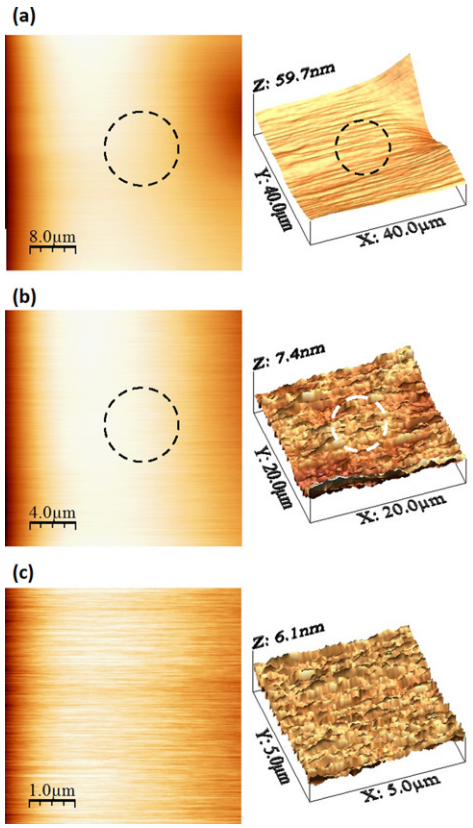

Figure 10 2D and 3D atomic force microscope micrographs at: (a) scale = 40 μm, (b) scale = 20 μm, and (c) scale = 5 μm for a smooth, untreated polycarbonate surface.[53,54]

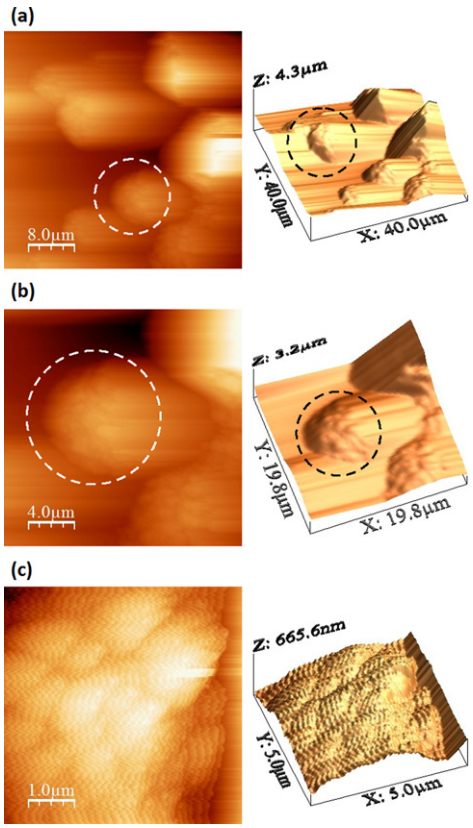

Figure 11 2D and 3D atomic force microscope micrographs at: (a) scale = 40 μm, (b) scale = 20 μm, and (c) scale = 5 μm for a textured polycarbonate surface by immersion in pure liquid acetone for 10 min.[53,54]

nearly 12 μm in width. The lines appearing as tails to the spherules are present due to AFM-tip slipping during the scanning process. In **Figure 11(b)** and at a scale of about 20 μm, the spherule appears more obviously and it can be noticed that the middle spherule is about 10 μm in width. By zooming in and reducing the scanning scale, the surface of the spherule shows more detail. **Figure 11(c)** illustrates that there is texture over the spherule's surface, which is clear also in the 3D micrograph. At lower scales, the surface of the spherule becomes more obvious and the texture over it can be obviously detected. It can be noticed that the surface of the spherule is not homogenous, in other words, the spherule's surface becomes hilly and this hilly surface is full of a grasslike texture, and this can be inferred from the 3D micrograph in **Figure 11(d)**. In both **Figures 11(e)** and **11(f)**, the scales are 1 μm and about 500 nm, respectively.

3.9.4.1.2 Texture profile micrographs

A line profile is drawn on the AFM micrograph and shows the morphology of the smooth PC surface. It can be noticed in **Figure 12**, that the surface texture does not exceed 2 nm in height. This indicates the degree of smoothness of the non-textured PC surface.

The study involves investigating the topology of the textured surface by using surface profile micrographs from AFM in order to follow up the effect of acetone on the PC surface. It is obvious that

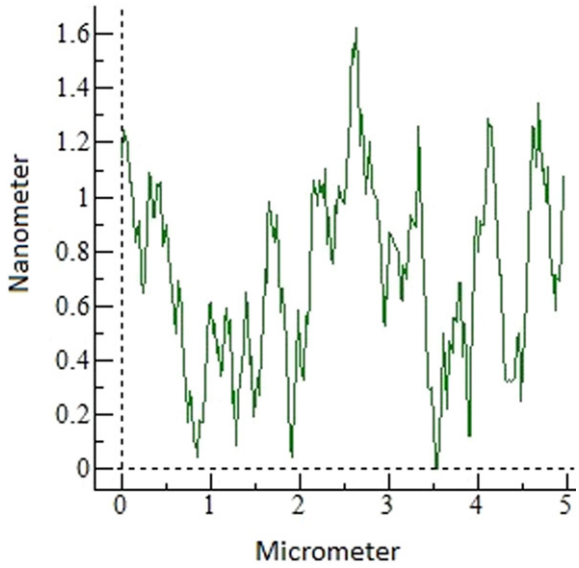

Figure 12 Atomic force microscope texture profile micrographs at 5 μm scale for a smooth untreated polycarbonate surface.[53,54]

through the various scales, from 40 μm to 5 μm, that the surface texture height is in the range of 1.75 μm. In **Figure 13(a)**, the height of the spherules can be measured and it is about 1.8 μm. The width of the middle spherule is about 13 μm. **Figure 13(b)**

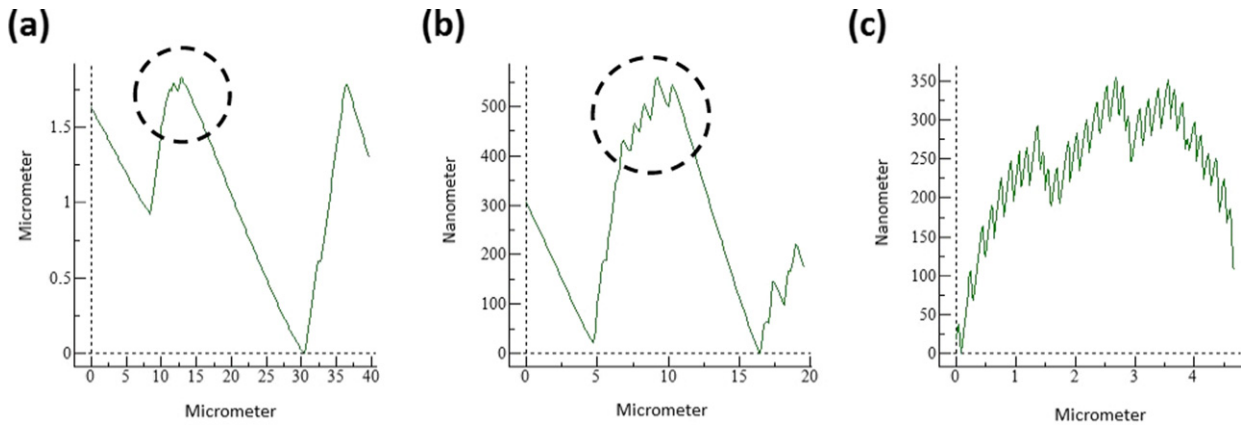

Figure 13 Atomic force microscope texture profile micrographs at: (a) scale = 40 μm, (b) scale = 20 μm, and (c) scale = 5 μm for a textured polycarbonate surface by immersion in pure liquid acetone for 10 min.[53,54]

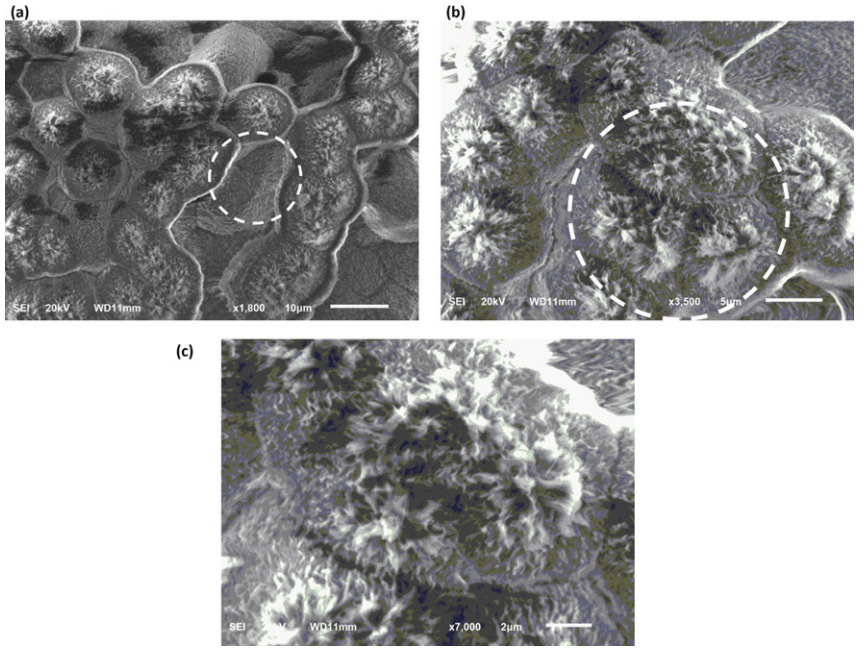

Figure 14 Scanning electron microscope micrographs at: (a) scale = 10 μm, (b) scale = 5 μm, and (c) scale = 2 μm, for a textured polycarbonate surface by immersion in pure liquid acetone for 10 min.[53]

illustrates a single and small spherule of 600 nm in height and nearly 12 μm in width. The texture over the spherule is shown in the figure. In Figure 13(c), a distinctive profile micrograph of the single spherule appears. The spherule contains three small elevations over its surface, each elevation is textured. This promotes the observation of the hilly surface and the grasslike hills, which is pointed out within the description of Figure 11(d).

3.9.4.2 Scanning Electron Micrographs

Scanning electron microscope is used to scan, on different scales, the PC surface after immersion in pure liquid acetone for 10 min. The resulted micrographs support the AFM and texture profile micrographs in proving that the crystallization process resulted in a textured crystallized PC surface with a hierarchical structure (Figure 14).

3.9.4.3 Surface Roughness

Roughness values of PC surfaces can be calculated using the AFM. Surface roughness was given concentration because it is one of the parameters that are responsible for the hydrophobicity of the surface. Roughness values are calculated for two different PC samples for comparison purposes: (1) smooth, untreated PC surface and (2) textured PC surface due to immersion in pure liquid acetone for 10 min. Two values of roughness can be given by the AFM for the single sample's surface, roughness root mean square (RMS) value and roughness average (Ra) value. Table 1 illustrates the Rms and Ra values of different PC samples. It's clear from the values of both the Rms and Ra that the textured PC surface by immersion in pure liquid acetone for 10 min is strongly roughed. This promotes the strong effect of the applied high hydrostatic

pressure on the treated PC surface due to immersion in pure liquid acetone, which allows deep diffusion of the acetone liquid within the polymer layer, leading to complete surface crystallization, pores formation, and as a consequence, high roughness in a very short duration.

3.9.4.4 Hydrophobicity Assessments

CA of the untreated PC surface is measured by dropping a deionized water droplet over the surface and measured using a goniometer. Different areas of the surface are taken into

Table 1 Roughness root mean square (RMS) and roughness average (Ra) values of the smooth (untreated), and solid–liquid interface textured polycarbonate (PC) sheets surfaces[53,54]

Scale (μm)	*Rms values (nm)*		*Ra values (nm)*	
	Smooth PC	*Textured PC*	*Smooth PC*	*Solid–liquid PC*
40	23.99	610	18.85	460
20	11.52	543.1	9.27	407
10	5.26	250	4.19	210
5	2.44	108.44	1.9	87.61
1	0.81	31.1	0.64	25.01
0.5	0.73	27.684 3	0.58	22.743 2

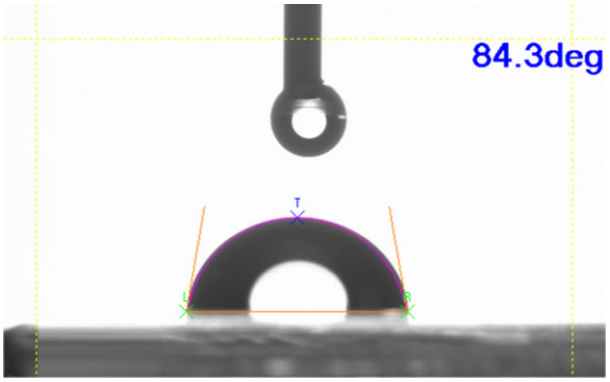

Figure 15 Contact angle of smooth untreated polycarbonate surface.[53,54]

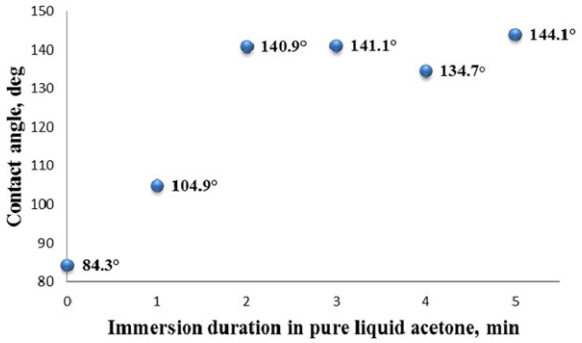

Figure 17 The effect of the immersion duration of polycarbonate sheets in liquid acetone on the contact angle.[53]

Table 2 Calculations of solid fraction values (f_s) of the textured polycarbonate glass samples by immersion in pure liquid acetone[53,54]

Immersion duration (min)	*Apparent CA (θ_{cb})*	*cos $\theta_{cb}+1$*	*Young's CA (θ_y)*	*cos θ_y+1*	*Solid fraction (f_s)*
1	104.9	0.743	84.3	1.099	0.676
2	140.9	0.224	84.3	1.099	0.204
3	141.1	0.222	84.3	1.099	0.202
4	134.7	0.297	84.3	1.099	0.270
5	144.1	0.190	84.3	1.099	0.173

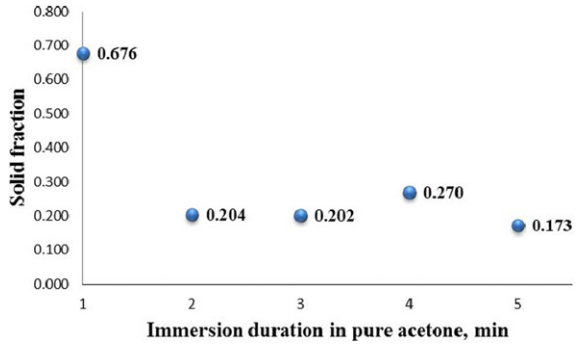

Figure 18 The effect of the immersion duration of polycarbonate in pure acetone liquid on the solid fraction (f_s) value.[53]

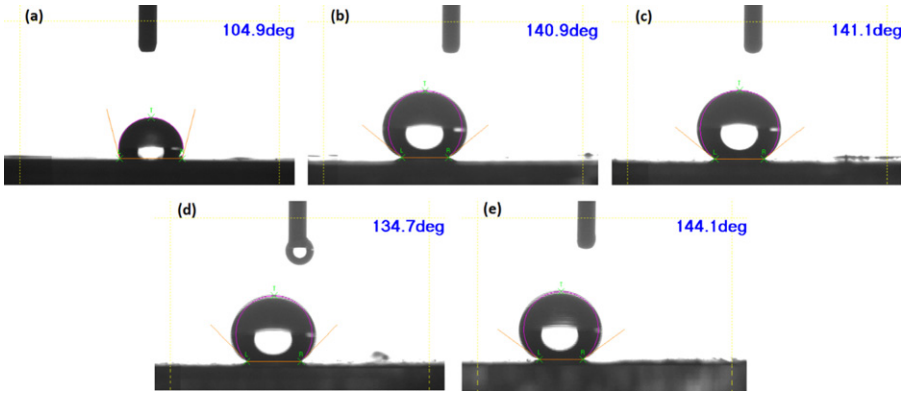

Figure 16 CA of textured polycarbonate sample by immersion in pure liquid acetone for: (a) 1 min, (b) 2 min, (c) 3 min, (d) 4 min, and (e) 5 min.[53,54]

consideration during the measurement. It is found that the average CA is 84.3°; indicating the slight hydrophilicity of the smooth PC surface (Figure 15).

Contact angles for textured PC sheets by pure liquid acetone have been calculated versus the immersion durations in the organic solvent. For an immersion duration of a PC sheet in pure liquid acetone for 1 min, the CA of the surface is 104.9° (Figure 16(a)). By increasing the immersion duration to 2 min, the CA dramatically jumped to 140.9° (Figure 16(b)). Then, by increasing the immersion periods to 3, 4, and 5 min, the contact angles fluctuate between 134.7° and 144.1° (Figures 16(c)–16(e)). Figure 17 illustrates the values of the contact angles of the immersed textured PC samples.

For the hydrophobic surfaces (CA $\theta > 90°$), Cassie–Baxter state can be applied to[24,54] eqn [5]:

$$\cos\theta_{cb} = f_s(\cos\theta_\gamma + 1) - 1$$

where θ_{cb}: the Cassie's (apparent) CA, $\theta_{cb} > 90°$, θ_γ: the Young's CA (CA of the corresponding smooth surface) and f_s: the solid fraction which is in contact with the water droplet. For

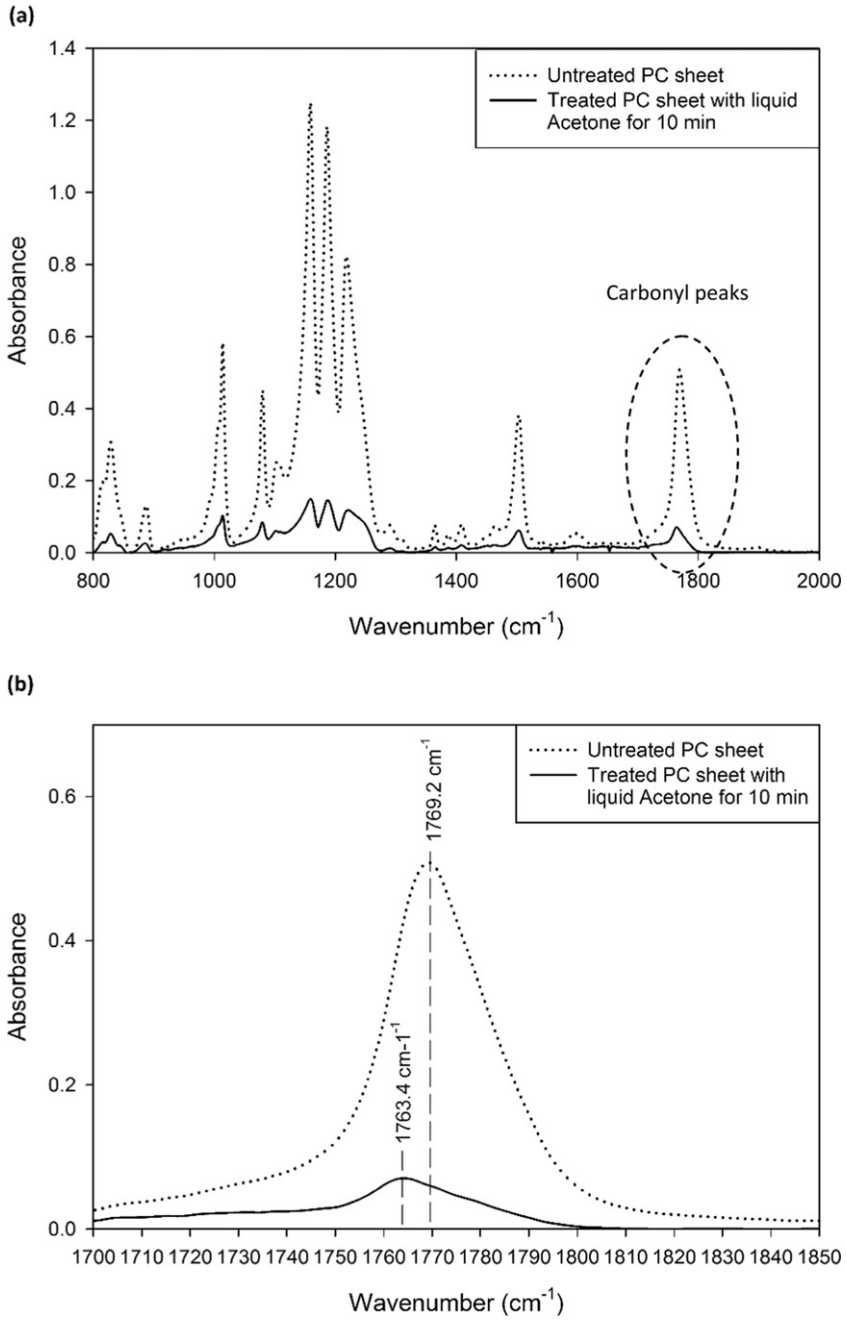

Figure 19 Attenuated total reflectance-Fourier transform infrared spectra of smooth, and liquid acetone-textured polycarbonate (PC) sheets surfaces, (a) whole spectra and (b) carbonyl stretching mode peak.[53,54]

calculating the value of f_s for the single textured hydrophobic surface:

$$f_s = \frac{\cos\theta_{cb} + 1}{\cos\theta_\gamma + 1} \quad [7]$$

Because the apparent contact angles of the textured surfaces, due to immersion in pure liquid acetone for different durations, are larger than 90°, so as a consequence, Cassie–Baxter's state is applicable. Calculations of f_s values for the six different textured surfaces are illustrated in **Table 2** and it is shown in **Figure 18** for different immersion durations.

3.9.4.5 Fourier Transform Infrared Technique Characterization

Fourier transform infrared (FTIR) technique is applied for determining the presence of chemical groups; functional, side, and terminal groups, within a certain chemical compound through the detection of the different stretching and bending modes of the bonds, present in these groups. FTIR technique is used to study the chemical structure of the PC surface before and after the treatment process. In addition, the technique gives an indication on the degree of crystallization of the surface after the treatment process through the peak intensity values. In **Figure 19**, FTIR spectrum of smooth, untreated PCs surface is illustrated. The study focuses on the wavelength at which the peak of carbonyl, C=O, stretching mode appears. Before the exposure to acetone, the peak of carbonyl stretching mode appears at 1764 cm^{-1}, with absorbance value of 0.34. The peak of the phenyl stretching mode appears at 1499 cm^{-1}, with absorbance value of 0.25.

However, in **Figure 19**, FTIR spectrum of textured PC surface, after immersion in pure liquid acetone, is illustrated. The study focuses on the wavelength at which the peak of carbonyl, C=O, stretching mode appears. Before the exposure to acetone, the peak of carbonyl stretching mode appears at 1762 cm^{-1}, with absorbance value of 0.16. The peak of the phenyl stretching mode appears at 1499 cm^{-1}, with absorbance value of 0.08.

Amorphous form of polymer gives a relatively higher degree of freedom to the polymers tail motion.[13] This permits the absorption of larger amounts of energy, and consequently, the performance of stronger vibrations, in case of molecules or groups that have a dipole moment (asymmetric chemical structure).[55]

Dybal *et al.*[56] noticed a shift in the carbonyl peak from 1770 to 1756 cm^{-1} with a tremendous decrease in the peak's intensity. Liu *et al.*[57] related this shift to the material-phase transformation from the amorphous state to the crystalline state. In addition, the decrease in the peak's intensity is related to the phase transformation of the polymer from the amorphous phase, which allows a higher degree of freedom to the chain motions and bond vibrations, to the crystalline phase, in which the molecules are tightly packed and consequently, the vibrations and motions are restricted.[13,58] It is also indicated that the acetone interaction with the PC is a physical process because no new peak emerged after the treatment process.[57]

3.9.4.6 X-Ray Diffraction Study

X-ray diffraction (XRD) technique is used to study the crystalline structure of the textured PC sheet surface. Both the sharpness and strength of the 2θ peak (**Figure 20**) shows clearly that the textured PC sample due to immersion in liquid acetone for 10 min possesses a thick crystalline layer.[54] This comes in agreement the FTIR data (**Figure 19**).

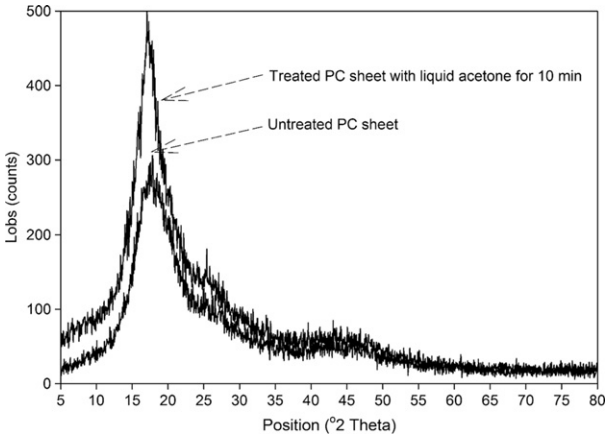

Figure 20 X-ray diffraction data for untreated polycarbonate (PC) sheet, and a textured PC sheet by immersion in pure liquid acetone for 10 min.[53,54]

Acknowledgments

The support of the National Plan for Science, Technology and Innovation (MAARIFAH) – King Abdulaziz City for Science and Technology through the Science and Technology Unit at King Fahd University of Petroleum and Minerals (KFUPM), The Kingdom of Saudi Arabia, through award number (11-ADV2134-04) is acknowledged. The support from the Center of Excellence for Research Collaboration with MIT is also acknowledged for support through projects numbers MIT11111-11112.

3.10.1 Introduction

Atomizers are commonly defined as a mechanical device that can disintegrate a liquid into smaller particles. In surface coating, atomizers create a finer spray and smoother finish than a brush. Atomizers can be optimized, so that up to 85% of the liquid coating ends up on the target and this high transfer efficiency limits air pollution.[1] Although coating is not the only industry associated with atomizers, the development and improvement of the atomizer are closely associated with improvements in the coating industry. The history of their codevelopment is discussed in the next section.

3.10.2 History

The history of surface coating is as old as the history of mankind. Paint is the earliest and most used surface coating in the world. Available evidence was found for the use of paint in Europe by Neanderthal or Cro-Magnon humans around 20 000 years BC. Ancient Aboriginal peoples used paint in North America around 9000 BC.[2] In these prehistoric times, the use of paint was more decorative than functional. The use of paint or other coating materials was seen in Egyptian history, where different organic and synthetic pigments, such as Egyptian blue, were developed.[3] Egyptian blue was made from lime, alumina, silica, soda ash and copper oxides. Their ships were coated with asphalt and balsam oil for preservation and waterproofing.[4] The Japanese and Chinese developed their famous lacquers from Urushi tree sap in order to protect their household instruments from wear and tear. Lacquer is a common term used for wood finish. It can be clear or colored solvent-borne coating.[3] In the fifteenth century, rosin, sandarac, and mastic varnish containing linseed oil were developed in Europe. Thinners were used to decrease the viscosity of paints, which resulted in easier application in cold weather conditions. In the late seventeenth century driers were introduced and the technical preparation of paints was first described by Watkin.[5] Later, the paint and varnish industry slowly started to develop for hand built cars and coaches.[6]

Although surface coating is now widely used for different types of products, other than architectural coatings the early invention and development of coatings was primarily associated with automobiles, masonry, and household products. In modern times, almost every industrial product is coated. In the automotive industry, layers of air drying paints were used in the early twentieth century.[7] Manual sanding and polishing took place after each layer was dried, which meant that several days were required to coat each vehicle. However, during the industrial boom of the Second World War, mass production of vehicles was required and enamel was developed for faster drying and curing. Coincidently, the number of layers was reduced to save time. Enamel is a liquid paint that air dries to a hard finish. These materials can be composed of different types of chemicals. Primers, containing different solvents, synthetic resins, and additive agents were used for corrosion protection, primer surfacers for chip resistance and smoothness, and the top coat for color and weather resistance.[8] In the late 1970s, solvents were recognized as major air pollutants and subsequently, waterborne and electro-deposition paints were introduced. The modern automotive industry applies as many as five coating layers to the exteriors of vehicle bodies.

The spray application of coating has also improved with the changes in coating chemistry. The paint brush was the only instrument used for coatings application up to the nineteenth century. The use of pneumatic guns and pressure pots of paints started being developed in the early twentieth century.[2] Electrodeposition was pioneered by Ford Motor Company in the 1960s for priming their automobiles.[9] This method quickly became popular and other coating industries started using it. However, strict rules for air pollution from the solvents and developing customer attention to color and finishing properties forced the industry to develop improved spraying techniques. Atomizers proved to be efficient and resulted in a better finish and thus became very popular for industrial use.[10]

Nowadays, computer guided robots with different types of atomizers are used in spraying.

3.10.3 Types and Methods of Surface Coating

The various existing paints are classified into three major categories: trade sale paints, industrial coatings, and inorganic coatings.[11] Coatings used on and in structures are the trade sale coatings and can be used for both esthetic and durability issues. For indoor use, appearance and quick drying are major features, while durability is very important for outdoor coating. Protecting the masonry structure remains the major function of this type of coating. Both solvent and water borne paints are used for this purpose.

Industrial coating can be broadly divided into six areas: appliance finishes, automotive finishes, marine coatings, can coatings, coil coatings, and aircraft coatings. Appliance finishes are used on almost all household appliances. Refrigerators, washers, dryers are regularly used, large household appliances where coating is important for their durability and esthetics. The finish of an appliance protects it from corrosion by water, salt, detergent, or even temperature.[12,13] Powder coat, epoxy, and modified acrylics are used as primers, whereas acrylics and alkyds are used as top coats. Flow coats or bell atomizers are used in this process.[13] Zinc phosphate is applied to the bare metal at 1.94–2.26 g m^{-2} when higher corrosion protection is required and iron phosphate is applied at 0.75–1.07 g m^{-2} when lower corrosion resistance can be tolerated.[11]

In the automotive industry, appearance, durability, and corrosion are the major factors affecting the quality of the coating.[11] Primer and topcoats are the major parts of this coating, where primers provide corrosion resistance and topcoat enhances appearance. Both primers and top coats confer different mechanical properties, such as film adhesion to substrates, inter-coat adhesion of different layers, film hardness, and retention of film integrity under deformation, bending, stretching, sharp impact, or stress developed by thermal shock.[11] Durability includes blister resistance or gloss loss due to humidity.[14]

Marine coating is one of the earliest coatings used by mankind and has been in use for the last 2000 years. Different parts of a ship are exposed to different environmental conditions and their coatings differ accordingly. The bottom of a ship is exposed to saltwater corrosion and fouling, while the deck area and the superstructure are exposed to the atmosphere and salt spray. The deck area suffers from regular abrasion and rubbing. The waterline area is exposed to both weather conditions and may be immersed in salt water depending on loading of the ship. These areas need the highest protection with special types of coatings.[15–17]

Can coating is used in both food and non-food type products. Various factors like nature of the product in the can, the type of can, and can manufacturing methods contribute to the type of coating used.[11] In the U.S. food industry, the coating needs to be FDA approved. Some can coatings, like those for cold drinks, should withstand cold temperatures and above-atmospheric pressures for a longer time, whereas cans containing meat products must withstand higher temperatures for a certain period of time.[18]

Coil coatings are mainly used in pre-fabricated products in building components and metal sheating. Coil coated products are pre-coated before assembling the product and allow for optimum use of paint. In this process, metal is cleaned and pre-treated to apply primer. Different types of primers are used depending on the intended exposure. A top coat is applied on top of the primer using rollers. Rollers allow uniform coatings and high production capacity.[11] The most common types of coil coatings are amine alkyds, vinyl alkyds, solution vinyls, thermoset acrylics, organosols, plastisols, etc. However, newer types like silicone polyesters, silicone acrylics, and fluorocarbon coatings are also used by the coil coating industry.[19]

Aircraft coatings are required to be erosion resistant, perform under extreme weather and temperature conditions, and be corrosion resistant. At the same time, the outer coating requires lightning strike resistance and camouflage for military application. Weight is a prime concern in aircraft coating and new developments are underway.[20,21] Hexavalent chromium (CrVI) is used in pre-treatment for corrosion resistance, while epoxy resin primer, and polyurethane enamel top coat are also used.[22]

3.10.4 Droplet Formation and Fate

It is important to know the mechanism of formation of droplets and film of the coating to understand the effects of atomizer properties and parameters on the final finish on the target surface. The basic physics is almost same for most of the atomizers, but their droplet formation technique can vary widely. After the coating is sprayed in the air, significant changes to the droplet occur on contact with the air or other medium. Because most of the atomizers are used in air, the contact between air and spray will be discussed here. It is important to understand evaporation of the coating solvent to understand the surface coating performance on the applied surface.

3.10.4.1 Basic Mechanism

The basic mechanism of atomization has been studied by many researchers, but a final, conclusive understanding of the whole operation is still pending.[37] However, the basic action of atomization is as simple as spraying water from a showerhead or dripping water from a simple capillary tube. Liquid flows along the wall of a capillary tube, forms a sheet of liquid and then is shed in drops.[37,43] These bigger drops may be further disintegrated because of combined internal and external forces and form smaller droplets (spray), which is directed to a surface. Formation of a fluid sheet is different for different types and models of atomizers.

3.10.4.2 Formation of Droplets

The atomization process starts in the atomizer where the fluid is forced through a nozzle. Pressure is applied in the liquid to force it through the nozzle, and as the pressure is released the liquid spreads out. As the length of the liquid front increases, by conservation of mass, the thickness of the liquid front must decrease.[28,79] The breakup of the liquid layer into droplets is a

complex phenomenon which occurs within a very short distance. Pressure, surface tension, and gravitational force are the driving forces to form unstable ligaments of fluid. Upon further propagation of these unstable ligaments, they contract by surface tension and break up into liquid droplets.[28] For different kinds of atomizers the initial ligament formation technique is different. However, after the formation of ligaments the droplets are formed in the same way.

3.10.4.3 Spray Air Contact

When a water droplet travels through the air, it is subject to evaporation and hence a decrease in size. The droplet also cools down due to evaporation and a saturated vapor layer surrounds it. At some point, the droplet reaches its wet bulb temperature. The temperature of the droplet is then lower than the surrounding air temperature, which causes heat flow towards the droplet, and evaporation starts again.[77,78] Thus, the rate of evaporation is not constant and the process is not steady, so the time required for evaporation can be divided into two steps. The first is the time from the formation of droplets to the time when droplets reach their wet bulb temperature. The second is a period of unsteady evaporation. The process continues until the droplet reaches the target surface, or the water completely evaporates. The principle can be applied to other solvents, as well. If the vapor pressure of the coating solvents in the medium is below that of the saturation pressure of the solvents in the medium, evaporation occurs. Evaporation of the droplet in-flight is important for environmental effects and atomizer efficiency as well as the surface finishing quality.

3.10.4.4 Coating Formation on the Surface

When the droplets reach the target surface, they stick to the surface and make a film. If an electrostatic charge is used, the particles lose their charge to the grounded surface.[43] Thus the surface does not repel further droplets from adding to the film. When a liquid drop comes into contact with a target, the drop may follow different scenarios, depending upon the inertia and the target properties. It may deposit into a thin disk, break into secondary and tertiary droplets, or if its inertia and cohesion are high, it may possibly bounce. When inertia is negligible the drop will deposit gently and spread over the surface until equilibrium is reached. If the substrate is roughened, the drop may even splash (lateral spread and rebound) upon impact.[81]

3.10.5 Types and Requirements of Atomizers

Atomizers are available in different types and shapes according to their use. The most common types are the pressure atomizer, rotary atomizer, air assist or air blast atomizer, and effervescent atomizer.[7] Electrostatic charging and ultrasonic atomizers are newer advancements in this area.

Pressure or pressure swirl atomizers are the most common type of atomizer used in the coatings industry. They are also used in aerosol spray cans for deodorants, paint, and air freshener.[7] In a pressure atomizer, the liquid is injected with a tangential velocity component into the swirl chamber. A vortex is produced which develops a low pressure at the axis of the nozzle. When turning on the flow, the external gas is sucked into the center of the vortex, forming an air-core. This forces the liquid to emerge as a cylindrical sheet in the exit orifice, with both axial and tangential velocity components. This causes a conical liquid sheet to form which then breaks down into a spray that has a hollow cone pattern. For finely atomized sprays, the spray angle reduces with distance downstream and the central zone gradually fills with drops, thus forming a solid cone spray.[23] The pressure swirl atomizer is recognized as the most energy efficient method of atomization where pressurized liquid is used, as the method requires a minimum supply pressure to provide a given drop size.[24] The breakup processes of the liquid sheet is generally complex and involves sheet waves, perforations, and ligament breakup. There is usually some repetition in the process which leads to droplet clusters.[24] A typical pressure swirl atomizer is shown in Figure 1. For a pressure swirl atomizer, the pressurized coating forms a ligament of fluid from the sharp edge of the atomizer, which then breaks up into droplets.

A Rotary Bell Atomizer (RBA) is a rotating device used to atomize liquid into spray. In the automotive coating industry, it is a widely used applicator which produces very small droplets and ensures smooth and consistent spray. The RBA allows close-in painting for high transfer efficiency and great penetration into part recesses. It has an excellent pattern control, which limits over-spray considerably for reduced paint waste. A common RBA consists of the following major assemblies: cartridge (optional), valve module, turbine, bell cup, shaping air ring, and the electrostatic system. The cartridge is a detachable vessel which can be refilled. In assembly line spraying, a continuous liquid feeding system is attached to ensure a continuous supply of paint. The valve module controls the flow of liquid by different tubing passages and valves. The turbine is a high speed motor that rotates the bell cup at 10 000–120 000 rpm. The bell is a conical cup attached to the turbine. The liquid is injected into the center of the concave side of the cup and the centrifugal force pulls the paint toward the

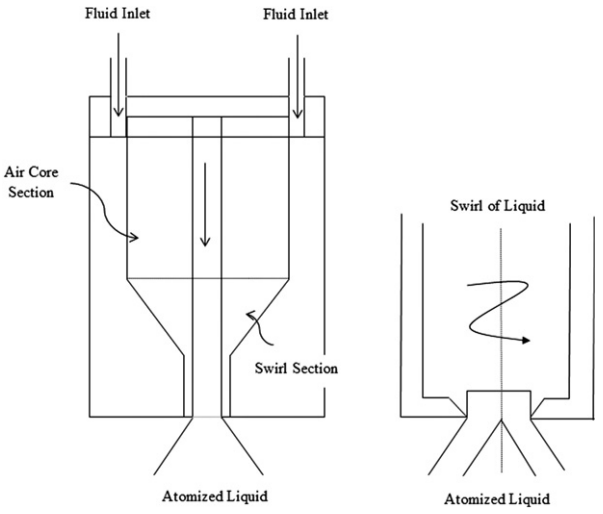

Figure 1 Pressure-swirl atomizer.

edge of the cup.[25,26] The rotating surface may take the form of a flat disk, vaned disk, cup, or slotted wheel.[27] A coaxial air jet termed the shaping air can be used to assist atomization. The shaping air ring has a series of small pinholes along its circumference from which air can be blown onto the outside of the bell circumference to control the spray pattern. The electrostatic system can be used to provide a high voltage (usually between 60 000 and 90 000 V DC) to the spray so that the droplets will be charged and attracted to the grounded target. The RBA can be used without electrostatic charge, but this is rare. Droplets with a high surface charge spontaneously break into smaller droplets. A typical RBA is shown in **Figure 2**.

The process of centrifugal atomization has been studied by several workers, including Hinze and Milborn,[28] Dombrowski *et al.*,[29] and Ray *et al.*[30–32] and has been described in the next section. Hinze and Milborn[28] did the initial investigation of the atomization of liquids using a rotating cup and divided the mechanism of droplet formation into three possible 'stages' depending on the supply rate of the liquid. In stage 1, a very low flow rate is present and a liquid sheet is formed. The sheet deforms by centrifugal forces and drops are formed. With an increased flow, stage 2 occurs where the sheet becomes ligaments of liquid. Higher flow rates increase the thickness and number of ligaments but the ligaments are not sustained long due to disturbances caused by external forces. These ligaments form droplets. If the flow rate is increased more, the ligaments reach their maximum thickness where an extending film is formed from the edge of the cup. This film later converts to a circumferential sinusoidal wave of ligaments and breaks down into droplets. This is termed stage 3.

However, when the rotating speed is high, the atomization process is continuous and occurs at the periphery of the rotating cup or disk. Ligament formation can be made to produce much finer drops if an electrostatic field is applied. Generally, it is found that atomization quality is improved (droplets are smaller) by (1) an increase in rotational speed, (2) a decrease in liquid flow rate, and (3) a decrease in liquid viscosity.

The air assist atomizer and air blast atomizer are almost the same kind of atomizer with a difference in air flowing style. There are beneficial effects of flowing air in assisting the disintegration of a liquid jet or sheet. A well-known disadvantage of the swirl type nozzle is that it has a pressure differential (between the liquid paint and the air) is too low to give good atomization. This problem can be solved using an air assist atomizer and controlling the pressure difference.[7] An extensive variety of air assist atomizers have been designed by various researchers for industrial use in gas turbines and oil-fired furnaces. The details of different types of air assist atomizer can be found in works by Romp,[33] Gretzinger and Marshall,[34] Mullinger and Chigier,[35] and Sargeant.[36] Regardless of the type of design, the primary concept is to impinge a high velocity gas into the liquid. Normally, the liquid has lower velocity and the assisting air can be used both internally and externally. If air is used internally, the spray cone angle is proportional to the decrease of air flow.[37] This type of atomizer is highly appropriate for viscous liquids. Atomization quality is high regardless of the liquid flow rates.[37] If air is used externally, a constant spray angle is produced for any liquid flow. However, external air assist nozzles have a special advantage in that they are less susceptible to air–liquid mixing. Their only drawback is a higher power requirement.[7] A typical internal air assist atomizer is shown in **Figure 3**.

The effervescent atomization technique was developed in the late 1980s by Lefebvre *et al.*[38–40] who called it aerated liquid atomization. In 1990 Buckner *et al.*[41,42] described it as effervescent atomization. This is actually an internal air assist atomizer where high velocity gas and lower velocity liquid go through internal mixing before atomization. But compared to other internal-mixing atomizers, the effervescent atomizer has a lower air flow rate. The air introduced into the liquid forms a bubbly two-phase mixture upstream of the discharge orifice.[38–40] This bubbly mixture has a relatively low density, which occupies most of the total cross-sectional flow area. This phenomenon improves atomization by reducing the characteristic liquid dimensions within the discharge orifice.[41,42] A typical effervescent atomizer is shown in **Figure 4**.

Figure 2 ABB rotary bell atomizer (RB1000 WSC series).

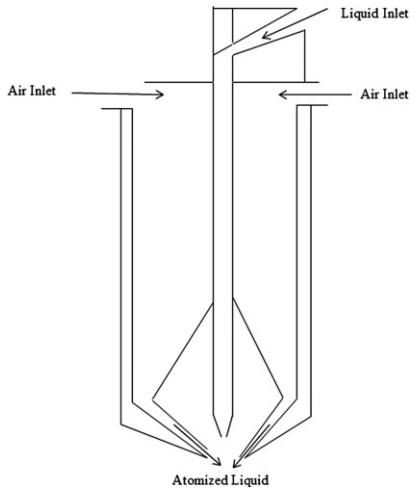

Figure 3 Schematic diagram of an air assist atomizer.

Ultrasonic atomization is a recent advancement where high frequency sound is used to atomize the coating. A simple basic diagram for ultrasonic atomization is given in Figure 5. A disc shaped transducer is used to impart mechanical energy as vibration amplitude in the direction of liquid flow. This vibration causes a transverse wave along the surface of the atomizer, from which droplets form from the peaks in amplitude on the surface.[69] Lord Rayleigh, who is considered as the pioneer of atomization, had started the work on ultrasonic atomization, published in his 'The Theory of Sound' around a century ago. He found that when a liquid is placed in a rotating smooth disk, it creates a vibration perpendicular to the motion of the disk.[43,68] This vibration energy is consumed by the liquid placed on it, which then takes a wave shape. These waves are actually capillary waves which later disintegrate due to the combined action of centrifugal and inertial forces.[43] Normally, atomizers are smaller for higher frequencies, so that less energy is consumed. A higher frequency also creates smaller droplets, which have a smaller maximum flow capacity and create a high transfer efficiency and smooth finish.[69,70]

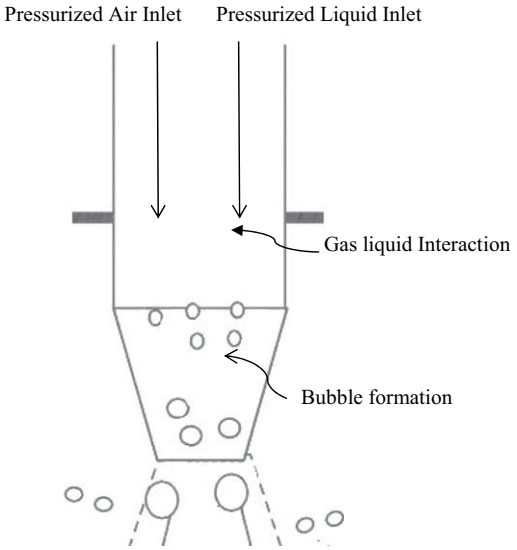

Figure 4 Schematic diagram of an effervescent atomizer.

The ultrasonic atomizers normally create a soft, low-velocity, fine mist which can be controlled to within square micrometers on the target area. This unique feature allows it to be used in different medical equipment, like spray nozzles for the ear, eye or nose.[71,72,80] It has also been used in recent nano-surgery, where protective layers of anti-inflammation medicine coating are used.

Electrostatic application is a technique wherein a high voltage, low current is used in the coating application to entice the spray towards its target. Because of the static charge, the repulsive forces between the particles keep them apart. Normally the charge is applied before or during the droplet formation. Electrostatic application is often used with rotary atomizers which cause a more evenly finished product.[65] The use of electrostatic forces during atomization balances the mechanical forces, like surface tension, and hence a proper combination of coating surface tension, viscosity, and electrostatic charge is required.[66] The precise combination of these three parameters has restricted the use of very high solids content or water borne coatings to get very good results while using electrostatic charge. Electrostatic application is used when coating the application rate is less than 4 $cm^3\ min^{-1}\ cm^{-1}$ of applied length; and the electrostatic charge is between 80–150 kV.[67,68] One of the main benefits of the use of electrostatic application is its higher transfer efficiency, which allows for lower consumption of paint.

3.10.6 Atomizer and Finishing Properties

The finished properties of a surface coating depend upon various other parameters in addition to the spray atomizer itself. Surface cleaning and preparation, coating preparation,

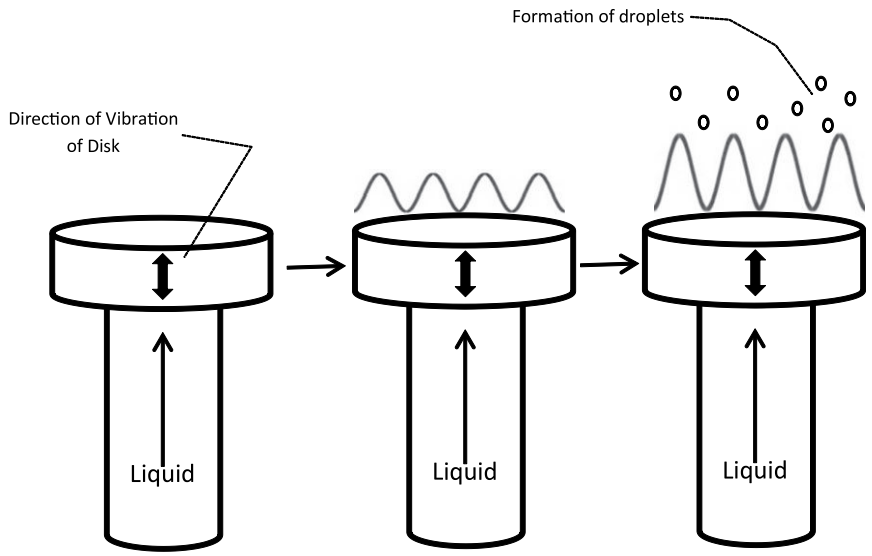

Figure 5 Formation of droplets in an ultrasonic atomizer.

and the spray booth environment influence finishing properties. For any surface and coating type, the surface should be cleaned thoroughly before it can be used for commercial coating. The surface may also require sanding, and primer application. The spray booth should be temperature and humidity controlled to avoid any inconsistencies that would set back production.[58]

The most common finishing problems with surface coatings are blistering, chipping, cracking, cratering, crawling, delamination, dissolution, mottling, and orange peel.[59] Blistering looks like a hollow bubble inside the coating, and generally occurs when sprayed paint is cured. Excessive air flow through the atomizer and improper curing of lower coating layers causes blistering in the final finish. Blistering is only visible after final curing and sometimes can occur after a few months to a few years. The only remedy for blistering is a costly removal and repaint of the surface.[60] Chipping is another problem which can be found anytime from the time of drying to regular use of the surface but mainly occurs after drying. Various portions of the coating can break away. Normally this happens due to incorrect application of the primer and sealer. However, variation of temperature and pressure in the spray booth can also create the problem.[62] Cracking can occur anytime in the cured coating. Normally, it happens in the top coat. High temperature and excessive use of coating are believed to be the major causes behind cracking. This is also a costly problem and repaint is the only remedy.[60,63] Cratering is found immediately after the coating is applied. It looks like a bubble has burst and left a hole in the coated area. Excessive airflow or contamination of the surface are the major causes of this problem. Because the problem is found before drying, it is comparatively cheaper to repaint, but still results in loss of paint and use of labour.[61] Crawling is the excessive waviness of a clear coat. It happens due to uneven or excessive amount of spray. Tapered or faulty atomizers can also create this. The problem can be identified immediately after or during the application of the coating. The clear coat needs to be removed and re-coated to fix this problem.[60] Delamination is a sudden, spur crack and happens on the side. Coating on an unfinished surface, lack of proper airflow, and insufficient drying causes delamination. It is found after drying, and re-painting is the only remedy.[64] Dissolution is not caused by the improper use of an atomizer: rather, it is caused by improper mixing of the coating before application. Mottling is a whitish appearance on the coating surface. Improper or faulty nozzle type and booth temperature are believed to be its major causes. The problem is generally found during spraying and can be fixed immediately.[65] Orange peel is a common problem and is found after drying. It is costly to fix as the problem often arises when the product is with the customer. Lack of surface preparation and improper temperature are the major causes.[60]

In a pressure-swirl atomizer, the liquid flow through a narrow channel results in a higher velocity of the liquid. The liquid pressure was already converted to kinetic energy by the pressure-swirl due to the angular velocity induced in the swirl area. These result in an air vortex which partially blocks the orifice. Both radial and angular velocity exist in the liquid when it emerges from the orifice, taking the shape of a hollow cone. Upon release, these velocities create a high velocity difference between the discharged liquid and the surrounding gas.[28] Pressure-swirl atomizers have better atomization quality than simple nozzles for the same discharge rate. Normally, a high liquid flow rate is maintained and governed by the spill flow rate. A liquid sheet is produced when it passes through the orifice. The liquid sheet thickness and the droplet size decrease with increasing rotating speed. However, the sheet thickness is independent of the flow rate of the discharged liquid.[43] The spray cone angle is independent, but varies with the spill return flow rate.[43]

Different researchers investigated the spray characteristics and performance of pressure swirl atomizers. Taylor[44] and Squire[45] were the pioneers who studied the breakup of liquid sheets generated by swirl atomizers due to liquid film instabilities. Other authors studied the relation between the physical properties of the liquid and droplet diameter. Dexter[46] found that when liquid with suspended solids was used, it did not substantially change the drop size distributions. However, both researchers found that regardless of the type of fluid, surface tension and viscosity play critical roles in the drop size distribution. Stelter *et al.*[47] found that the liquid elasticity was significant for drop formation. An increase of the liquid elasticity increased the average drop diameter and decreased the volume fraction of small droplets in the sprays. Schütz *et al.*[48] used water–glycerol solutions and showed an increase of mean drop size with the increasing flow rate. Rhim *et al.*[24] found that an increase of the liquid flow rate decreased the sheet break-up length, while an increase in the water content increased the break-up length. While using emulsion sprays, Sheng *et al.*[49] found that the mean drop diameter increased with increasing aqueous phase concentration.

Rizk and Lefebvre[50] investigated the impact of geometrical dimensions of a pressure atomizer on the sprays produced. Normally, a very high velocity liquid is used in a pressure swirl atomizer, causing instabilities in the liquid sheet. The liquid sheet breaks up into ligaments and forms a conical shape before the instability converts the ligaments into droplets.[7] The larger droplets populate the outer regions of the spray while moving along their original flight angles. By the same mechanism, the number of smaller droplets is reduced in the core of the spray.[7]

Several investigators worked on RBAs and their effect on liquid atomization. Fraser *et al.*[51] conducted a series of investigations to understand the formation of droplets and liquid sheets during atomization. A rotary atomizer was used with an air spray to confine the fluid spray. They did not find any significant impact of air containment on atomization. However, they found that the initial drop size from the breakup of the liquid sheet was a function of sheet thickness. They concluded that a good finish is dependent on the sheet uniformity and depends on bell speed, flow rate, and viscosity of the fluid.[51]

Di Domenico and Henshaw[52] set up a full factorial two-level DOE matrix to show the relationship between the paint finish appearance and variable RBA parameters: flow rate, bell speed, shaping air, and electrostatic potential. The distinctness of image, surface waviness, and multi-angle color were measured for evaluation. They concluded that a change of particle diameter due to the change in these parameters played an important role in the evaporation of the paint droplets. They hypothesized that greater in-flight evaporation of the spray resulted in a smoother finish.

Corbeels *et al.*[53] investigated the relation between bell speed, flow rate, and mean drop size. A higher bell speed caused higher centrifugal and Coriolis forces and decreased the mean drop size. But, a higher flow rate increased the mean drop size when the bell speed was below 20 000 rpm. The average droplet size increased as a result of increasing the flow rate at constant bell speed. A higher bell speed with a constant flow rate decreased the average drop size and increased the droplet number.

A shadowgraphy technique was used by Basu *et al.*[54] to understand the particle size characteristics of atomization caused by a rotary atomizer. They used metallic, solvent borne, and water borne paints as sprayed liquids. Within the 30 000–50 000 rpm bell speed range, the mean particle size decreased with increasing bell speed; but the rate of decrease fell outside of this range.

In a spray, there is a direct relation between the average droplet size, surface area, and evaporation rate. The higher the drop size, the lower the total surface area and the lower the total evaporation. In an investigation using water spray,[30,31] Ray *et al.* used a Particle Dynamic Analyzer to show the effect on evaporation of different atomization speeds, air flow rates, and water flow rates. They also introduced electrostatic charging while performing the same experiments using clear coat.[32] They held other variables, like atmospheric pressure and temperature constant, and calculated evaporation ($cm^3\,s^{-1}$) between planes 22.5 and 37.5 cm from the atomizer. It was found that the droplet diameter decreased and hence the evaporation increased with higher bell speed or lower flow rate for both water and clearcoat.

Effervescent atomizers are relatively new and various researchers performed detailed experimental studies on them. They tried to compare the performance and spray characteristics of effervescent atomizers over other types of atomizers. The results of this research specify that effervescent atomizers (EAs) exhibit several advantages over conventional pressure or rotary atomizers. Compared to other twin-fluid atomization, air flow-rates are lower in EAs.[55–57] Other conventional atomizers are higher in injection pressure and EAs achieve better atomization.[55,56] EAs have a larger outer orifice diameter, which decreases the chance of fluid clogging. In combustion applications, effervescent atomizer-produced sprays result in lower air pollution due to air existing in the spray core.[55] Research showed that the mean droplet size produced by EAs is relatively unaffected by liquid viscosity, meaning that this single atomizer can be used for a variety of liquids without compromising performance.[7,57] When a liquid with suspended solids is used, EAs have an advantage of less erosion at orifices due to the lower flow rate.[7,57] EAs are more energy efficient compared to pressure or rotary atomizers.

Ultrasonic atomizers are better than traditional atomizers in terms of operating energy requirements. Traditional atomizers use most of their energy to create a velocity difference in order to disintegrate the particles, whereas ultrasonic atomizers use more efficient ultrasonic energy. To achieve full disintegration of the fluid, it is important to operate the atomizer defect-free. The nozzles of the atomizer should be clog-free to get the most uniform coating. Ultrasonic atomizers are free from clogging as the liquid is placed around a sonotrode; a solid vibrating element that does not have any pores to clog.[37]

Bittner *et al.* used an ultrasonic atomizer to study the feasibility of ultrasonic atomization combined with subsequent organic solvent extraction.[73,74] The results of these works showed that ultrasonic technology has the potential for both aseptic processing and upscaling. In the pulmonary drug industry, aerosol spraying is widely used and research is continuing in drug delivery systems by microparticles created using a spray-congealing technique.[75] Passerini *et al.* found that the administration of certain low melting point, poorly soluble drugs can be improved using the ultrasonic atomizer.[76]

The properties of the final finish of the coating depend on the target surface and its application. However, some of the major properties are discussed in the following paragraphs.

Humidity is a vital concern for all types of coating. However, special consideration is given in automotive, marine and aircraft coatings. Condensation resistance is tested for surface coatings used in several food industries and building surface coatings to avoid blistering. For automotive coating, ASTM D714-02 is followed to evaluate the degree of blistering in paints.[82] This standard provides reference photographs to quantify blistering, but the treatment to induce blistering is usually specified by the company purchasing the coated product. The atomization technique, its application method and surrounding pressure and temperature are vital to maintain the proper condensation resistance of the surface.

In the automotive industry salt spray resistance is important, especially in winter countries or marine painting where steel is exposed to salt, the coating should have a standard salt spray resistance capability. In ASTM D610-08 a scale and description of rust ratings are established.[69] The coated steel surface may be exposed to a fog of salt spray, acetic acid, salt/SO_2, or copper and sodium chloride in acetic acid. Though salt spray resistance does not have any direct relation with the atomizer properties, the thickness of the coating sprayed reduces the chance of corrosion due to salt. An even thickness of coating minimizes coating use, and good atomization is a key in this respect.[83]

Weather resistance is important for all the major coating industries except the food industry. The accelerated weathering resistance test is done to find the durability of a coating in different environments. Accelerated weather testing is done with a combination of UV light, cool-down periods, and exposure to moisture or salt spray. Some of the after-paint problems discussed earlier in this section, which are related to paint appearance, are tested here. The final coating should not have any kind of chipping, cracking or flaking. For testing the gloss of the surface, ASTM D523-14 is used.[84] The method uses a Parallel-Beam Glossmeter to measure the reflected light at 60, 20, or 85 degrees from normal. The change in color due to weather (or when comparing two different surfaces) is quantified by ASTM D2244-15a.[85] This method compares coatings by measuring color coordinates based on daylight illumination of color tolerances and color differences between specimens. The differences in color between the standard reference and a test specimen are measured by the use of a colorimeter. Reflectance readings from colorimeter are then converted by computations to color-scale values.

Film adhesion is an important criteria for any surface coating. Since adhesion is the major property which binds coatings on surfaces, a poor adhesion indicates poor quality

of the coating, which may lead to blistering, chipping, and delamination. In the automotive industry, ASTM D3359-09e2 is followed to measure adhesion by the Tape Test[87]. An x-cut is made through the coatings with a razor blade. Pressure sensitive tape is applied to the cut and pulled off. Then the adhesion is assessed qualitatively using a visual scale.

The uniform thickness of coating directly depends on the types of the atomizer and its operating conditions.[86] Studies showed that rotary bell atomizers are the most efficient when automotive coatings are applied.[37]

Abrasion resistance is the property of a coating which resists surface coating wear due to other materials. In the marine industry, abrasion resistance is important as water is always the cause of flat rubbing on the surface. For abrasion resistance ASTM D4060-14 is used, where the abrasion resistance of coatings is measured by the Taber Abraser. The cured coated surface is abraded using rotary rubbing action by a two way rotary abrading wheel. The resulting abrasion marks on the specimen are measured.[87]

3.10.7 Conclusion

The theoretical description in this chapter is a summary of our understanding of the types of surface coating, types of atomizers, and their effects on atomized fluid particles. The durability and esthetic of surface coating are dependent on droplet size distributions, which in turn are dependant on physical properties like surface tension and viscosity of the liquid. The current discussion was limited to the direct effects of the operating conditions of various types of atomizers on the droplet size. However, different defects in surface coating, and their origin in relation with application of coatings are also discussed here.

3.11.1 Introduction

Aluminum extrusion die is exposed to high temperatures resulting not only from the heated billet but also from heat produced by friction and deformation. Moreover, the die is susceptible to considerable frictional forces at the die bearing land due to high pressure in the extrusion process. In aluminum extrusions, the hard oxide film, which forms instantly on the surface of the extruded metal, causes extensive wear of the die bearing during service. In general, AISI H13 is used for extrusion dies and other tooling components for production of standard aluminum profiles, which are characterized by good resistance to wear, high level of toughness, uniform and high level of machinability, high-temperature strength, and resistance.

Among the different methods available for the enhancement of the surface properties of extrusion dies with complex-shaped cavities, gas nitriding is one of the most efficient; it involves atomic nitrogen from dissociating ammonia gas at temperatures in the range 450–590 °C diffusing into the steel surface. The nitriding of the steel can be visualized bringing N_2 gas into contact with the surface of workpiece under extremely high pressure, which becomes possible by using NH_3 mixed with N_2 or H_2 gas.[1,2,3] Formation of the nitrided case begins through a series of nucleated growth areas on the surface of the steel, a 'compound layer,' with the diffused and reacted nitrides forms beneath the surface called the 'diffusion zone.' The area below the diffusion zone is the core of the steel consisting of tempered martensite. The compound layer occurs as epsilon phase ($\varepsilon - Fe_{2-3}N$), gamma phase ($\gamma' - Fe_4N$), or mixed phase ($\varepsilon + \gamma'$).

In traditional gas nitriding, which has limited control of the growth of the nitrided layer, the process is usually performed in an atmosphere containing partially dissociated ammonia gas at 500–600 °C. In this process, the nitrogen concentration at the surface cannot be properly controlled and oversaturation of the nitrogen can result in excessively porous and brittle superficial

 doi:10.1016/B978-0-12-803581-8.09174-8

'compound layer.' Such an external porous zone has lower hardness, is brittle, and is of spalling nature. It is important to emphasize the fact that the compound layer is very beneficial in the case of hot extrusion dies with regard to wear and corrosion resistance if the porosity is appropriately controlled. Moreover, the conventional nitriding equipment requires frequent monitoring and manual adjustments of atmosphere flow by the operator and, hence, repetitive and consistent results from one process to another cannot be guaranteed. These disadvantages highlight the need for automated controlled gas nitriding. It uses a mixture of ammonia and an additive gas and is controlled by a parameter known as nitriding potential (K_n) instead of the dissociation rate. Due to proper selection of atmosphere composition and adjustment of its flow rate through the retort (i.e., K_n), it is possible to form layers of the required phase composition with the required thickness of individual zones. Mathematically, K_n is the quotient of the partial pressure of the ammonia still present in the retort (the amount of ammonia that has not yet dissociated) and the partial pressure of the hydrogen that has already formed by ammonia dissociation. The nitriding potential can be viewed as the nitriding capability of the atmosphere, and its physical interpretation is that its value strictly corresponds to the equilibrium concentration of nitrogen in the workpiece surface for any given temperature.[4] The ability of the controlled nitriding process for extrusion dies is becoming a requirement in extrusion plants.

Considerable research studies were performed to examine gas nitriding treatment of various alloys with regard to various factors like the surface preparation, die geometry, multiple nitriding, process variables, and others. Sueyoshi *et al.*[5] examined the influence of the mechanical pretreatment on gas nitriding behavior of austenitic stainless steels and found that the nitriding reaction can be enhanced markedly with increasing surface roughness when its value exceeds 6 and 1 μm for SUS310 steel and SUS316 steel, respectively, whereas no reaction is recognized for the surface roughness less than these values. Cselusniak *et al.*[6] showed that a soft and shallow nitrided case is achieved in H13 steel extrusion dies if the bearing surface of the die is not activated before gas nitriding. They suggested that the bearing surface of die should be properly polished for effective nitriding. Bei *et al.*[7] studied the effects of surface ultrasonic peening (SUSSP) on gas nitriding of mild steel. They observed that when gas nitriding at temperatures below 560 °C, SUSSP treatment could not only enhance both diffusion coefficient and mass transfer coefficient dramatically during gaseous nitriding process but also reduce the threshold nitriding potential. With this surface treatment before gas nitriding, the nitriding rate can be accelerated so dramatically that nitriding time can be reduced to the half, or the conventional nitriding temperature could reduce approximately 50%. Wroblewski and Skalski[8] demonstrated that the combination of shot peening with gas nitriding on Armco iron leads to a change in surface layer formation as well as to the improvement in its properties. The plastic deformation generated by the glass shot impacts stimulates diffusion processes and results in increased thickness of nitrided layer in comparison with classical gas nitriding. Baranowska *et al.*[9] investigated that cathode sputtering used as a pretreatment before gas nitriding increases the rate of nitride layer formation in iron. They reported that the ground sample exhibits a thicker nitrided layer after nitriding as compared to the polished sample due to the structural changes observed in the ground samples. They considered surface activation as a positive effect on the gas nitriding kinetics.

Kwon *et al.*[10] studied the growth behavior of the nitrided layer inside a Cr–Mo steel hollow tube with corrugation over the internal surface. They observed differences in the compound and nitrided layer thicknesses on the land and groove surfaces and their dependence on the size of geometric features. Nonuniformity in the nitrided layer thickness and variation with size and shape of the test specimen during plasma nitriding was reported by Ataide *et al.*[11] Alves *et al.*[12] studied the growth behavior of plasma-nitrided layers on AISI 316 stainless workpieces with complex geometry. They found significant differences in thickness and hardness of the resulting nitrided layers as a function of nitriding parameters. The observed thickness of nitrided layers increased with sample height. Tercelj *et al.*[13] studied the ionic and gas nitriding of dies made of H10 tool steel with narrow and deep gaps. A similar type of study was performed by Kugler *et al.*[14] for AISI H13 dies. In both studies, variation in the nitriding depth and compound layer thickness with varying gap sizes were observed. Nayal *et al.*[15] presented a comparison of pulse-plasma-nitrided flat coupons and complexly shaped substrates such as twist drill test bits and showed that the incorporation of nitrogen depends strongly on the substrate geometry. They showed that the amount of nitrogen incorporated at the cutting edge of a drill was systematically higher than in flat coupons nitrided under identical plasma conditions. Reinhold *et al.*[16] performed plasma nitriding in a commercial plasma nitriding facility on various aluminum alloys to study the formation of aluminum nitride layers dependent on the chemical composition and geometry. In addition to simple flat specimens, more complexly shaped samples were investigated to get information about the uniformity of film covering.

Rolinski *et al.*[17] reported that the kinetics of re-nitriding under the plasma nitriding process is a continuation of pre-existing case growth, and long exposure to the nitriding temperatures has a negative effect on the hardness of the 3% Cr–Mo–V steel. Somers *et al.*[18] and Thomas Greßmann[19] have reported that upon long nitriding treatment, the formation of porosity in iron nitrides in the compound layer is very common and can be attributed to the metastable nature of the iron nitrides with respect to the decomposition into iron and molecular nitrogen gas at normal pressure. Czelusniak *et al.*[20] reported that die surfaces require re-nitriding after certain work time. They suggested that die face, unlike die bearing, is exposed to much less wear during the extrusion process, and it may suffer from over-nitriding during the re-nitriding process, resulting in spalling or exfoliating effects.

Hernandez *et al.*[21] proposed a method based on hardness data corresponding to the hardness depth profile of AISI H11 steel in conjunction with Fick's second law. They validated the procedure by computing an estimate of the diffusivity parameters of nitrogen in the α–Fe matrix. Spies *et al.*[22] showed that the main condition for formation of nitrided layers with controlled quality and specified structure is possible by controlling the nitriding potential in the working medium. *In situ* control of a nitriding process with the help of analyzers makes it possible to meet the requirements on the surface layer, prevent disturbance of the equilibrium due to uncontrolled

arrival of oxygen, and ensure the requisite proportion of the gas phases, thus optimizing the structure of the layer and its quality. Mridha and Khan[23] studied the effects of nitriding process variables and prior austenitizing and tempering temperatures for En40B steels gas-nitrided at various temperatures and in different nitriding potentials. They found that surface hardness increases and steeper hardness profiles are obtained with increasing nitriding potential using lower nitriding temperatures. Akhtar *et al.*[24] studied the influence of mechanical pretreatment in terms of surface roughness on nitriding kinetics of AISI H13 tool steel during controlled gas nitriding, and they found that the surface texturing by surface roughening prior to nitriding significantly enhances the nitriding kinetics and is expected to increase wear resistance of H13 steel used for aluminum extrusion die while resulting in its increased service life. Keddam *et al.*[25] presented results of simulation of the diffusion process of nitrogen on pure iron and showed that it is possible to predict both the microstructural nature and the thickness of nitrided layers as well as the nitrogen profile within the formed phases during gas nitriding. Hu *et al.*[26] showed that the change in the concentration field and the factors affecting it can be addressed quickly and accurately using a mathematical model. They also presented a measurement technique for the diffusion coefficient and the activity coefficient of nitrogen.

The purpose of this chapter is to evaluate the applicability of the controlled nitriding process used for the nitriding of AISI H13 dies in the extrusion industry and the benefits that can be achieved in terms of die performance. The study is implemented by undertaking various case studies wherein the H13 specimen is nitrided with the help of automated controlled nitriding equipment with preprogrammed nitriding potential values, and the effects of surface pretreatment, die profile geometry, and multiple nitriding are analyzed both experimentally and numerically. The nitrided layers of samples were compared in terms of microstructure morphology, nitride case depth, hardness depth profile, and quality.

3.11.2 Experimental Procedures

3.11.2.1 Sample Preparation

All the samples used in the current study are H13 tool steel (commercial name: ORVAR 2 Microdized), a typical die steel used for hot extrusion dies with the following composition (%wt): 0.39% C, 1% Si, 0.4% Mn, 5.3% Cr, 1.9% Mo, 0.9% V, and balance Fe. The samples were heat-treated with proper environmental controls using a vacuum furnace to prevent decarburization. The heat treatment cycle included: stress relieving at 650 °C; preheating at 815 °C; austenitizing at 1030 °C; quenching; and double tempering (first at 550 °C and second at 605 °C). After first tempering, the expected embrittling effects of coarse carbide structure, formed by the transformation of retained austenite to tempered martensite, were alleviated by a subsequent second tempering step.

3.11.2.2 Nitriding Cycle Used for Samples

Nitriding technology with state-of-the-art equipment and a user-friendly software program, allowing full automation of all functions, process stages, and safety procedures with closed-loop processing parameters, were used in collaboration with a local industrial setup. The system was capable of maintaining the preset values of nitriding potential ($K_n = p_{NH3}/(p_{H_2})^{3/2}$ where p is the partial pressure of constituting gas). The values of nitriding potentials (K_n) were maintained within certain limits as desired for each processing stage by continuous self-correction. The system set the flows for nitrogen and ammonia according to the preset program. Figure 1(a) shows the variations of temperature and gas flow rate (Q, liters per minute) in the retort during two-stage nitriding. Operating parameters for stage 1 were 490 °C and set-point K_n of 6.4 $(atm)^{-1/2}$; those for stage 2 were 530 °C and set-point K_n of 0.323 $(atm)^{-1/2}$. The furnace was first preheated and equalized to the preset temperature (450 °C) for approximately 3 h. The air in the retort was replaced by the ammonia and nitrogen gas mixture. The filling time (1 h and 40 min) was calculated automatically by the control system based on the furnace volume and incoming gas flow. During each process stage, the temperature and gas flow were controlled to achieve the set-point K_n values, which depend on the ammonia dissociation percentage. The variation of K_n during the nitriding cycle is shown in Figure 1(b) and was recorded at in intervals of 10 min; in which case, K_n variation depicted the decrease of ammonia percentage from stage 1 to stage 2 (i.e., an atmosphere with increased dissociation of ammonia from stage 1 to stage 2). The heat stages were activated automatically, before the next process stage commenced. The times of heating 1 and heating 2 prior to stage 1 and stage 2, respectively, were set to 1 h. The process times for stages 1 and 2 were 1.5 and 3.3 h, respectively. After the second stage, a cooling fan was automatically activated until the preset cooled temperature (110 °C) level was achieved. The total nitriding cycle took approximately 15 h; however, the actual nitriding time was approximately 6.8 h, corresponding to heating 1 through stage 2, as illustrated in Figure 1(a).

3.11.2.3 Nitrided Layer Characterization

The samples were prepared for cross-sections for optical and scanning electron microscopy (SEM). The cross-sections were investigated using an Axioplan 2 imaging optical microscope. The samples were mounted, polished with diamond paste (initially with 3 μm and finally with 0.25 μm), and etched with nital (1 vol% HNO_3 in ethyl alcohol) for approximately 7 s before examination. The SEM micrographs were analyzed with a Jeol JSM-6460LV scanning electron microscope equipped with energy-dispersive spectrometry (EDS). The EDS line-scan technique was used for qualitative analysis of nitrided layer microstructures. X-ray diffraction (XRD) analysis was used to determine phase characterization of nitrided surfaces using LabX XRD-6000 X-ray diffractometer by SHIMADZU. Measurements were performed using Cu–Kα radiation in the scan range of $2\theta = 10^\circ$ to 80° with a step size of 0.02°. International Centre for Diffraction Data (ICDD) database was used for the identification of phases from the positions of diffraction peaks. The microhardness measurements were performed across the cross-sections of the nitrided specimens using a BUEHLER Wirtz Vickers test apparatus under an applied load of 300 g.

3.11.3 Modeling of Gas Nitriding Process

3.11.3.1 Theoretical Background

In gas nitriding, atomic nitrogen forms through a catalytic dissociation of ammonia (NH_3) on the surface of steel. This dissociation obeys the following reaction:

$$NH_3 \Leftrightarrow [N] + 3/2(H_2) \quad [1]$$

where [N] represents N dissolved in the steel surface. It is assumed that equilibrium has been established during this reaction. In practice, this means the occurrence of local equilibrium at the workpiece surface. The dimensionless nitriding activity can be expressed as[1]:

$$a_N = K^{(1)} K_n \quad [2]$$

where $K^{(1)}$ is the equilibrium constant for reaction [1] and has the dimensions of pressure, whereas K_n has the dimensions of

(pressure)$^{-1/2}$. The temperature-dependent $K^{(1)}$ is given by:

$$\ln K^{(1)} = 14.05 + (-6594/T) \quad [3]$$

Temperature T in eqn. [3] is between the range of 700–1400 K and should be expressed in Kelvin.

3.11.3.2 Governing Equations and Constitutive Behavior

Gas nitriding is a surface treatment process involving diffusion that is defined by the requirement of mass conservation for the diffusing phase. The governing equation is:

$$\int_V \frac{\partial c}{\partial t} dV + \int_S \mathbf{n}.\mathbf{J}\, dS = 0 \quad [4]$$

where, $c = c(x, t)$ is the mass concentration of the diffusing nitrogen at any point x in the material at any time t, V is any volume whose surface is S, $\mathbf{n}$ is the outward normal to the surface S, $\mathbf{J}$ is the flux of concentration of diffusing phase, and $\mathbf{n}.\mathbf{J}$ is the flux of concentration leaving S. Using the divergence theorem,

$$\int_V \left(\frac{\partial c}{\partial t} + \frac{\partial}{\partial x}\mathbf{J}\right) dV = 0 \quad [5]$$

$$\int_V \left[\delta\varphi\left(\frac{\partial c}{\partial t}\right) + \frac{\partial \delta\varphi}{\partial x}\mathbf{J}\right] dV + \int_S \delta\varphi \mathbf{n}.\,\mathbf{J}\, dS = 0 \quad [6]$$

where $\delta\phi$ is an arbitrary scalar field. Here, ϕ is normalized concentration, $\varphi = c/s$ where s is the solubility of diffusing material in the base material.

The gradient of nitrogen concentration has been formed by increasing the nitrogen concentration at the surface of the steel, which causes the nitrogen atoms to diffuse from the surface to the inside. The diffusion in the solid phase is assumed to be driven by the gradient of concentration, Fick's First Law, which is

$$\mathbf{J} = -D\frac{\partial c}{\partial x} \quad [7]$$

where $\partial c/\partial x$ is the gradient of nitrogen concentration and D is the diffusion coefficient. The units of diffusion coefficient are (length)^2/time and can be expressed as mm^2 per sec. Changing variables, $c = \phi$s, and assuming s as constant, we can write:

$$\mathbf{J} = -sD\left(\frac{\partial \varphi}{\partial x}\right) \quad [8]$$

Introducing the constitutive assumption of eqn [8] into eqn [6] yields:

$$\int_V \left[\delta\varphi\left(s\frac{\partial \varphi}{\partial t}\right) + \frac{\partial \delta\varphi}{\partial x}.sD\left(\frac{\partial \varphi}{\partial x}\right)\right] dV = \int_S \delta\varphi(-\mathbf{n}.\mathbf{J}) dS \quad [9]$$

3.11.3.3 Numerical Solution for the Mathematical Model

Equilibrium in a finite element (FE) model is approximated by a finite set of equations through the introduction of appropriate interpolation/shape functions. Discretized quantities are indicated by uppercase superscripts (e.g., φ^N). The summation convention is adopted for the superscripts. These represent nodal variables, with nodes shared between adjacent elements and appropriate interpolation chosen to provide adequate continuity of the assumed variation. The virtual normalized concentration field is interpolated by:

$$\varphi = \varphi^N N^N \quad [10]$$

where $N^N(x) = N^N(x, y, z)$ are interpolation functions. Then, the discretized equations can be written as:

$$\int_V \left[N^N\left(s\frac{d\varphi}{dt}\right) + \frac{\partial N^N}{dx}.sD\left(\frac{\partial \varphi}{dx}\right)\right] dV = \int_S N^N(-\mathbf{n}.\mathbf{J}) dS \quad [11]$$

Time integration in transient problems utilizes the backward Eularian method; therefore, we can write the integrated equation as:

$$\int_V \left[N^N\left(s\frac{\varphi_{t+\Delta t} - \varphi_t}{\Delta t}\right) + \frac{\partial N^N}{dx}.sD\left(\frac{\partial \varphi_{t+\Delta t}}{dx}\right)\right] dV = \int_S N^N(-\mathbf{n}.\mathbf{J}) dS \quad [12]$$

3.11.4 FE Analysis

3.11.4.1 Geometric Model

The same geometric model is used in the numerical study as it is used in experimental work. As an example, the sample used in experimental and numerical studies related to profile geometry is shown in **Figure 2**. The FE mesh is composed of a linear triangular heat transfer/mass diffusion element with three nodes (type DC2D3). A very fine mesh was needed in the vicinity of the surface to capture the mass diffusion as a result of nitriding. Mesh convergence studies were conducted with respect to the number of elements in the surface region to arrive at the final mesh size.

3.11.4.2 Simulation Model

The actual nitriding cycle (**Figure 1**) is simulated for H13 steel using a sequentially coupled thermal diffusion analysis conducted in ABAQUS. The diffusion simulation is performed by first solving the transient heat analysis for heating 1 and heating 2 prior to constant temperature stage 1 (at 490 °C) and stage 2 (at 530 °C), respectively. The results of the corresponding temperature solution obtained in heat analyses were then coupled with diffusion analysis as a predefined field. A simple interface is provided that uses the output results from the heat transfer analysis to define the temperature field at different times in the mass diffusion analysis.

3.11.4.3 Material Model

For heat analysis, the following material properties for H13 hot work die steel are used: thermal conductivity = 32.65 W m^{-1} K^{-1}; specific heat = 603 J kg^{-1} K^{-1}; and density = 7700 kg m^{-3}.

For diffusion analysis, the following diffusivity D from the experimental work of Hermandez and Cabrera[21] for H11 material is used:

$$D = 0.103 \exp\left(\frac{-83100}{RT}\right) \quad [13]$$

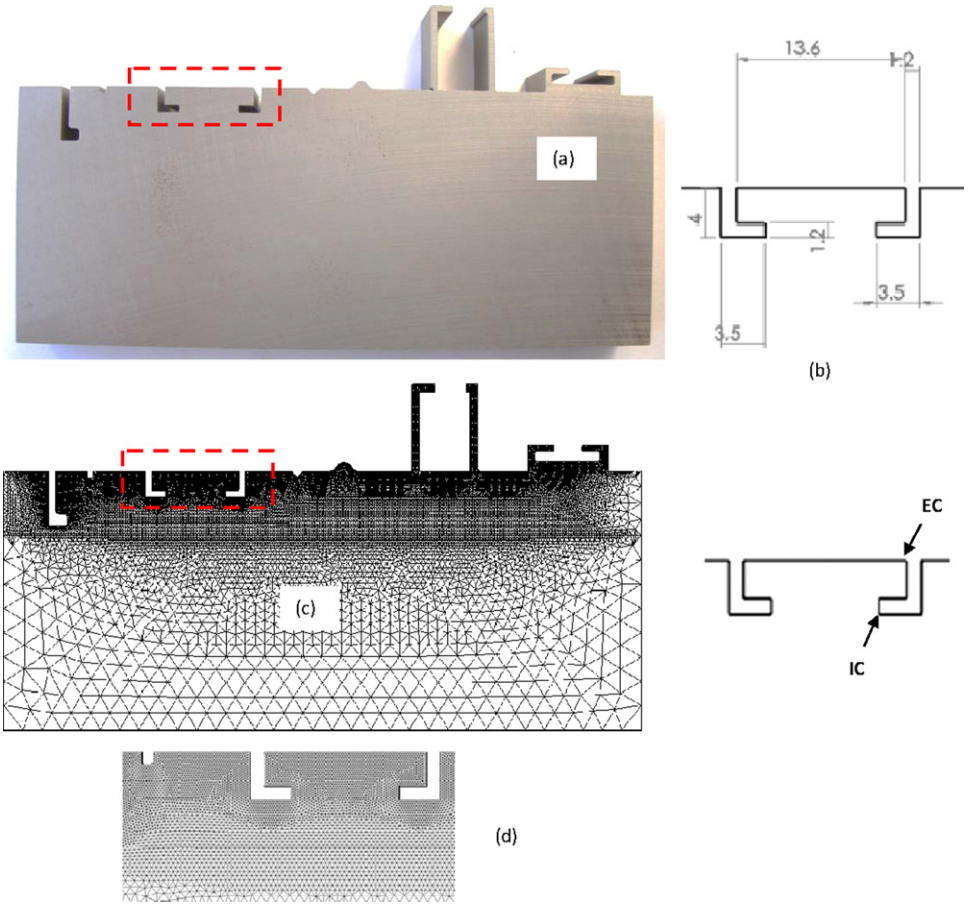

Figure 2 (a) Sample after EDM wire cutting. (b) Dimensional drawings of the studied profile (all dimensions are in mm). (c) Finite element geometric model and mesh layout. (d) The studied profile is shown in close-up.

where the unit of D is in $mm^2\,sec^{-1}$, T is temperature in Kelvin, and $R=8.314\ J\ mol^{-1}\ K^{-1}$ is the universal gas constant.

3.11.4.4 Initial and Boundary Conditions

The driving force for nitrogen transformation from gas to solid is the difference in nitrogen concentration between the gas and solid phases. The flux of nitrogen, J, to the surface of the steel per unit time and per unit surface area is described as[27]

$$J=\beta(C_g-C_s) \qquad [14]$$

where β is the coefficient of mass transfer across the interface and is abbreviated as the mass transfer coefficient, C_g is the nitrogen concentration in the gaseous nitriding medium, and C_s is the nitrogen concentration at the surface of the steel. The units of J are (unit of matter)/(area × time), whereas those of concentration are (unit of matter)/volume. This makes the units of the mass transfer coefficient (length)/time, which can be expressed as mm persec. The unit of matter in both concentration and the flux must be consistent, either as matter or mole or atoms. As atoms, concentration will be in atoms per mm^3, whereas the flux will be in (atoms per mm^2 per sec).

The initial condition is

$t=0,\ C=0$

The external boundary condition is

$$x=0,\quad \beta(C_g-C_s)=-D\frac{\partial c}{\partial x}\Big|_{x=0}$$

where $\frac{\partial c}{\partial x}|_{x=0}$ is the gradient of nitrogen concentration at $x=0$. Surface concentration was taken as zero ($C_s=0$).

3.11.4.5 Solution Procedure

For heat analysis, surface heat flux was applied to increase the temperature during the heating stages of the nitriding cycle. However, no heat analysis was performed for stage 1 and stage 2, and diffusion analysis was conducted at constant temperatures of 490 and 530 °C, respectively. Heat transfer coefficient of 3.5 $W\ m^{-2}\ K^{-1}$ was used.

For diffusion analysis, the following procedure was adopted:

Step 1: The activity in the gas phase (a_N) was first calculated for the nitriding cycle using eqn [2]. $K^{(1)}$ (equilibrium constant for dissociation reaction eqn [1]) was calculated from eqn [3] as a function of temperature in the nitriding cycle. Nitriding potential K_n is known for the nitriding cycle as a function of time (**Figure 1(b)**).

Step 2: To determine nitrogen flux J, eqn [14] to be used as input in ABAQUS, the nitrogen activity (a_N) was converted to

nitrogen wt% using the following relationship[26]:

$$a_N = f_N[\%N] \quad [15]$$

where f_N is the activity coefficient of nitrogen and [%N] is the concentration of nitrogen in steel. Due to the unavailability of f_N for H13 tool steel, the following activity coefficient of nitrogen in 38CrMoAl steel at 500–560 °C has been used[26]:

$$f_N = (2.775 + 2.197[\%N])\exp\left(\frac{-15734}{T} + 13.44\right) \quad [16]$$

Combining eqns [15] and [16], the activity was converted into nitrogen %wt with the help of Engineering Equation Solver (EES) software.

Step 3: The in-process varying nitrogen concentration in %wt. (determined in step 2) was then converted to appropriate concentration of atoms N per mm^3 by considering a unit cell of BCC α-Fe with two atoms with a lattice parameter of 2.87 A°.

Step 4: The mass transfer coefficient, β (to be used in eqn [14]), was determined from the following expression as proposed for 38CrMoAl steel by Hu *et al.*[26]

$$\beta = 0.0621\exp\left(\frac{-6267}{T}\right) \quad [17]$$

where the units of β are mm sec^{-1} and T is in Kelvin.

Step 5: The flux of nitrogen to the surface of the steel in the nitriding cycle (used as input in diffusion simulation in atoms per mm^2 per sec) was determined from eqn [14] by using in-process varying nitrogen concentration C_g (in atoms/mm^3) and mass transfer coefficient β (mm sec^{-1}).

3.11.5 Results and Discussions

The kinetics of gas nitriding of AISI H13 steel with the help of a microscopic investigation of nitride cross-section and FE simulation is considered. FE code ABAQUS is used to simulate the nitriding process using mass diffusion analysis in line with the experimental setup. The nitrided layers were characterized using different techniques, including optical microscopy, SEM, XRD analysis, EDS mapping, and microhardness analysis. Both experimental and numerical results are found in close agreement in terms of nitrogen concentration and corresponding microhardness profiles. The effects of surface texture, multiple nitriding, and profile geometry on the nitriding kinetics have been studied and the findings of the conducted investigations are provided.

3.11.5.1 Influence of Surface Texture on the Nitriding Kinetics

The effect of prenitriding surface texture of AISI H13 steel on the behavior of gas nitriding process under controlled nitriding potential is studied with the aim of finding how efficiently surface activation can be used for better die performance. The nitrided layers of three samples, which were ground, polished, and lapped before nitriding, were studied in terms of morphology of diffusion zone and compound layer, case depth, and hardness depth profile. A sample without surface preparation (designated as unprepared sample) was also included in the investigation for comparison purposes. Samples were polished and lapped using an OMNILAP 2000 lapping machine (South Bay Technology). Surface roughness of the samples was measured by a SJ-400 surface roughness tester (Mitutoyo Corporation, Japan). The samples were cut into two pieces after nitriding and prepared for cross-sections for optical and SEM. The discussions on effect of surface texture are presented in line with the previous study.[24]

3.11.5.1.1 XRD measurement and phase analysis

Figure 3 gives the XRD diffractograms for the surface of unprepared, ground, polished, and lapped samples after gas nitriding treatment. The major phases in the surface of all samples are iron nitrides, which confirm the presence of the superficial compound layer. The major phases identified in the unprepared sample are $\varepsilon - Fe_3N$ corresponding to (110) and (200) planes with small peaks of mixed nitride phases' peak of $\varepsilon - Fe_3N$ (002) + $\gamma' - Fe_4N$ (111) and $\varepsilon - Fe_3N$ (112). Moreover, additional $\varepsilon - Fe_3N$ peaks were also observed corresponding to (101), (103), and (113) planes for surface-treated samples. A small peak of $\varepsilon - Fe_3N$ (110) was also observed in ground and polished samples. The various iron nitride peaks indicate that surface preparation facilitates the incorporation of more nitrogen atoms into the subsurface diffusion zone. High-intensity peaks of α-Fe (110) + CrN (200) in the case of surface-treated samples were observed that can be associated with a thin compound layer. Because the compound layer is thin, it is probable that the Fe and CrN reflections were detected from the subsurface diffusion matrix and not due to the compound layer. No pronounced ferrite (α-Fe) and CrN peaks were detected in untreated samples. This is because the compound layer thickness is longer than the X-ray penetration depth and the Cu–Kα probes to a few microns. The values of lattice spacing (d) corresponding to α-Fe (110) is shown in Table 1. The d-values reduce with increasing prenitriding surface roughness (R_a). These reduced d-values with increasing R_a values are also associated with a corresponding increase in 2θ values. The reduced lattice spacing in ground samples with the highest initial surface roughness of 0.13 ± 0.035 μm after gas nitriding can be associated with the highest compressive stress. The high compressive stress is likely due to comparatively more free atomic nitrogen available to diffuse into the matrix due to more surface activation by the grinding process. This observation is in line with relatively high-nitride XRD peaks in the case of the ground sample. Iron oxide (Fe_2O_3/Fe_3O_4) peaks as revealed in XRD measurements detected from the surface of roughened samples are an indication of oxidation due to partially oxidized rough surfaces prior to the nitriding process.

3.11.5.1.2 Morphology of nitrided layers

The optical microstructures of the nitrided cross-sections of as-received, ground, polished, and lapped samples are shown in Figures 4(a)–4(d). Figure 5 shows the corresponding scanning electron micrographs of the surface vicinity of the nitride layers. All microstructures consist of an internal core of tempered martensite and a nitrided layer at the free surface. The nitrided

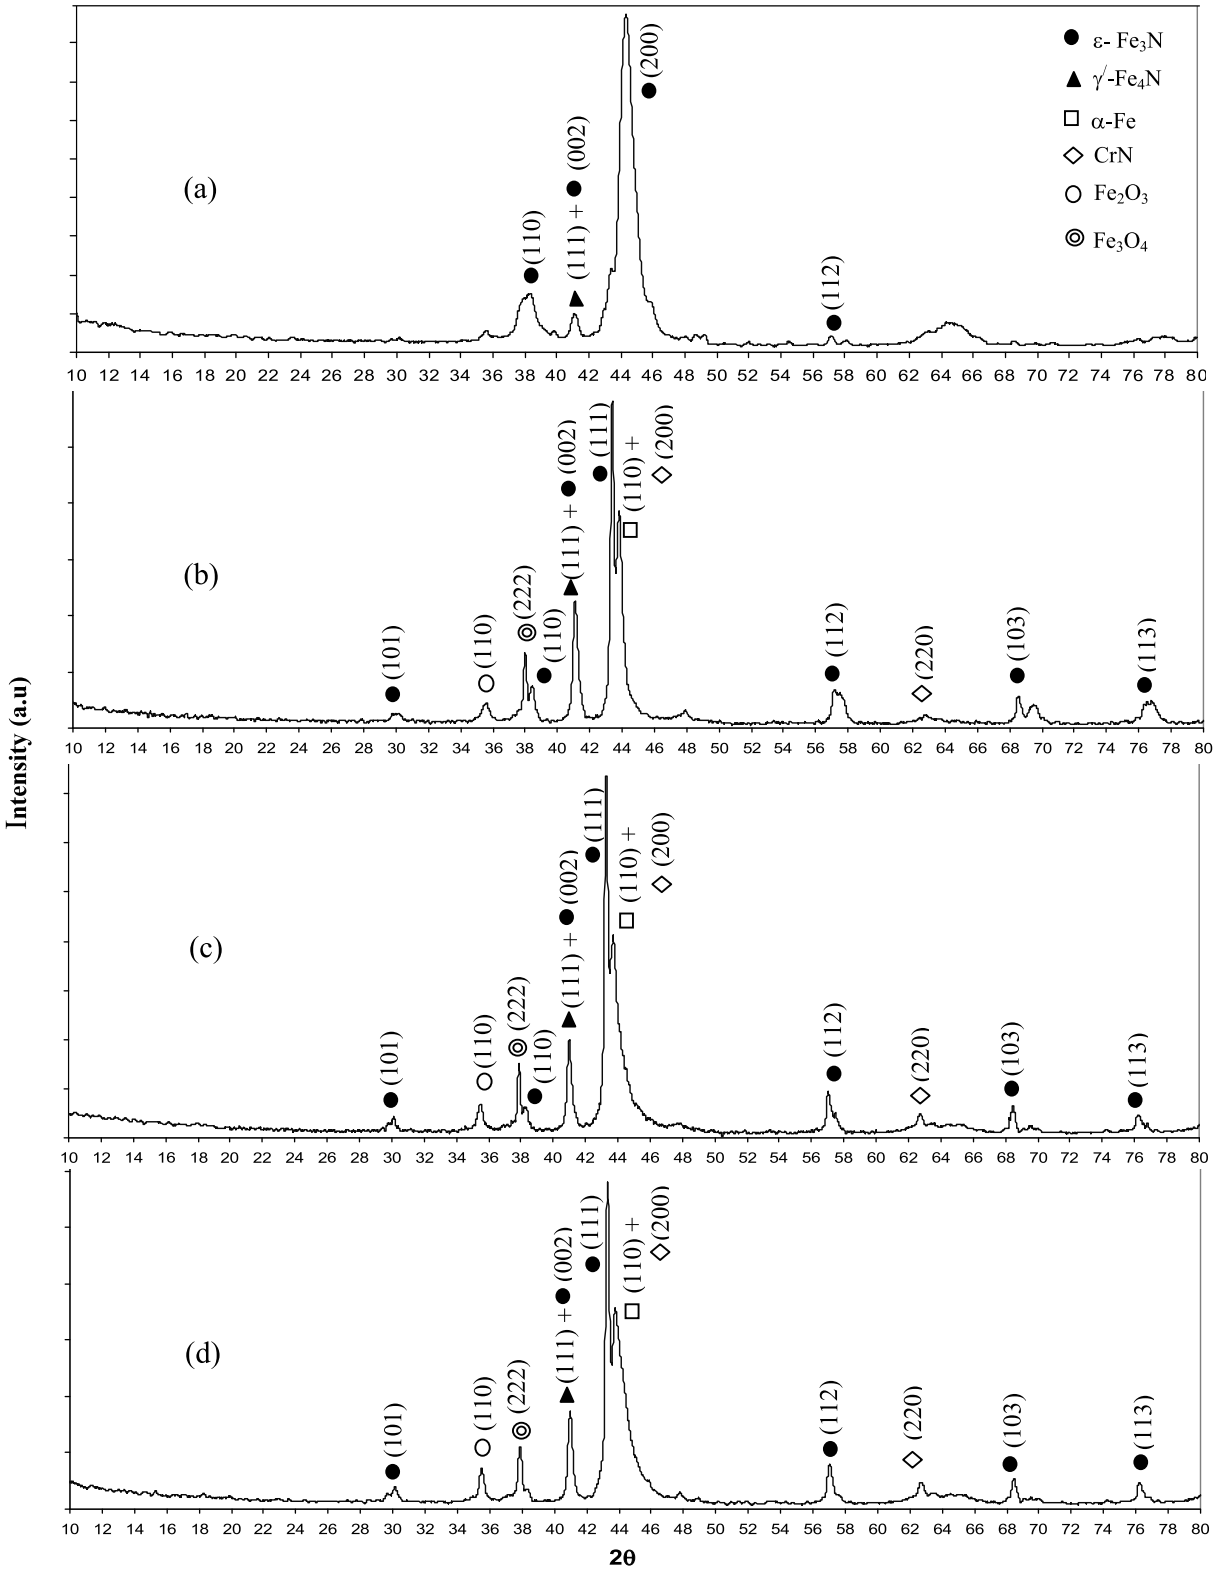

Figure 3 XRD diffractogram recorded from the surface of nitrided AISI H13 samples: (a) as-received sample; (b) ground sample; (c) polished sample; and (d) lapped sample.

layer consists of a diffusion zone with fine nitride precipitates (dark regions in the optical and lamellae structure in the SEM micrographs) and a compound layer at the surface. It is clearly visible from the microstructures that surface texture has significant implications in the thickness and uniformity of the nitrided layer. The shallow and uneven nitride layers in the

Sample	R_a *(μm) before nitriding*[a]	*2θ (degree) α-Fe (110)*	*Lattice spacing d (A°) for α-Fe (110)*	*Effective case depth at 700 HV (μm)*
As-received	–	–	–	75
Ground	0.13 ± 0.035	43.80	2.06522	135
Polished	0.08 ± 0.015	43.70	2.06971	120
Lapped	0.04 ± 0.009	43.68	2.07061	85

[a] R_a values are given as average $\pm$ standard deviation.

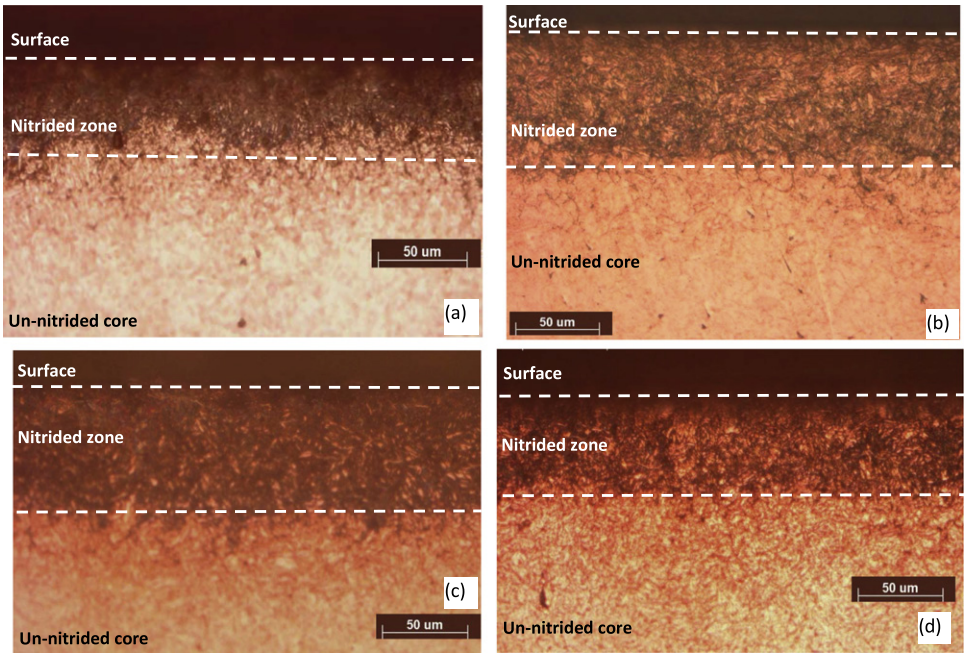

Figure 4 Optical micrographs of nitrided cross-sections: as-received sample (a); ground sample (b); polished sample (c); and lapped sample (d).

case of as-received samples are due to insufficient nitriding treatment, which greatly depends on the ability of free atomic nitrogen to diffuse into the iron matrix. If the surface is not properly textured via mechanical surface treatment, any expected superficial film or deposit, even of infinitesimally small thickness, can partially or completely prevent the access of active nitrogen to the surface, and the availability of nitrogen that manages to get through the film can be insufficient. This, in turn, results in the insufficient quantity of sub-microscopic nitrides that could precipitate during the nitriding cycle, as can be seen from SEM micrographs. Unlike untreated sample surfaces, all the textured surfaces depict deep and uniform diffusion zones with some differences in depths. The diffusion zone increases with increase in initial surface roughness. Moreover, the ground sample resulted in a deep diffusion zone followed by a polished sample. The lapped sample with the lowest surface roughness has the lowest depth of diffusion zone among the textured surface samples. As indicated, the reduced lattice spacing with increased roughness facilitates enhancement of nitrogen diffusion; therefore, the depth of the diffusion zone increases with the increasing surface roughness.

The compound layers formed at the surface of as-received, ground, polished, and lapped samples are shown in Figure 5. Unprepared samples have uneven and thick compound layers as compared to the textured surface samples. The thick compound layer can be strongly associated with slow diffusion rate and nitrogen pressure at the surface. Among the textured surface samples, the ground sample has a more uniform and slightly thicker (2.5–3 μm) compound layer as compared to polished ($\sim$1.5 μm) and lapped ($\sim$1 μm) samples. The thickness of the compound layer of the samples is in line with the thickness of the diffusion zone, which reduces with decreasing surface roughness. This can be associated with high XRD counts of iron nitrides for ground samples, particularly the mixed phase peak of $\varepsilon - Fe_3N\ (002) + \gamma' - Fe_4N\ (111)$, as observed in the XRD diffractogram.

3.11.5.2 Effect of Profile Geometry on the Nitriding Treatment

The influence of most common profile features on the behavior of case hardening quality for AISI H13 tool steel samples were studied both experimentally and numerically. AISI H13 steel samples are manufactured with profiles similar to those used in hot extrusion dies and subsequently gas-nitrided under controlled nitriding potential. Nitrided layers of corner features in the samples are then investigated and uniformity and depth are compared in terms of compound layer and total case depth. Microhardness measurement and both optical and SEM techniques have been used for this purpose. The nitrogen

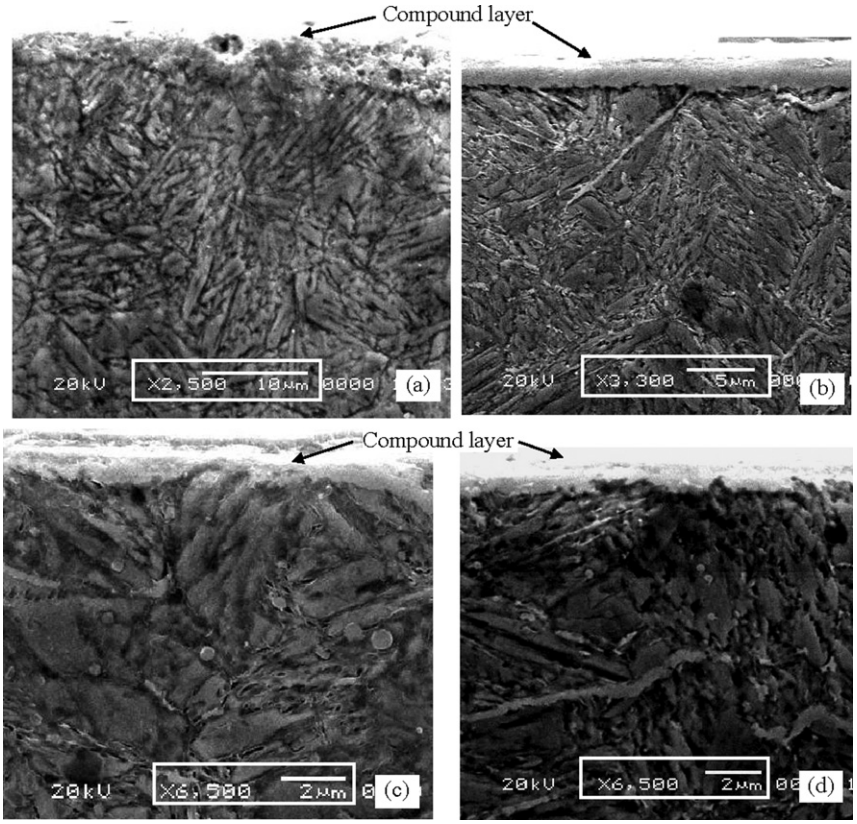

Figure 5 Magnified SEM images of compound layer developed after controlled gas nitriding at the surface of: as-received specimen (a); ground specimen (b); polished specimen (c); and lapped specimen (d).

concentration field is also modeled for corresponding features using the FE method and compared with experimental results. The FE model is then modified for optimum nitride layer formation of these features. Some optimization guidelines are set-up in light of the modified FE models, and recommendations are devised for their implementation to improve the die service life. Discussions of the effects of profile geometry on the nitriding kinetics are presented in line with the previous studies.[27,28]

3.11.5.2.1 Geometric features selected for the current study

The profiles shown in Figure 2 encompass some very common features, such as convex and concave surfaces, flat surfaces, internal corner (IC), external corner (EC), and others. For the present study, only IC and EC were selected based on the fact that these features are the most critical in terms of nitriding layer development.[27] The features reported in the current study are shown in Figure 2, namely EC and IC.

3.11.5.2.2 Metallography and numerical results

Metallographic investigation is performed using optical and scanning electronic microscopes, followed by microhardness measurements to observe the nitride layer formation and its uniformity. The optical and scanning electron micrographs of the nitride cross-sections of the selected features are shown in Figure 6 for corner features, EC, and IC. The corresponding hardness depth profiles are shown in Figure 7. The hardness measurements were taken at a specific location (depth) starting from approximately 25 µm away from the surface. Each indentation point in the hardness depth profiles is the result of average of five measurements at each location.

Numerically predicted nitrided layers developed for the features EC and IC are shown in Figure 8, whereas Figure 9 shows the corresponding variation of nitrogen concentration along the depth for these features.

It can be observed that the compound zone is only visible in SEM micrographs and could not be detected in the optical micrographs due to thinness. The thicknesses of the compound layer at both feature locations is estimated from corresponding SEM micrograph and listed in Table 2. Please refer to previous work[29] for details regarding the formation of the compound layer and morphology of the nitrite layer in relation with the nitriding potential and corresponding nitrogen activity. The critical nitriding potential values and, hence, the nitrogen activities above which the iron nitrides in the compound layer ($\gamma' - Fe_4N$ and $\varepsilon - Fe_3N$) develop were identified from the Lehrer equilibrium diagram. The actual variation of K_n (Figure 1(b)) indicated that the compound layer would form at the surface. It was confirmed from the Lehrer equilibrium diagram that the $\gamma' - Fe_4N$ phase of the compound layer begins to form when K_n of the atmosphere exceeds the upper limit of the nitrogen concentration in the diffusion zone at the nitriding temperature. A further increase in K_n causes the formation of the $\varepsilon - Fe_3N$ phase in the steel surface. The recommended ranges, K_n values, and maximum allowed thickness of

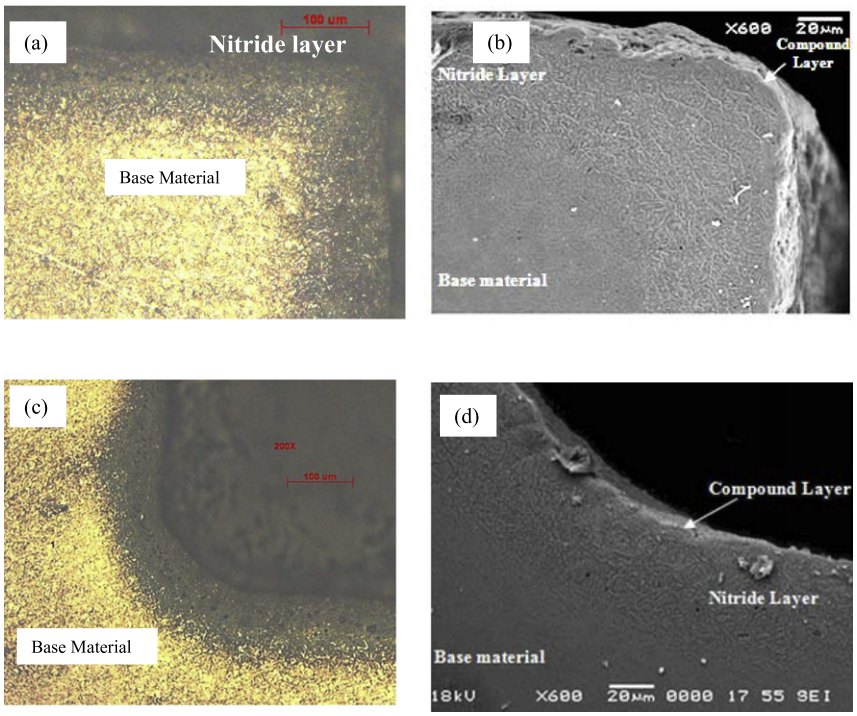

Figure 6 Optical micrographs (a) and scanning electron micrograph (b) observed at the external corner. Optical micrographs (c) and scanning electron micrograph (d) observed at the internal corner.

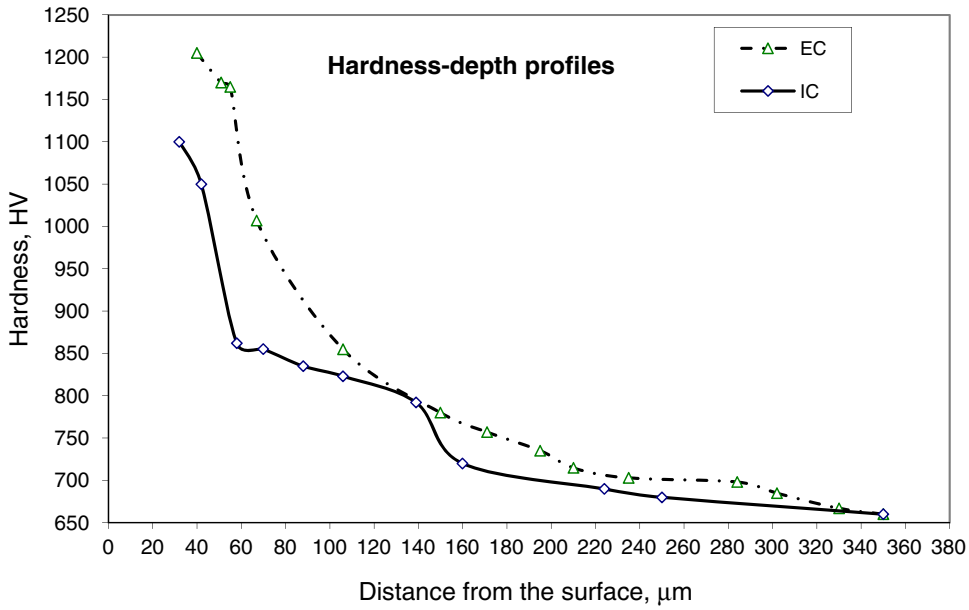

Figure 7 Hardness depth profiles for the external corner and internal corner features.

the compound layer for different classes as classified by AMS per requirement of AMS 2759/10A were used.[30] The thicknesses of the compound layer achieved in both features, EC and IC, are less than the maximum specified by AMS. The compound layer and nitrided depth at each location are given in Table 2.

It can be seen that the pattern of hardness and concentration depth profile are the same for all features, maximum near the surface, and decays toward the core of material. This implies that the nitriding process was successfully performed both experimentally and numerically. Comparing experimental and numerical results, it can be seen that hardness across the nitrided layer cross-section scales fairly well with the decay of nitrogen concentration from surface to core. However, the values of hardness corresponding to any specific depth vary significantly in the samples made of the same material and are

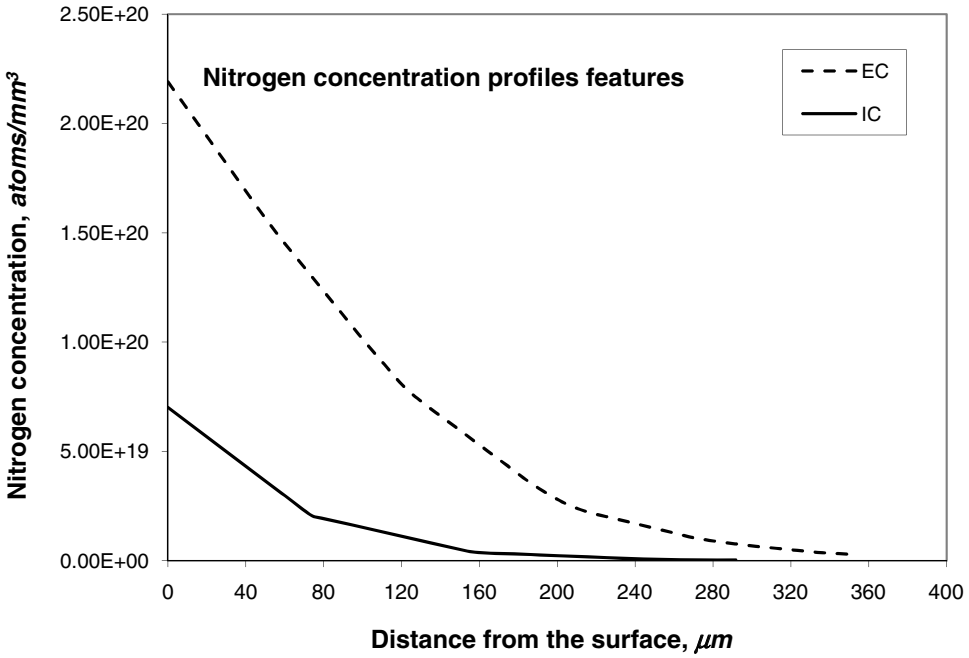

Figure 8 Nitrogen concentration profiles for features of the external corner and the internal corner at the end of nitriding cycle.

nitrided under same conditions. The core hardness was approximately 660 HV in both locations. The nitrided case depth at each feature location is determined from the hardness depth profile (from the experimental study) and the concentration depth profile (from the numerical study). For this purpose, the following criteria are used[27]:

1. Nitriding depth from hardness profile: the depth below the surface at which microhardness is 10% higher than that of the core, as set forth by ASM.[30]
2. Nitriding depth from concentration profile: the depth where the concentration is 10% higher than the average minimum concentration.

Comparing experimental and numerical results, numerically predicted case depths compare well with experimental results for both feature locations. However, slightly higher values can strongly be attributed to nonexact coefficients of diffusion used for diffusion analysis of H13 steel samples. Moreover, in computer simulation, the application of boundary conditions (i.e., surface concentration) is ideal in the sense that it is directly applied to the surface irrespective of the location. However, in the real nitriding process, nitrogen access to different locations is different depending on size, gaps, and orientation of different features (i.e., some locations are exposed and permit easy accessibility but others may be concealed, making it difficult to receive the required nitrogen content).

It can be noted from the micrographs as well as from the numerical predictions that all the flat features of the samples result in uniform and fairly identical nitrided layers. However, the external and ICs significantly influence the uniformity and quality of the nitride formation. The outer corner feature, EC, results in comparatively deeper case depths measured experimentally as well as predicted numerically. This is associated with the simultaneous diffusion from two convergent directions at the corners. Compound layer thickness for these features is less than that found on flat features[27] and are given in **Table 2**; they can be observed from the corresponding SEM micrographs. The hardness curve for the EC feature, EC, is relatively less steep and has a deeper hardening effect, in line with greater case depth. However, oversaturation of nitrogen at the extreme corners resulted in somewhat of a 'corner effect' despite the controlled nitriding process. Such a corner effect results in greatly reduced initial hardness values. As reported by Liliental *et al.*,[4] many problems are experienced with aluminum extrusion dies, with the most common including 'choke' and 'relief' formation when debris from a brittle and spalling nitrided layer at the corner lodges in the die bearing area.

The IC feature has significantly smaller case depths, as can be observed in **Figure 6** (for IC). The pattern of nitrogen diffusion at these locations can be more clearly understood from numerically predicted results (**Figure 9**). Unlike EC features, simultaneous diffusion from two divergent directions results in a reduced nitride case at the corner. As compared to flat surfaces, nonuniformity in the nitrided layer can also be observed. The compound layer developed at the IC is also slightly uneven, and its thickness is approximately 3 μm, which is less than that achieved in flat surfaces.[27]

3.11.5.2.3 Design modifications and recommendations

Based on the present observations, it can be stated without any doubt that die geometric features have a significant effect on the surface hardness, case depth, and compound layer formation, even under the controlled nitriding process. The results of this study highlight the need to include the effect of the die profile on the nitrided layer for optimal die design with improved service life. In the current section, the validated numerical study was extended and some modifications in the path brush features, namely EC and IC, were performed to see

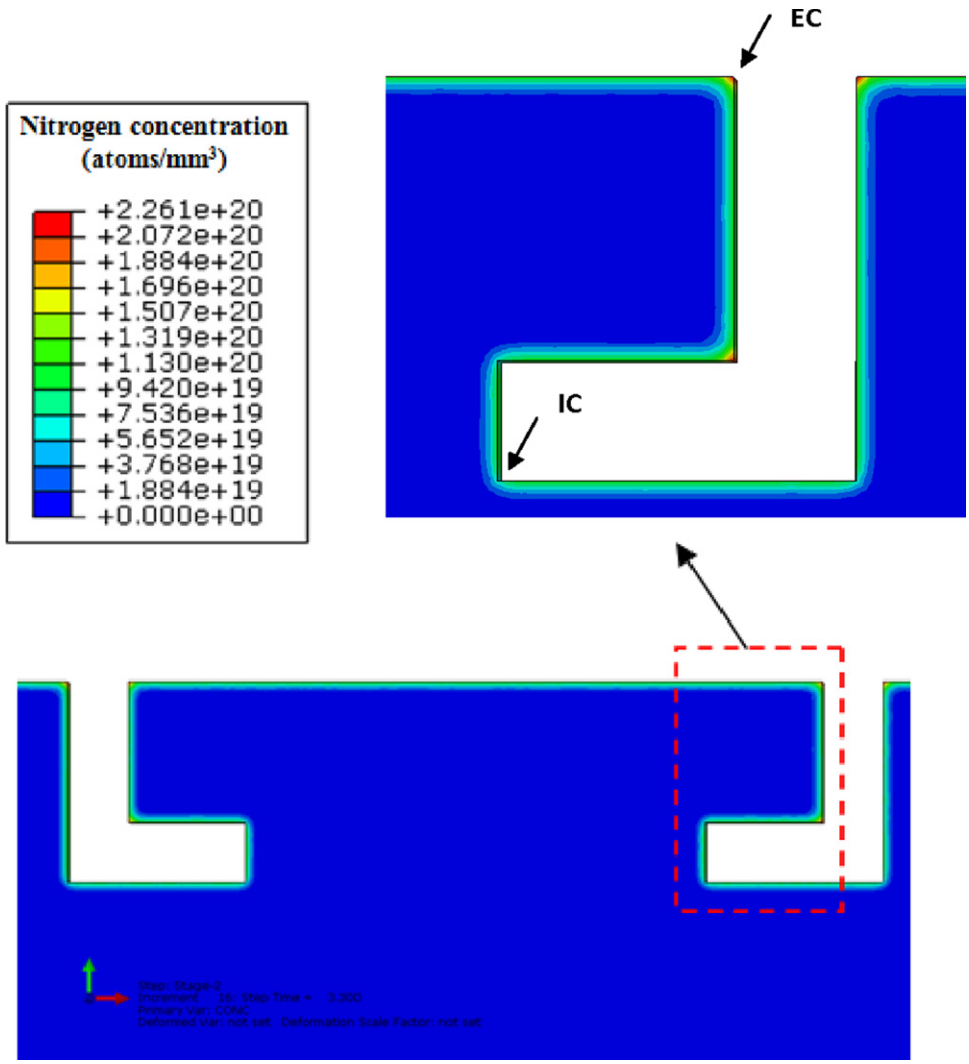

Figure 9 Numerically predicted nitrided layer for features of the external corner (EC) and internal corner (IC) at the end of nitriding cycle. The nitrogen concentration is in atoms per mm^3.

Table 2 Summary of experimental and numerical results

Geometric feature	*Experimental measurements*		*Numerical simulation results*
	Compound layer thickness (μm)	*Minimum case depth (μm)*	*Nitriding depth (μm)*
External corner (EC)	~3–5	208	215
Internal corner (IC)	~3–4	145	160

the effect of geometric shape on the uniformity of nitride layer development on these corner features. As observed, the ECs in the die profiles can present a severe threat to the life of the entire die due to the oversaturation of nitride layer formation. Moreover, the ICs result in the development of a nonuniform nitride layer. Therefore, EC feature and IC feature are modified by incorporating fillets. Two fillet radii, 0.2 and 0.5 mm, are used. Figure 10 shows the effects of external and IC fillets on the nitrogen concentration. It is obvious from the contour plots of the nitrogen concentration that the nitriding layer becomes uniform as we increase the fillet radius from 0 to 0.2 mm to 0.5 mm. It can be observed from Figure 10(c) that incorporation of a fillet at the EC and IC results in uniform growth of nitrogen concentration, which will certainly positively influence the hardness and effectiveness of these corner features. However, it must be remembered that the modified features should not affect the final profile geometry and the desired tolerances of the final extruded section. The suggested modifications in the existing die designs would serve as a baseline for the optimized die designs that will benefit both local and international die manufacturers.

3.11.5.3 Influence of Multiple Nitriding on the Nitriding Kinetics

Repeated nitriding is an indispensable process in the hot extrusion of aluminum profiles and cannot be avoided. The purpose of this section is to examine the effects of the

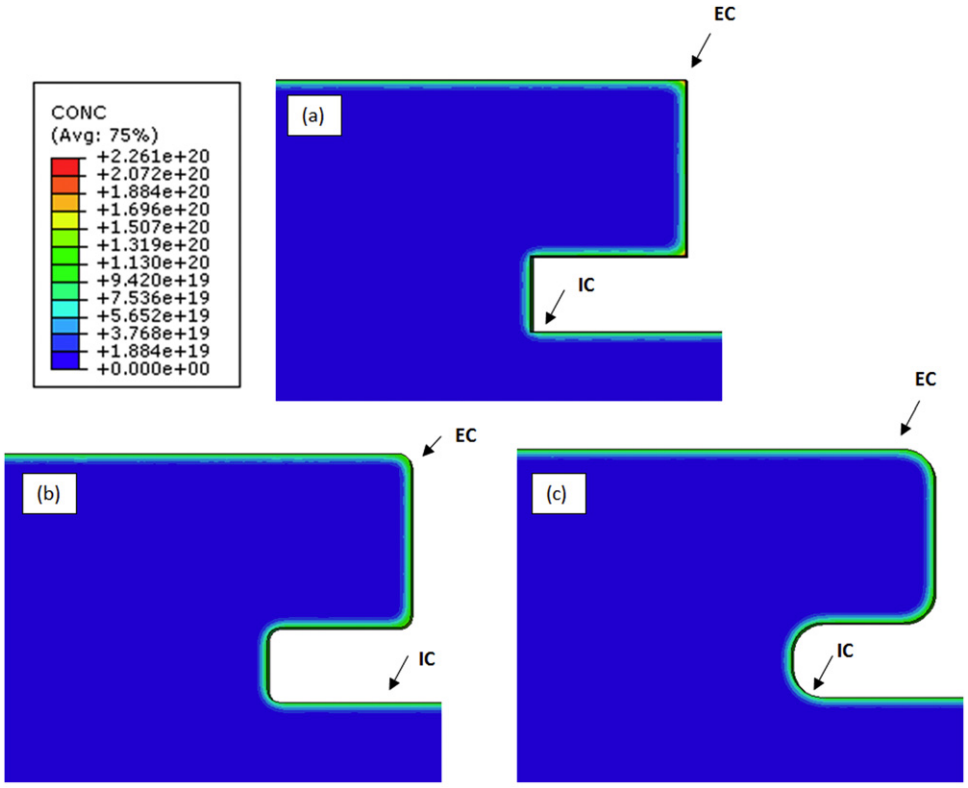

Figure 10 Nitrogen concentration contours for modified external corner (EC) and internal corner (IC) features. (a) Original features, (b) when fillet radius of 0.2 mm is used, and (c) when fillet radius of 0.5 mm is used.

re-nitriding process on the morphology and hardness of the nitride layer when dies are exposed to such practices. The results reported here are in line with the previous study.[31] This study serves as a baseline to identify the re-nitriding conditions through numerical investigation of the process for the extrusion industry. The effect of re-nitriding treatment on the AISI H13 steel surface is studied, both experimentally and numerically, using a two-stage gas nitriding process under controlled nitriding potential, as discussed earlier. The nitride layers of three samples treated with single-, double-, and triple-nitriding processes, respectively, were compared in terms of microstructure morphology, nitride case depth, hardness depth profile, and quality. All the samples were properly heat-treated (quenched and tempered) prior to the nitriding process in line with real extrusion die surface treatment and then subjected to almost the same nitriding cycle during the nitriding and re-nitriding treatments. No prior surface treatment was performed and the samples were re-nitrided with the pre-existing nitride case. Nitrogen concentration profiles predicted from numerical analysis for the cross-sections of single-, double-, and triple-nitrided samples are compared with the hardness profiles of their counterparts obtained from the experiments. The findings reveal that both results are in good agreement.

3.11.5.3.1 Morphology of nitride layers

The variation in total nitride layer thickness in single-, double-, and triple-nitrided sample was found to be significant; it increased from 80 μm in the case of single-nitrided samples to 100 μm for double-nitrided samples and approximately 115 μm for triple-nitrided samples.[31] Multiple-nitrided samples have more dense lamellae colonies, and more precipitates can be observed at the grain boundaries with deeper affect, as shown in Figure 11. This increased amount of precipitates is due to the aggregate long duration at nitriding temperatures during repeated nitriding treatment.

As can be observed from Figure 11, the compound layers in the double- and triple-nitrided samples are much thinner (approximately 1–2 μm) compared to those of single-nitrided samples (4–8 μm). This result is in agreement with previous results[32] indicating that controlled gas nitriding recreates a uniform but thinner nitrided white layer during re-nitriding treatment of H13 dies. It is reported that the critical temperature for the decomposition and compound layer is 500 °C, although in some cases it can start even at 350 °C for hot-working steels.[33] Such decomposition of iron nitride phases in the compound layer at high temperatures results in backward diffusion of nitrogen and destruction of the already existing compound layer. The thinner compound layer during re-nitriding reveals that decomposition of the iron-nitrided phases is dominant compared to re-development of the compound layer during simultaneous re-nitriding treatment.

3.11.5.3.2 XRD analysis

Figure 12 gives the XRD spectrums produced on the surface of nitrided samples and shows the influence of multiple nitriding

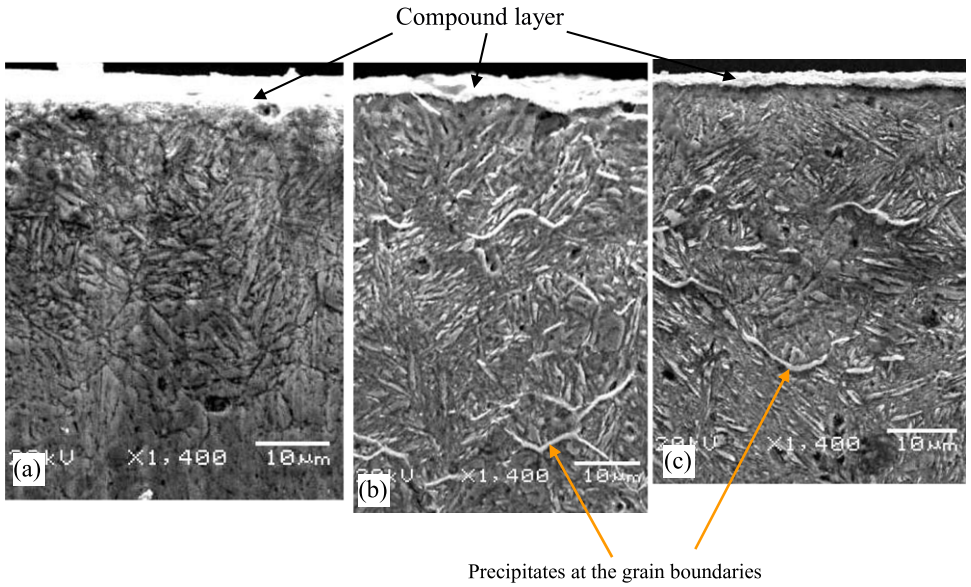

Figure 11 Lamellar structure in the nitrided zone: single-nitrided specimen (a); double-nitrided specimen (b); and triple-nitrided specimen (c).

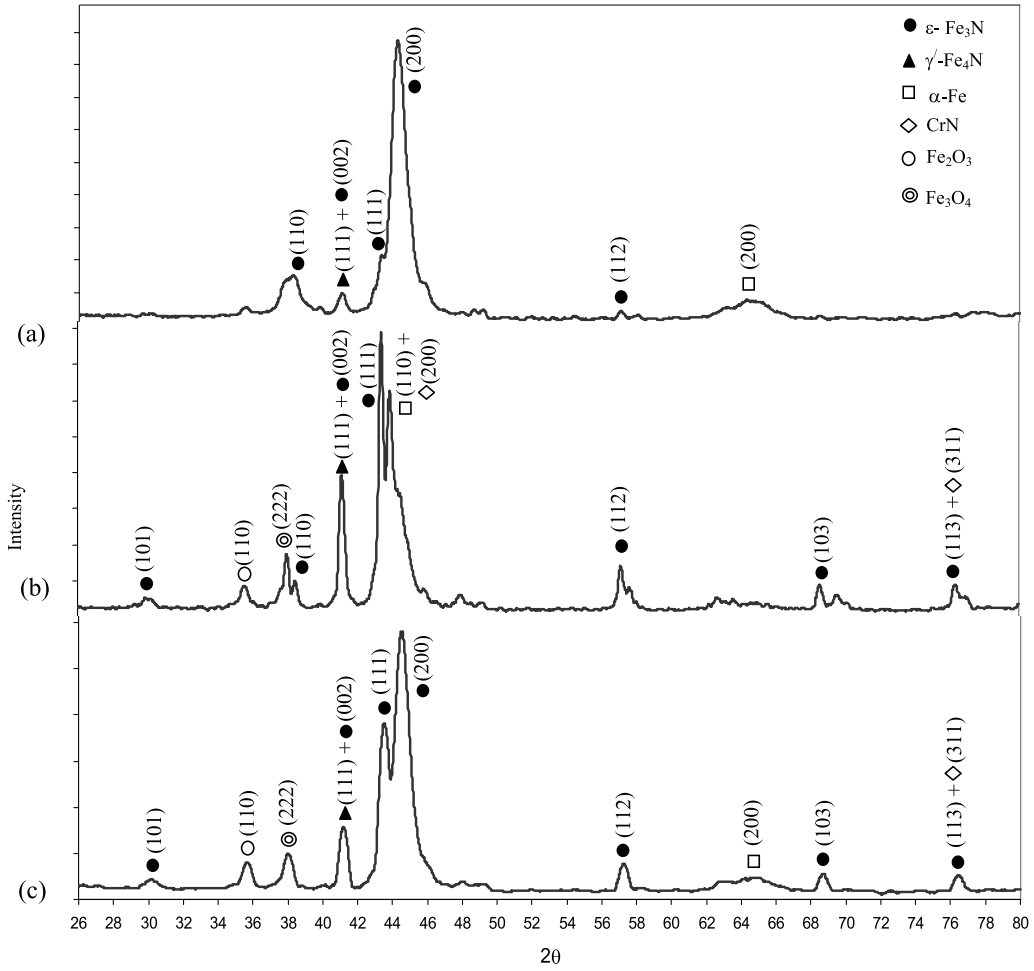

Figure 12 XRD diffractogram recorded from the surface of nitrided AISI H13 samples: (a) single-nitrided sample; (b) double-nitrided sample; and (c) triple-nitrided sample.

treatments on phase formation. As observed, the major phases were identified to be $\varepsilon - Fe_3N$ and $\gamma' - Fe_4N$ in all the three samples, thus confirming the presence of the superficial compound layer. The spectrum related to the single-nitrided sample reveals the presence of a considerably large amount of the $\varepsilon - Fe_3N$ phase compared to the $\gamma' - Fe_4N$ phase, which is relatively close to the monophase ε based on the ratio of ε/γ', as estimated from XED peaks. In contrast, a quite comparable $\gamma' - Fe_4N$ phase in addition to the $\varepsilon - Fe_3N$ phase was detected in double- and triple-nitrided samples, which show that the pre-existing compound layer before re-nitriding significantly affects the fresh compound layer formation in the subsequent re-nitriding process under the same conditions used for un-nitrided sample.

The existence of a comparatively large amount of $\gamma' - Fe_4N$ in multiple nitrided samples can be associated with loss of existing nitrogen (dissolved in $\varepsilon - Fe_3N$) by nitrogen enrichment during the re-nitriding process, which leads to transformation of $\varepsilon - Fe_3N$ to $\gamma' - Fe_4N$. Such a transformation can be attributed to excessive nitriding cycle time during repeated nitriding. It should be mentioned here that the monophase structure ($\gamma' - Fe_4N$ or $\varepsilon - Fe_3N$) of the compound layer is recommended[34] due to homogeneity and increased mechanical properties. In the case of the presence of both phases, relatively higher residual stresses are present in the compound layer due to their different structures (FCC and HCP, respectively), which will result in reduced toughness and generate microcracks under applied stresses. Comparatively narrow full-width at half-maximum (FWHM) observed in the single-nitrided sample XRD peak corresponding to the $\varepsilon - Fe_3N$ phase also indicates less disorder in the compound zone. It is generally recognized[32] that the $\varepsilon - Fe_3N$ phase features better wear resistance than $\gamma' - Fe_4N$. For this reason, $\varepsilon - Fe_3N$ in the compound layer should be viewed as a positive effect for better die performance.

3.11.5.3.3 Comparison of hardness and nitrogen concentration profiles

Figure 13 presents a comparison between the variations in microhardness of the nitride layer as a function of the distance from the surface for single-nitrided and multiple-nitrided samples. In these curves, each point represents the average value of five indentations. The extent of the nitrided regions after repeated nitriding treatment can be compared based on hardness depth profiles. For the initial 15-μm depth of the nitrided zone in the multiple-nitrided samples, reduced hardness was observed: 910 HV for double-nitrided and 860 HV for triple-nitrided samples. This reduced hardness is associated with oxidation and porosity observed in the near-surface diffusion zone. Maximum hardness was found at a depth of approximately 20 μm: 1200 HV for double-nitrided and 1240 HV for triple-nitrided samples. Single-nitrided samples show reduced hardness values in comparison with multiple-nitrided samples, except for the initial depth of 15 μm due to the absence of oxidation and porosity. Hardness depth profile corresponding to the single-nitrided sample behaves in a monotonically decreasing manner with a maximum hardness of approximately 1180 HV at the surface. Comparing double- and triple-nitrided samples, hardness decay toward the core is more gradual and deep in triple-nitrided samples than in double-nitrided samples. The decay of hardness across the nitrided layer cross-section can be strongly related to the decay of nitrogen concentration from surface to core. As explained, near the surface, where the nitrogen supersaturation is maximum, the driving force for nucleation of the lamellae structure is at maximum, causing more abundant and fine structures. The increase of lamellar spacing (coarsening of lamellar structure) with depth induces a pronounced decrease of hardness with depth in the nitrided zone.[35]

Figure 14 shows predicted case depth development after single-, double-, and triple-nitriding treatment simulated

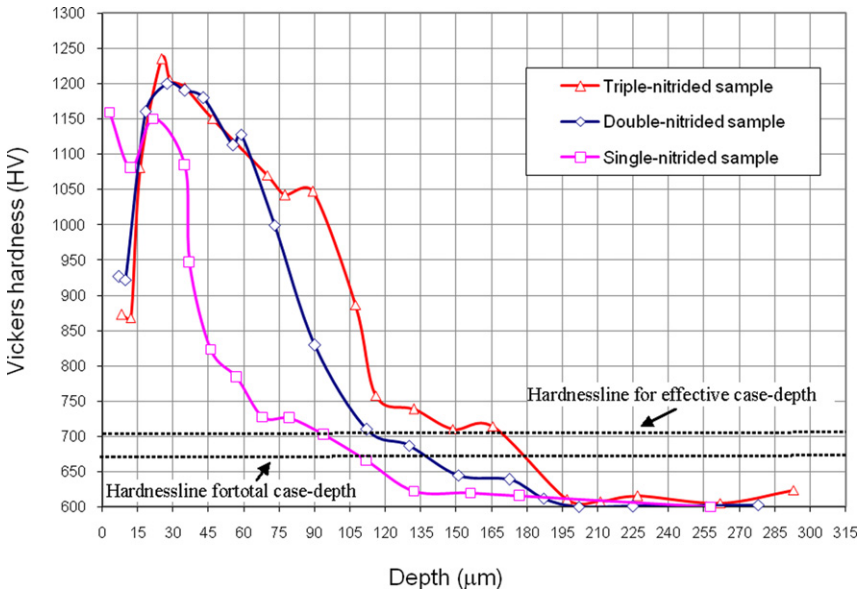

Figure 13 Vickers hardness depth profiles of nitrided cross-section for single-, double-, and triple-nitrided samples: hardness measured under 300 g load.

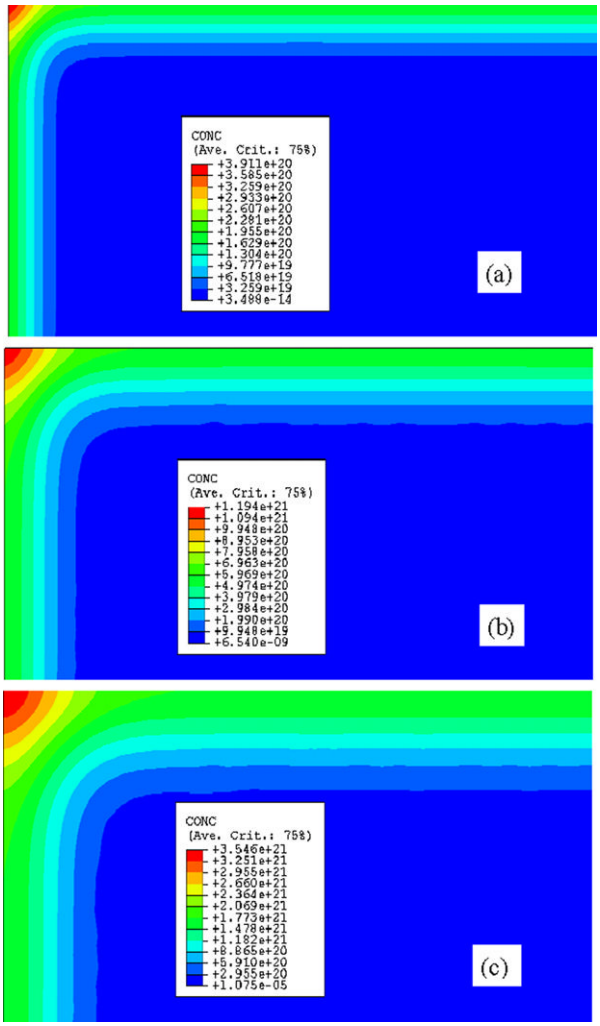

Figure 14 Nitrogen concentration distribution (in atoms per mm^3) and case depth formation at the end of the nitriding cycle: (a) single-nitrided sample; (b) double-nitrided sample; and (c) triple-nitrided sample.

numerically. The corresponding nitrogen mass concentration (in atoms of N per mm^3) profiles are shown in **Figure 15**.

Nitriding depth estimated from numerically obtained concentration profile is based on the depth where the nitrogen concentration is 10% higher than the average minimum concentration, as discussed. **Figures 13** and **15** are used for estimating the case depths from hardness and concentration profiles, respectively. Based on the average core hardness value of 620 HV, the total case depth was obtained corresponding to 680 HV from microhardness profiles of single-, double-, and triple-nitrided samples. The average minimum nitrogen concentration in each case is calculated from the contour legends of **Figure 14**. The comparison of case depth obtained from experimental and numerical results is provided in **Table 3**. Table 3 also provides the effect of multiple nitriding treatments on H13 samples and shows a continuous increase in the case depth with multiple nitriding treatments.

It can be observed that the case depth resulting from FE simulation compares well with experimental measurements. A slight increase in the numerically predicted case depth could be due to two reasons. First, the coefficient of diffusion may not be exact for H13 steel and based on experiments found in the literature. Second, the computer simulation of the diffusion process does not take into account the formation of nitride phases in the form of the superficial compound layer during the nitriding process. These phases significantly reduce the diffusion mechanism due to the reduced coefficient of diffusion. Assuming that the decay of hardness scales fairly well with the decay of nitrogen concentration, concentration depth profiles for single- and multiple-nitrided samples obtained numerically agree well with corresponding hardness depth profiles resulting from experiments. However, a slight difference is found if we compare the depth at which maximum hardness and maximum nitrogen concentration occur. Because numerical simulation did not take into account the compound layer development and porosity effect near the surface, the near-surface hardness values can be ignored when comparing experimental and numerical results.

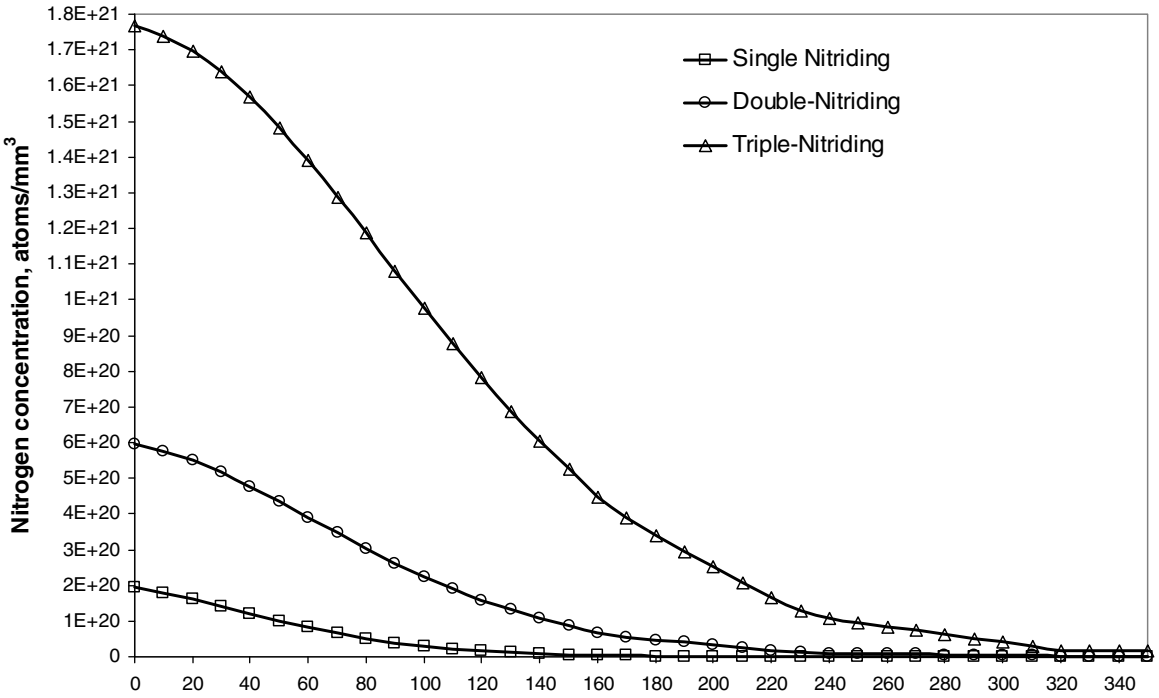

Figure 15 Numerically predicted nitrogen mass concentration as a function of nitriding depth for single-, double-, and triple-nitrided samples.

Table 3 Comparison of nitrided case depth from experimental and numerical studies

Sample	*Nitrided depth (μm)*	
	Experimental results	*Numerical results*
Single-nitrided	105	120
Double-nitrided	135	165
Triple-nitrided	180	200

3.11.6 Conclusions

The conclusions drawn from the current study are grouped into three subsections. In the first subsection, conclusions of the effect of surface texture on the nitriding treatment are presented, whereas in the second section the influence of the profile geometry on the nitriding behavior is discussed. In the laser section, the effect of multiple nitriding is discussed.

3.11.6.1 Consideration of Surface Texture on the Nitriding Kinetics

The influence of mechanical pretreatment (surface texture) in terms of surface roughness on nitriding kinetics of AISI H13 tool steel during controlled gas nitriding was studied. It is found that the surface texturing by surface roughening prior to nitriding enhances significantly the nitriding kinetics and is expected to increase wear resistance of H13 steel used for aluminum extrusion die while resulting in its increased service life. The XRD analysis confirmed that the compound layer consists of iron nitrides mainly $\varepsilon - Fe_3N$ phase and small fraction of $\gamma' - Fe_4N$ phase, which was expected from the values of in-process varying nitriding potential during gas nitriding cycle. Ground sample has more uniform and slightly thicker (2.5–3 μm) compound layer as compared to polished (~1.5 μm) and lapped (~1 μm) samples. Ground sample with high surface roughness exhibits deeper diffusion zone and effective case depth as compared to polished and lapped samples. This can be associated with the reduction in lattice spacing of α-Fe. The reduction in lattice spacing suggests comparatively large number of free atomic nitrogen, which is available for diffusion and induction of high compressive stress at the surface.

3.11.6.2 Consideration of Profile Geometry on the Nitriding Treatment

The geometric features commonly used in the design of aluminum extrusion profiles have been considered to investigate the effect of geometric features on the case hardening of the AISI H13 steel. Numerically predicted case depths compare well with experimental results for EC and IC feature locations, and the current model can be very useful for the die manufacturers during the design stage of die cavities. The EC features resulted in comparatively deep nitride case depth due to simultaneous diffusion from two convergent directions at the corners. The hardness profiles for the EC feature locations are relatively less steep and have a deeper hardening effect, in line with greater case depth. However, oversaturation of nitrogen at the extreme corners resulted in the 'corner effect' despite the controlled nitriding process. It was found that the IC features resulted in reduced nitrided case at the corner due to simultaneous diffusion from two divergent directions. The oversaturation effect in the case of external features and insufficient and nonuniform nitride layer development in the case of

internal features were almost eliminated when the geometry of these features were modified in the FE model by incorporating the fillet. It was found that the incorporation of a 0.5-mm fillet at the external and ICs results in uniform growth of nitrogen concentration. Such a modification is expected to have a certain positive influence on the hardness and effectiveness of these corner features. The results have shown that various die design features can be optimized effectively with the help of the current FE model, keeping in view the target tolerances of various extruded sections.

3.11.6.3 Consideration of Multiple Nitriding on the Nitriding Kinetics

The effect of multiple nitriding on the microstructure of AISI H13 tool steel during controlled gas nitriding treatment was studied. The nitrided layer depth increased with multiple nitriding treatments. Multiple-nitrided samples have more dense lamellae structures of nitrides of alloying elements/α-Fe, and more precipitates were observed at the grain boundaries with deeper effects. The increased amount of precipitates is due to the aggregate long duration of repeated nitriding treatments. Single-nitrided samples reveal the presence of the monophase ε-Fe_3N compound layer in agreement with the nitriding potential values during the nitriding cycle. A mixed phase of γ′-Fe_4N and ε-Fe_3N was detected in multiple-nitrided samples, which can be associated with loss of pre-existing nitrogen dissolved in ε-Fe_3N, which leads to transformation of ε-Fe_3N to γ′-Fe_4N. This mixed-phase microstructure resulted in reduced hardness at the surface. Thinner compound layers were observed in multiple-nitrided samples (approximately 2 μm) compared to single-nitrided samples (approximately 4–8 μm), which is likely due to the fact that the decomposition of iron-nitrided phases in the compound layer is more dominant than re-development of compound layer formation during simultaneous re-nitriding treatment. The case depth and nitrogen concentration depth profiles for single- and multiple-nitrided samples resulting from FE simulation compare well with experimental measurements. Because numerical simulation did not take into account the compound layer development and porosity effect near the surface, a slight difference is found if we compare the depth at which maximum hardness and maximum nitrogen concentration occur. Experimental verification of the nitriding process by FE analysis indicates that the FE model currently developed can serve as a powerful tool to improve the nitriding and re-nitriding cycles of H13 extrusion dies by adjusting the nitriding potential activity, nitriding time, and temperature. Hence, optimization of the nitriding process is viable from the present simulation model of a real-world nitriding cycle.

3.12.1 Introduction

Galvanizing is a well-known and widely used surface coating process used to protect metals from corrosion.[1,2] In recent years, galvanizing has been updated by applying new procedures. It is very important to obtain optimum coating thickness by putting the sample into a zinc bath for a predetermined immersion time.[3] Increasing the immersion time resulted in a decrease in plasticity of the coating.[3] Corrosion is basically an electrochemical process. It occurs because of differences in electrical potential that exist between dissimilar metals in contact or between small areas on a metal surface in the presence of an electrolyte. Corrosion causes deteriorative loss of a metal as a result of dissolution environmental reactions due to chemical reactions with environment or electrochemical reactions in the inter-zone of the metals in contact. When dissimilar metals are in contact physically, more anodic ones corrode. As one of the controlling techniques of corrosion, a more anodic material is attached to the one to be protected by covering, depositing, or coating methods.[4–9]

Galvanizing has been known since the seventh century. It is a quite simple process that includes immersion in a galvanizing bath and drying processes of the metal pieces. It has been widely used in many industries, such as automotive, construction, electricity distribution towers, heat exchangers, protective barriers, chains, bolts and nuts, traffic signs, lighting poles, and advertising poles.[10,11]

Today, galvanized steels are still the dominant materials used for car bodies. Therefore, many galvanizing plants exist. Electrodeposition and hot-dip galvanizing processes are the main processes for galvanizing automotive body steels.[12] Electrodeposition produces a layer of pure Zn on steel when Zn is applied by using an electricity current. It results in a thinner coating than that attained with hot-dip galvanizing. Generally, it is not suitable for outdoor applications for which a thick coating is required. Its advantages are its brightness, uniform color, and esthetics. There is a strong desire within the automotive industry to move to alternative Zn coating methods offering improved corrosion resistance without increasing coating thickness.[12] It is a known fact that a thick coating increases the cost and decreases the surface quality. For this reason, the hot-dip galvanizing process is an excellent choice for achieving better corrosion properties by adding additional elements or alloys to the Zn bath. The process has several attractive advantages, including low cost, long service life, homogenous surface, flexibility of the process, easy to apply, high resistance to scratches, possible painting, and recycling potential.

In the galvanizing process, the main coating element is zinc (Zn). The position of Zn on the periodic table is the first element of group 12 in the transition metals class. It has a $+2$ ion and hexagonal close-packed crystal structure. Its appearance is blue, and it has very low ductility (brittle nature) at room temperature (RT). Because it has limited slip planes at RT, plastic deformation is limited. Its density is close to that of steel, approximately 7140 kg m^{-3}, and the melting temperature is approximately 400 °C. Electrochemically, Zn has more negative value than iron. Thus, Zn is a metal that is subject to corrosion as an anode. Zn coatings prevent corrosion of the protected metal by forming a barrier and by acting as a sacrificial anode if this barrier is damaged. When exposed to the atmosphere, Zn reacts with oxygen to form ZnO, which further reacts with water molecules in the air to form Zn-hydroxide. Finally, Zn-hydroxide reacts with CO_2 in the atmosphere to yield a thin, impermeable, tenacious, and quite insoluble dull gray layer of Zn-carbonate, which adheres extremely well to the underlying Zn, therefore protecting it from further corrosion. It is well-known that the Zn coating is extensively used for coating steels. In **Figure 1**, galvanizing applications on steel parts and surface appearances are given.

Types of Zn coatings are hot-dip galvanizing, electroplating, spraying, plating, and painting. Among the all galvanizing methods, the hot-dip galvanizing technique is the most common because it results in excellent properties such as high strength and formability, lightweight, corrosion resistance, low manufacturing cost, and recycle potential.[13] Coating thickness varies depending on the working conditions of the material. Therefore, the coating thickness considerably affects the cost of the process.

3.12.2 What Is Galvanizing and How Is It Performed?

Galvanizing is a simple metallurgically bonded coating process applied in two different ways. These are the hot dip galvanizing process and electrogalvanizing methods. A schematic representation of hot-dip galvanizing is shown in Figure 2. It is well-known that the hot-dip galvanizing process is the most effective and common method to protect steel from corrosion. As seen in this figure, the first step is to degrease the surfaces that will be coated. The good coating is directly related to surface quality. Therefore, part surfaces must be cleaned so that there is no rust and oil, or acceptable coating quality cannot be achieved. First, the rusted surface must be cleaned by performing a surface cleaning operation. If the surface is heavily rusted, then abrasive blast cleaning or mechanical processes including machining might be needed. After blast cleaning, surfaces should be cleaned so they do not contain any oils, paints, greases, or other contaminants. This step involves a process of immersing parts into a degreaser fluid. Degreasers

are usually present in an acid bath. The second step is to rinse the degreased parts with water. The water can be at different temperatures, depending on need. After the surface cleaning process, the following processes are applied, in order: pickling, rinsing, fluxing, drying, galvanizing, and cooling. The fluxing stage is a process required for the binding of Zn to the surface. The temperature of the molten Zn bath is approximately 450 °C. Temperature can be changed slightly depending on the composition of the bath (molten alloy content).

Pickling is a cleaning process in an acid tank filled with either hydrochloric acid or sulfuric acid. These chemicals generally remove rust, mill scale, and other metal oxides. The term 'scale' is typically used to describe the iron oxides that form at high temperatures, such as during hot rolling, annealing in air, or welding. Rust is the product of corrosion of the steel surface when it gets wet. Both types of iron oxides need to be removed prior to the application of the Zn coating. Another rinsing process will take place following the pickling. Fluxing is a protection process involving the cleaned parts. Actually, it coats the parts to prevent part rusting before the galvanizing process (immersion of metal into the bath). There are two different fluxing methods: dry and wet processes. The dry process is performed by prefluxing in a Zn ammonium chloride solution. The wet process uses a molten flux blanket on the Zn bath surface. Flux solution is a slightly acidic solution that contains a combination of Zn chloride and ammonium chloride in the tank. Flux is the same as flux used in soldering. At this stage, the part surfaces are completely free of any oxides or any other contaminants. Any type of contaminants on the surfaces might affect the coating quality and composition. The parts that were fluxed are dried prior to the galvanizing process.

As mentioned previously, the second major step of the galvanizing process is 'galvanizing.' During this step, cleaned parts are submerged into a liquid Zn bath in the tank. During the first minute of immersion in the galvanizing bath, Zn–iron alloy layers grow rapidly on the surfaces of the steels that are most commonly galvanized. Sometimes other elements may be added to the molten Zn bath to obtain desirable properties. Hot dipping not only is a thermal process but also includes chemical reactions and intermixing diffusion reactions. As a result, alloy layers develop. Although only Zn is coated on the outer surface, intermetallic alloys starts to occur between the Zn layer and the base metal's surface, as seen in **Figure 3**. Although pure Zn is coated on the outer layer, compounds consisting of iron are located toward the inner core. New phases developed during coating are shown in **Figure 3**. The interaction of atoms (diffusion) creates a nonuniform coating due to different chemical composition. In the outer zone, the coating is rich in Zn, whereas in inner zone the coating is rich in iron. **Figure 3** indicates several layers that are developed during coating. **Table 1** indicates composition details of each layer developed during galvanizing.

The eta layer is a relatively pure outer coating of Zn. The zeta layers include Zn–iron alloy containing 5.8–6.2% iron. In the delta layer, the amount of Zn is slightly less, with the Zn–iron alloy containing 7–12% iron. The gamma layer just above the base metal is a thin molecular layer containing 21–28% iron. In **Figure 3**, the bottom layer is the base metal. When the galvanizing process is completed, the parts are removed from the tank. The process is usually completed in a short period of time. It may take less than 10 min depending on the desired thickness. The hot-dip galvanized coating usually forms in 3–5 min, depending on the metal thicknesses.

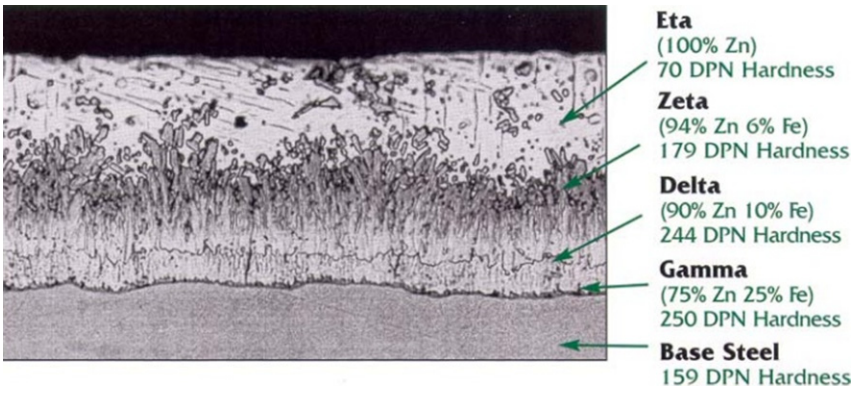

Figure 3 Photomicrograph of batch hot-dip galvanized coating.[2]

Table 1 Composition and properties of alloy layers in batch hot-dip galvanizing[14]

Layer	*Alloy*	*Iron (%)*	*Melting point*		*Crystal structure*	*Alloy characteristics*
			°C	*°F*		
Eta (η)	Zn	0.03	419	787	Hexagonal	Soft, ductile
Zeta (ξ)	$FeZn_{13}$	5.7–6.3	530	986	Monoclinic	Hard, brittle
Delta (δ)	$FeZn_7$	7.0–11.0	530–670	986–1238	Hexagonal	Ductile
Gamma (Γ)	Fe_3Zn_{10}	20.0–27.0	670–780	1238–1436	Cubic	Thin, hard, brittle
Steel base metal	Iron	99+	1510	2750	Cubic	–

In general, coating thicknesses vary from 45 to 85 μ. In the galvanized sheet metals, the amount of Zn is given in terms of gram per square meter (e.g., 80 g m^{-2} Zn).

Finally, parts are removed from the galvanizing tank and transferred to a storage area or quenching tank. Then, post-treatment to enhance the galvanized coating may be applied. This process is generally a quenching process in the water tank. Sometimes the parts are cooled in air.

The second common method of Zn coating is electro-galvanizing, which is applied by setting Zn as an anode and galvanized metal as a cathode in a suitable electrolytic liquid. This process is illustrated in **Figure 4**. Electrogalvanizing is a preferred process if the temperature of molten Zn bath can damage the piece to be galvanized. Also, it is applied to the decorative items for which surface quality is an important issue. Coating thickness should be usually up to 20 μ. Low coating thickness is the main disadvantage of the process.

In the galvanizing process, coating thickness, alloy structure, and finish of galvanized coatings are influenced by surface condition and material compositions. Increasing the period of immersion in the galvanizing bath will not increase the coating thickness, except in the case of silicon (Si)-containing steel. Grit blasting increases the coating area and creates plastic deformation, which makes surfaces highly reactive to molten Zn. Surface thickness is determined depending on the application under which substrate is to be used. It is a fact that a thick coating has a longer life but poor surface appearance.

The amount of elements can have major effects on the structure, appearance, and properties of galvanized coatings.[15–17] The most critical elements are Si and phosphorous (P) in the galvanizing process. In extreme cases, coatings can be excessively thick, brittle, and easily damaged. Si causes excessively thick coatings. Excessive growth in coating thickness takes place on steels with Si contents in the range 0.04–0.14%. Growth rates are less for steels containing between 0.15 and 0.22% Si, but they are more with increasing Si levels above 0.22%. Presence of P (such as approximately 0.05%) in steel produces a marked increase in reactivity of steel with molten Zn and rapid coating growth. When present in combination with Si, P can have a disproportionate effect, producing excessively thick galvanized coatings. As a guide to the suitability of steels containing Si and P for galvanizing, the following criteria should be applied:

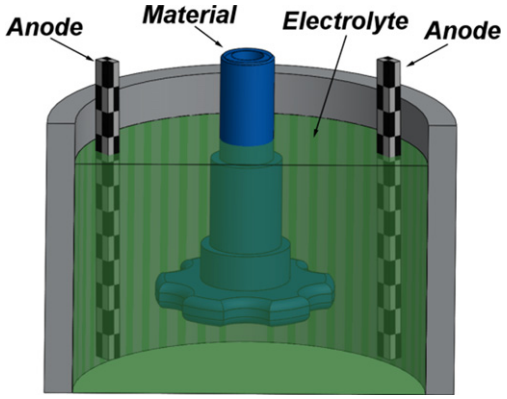

Figure 4 Electrogalvanizing method.

$\%Si < 0.04\%$ and $\%Si + (2.5 \times \%P) < 0.09\%$. Galvanized coatings on Si steels are usually dull gray or patchy gray in color with a rough finish, and they may be brittle. Coating service life is proportional to the increased thickness and is unaffected by appearance, provided that the coating is sound and continuous. In general, the thickness, adherence, and appearance of galvanized coatings on Si and P steels are outside the control of the galvanizer.

Obtaining a proper bonding zone during the hot-dip process is important to achieve the desired galvanizing benefit. The thicker Zn coating does not always mean a longer working life. Alloy layers are hard and brittle, so cracking on the coating layer may occur and propagate easily in any force application case. If any post process will be applied on the part, such as deep drawing after galvanizing, then the alloy layer has to be thin and suitable to prevent formation of cracks. Also, if the part is already fabricated and no additional forming is required, then the thicker Zn coating means a longer working life, but the thicker Zn coating requires additional process time and cost.[18–20]

Double dipping, or galvanizing two times, will not increase the thickness of the galvanized coating and may adversely affect the coating appearance. The terms 'double dipping' and 'double-end dipping' are sometimes confused. Double-end dipping is a method of galvanizing articles too long for the available bath by immersing one end of the work at a time. However, it was previously mentioned that coatings of double layers by galvanizing and organic coatings increase the service life of galvanized steels under various environments.[21,22]

Designing the galvanizing process is very important in terms of the finished product. Consistent section size is important for good galvanizing. Molten Zn should flow freely and easily. Ventilation is necessary to prevent air traps. Folds and tight curves should be avoided as much as possible.

After the galvanizing process, visual inspection takes place to check Zn on the materials. It is often possible to see improper coatings, and even in some areas no Zn is reached. Zn thickness is measured at various locations of coating and checked to see whether desired thickness is achieved. Thickness gages are used for measurement. Variations in colors are checked. Actually, color variations are related to the composition of the steel. For example, silicon steel has a dull surface appearance.[23]

For the packing of the galvanized products, no metal straps are used because they damage the coating. Only plastic straps are used as much as possible. If they are stacked together, then air flow circulation between surfaces should be allowed because, otherwise, moisture will form and rust will occur. It is a key point that moisture should always be eliminated and stacked items should be kept dry. The stacks need to be ventilated during transportation. The finished product is always labeled, indicating how material is coated and the thickness of the coating.

3.12.3 Continuous and Batch Hot-Dip Galvanizing Processes

Hot-dip galvanizing processes can be performed as continuous or batch, depending on the need and application. A continuous

process is only limited for sheet, strip, and wires. The coated sheet is then blanked or sheared and formed into a final part. The aforementioned steps are automated in the process. The process can easily be controlled and very accurate thickness can be achieved. The other method is the batch hot-dip galvanizing process, which is a discrete process used after fabrication of the parts. Parts as small as fasteners to as large as bridge structural girders can be galvanized using the batch method. In continuous process, wherein the steel is immersed for a very brief time, the batch process requires the part to be immersed for much longer times.

The continuous hot-dip galvanizing process is suitable for galvanizing coiled sheet metal. When the coil at the entry end finishes, another coil is welded to the tail of the previous one, as seen in **Figure 5**. Therefore, process may continue for days. Tension at both ends of the line provides additional constraint to sheet metal. This constraint prevents thermal distortion of thinner sheet metal. Also, thinner sheets (up to 0.15 mm) can be galvanized, avoiding distortion as an advantage. As a disadvantage, thickness is limited up to 6 mm.

Generally after galvanizing, sheet metals undergo post-deformation processes such as deep drawing or roll forming. Therefore, it is vital to not damage the coating layer during deformation after the galvanizing process. The thinner coating allows more intricate deformation without any damage on the coating layer. Because the alloy layer is hard and brittle, the fineness of the alloy layer is essential for good formability.

The thickness of the galvanic layer can be controlled by the speed of the production line and the addition of aluminum (Al) to the Zn bath. Production line speed can be 200 m s^{-1}. Sometimes this speed may not be enough due to thinner coat requirements during continuous hot-dip galvanizing processes. Al can be added to decrease the diffusion speed. A slow Zn–iron reaction rate leads to formation of a thinner coating layer.[24–26]

A batch hot-dip galvanizing process is suitable for bigger workpieces. A thicker coating layer can be achieved without any thermal distortion. As seen in **Figures 2** and **6**, fluxing can be applied in two ways: dry or wet. In a study of dip galvanizing, a wire was coated in a molten zinc bath after being treated in a nitrogen (N) and hydrogen (H) atmosphere and fluxing.[3] In the dry method, fluxing is applied before the Zn bath. In the wet method, flux is added into the Zn bath. Due to the fact that density of flux is less than that of Zn, flux floats on the molten Zn bath upper surface. When the part starts to enter the Zn bath process, it is first covered with flux and then is dipped in the Zn bath.

For both methods, the galvanizing process consists of common subprocesses like surface preparations (cleansing, rinsing, pickling, fluxing), galvanizing (dipping into molten Zn bath), and final inspection. The ability of the coating layer to stick to base metal depends on surface preparations.

Lead (Pb) or bismuth (Bi) can be used to easily dispose of excessive Zn after the dipping process. When Si content in the base metal is high, nickel (Ni) can be added to improve the galvanizing process. **Table 2** gives a general summary about both methods and shows a comparison of both methods.

Steels were continuously reheated (annealed) at different temperatures before the galvanizing in another study.[27] Moreover, a reducing atmosphere removed the oxides formed at RT that were present at the surface.[27] Rather than the

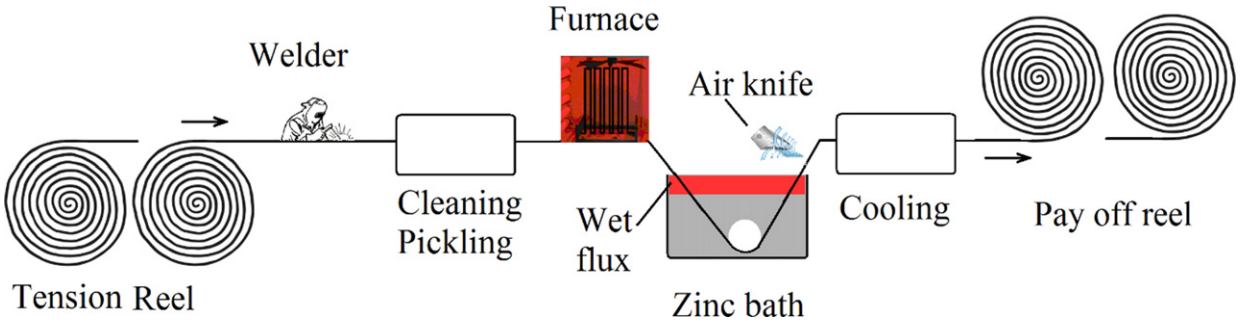

Figure 5 Schematic of continuous hot-dip galvanizing process.

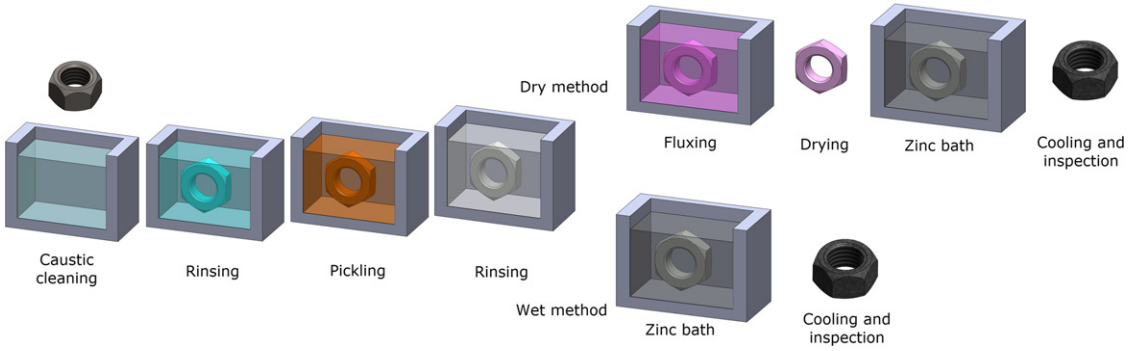

Figure 6 Batch hot-dip galvanizing process.

Table 2 Properties of hot-dip galvanizing processes

	Continuous hot-dip galvanizing	*Batch hot-dip galvanizing*
Part thickness	Sheet metals (very thin, limited to 6 mm)	Only thicker parts due to thermal distortion of thin parts
Zn bath ingredient	Al (slows the reaction)	–
Speed of process	Very high speed	Slower than continuous process

reheating temperatures of 550 and 650 °C, at 750 °C the carbides formed at the steel surface were dissolved.[27] This reheating temperature was observed as the best condition for galvanizing.[27] Furthermore, cooling conditions affect the grain size of the coatings.[28]

Si-killed steels were Zn-coated with a high-temperature hot-dip galvanizing procedure.[29] However, it was found that immersion time did not affect the coating thickness and presence of the phases during coating.[29] High-temperature hot-dip galvanizing resulted in higher hardness values than those of normal galvanizing at moderate temperatures.[29] High-temperature hot-dip galvanizing resulted in coating with minute amounts and phases.[29] Steels were fully coated in high-temperature ranges of 520–555 °C; the conventional galvanizing temperature is 455 °C.[30]

Bicao *et al.*[31] investigated the effect of Zn galvanizing bath temperature on coating morphology and thickness. Samples were galvanized at a bath temperature between 450 and 530 °C.[31] When the galvanizing temperature was between 450 and 470 °C, galvanized coating was coherent and a delta layer and a compact zeta layer were at the top.[31] A very thick Zn coating was observed after a galvanizing bath temperature of 480 °C.[31] When the bath temperature was increased to more than 500 °C, the delta phase was mainly observed during the coating.[31]

3.12.4 Recent Research and Development Activities in Hot-Dip Galvanizing

Research has been conducted to attain better corrosion behavior from the hot-dip coated steels.[12,32–34]

Metallic coatings containing magnesium (Mg) have been widely investigated. Several studies have been published regarding Mg addition to Zn coating. Hosking *et al.*[12] reviewed the effect of the addition of Mg to a Zn bath. They showed that steel coated with Zn–Mg has greater corrosion resistance in a sodium chloride–containing atmosphere than conventional Zn-coated steel with a similar coating thickness. They proposed a proper mechanism with the following guidelines:

- Quenching of oxygen reduction reactions at the cathodes by the formation of protective magnesium hydroxide.
- Decreased oxygen reduction facilitates the formation of stable simonkolleite.
- Hydroxides associated with simonkolleite formation are neutralized by carbonization at the cathodes.
- Magnesium hydroxide at the cathodes is transformed into carbonate-containing hydroxides, which in turn facilitate further formation of protective simonkolleite.

Prosek *et al.*[33] showed that Zn–Mg alloy containing from 1 to 32 wt% Mg, pure Zn, and pure Mg was contaminated with sodium chloride and exposed to humid air for 28 days. They found that Mg was substantially decreased as a result of weight loss of ZnMg alloys in atmospheric conditions in the presence of chloride. The effect of Mg was most profound at 4–8 wt% Mg in the structure. Finally, they recommended that 'the optimal corrosion protection of ZnMg alloys in atmospheric conditions is related to combination of relatively noble free corrosion potentials close to that of Zn and the presence of Mg-based films with good stability and barrier properties.' Hausbrand *et al.*[32] studied the progress of the corrosive degradation of the alloy coating–paint interface. They proposed a degradation mechanism model. Results reveal that adjusting the composition of the Mg–Zn oxide at the coatings can inhibit anodic delamination. Schuerz *et al.*[35] studied the corrosion behavior of steel sheets coated with Zn and Zn–Al–Mg with a thickness of 7 μ tested in a salt environment. They found that the corrosion resistance of steel coated with Zn–Al–Mg was better than steel coated with Zn. They concluded that the transformation of the Zn–Al–Mg coating into the Al-rich oxide layer is the key reaction in the corrosion process and is necessary for improvement. Dutta *et al.*[10] studied hot-dip Zn–Mg and Zn–Mg–Al alloy coatings on steel sheets. They studied both low and high Mg contents in Zn–Mg alloy. The results indicate that the Zn–Mg–Al bath shows better corrosion resistance than pure Zn and Zn–Mg baths. It was also mentioned that Al addition suppressed the oxidation of Mg. This improves the coating quality enormously. It was also pointed out that the Mg oxide layer is more protective than the Zn oxide layer. Li *et al.*[36] investigated the effects of Mg addition (0, 0.5, 1.5, and 2.5 wt%) on the microstructure and corrosion resistance of Galvalume coating (Zn–55Al–1.6Si). Results show that a new intermetallic phase ($MgZn_2$) appears in the Zn-rich interdendritic area of the Mg-containing Galvalume coating. The corrosion product formed on Zn–55Al–1.6Si–1.5Mg coating displays a densely packed microstructure, showing the best barrier protection characteristics. It was obvious that Mg improves the corrosion performance. This issue was reported many times in the past for Zn and Zn–Al coatings.

Formation of the Fe–Al inhibition layer was discussed previously.[37] They characterized the formed inhibition layer on TiNb-stabilized interstitial-free (IF) steel after a short galvanizing process. They determined heterogeneous growth of Fe_2Al_5. Higher growth was seen on Zn side. In a computational study, production sequencing problems related to a continuous galvanizing line of a company were solved in a progressive way by developing a simple model and a proposed tabu search algorithm.[38]

Doehlert design was applied to reduce the Zn consumption in the galvanizing bath, along with considering the effects of bath temperature, immersion time, and the withdrawal speed.[39] The substrate alloy relation to the coating of Zn-free layers can be controlled by the galvanizing bath temperature.[39] It was shown that coating thickness can be adjusted by changing the

immersion time.[40] The amount of unalloyed Zn adhered to the substrate can be controlled with withdrawal speed.[39] Therefore, it was shown that the galvanizing process and steps can be optimized to obtain a coating with a minimum thickness without changing the composition of the galvanizing bath.[39] In this study, optimum operating conditions for bath temperature, immersion time, and withdrawal speed were found to be 444 °C, 90 s, and 4 m min^{-1}, respectively.[39] However, sample dimensions and geometries are also important factors affecting the physical properties.[39]

Texture greatly affects the coating properties. Pure Zn galvanizing bath temperature under hot-dip galvanizing conditions resulted in (0001) plane texturing of Zn after solidification.[28] The presence of Al and copper (Cu) in the galvanizing Zn bath also triggers some texture formation.[28] When Pb is added to this galvanizing bath, this texture formation starts to diminish and dentritic growth starts to form.[28] Moreover, the presence of Ni in the galvanizing bath also starts to decrease the texture formation.[28,41]

When elements of Sb, Bi, tin (Sn), Al, or Pb are present in the galvanizing bath, large grains (spangles) are formed at the coatings.[28,42–45] Presence of these elements changes the surface tension of the Zn and orientation of Zn grains.[15] Therefore, spangles are highly requested by customers purchasing hot-dip galvanized coatings.[15] Moreover, addition of Pb in the galvanizing bath decreases the coating thickness and Zn consumption.[28]

As a result of formation of large bright spangles on the coating, smooth surfaces form and textures with (0001) basal planes form.[43] However, dull spangles result in formation of other planes.[43] Moreover, large and dull spangles diminish the corrosion characteristics of the hot-dip galvanized coatings.[44]

3.12.5 Presence of Elements in Galvanizing Bath

One or more alloying elements may be added to the bath to improve coating performance. Therefore, in the hot-dipping galvanizing process, various alloying elements in galvanizing bath affect the coating properties.[46] Recent research and development activities for this purpose have been summarized as follows. Galvanizing bath can be adjusted by adding small amounts of various elements such as Al, Pb, Ni, Bi, germanium (Ge), titanium (Ti), Cu, Cadmium (Cd), Sn, and others to improve the coating morphology, thickness, quality, appearance, and adherence to the substrate.[42,46–52] Moreover, additives such as Al, Bi, Mg, Ni, and others are commonly used in galvanizing baths to increase the Zn fluidity and its diffusion.[52,53]

The corrosion performance of Zn coatings could be improved with the deposition of a zinc–manganese (Zn–Mn) coating because Mn protects the Zn due to its anodic behavior.[54] This method is faster and easier and produces thinner coatings.[55] Hosking *et al.*[12] noted, 'There is a desire within the automotive industry to move to alternative Zn coatings offering improved corrosion resistance without increasing coating thickness. Thinner (less than 7 μ) metallic coatings are attractive as they may alleviate processing difficulties such as spalling of the coating during forming and brass formation on spot welder electrodes.' Moreover, Pistofidis *et al.*[55] pointed out, 'Mn islands are very beneficial with regard to the corrosion performance of the coating, because they act as sacrificial anodes that protect Zn.'

Wang *et al.*[37] investigated the interaction between the Al in the Zn bath and the surface oxides formed by selective oxidation on 1.2Si–1.5Mn transformation-induced plasticity (TRIP) steel during hot-dip galvanizing. Results show that the SiO_2 films were the most stable of the oxides and were barely reduced by the amorphous $xMnO \cdot SiO_2$ oxide that reacted with Al to form a Si–Mn–Al-containing oxide.[23] Presence of Al in the Zn bath can reduce surface oxides such as MnO, Cr_2O_3, SiO_2, and others on the steel substrate.[56] Al in the galvanizing bath controls the coating morphology and formation of intermetallic compounds of Fe–Zn.[40] Low concentrations of Al (such as less than 0.09 wt% Al) resulted in formation of a coating with eta, zeta, delta, and gamma phases.[50] Moreover, high concentrations of Al (such as more than 0.16 wt%) resulted in thick coatings with high concentrations of Zn and presence of the eta phase.[50] Therefore, growth of the Zn–Fe phases is generally adjusted by including 0.18–0.30% Al in the galvanizing bath.[49] Due to the presence of Al in the galvanizing bath, development of Fe–Zn intermetallic compounds can be inhibited.[49]

The effect of Si on the galvanizing reaction is generally called the Sandelin effect, which prevents the formation of a stable and passivating layer in the bath. Sn, Ni, and Al have moderate Sandelin effects. Chromium (Cr) slows the kinetics of metallurgical reactions.[17]

The influence of Ni is important with respect to the development of the Zn/iron alloy layer, especially when galvanizing steels containing high Si. This development is still quite new and all the metallurgical aspects related to the addition of small amounts of nickel are still being discovered. The reaction between Fe and Zn can be suppressed by adding a small amount of Fe and Al, forming Fe_2Al_5.[57–59]

Hot-dip galvanized coatings comprise essentially pure Zn, provided that controlled amounts of Al or Si are added to the molten Zn bath to suppress the formation of intermetallic Zn–iron. Surfaces coated with the hot-dip process possess generally very large grains that are called spangles when elements of Pb, Sb, and Bi are added to the bath with aluminum.[42,48,52]

Peng *et al.*[60] studied typical spangles on a batch hot-dip of Zn–0.05Al–0.2Sb alloy coating. They observed shiny, feathery, and dull types of spangles. It was determined that antimony (Sb) segregates extensively on the spangle surface. The segregation degree increases from shiny to feathery to dull spangles. The hot-dip coating process has received more attention in recent years due to its beautiful appearance. Many galvanizers have attempted to develop processes for decoration purposes.[60–63]

The effect of vanadium on galvanizing Si-containing steel was studied by Su *et al.*[64] Three different steels with effective Si contents of 0.158, 0.242, and 0.363 wt%, were immersed for 0.5–8 min in Zn baths with four levels of vanadium (V), ranging from 0 to 0.16 wt%. Results reveal that addition of V to the bath suppresses Si reactivity; it was known that Si caused an excessively thick coating. The excessive growth in coating thickness takes place on steels with Si contents in the range of 0.04–0.14%. Thick coating causes poor adhesion, which

affects the quality of the coating. Steels with high Si contents (Si > 0.05%) can be successfully coated in a galvanizing bath containing 0.04% Ni and 0.1% Bi.[51] For steels with high Si content, coatings with the same or better quality can be obtained with using less Ni in the galvanizing bath.[51] Moreover, improved properties were obtained for Zi–Ni–Bi alloys, which can be used in industrial applications as an alternative to the galvanizing baths containing Pb, especially considering the associated health issues.[11]

The presence of Cu and Cd changes the coating phases because of the formation of intermetallics in the coatings, whereas Sn (up to 3% in the galvanizing bath) does not contribute any change in coating phase and thickness.[46] However, presence of Cu in the galvanizing bath results in poor adherence of the coating to the substrate.[46] Di Cocco *et al.*[50] studied the effect of Cu, Sn, and Ti additions in the coating baths for an ipersandelin steel. Results indicate that Cu, Pb, and Sn do not change the morphology of the intermetallic phases. Ti results in the presence of an outer layer characterized by a double phase and a brittle dispersed phase. Moreover, a small amount (0.04%) of Ti in the galvanizing bath makes the coating more stable, delays the combination of Fe–Zn, and inhibits the growth of Fe–Zn intermetallic compounds.[49]

In addition to the above elements, strontium improves both the adhesive strength and corrosion resistance of hot-dip galvanized coating.[65] V_2O_3 is commonly included in the galvanizing bath because it is included at coatings under atmospheric conditions for galvanic corrosion.[53,66] However, ZnO resisted to galvanic corrosion of the coatings better than V_2O_3.[13]

3.12.6 Galvanizing of Advanced High-Strength Steels

In recent years, a tremendous amount of research has been performed to determine how to use advanced high-strength steels (AHSS) in the automotive industry to reduce fuel consumption and lighten the structure by using a thin sheet instead of a thick sheet without sacrificing performance and safety.[67,68] AHSS are developed by steelmakers in accordance with the requirements of the automotive industry (passenger safety, lightness, fuel economy, formability). Examples of steels in this group are martensitic steels, dual phase (DP), TRIP, complex phase steel, twinning-induced plasticity (TWIP), and others. The use of AHSS has increased dramatically in past two decades. As an example, **Figure 7** displays steel usage in some car models.[69] Although these steels have very attractive properties, they have some problems. One of them is a galvanizing issue.

A number of problems in the Zn coating against corrosion of AHSS steel have been addressed by several investigators.[56,70–72] In these steels, alloying elements such as Mn, Si, molybdenum (Mo), Cr, and others during recrystallization annealing lead to the formation of oxide on the steel surface.[73–75] **Figure 8** indicates four methods to prevent Zn coating defects in the hot-dip galvanizing process for AHSS steels. This oxide layer leads to poor results in the galvanizing process.[76] In the hot-dip galvanizing process of AHSS steel, bare spots, flaking of the Zn layer, and cracks with deformation occur.[76] Ti–IF and DP steel annealing time and the composition of the protective atmosphere of H_2–N_2 at a low dew point were examined by Cvijović *et al.*[77] As a result of this study, it was observed that Mn, Al, Si, and Cr make oxide in all conditions, but these high Mn and Si concentrations increase the concentration of nonwettable $MnSiO_3$ particles in DP steel. Also, although the increase of annealing time led to an increase in surface oxide layer, the increase of H_2 in the created gas atmosphere helps to increase the wettability. Khondker *et al.*[78] investigated the effect of oxidation potential of an annealing atmosphere in DP steel. In the experimental study, they emphasized that Mn causes important selective oxidation. However, they have found that before dipping, Mn oxides on the steel surface provide good coating adhesion to annealed samples.

Cold-rolled steels have much better Zn coatings than hot-rolled steels.[79] However, many studies have been performed to increase the Zn coating of the hot-rolled steels.[79]

Liu *et al.*[80] investigated the galvanizing ability of TRIP steel, which has four different chemical compositions. Consequently, they stated that the galvanizing ability of the low Si and Mn contents are good, and Al in the Zn bath makes a good contribution to galvanization. Galvanizing ability can be greatly increased with the optimization of critical factors (steel composition, dew point, and bath chemistry).[81] In another study of galvanizing of TRIP steel,[82] it was emphasized that the TRIP steel is not suitable for traditional hot-dip galvanizing due to the high Si content, defects on the steel surface occur, and the Zn coating does not have good quality. In the

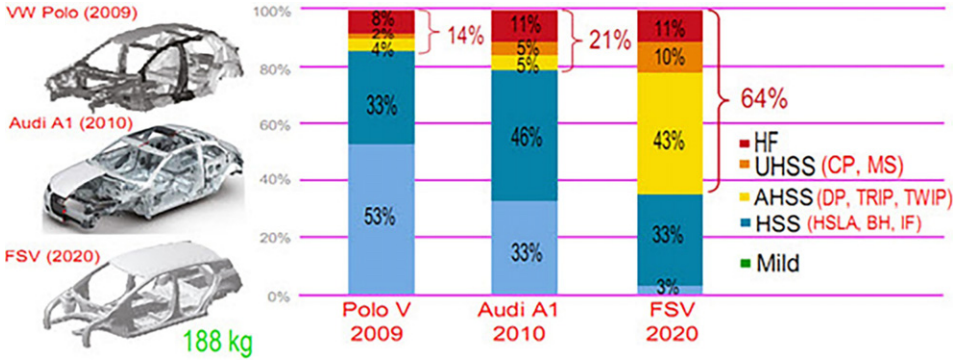

Figure 7 The use of AHSS in some automotive models.[69]

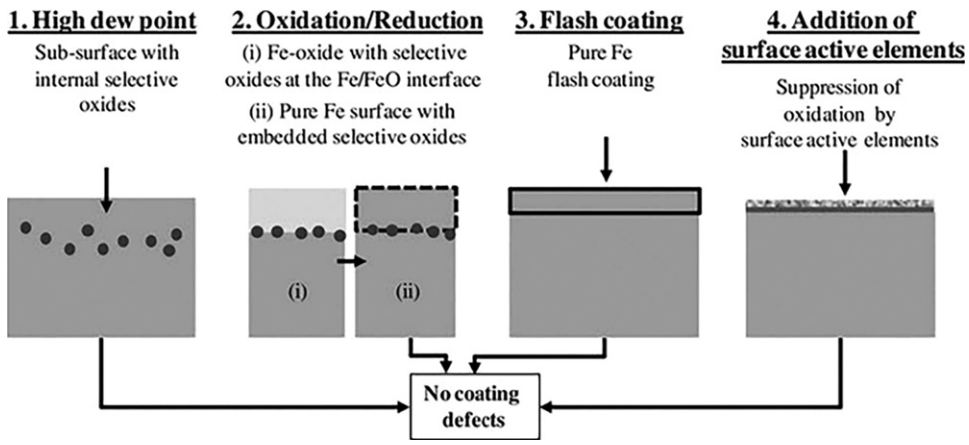

Figure 8 Schematic illustration of the four proposed methods to prevent Zn coating defects in the hot-dip galvanizing process in AHSS steel.[73]

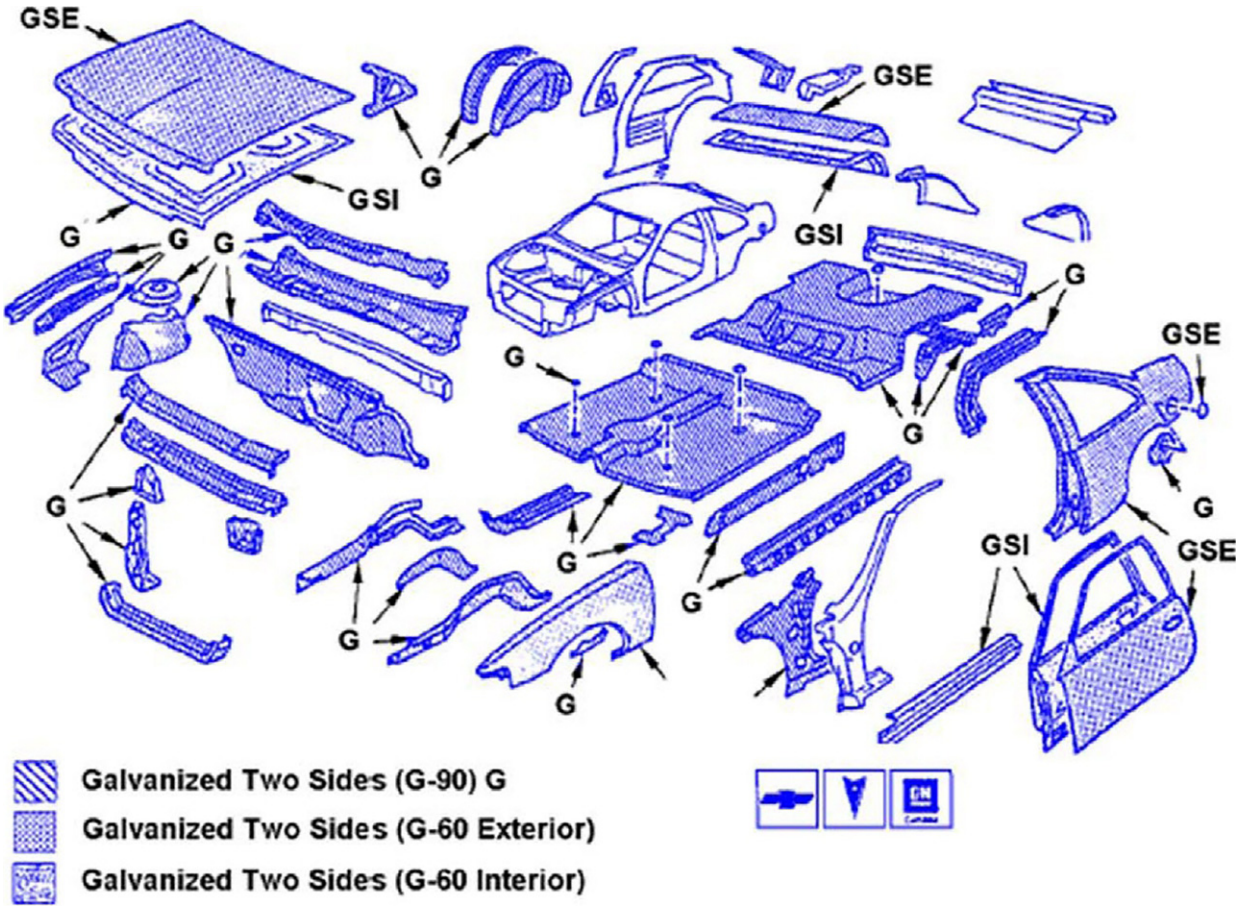

Figure 9 Galvanizing applications in the automotive parts.[84]

galvanizing of AHSS steel, various technological methods (precoating, preoxidation, and dew point control) are recommended.[83]

Galvanized parts are shown in Figure 9.[84] In AHSS steel galvanizing operations, one of the most common problems is galling. Galling is the removal of coating or the adhesion during metal-forming processes. During the forming of galvanized AHSS parts, factors between die material and coating have been investigated.[37,85] Details of the galling process are illustrated in Figure 10.

TWIP steel, which is a new material for the automotive industry, hot-dip galvanizing, and hydrogen-induced delayed cracking problems were examined by Blumenau *et al.*[86] In this work, for the first time, the effect of selective oxidation on

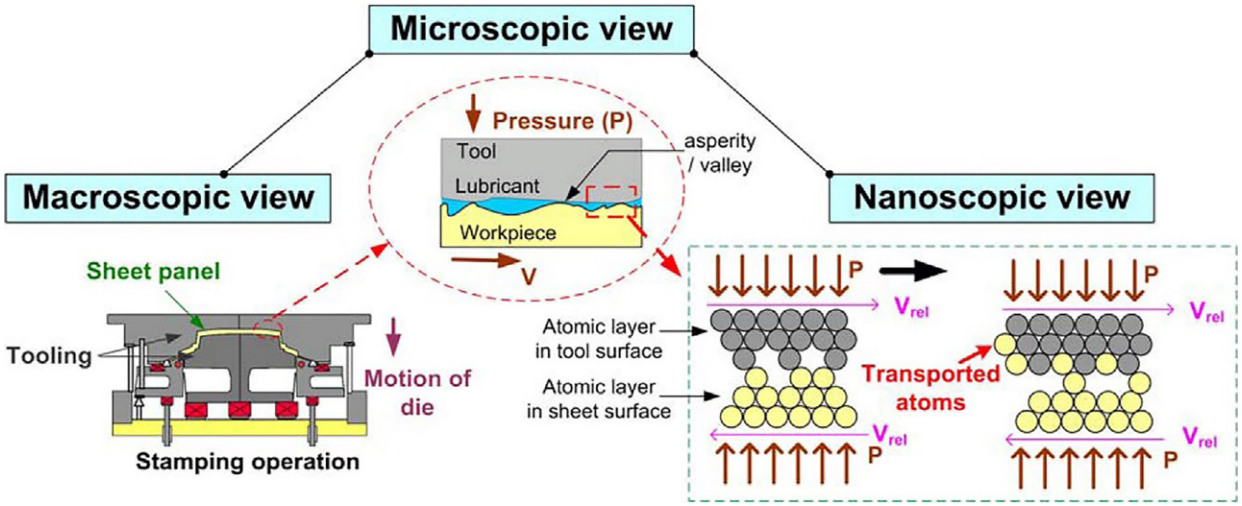

Figure 10 Schematic representation of galling process.[84]

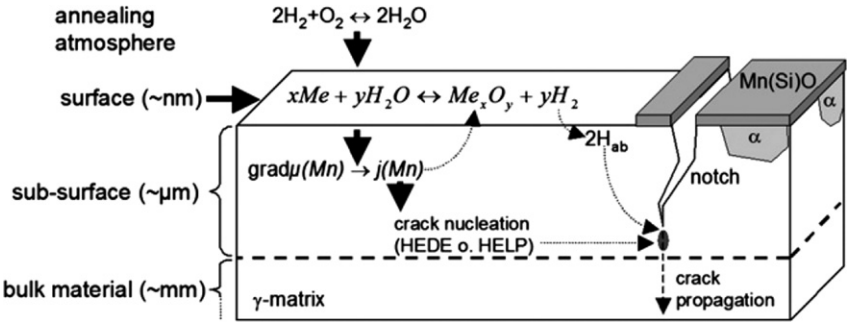

Figure 11 Schematic representation of the proposed model.[86]

hydrogen-induced delayed cracking was verified. Their models are displayed in Figure 11. The models emphasize that removal of solid solute Mn on the subsurface plays a key role.

The hot-dip galvanizing process was applied to dual-phase steel by Belousov *et al.*[87]; high-strength steel sheets (strength, 450–600 MPa) were produced. In another study, the effect of heat treatment was examined in the dual-phase steel, which is made with hot-dip galvanizing and, and was sensitive to the yield strength of the annealing program regardless of the total elongation.[88]

3.12.7 Failure Mechanisms in Galvanized Steels

In the hot-dip process, some unwanted microstructures and failures have commonly been seen. It is known that the presence of cracks in the coatings weakens the coating barrier.[11] Failure mechanisms during galvanizing were investigated by a European project and were prepared to show and share these problems with industries.[89] The most common problem is liquid metal-assisted cracking (LMAC), as shown in Figure 12. This is a condition that occurs only when there is contact with the molten Zn. LMAC is a failure that quickly passes to a brittle structure with a covering of a normally ductile metal or with

Figure 12 Liquid metal-assisted cracking.[92]

contact with a liquid metal.[90] LMAC can occur after galvanizing or may occur when there is a subsequently applied force. Even a small crack in a working environment under successive loads can become a very large crack. Figure 13 shows cracks forming during galvanizing.[89] Repair is performed using a welding method to eliminate this problem. Numerous

Figure 13 Photo of cracking occurring during galvanization.[89]

studies have been performed to attempt to protect against this cracking.[90,91]

Many environmental factors affect the failure of steel parts (or structures) during galvanizing.[89] At a galvanizing temperature of 450 °C, a decrease in impact and strength values of the structural steels was generally observed.[89] Moreover, it was observed that Zn–Bi–Pb–Sn baths resulted in more brittle coatings than the Zn–Pb baths.[89] Surface roughness as a result of fluxing increases the probability of local embrittlement formation similar to notch-like effects.[89]

Liu *et al.*[93] showed that presence of Cl^- can cause the formation of pitting corrosion, which increases corrosion rate as the temperature increases. Moreover, the polarization resistance increases with increasing hydrostatic pressure.

Coatings formed after galvanization at 560 °C in a pure Zn bath were investigated by three-point bending.[94] Crack population and statistical analyses results indicate applied strain on the coating affects the crack density created during three-point bending. However, coating thickness did not contribute any statistical information in terms of crack density.[94] Moreover, the density of cracks acted as a barrier to stop crack propagation at the thickness of the outer Zn-rich layers.[94]

3.12.8 Conclusion

In this chapter, hot-dip galvanizing processes were addressed due to their high application in the coating of automotive body materials. Mg–Zn coatings have been identified as a potential next generation of galvanized steel. Addition of Mg to the Zn bath can improve corrosion performance without increasing the thickness of coating. Effects of various elements present in the galvanizing bath were discussed related to coating properties. Improvements in AHSS galvanizing is a challenging issue and more efforts are still needed in this regard.

3.13.1 Introduction

Thermal spray processes involves spraying fine molten or semi-molten particles onto substrates to form a coating layer (Figure 1).[1] The feedstock materials can be in the form of wire or powder. The electrical sources can be used to heat the feedstock such as arc or plasma spraying systems. The combustion is another source of heat which

is used in flame and high velocity oxy-fuel (HVOF) spraying.[1–4]

The typical microstructure of a thermally sprayed coating is shown in Figure 2.[5] A lamella structure is observed due to flattening of particles when striking into the substrate. The inflight surface oxidation of particles results in presence of oxides in the coatings. The porosity of coatings is also arisen form vacant spaces between splats. The roughness is evident in sprayed coatings due irregularities of splats at the surface.

Many kinds of metallic, ceramic, polymeric, and composite materials can be deposited using thermal spray processes. The composition of feedstock material, pre-treatment of substrate and spraying method affect the performance of the as-sprayed coatings. The finishing and post-treatment of as-sprayed coatings are often inevitable. The control of roughness and dimension is the main reason for finishing of coatings. In the case of thermal treatment, microstructural improvement may be considered. While chemical treatment is used to seal the open pores. Recently, other post-treatments were used to achieve novel microstructures. The service life of coatings depends also on final treatments.

3.13.2 Mechanical Finishing

The as-sprayed coatings are relatively rough. Depend on the spraying method and coating material, the as-sprayed roughness (R_a) can vary between 3 and 40 μm approximately.[1–4] The high roughness can results in:

- Increased friction and wear
- Leakage of fluid and unsuitable sealing in mechanical systems and in parts like valves
- Out of tolerance dimensions

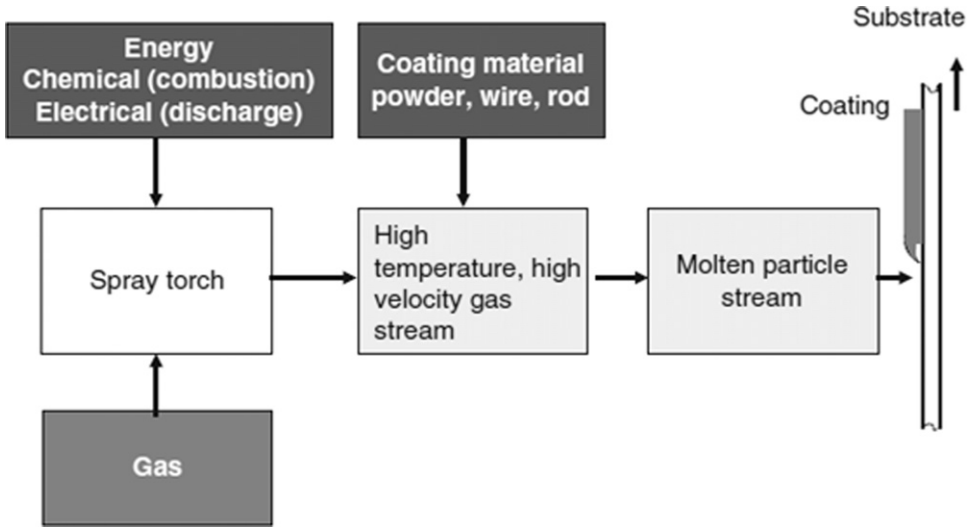

Figure 1 Schematics of thermal spray procedures.[3]

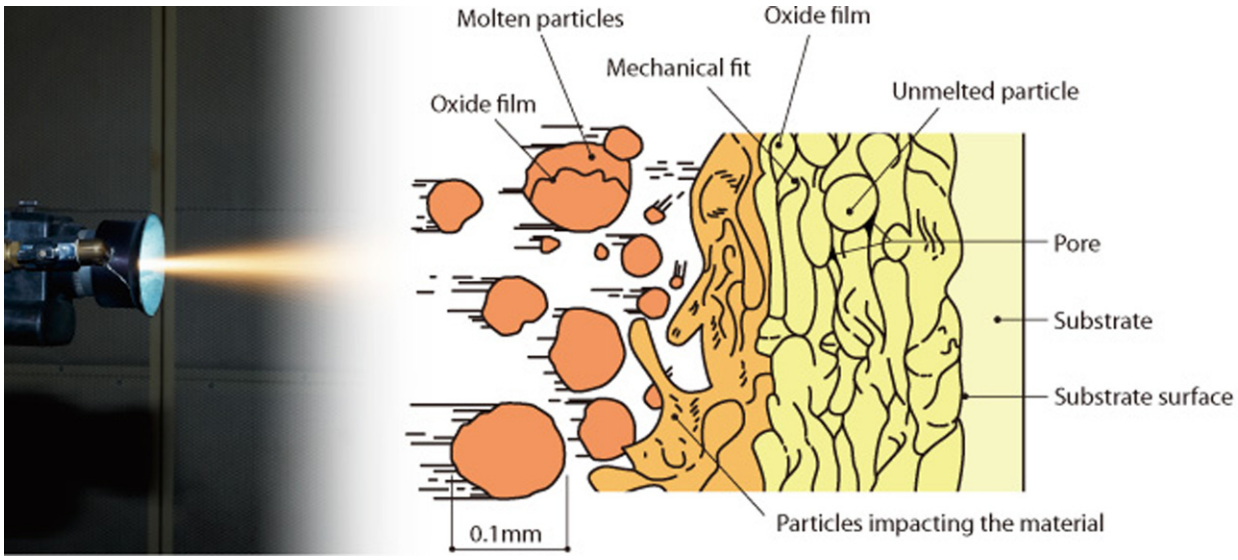

Figure 2 The nature of thermal spray coatings.[5]

To eliminate the deleterious effects of roughness and to ensure the desired dimensions, the coatings are often turned and ground. In some cases, the as-sprayed coatings may be used. Decorative coatings or corrosion resistant coatings are the examples. However, the final roughness and dimension depends on the application criteria.

3.13.2.1 Turning; Milling and Machining

Turning of thermal spray coatings is performed to remove as-sprayed roughness and to control the dimensions. Due to different bonding and microstructural conditions of the coatings in comparison to those of bulk materials (cast or wrought alloys), the use of traditional turning techniques may not be successful. As a result, the coating may be impaired or the tool may be failed. The problems during turning may be arisen form one or more following reasons[3,4]:

- Presence of porosity which may cause pull-out of coating;
- Lamella structure of coatings; the improper machining may results in debonding;
- Mechanical substrate-coating bonding which is relatively weak in comparison to physical and metallurgical bonds;
- Low machinability of some coating materials like cermets or ceramics;
- Penetration of coolants or lubricants through the coating;
- Thickness of coating; the over pressure can be remove all the coating layers to reach the substrate especially in thinner coatings.

The metallic coatings can be turned without any significant concern. However, cermet coatings must be carefully turned using carbide tools. In the case of brittle ceramic coatings, machining is not performed due to catastrophic failure of coatings. The lubricants and coolants (if used) may penetrate through the open pores after turning. So, the turning process must be performed carefully. Due to splat granular structure of coatings, crumble chips are formed during machining. The machined surface seems to be dull with fine pores.[1–4]

For machinable thermal spray coatings, carbide tools are generally used for turning. Use of other kinds of tools, can increase tool wear significantly. Tool angles recommended for turning using carbide tools are seen in **Figure 3**.[3] High-speed steel tools can be used for machining of metallic coatings. Some recommendation for wheel speed can be found elsewhere.[4]

The machining process is started by removal of heavy sprayed material at the end of part. The speed of rough machining is lower than that of finish machining twice. The depth of cutting can be up to 0.75 mm. Sometimes multi-passes are necessary for machining. 0.13–0.25 mm on the radius must be remained for finishing.[4]

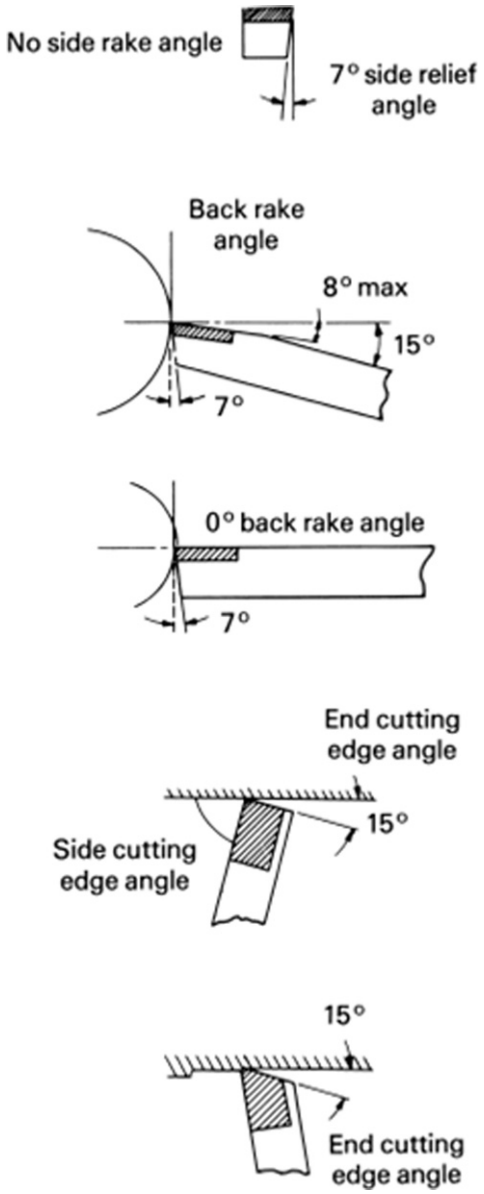

Figure 3 Tool angles recommended for machining of thermal spray coatings using carbide tools.[3]

3.13.2.2 Grinding

3.13.2.2.1 Conventional grinding

In comparison to machining (turning), grinding provides better finish and tolerance but is more expensive. In addition, the machining cannot be applied on ceramic coating so the grinding is inevitable. However, the material removal is much lower than that in machining. The coating thickness after grinding is close to final size ($\pm 5\,\mu m$).[1] Outside diameter grinders, internal grinders and surface grinders can be used for grinding. In the case of complex shapes, the machines with six axes or ultrasonic machining or CNC may be used.[1,4] As mentioned above, the finishing of thermal spray coatings is different from that of conventional materials due to specific microstructural aspects. So, the consideration must be taken to avoid coating failure or tool wear. Due to better freedom in wheel and abrasive selection, wet grinding is preferable. In this case, the hard wheel can be used to improve surface finish and decrease dressing (it should be noted that due to loading of wheel face or wear of abrasive grains, the wheel may be dresses by diamond tool).[4]

The type of grinding wheel (the material, grit size, and bond type) is selected based on microstructure and hardness of coating and the required finishing. To decrease the tool wear, the coarse grain wheel containing low binder can be used. For ceramic coatings, boron nitride and diamond are used. WC-based cermets require diamond wheels. In the case of metallic coatings, SiC, or Al_2O_3 wheels can be used. The details of wheel selection can be found in thermal spray literature.[4]

The sharp wheels must be used to cut without overheating. The wheels must provide free cutting action. The wheel must be compatible with operation and equipment. The grit size is usually between 37 and 180 μm. finer grit size can be used for better finish but the grits may penetrate through the coating via open pores. Vitrified bonds are mostly used for grinding due to good chemical and thermal resistance (for speeds up to 33 m s^{-1}). For higher speeds (up to 48 m s^{-1}), resin bonded materials can be used.[1,4]

The important parameters during grinding are[1–4,6]:

- Wheel speed: the lower wheel speed is, the softer action is expected. The wheel speed must be controlled to achieve best grinding performance and decrease wheel wear. It was reported that super high-speed grinding of HVOF WC–Co coating, results in improved grinding efficiency, the surface finish and the wheel life.
- Work speed: the increase in part speed, finishing is performed better.
- Area of contact: by increase of pressure (at contact area), the grinding depth decreased. In such conditions, the narrow wheels are more effective than wide ones.
- Use of water or lubricant: wet grinding is preferred especially in the case of hard coatings due to decrease cracking, overheating, and blistering. Water soluble oils are used with antiwelding agents.

In the final stage of grinding, the sparking must be avoided. The cracking or delamination of coating may occur during grinding due to exceeding pressure especially in the case of ceramic coatings or coatings with low adhesion strength.[3]

3.13.2.2.2 Abrasive belt grinding

Coated abrasive belts can be used for grinding and finishing. The advantages are low overheating, no need to dressing, low cost and ability to be changed easily. The coated part can be place on a lathe or mounted in a fixture. The part is rotated or transverses under the head of belt. The belt speed varies between 30 and 40 m s^{-1} while the speed of the specimen is between 0.13 and 1 m s^{-1}. The speeds must be controlled depending on size of part and type of coating. The grit size is selected based on required surface finish and rate of material removal. It is difficult to minimize the out of roughness using this technique.[1,4]

3.13.2.3 Polishing Techniques

Polishing is somewhat similar to grinding when the used abrasives are finer. The surface roughness (R_a) down to 1 μm (even near to 0.2 μm) can be obtained using polishing procedures. To achieve lower roughness, lapping techniques may be used.

3.13.2.3.1 Superfinishing and honing

Superfinishing involves rotation of the part against an abrasive stone or a tape. The lubricant and solvents are determining factors in superfinishing. The higher viscosity of fluid is, the finer finishing is attained. Honing rules and results are similar to those in superfinishing.[4]

3.13.2.3.2 Hand stoning and buffing

Buffing and hand stoning can be performed using paper, stone, wheel, or stick. Soft metal coatings like zinc and aluminum are easily stoned. Coarse abrasive are used firstly then finer ones. Cermets and ceramics can be stoned to achieve a light finish.[4]

3.13.2.3.3 Tumbling and burnishing

Tumbling is done using a rotating tub including water and abrasives. In the case of burnishing, hard ball are used. These processes are economically when a large number of small parts are present or the part has uncommon contours.[4]

3.13.2.3.4 Lapping

Lapping is a finishing process in which abrasive agents are suspended in oil or grease. High surface finish can be obtained by lapping (R_a of 0.05–0.1 μm). Low speed and high pressure result in the best finishes. Fused coatings must be lapped drily.[1,4]

3.13.2.4 Effect of Finishing on Coatings Characteristics and Properties

In the practical point of view, it is important to understand the effect of finishing on functional properties of the coatings. The change in coating properties can be rationalized in two terms; (1) the change in surface conditions due to the elimination of roughness and removal of superficial layers and (2) the change in coating body structure such as generation of residual stresses, formation of microcracks, or splat pull-out. As a result, the adhesion and cohesion strength, microhardness, fracture toughness, fatigue, wear, and corrosion resistant can be altered after grinding.

Corrosion resistant coating can be used in both as-sprayed and ground conditions depending on the application. The effect of grinding on corrosion resistance is complicated. As-sprayed coatings usually show higher corrosion rate due to formation of local galvanic cells on the surface (increased surface area). However, the corrosion resistant can be lowered if microcracks are produced during grinding. The microcracks can act as local electrochemical cells or enhance penetration of electrolyte through the coating body. Guilemany *et al.*[7] reported that grinding of HVOF-sprayed NiTi increases the corrosion rate due to formation of microcracks inside the coating. Moskal *et al.* investigated the effect of grinding on morphology and thickness of oxides formed after oxidation of plasma sprayed NiCrAlY at 1000 and 1100 °C. It was found that the oxide thickness is higher in the case of as-sprayed coating.[8]

Erosion resistance of as-sprayed and ground of WC–Co–Cr coatings fabricated by detonation gun and HVOF processes was investigated. The ground samples showed better erosion

resistance due to generation of compressive residual stresses in the coatings.[9] In the case of sliding wear applications, the coatings are often used in polished conditions as friction and wear increases with roughness. As-sprayed coatings are rarely used for wear applications. The role of grinding on plain and fretting fatigue behavior of detonation gun sprayed Cu–Ni–In coating on Al–Mg–Si alloy was investigated. Ground coatings exhibited better resistance due to better surface finish and residual compressive stresses at the surface.[10]

Masoumi *et al.*[11] investigated the effect of grinding on adhesion strength and residual stresses in HVOF WC–10Co–4Cr coating. The porosity content increased in ground coatings due to loading between part and wheel. The microhardness, adhesion and cohesion strength improved after grinding. All these results were discussed based on compressive residual stresses. The ceramic coatings are more susceptible to cracking during grinding process due to lower fracture toughness. Liu *et al.*[12] investigated the modeling of residual stresses in nano-ceramic coatings. It was found that the grinding temperature and parameters affect the type and magnitude of residual stresses. By selecting optimum conditions, beneficial compressive stresses can be expected. The high grinding temperature can also favor phase transformation in some coatings such as WC–Co during grinding.[13]

3.13.2.5 Modeling the Finishing Processes

In recent years, efforts have been made to model finishing processes. An analytical model was investigated by Hiegemann *et al.*[14] to predict roughness thermal spray coatings after ball burnishing where the surface asperities were simulated by pyramids. The deformation of these pyramids was modeled by considering acting forces. There was a good agreement between the theoretical and experimental results. Rausch *et al.* used constructive solid geometry technique to model grinding process using a geometric-kinematic simulation. The model was used for optimizing the grinding procedure and predicting surface topography. Cutting tool durability was modeled using statistical approaches in 40C130 steel coating. Friction has been also analyzed in burnished and ground WC–12Co coatings. Arc sprayed WC–Fe and HVOF WC–Co coating were ground on a machining center by using mounted points. A force model was proposed based on the design and analyzes of computer experiments.[15] The mathematical models composed of linear terms were used to model the role of grinding parameters on the grinding force during grinding of HVOF WC–Co–Cr coating.[16]

Partition coefficient was also modeled to a thermo-mechanical approach during grinding of HVOF WC–Co–Cr coatings. The maximum temperature was measured using finite element solution. The temperature in arc of cut was measured using a novel grindable thermocouple.[17]

3.13.3 Thermal Post-Treatments

Thermal treatment of coatings involves various heating procedures such as remelting, fusing, sintering and annealing. The goals can be listed as[1–4]:

- elimination of pores and splat boundaries to improve cohesion strength and enhancing in bonding strength by creation of metallurgical bonding between coating and substrate;
- improvement in thermal shock resistance or fracture toughness due to microstructural refinement and metallurgical bonding;
- microstructural modifications such as stress relieving;
- to complete the reaction between elements; for example, formation of final compounds like intermetallics;
- crystallization of amorphous coatings;
- to enhance wear and corrosion resistance by eliminating open pores.

3.13.3.1 Fusing of Self-Flux Alloys

Self-fluxing alloys are alloys which can form a low melting point borosilicate phase during heat treatment (fusion). These Ni or Co-based coatings contain B and Si elements reacting with metal oxides to form a borosilicate phase. Cr is added to the alloy to improve corrosion resistance. The formation of B-bearing precipitates such as $Cr_2Ni_3B_6$ precipitate[18] may be responsible for increase of hardness after fusing. Borosilicate acts as a deoxidizer. In addition, the melting point of this phase is 300 or 400 lower than that of the matrix alloy. So, a kind of liquid phase sintering occurs. As a result, the pores are eliminated and the cohesion strength increases. Due to low density of the borosilicate phase, it comes to the surface and can be removed by grinding. The fusing temperature is between 1000 and 1100 °C (it is selected based on chemical composition of the coating). Due to high-temperature of process, the coating diffusion occurs at the interface so metallurgical bonding is formed. About 10–20% shrinkage occurs during fusing because of pore elimination.[1–4] Fused self-flux coatings show good impact resistance as well as desirable wear and corrosion behavior. Fusing process can be performed by flame (torch), furnace, induction, or even laser. The details of fusing procedures can be found below.

Torch heating is widely used for fusing of self-flux alloys because it is cost-effective and rapid. A single or multi jet troch pass can be used. Natural flame is used for Ni-alloys and slightly reducing flame for Co-alloys. Acetylene or propane is used as fuels. The coated part is preheated to 760–870 °C before achieving fusing range. The flame must be low speed or in the case of cylindrical parts, the motion of part must be low to prevent loss of molten metal. The key factor in torch fusing is temperature control which depends on operator skills (based on color and flow). The process can be also performed automatically.[1–4]

In comparison to torch fusing, the use of furnace fusing results in better temperature control and high production rate. It is useful for thin coatings, flat samples, large parts, and irregular shapes. The most advantage of this method is less thermal shock due to controlled heating and cooling rate. Argon, vacuum, and hydrogen can be used as furnace atmosphere. Due to saved time and energy, induction fusing has been developed rapidly especially for large parts.[1–4] Laser can be used for fusing if parameters are controlled well and proper preheating. However, it is more expensive than conventional methods.

Houdková *et al.*[19] investigated the effect of four different fusing treatments (furnace, flame, induction, and laser treatment) on microstructure and properties of flame and HVOF-sprayed NiCrBSi alloy. All fusing procedures resulted in elimination of splat boundaries and improvement in corrosion, hardness, and wear resistance. The main difference was the dilution between coating and substrate, which was noticeable in the case laser fusing. It may be confusing that the laser treated samples showed the thickest diffusion layer. However, laser process parameters were selected to obtain fully melted and crack-free structure. So, the interfacial regions may incorporate in the laser process and the dilution has increased.

Although self-flux alloys can be deposited on various substrates, however, fusing treatment may encounter problems. Fusing treatment cannot be performed on low melting point alloys like Al and Cu alloys. When there is a large difference between thermal expansion of coating and substrate, the fusing may result in cracking or spallation of the coating. In such cases, slow cooling and heating rates or preheating are preferred. In the case of insufficient wetting or melting or overheating, the porosity may remain. For large parts or complex shapes, non-uniform heating may be observed. The distortion is another possible problem which may occur during fusing that can be controlled by proper heating and cooling rates.[1–4]

3.13.3.2 Remelting

In recent years, some efforts have been made to remelt thermal spray coatings. The main goals are to remove splat structure and pores, formation of metallurgical bonding and improvement in fracture toughness and impact resistance as well as corrosion and wear resistance. After remelting, a rapidly solidified structure is attained which shows refined microstructure.

Laser remelting has been used extensively due to precision control and position. Electron beam is another source for remelting but needs high vacuum. Tungsten inert gas (TIG) process was also used as a cost-effective process but may invilve dilution (up to 30%).

3.13.3.2.1 Laser remelting

Laser remelting has been used due to controlled heating and melting. Many types of coatings including wear or corrosion resistant coatings, biomedical coatings, and thermal barrier coatings were subjected to remelting. The types of lasers used for remelting are:

- continuous CO_2 lasers with powers up to 5 kW;
- continuous CO_2 lasers with powers in order of 100 W;
- pulsed Nd/YAG lasers;
- power diode lasers with powers in order of few kW.

The reflection coefficient must be considered to control the laser absorption by the surface. In the case of coating materials with low thermal conductivity (such as ceramics), the micro or macrocracks may be formed during the treatment.[2]

Flame sprayed polyether ether ketone (PEEK) coatings deposited on 304 L stainless steel were remelted using Nd:YAG, CO_2 or diode lasers. The adhesion improved and the porosity decreased after remelting.[20] The remelting of metallic and cermet coatings has been investigated extensively. Ceramic coating remelted by laser includes wear resistant coatings like Al_2O_3–TiO_2 and Cr_2O_3 coatings, thermal barrier coatings such as YSZ and hydroxyapatite (HAp).[1]

3.13.3.2.2 Electron beam remelting

Electron beam was used for post-spray treatment of small areas. In spite of small spot size, it is very costly and needs high vacuum ($<10^{-4}$ Pa). So, electron beam was used less in comparison to laser.[2]

Electron beam treatment of arc sprayed FeCrAl coatings resulted in discrete bulged nodules composed of Fe–Cr column grains and improvement in corrosion behavior.[21] HVOF CoNiCrAlY coating treated by electron beam showed one thin and homogenous oxide layer after cyclic oxidation.[22] Improvement in oxidation resistance has been seen also for YSZ coatings.[23]

3.13.3.2.3 TIG remelting

TIG process has been used both for remelting and surface alloying purposes. The procedure is similar to TIG surfacing process. It is cheaper than laser, but, the control of heat and position is difficult. The high dilution (up to 30%) is the main limitation of this method.

Decreases of porosity and roughness and improvement in adhesion were observed after remelting of Cr_3C_2/Ni–Al and W_2C–WC/Co cermet coatings.[24] Role of lanthanum oxide addition and remelting on flame sprayed Ni–WC coating was investigated.[25] The microhardness and wear resistance of remelted coatings were higher than those of as-sprayed coating. Fe-based amorphous composite coatings deposited using arc spraying were subjected to TIG remelting.[26] The porosity decreased after remelting and a metallurgical bonding was formed at interfacial region. A dendritic microstructure formed after remelting while the hardness increased. Remelting of FeNiCrAlBRE self-flux alloy coatings fabricated by high velocity arc spraying was investigated.[27] The microstructure changed from lamellar to cellular structure after remelting. As a result, the defects decreased and wear resistance improved.

Tungsten-rich dendrites and W_6Co_6C and Fe_6Co_6C carbides were observed after remelting of plasma sprayed WC–Co coating. The hardness increased from 900 to 1250 HV after remelting and wear resistance improved.[28] A diffusion layer (diluted region) was observed between remelted coating and substrate. The cross-section of as-sprayed and TIG-remelted coatings are seen in **Figures 4(a)** and **4(b)**, respectively.

Ceramic coatings such as Al_2O_3–TiB_2 coating were also remelted using modified TIG process (**Figure 5**). This is an arc-independent technique unlike traditional TIG process. The results showed that the porosity and roughness decreases after remelting.[29]

Fe–Al intermetallic coatings were fabricated on steel substrate using arc spraying of Al coating and subsequent TIG remelting (**Figure 6**).[30] The dilution of coating with substrate resulted in formation of Fe–Al intermetallic phases. The Al layer was 200 μm thick while the intermetallic layers were 500 μm (**Figure 7**).

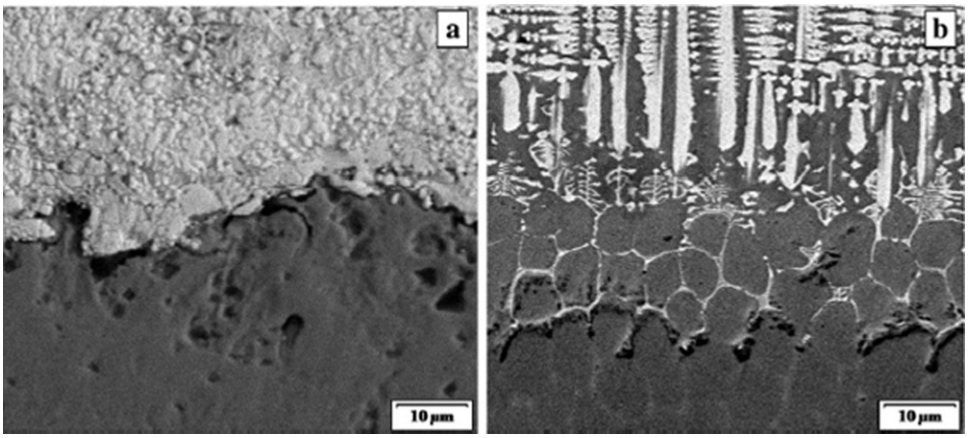

Figure 4 The cross-section of (a) plasma sprayed and (b) TIG-remelted WC–Co coatings.[28]

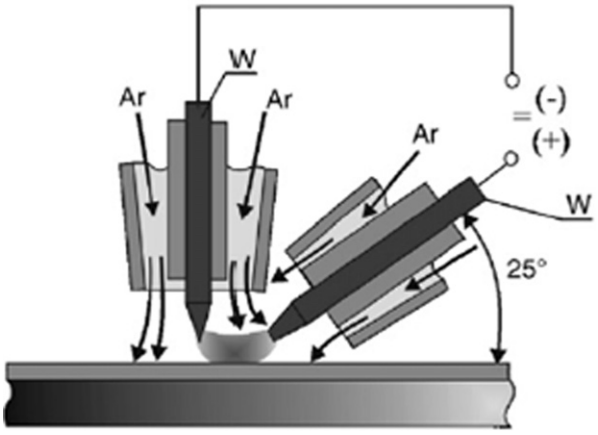

Figure 5 Modified TIG process used for remelting of ceramic coatings.[29]

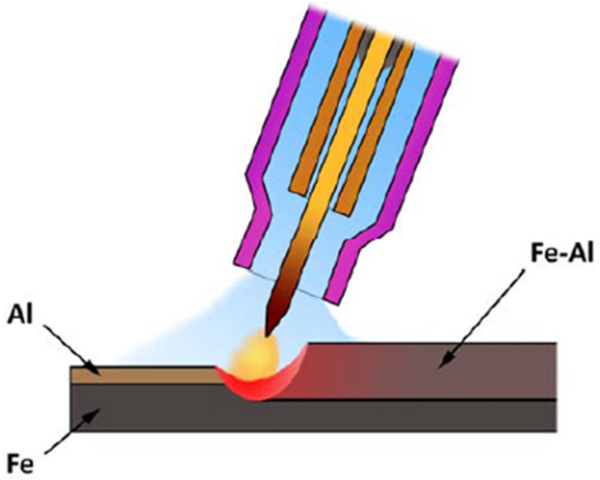

Figure 6 Schematic of TIG remelting of Al coatings to produce Fe–Al intermetallics on steel susbtrate.[30]

3.13.3.3 Solid State Heat Treatment

3.13.3.3.1 Pressure-assisted sintering

Pressure-assisted processes like hot isostatic pressing (HIP) and spark plasma sintering (SPS) and pressure-less procedures like microwave and furnace sintering have been used as post-treatments of thermal spray coatings. Sintering processes are performed at 0.7–0.8 of melting point of final compound. Solid state diffusion occurs at these temperatures so that the porosity decreases. The pressure enhances the densification. In addition, metallurgical bonding is formed at interface while cohesion strength increases.[1,2] The goals are similar to those of remelting. The advantage of sintering versus remelting is absence of cast structure and decreased thermal stresses. The main limitations of pressure-assisted sintering are (1) size limitation for large parts and (2) high running costs.

HIP is a hot consolidation process in which high-pressures (up to 300 MPa) is applied on the powder samples at high temperatures (0.7–0.8 of absolute melting point of final compounds). The sample is sealed using a glass vessel or metallic foil.[1,2] Then, the pressure is applied using an inert gas. This process is ordinary used for P/M parts but has been developed for thermal spray coating. It is costly and can be performed only on small parts. So, it has not found widespread application.

SPS is a rapid sintering process. In this method, a current applied through the electrodes attached to the graphitic die. The Joul effect is responsible for heating of metallic materials. In addition, the formation of plasma (in the presence of inert gas) between the particles generates heat and favors the diffusion. So, SPS process is faster than other sintering processes even than HIP. The time of sintering in SPS about 10–20 min and the temperature is about 0.6 of melting point of final compound. The uniaxial pressure is applied which is in order of tens of MPa. SPS has been used to improve the properties of ceramic coatings such as YSZ.[1,2]

3.13.3.3.2 Pressure-less sintering and annealing

Sintering procedure can be done without application of pressure. It is cheaper than pressure-assisted sintering. The large pores may remain after sintering unlike pressure-assisted approaches while the open pores can be closed. The different atmospheres like argon, vacuum, hydrogen, nitrogen, and other gas mixtures can be used.

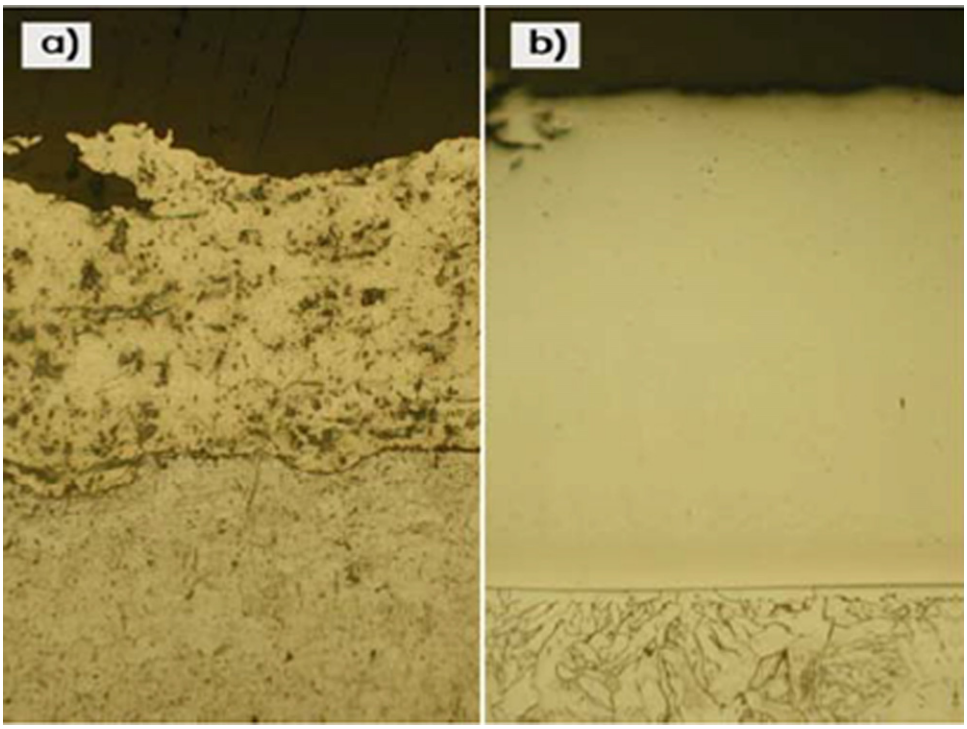

Figure 7 Optical micrograph of the cross-section of as-sprayed Al coating (a) before and (b) after TIG remelting.[30]

Frodelius *et al.*[31] investigated the phase transitions during annealing of HVOF-sprayed Ti_2AlC coating on hastelloy X substrate. As-sprayed coatings were composed of Ti_2AlC, Ti_3AlC_2, TiC, Ti–Al, and oxides. Up to 500 °C no new phase was formed. Between 550 and 700 °C, the amount Ti_3AlC_2 increased. Above 700 °C, Ti_2AlC formed from TiC and Al. The decomposition of Ti_2AlC and Ti_3AlC_2 was observed and TiC and Al_2O_3 were formed at 900–1100 °C.

HVOF WC–Co and NiCr–Cr_3C_2 on steel substrate were annealed at 500 for 24 h and at 550 °C for 5.5 h. It was found that the hardness of WC–Co increased from 1200 to 1500 HV after annealing at 500 °C. The microstructure of this coating was homogenized after post-treatment. The voids formed at coating/substrate interface in the case of NiCr–Cr_3C_2 coating.[32]

Microwaves are waves with the wavelength of in order of millimeter to meter. In microwave sintering, electromagnetic energy is transformed into thermal energy. The papers investigated microwave sintering of thermal spray coatings are scanty. APS YSZ coatings were treated using microwave for solid oxide fuel cell applications. The results showed that the ionic conductivity of sintered coatings was higher than that of as-sprayed coating by on order of magnitude.[33]

Thermally sprayed intermetallic coatings were investigated in recent years for wear, aqueous, and high-temperature corrosion applications. The intermetallic powders are often selected as feedstock. However, the activated powders can be used due to lower costs. In this case, the reaction may be incomplete during spaying due to rapid heating and cooling. Post-spray heat treatment can be performed to complete the reactions. There are a few papers dealing with this matter.

Mechanically activated Ni–Ti powders were sprayed using vacuum plasma spraying process. The as-sprayed coatings were somewhat porous but unreacted Ni and Ti were present in the coatings. After heat treatment at 900 °C, the elements fully reacted and a diffusion layer was formed between coating and substrate.[34]

Two studies were formed by arc spraying using different wires. Al wire as cathode and steel wire as anode were melted using arc spraying.[35] No intermetallic phase was formed during spraying but heat treatment of coatings at 550 and 650 °C resulted in formation of Fe–Al intermetallic phases while Fe was still present. A similar study was performed using Mg wire as cathode and Al as anode on Mg substrate. Intermetallic phases were not formed during spraying while annealing at 430 °C, the elements reacted completely.[36]

Due to rapid cooling involved during praying (10^5 K s^{-1}), amorphous structures can be deposited depending on glass formability of the feedstock. These coatings show good corrosion resistance. Crystallization heat treatment can be performed to form nanocrystalline structure to improve hardness and wear resistance. The crystallization temperature is selected based on thermal analysis.[1] It must be noted that the crystallization temperature is lower than that of sintering processes to avoid grain growth.

3.13.3.3.3 Austempering

Austempering heat treatment (or molten salt heat treatment) has been performed on plasma sprayed WC-based coatings. A two-step heat treatment including immersion of samples at 870 °C for 30 min and subsequent quenching in another salt at 315 °C was performed. The results of that study showed that undesirable W_2C phase can be eliminated and metallurgical bonding can be obtained after austempering. The hardness increased after post-treatment due to compressive residual stresses.[37]

3.13.3.4 Diffusion Annealing of Aluminum and Chromium

Diffusion annealing is used to diffuse the aluminum into a metallic substrate or another coating to improve high-temperature corrosion resistance. Diffusion of Al coating into steel or silicon bronze is performed at about 870 °C. An Al-rich surface layer id formed which exhibit good oxidation resistance due to formation of Al_2O_3 protective layer.[4]

Ti-49 at.% Al alloy has been aluminized by applying 100 μm arc sprayed Al and subsequent induction diffusion annealing at 1100 °C under Ar atmosphere. The annealing time varied between 2 and 30 min. $TiAl_3$ was formed as the outermost layer which grew by increases the annealing time. The intermediate layers between the top layer and substrate consisted of Ti_2Al_5, $TiAl_2$, and Al-rich TiAl. The aluminized coating, exhibited better oxidation resistance at 900 °C in air.[38]

Al coating and be deposited as a top coat on another coating. The diffusion treatment results in formation of a ternary coating such as FeCrAl and NiCrAl. NiCr or FeCr is deposited first and the Al is applied. Finally, the diffusion treatment is performed.

Belluci *et al.*[39] investigated the role of pack aluminizing on high-temperature corrosion resistance of HVOF Fe–Cr coating in a simulated coal-fired energy system. The oxide layer formed on as-sprayed coating was not protective due to vaporization of Cr(VI)oxide hydroxide in the presence of oxygen and water. Al-modified coatings showed better resistance due to thin Al_2O_3 layer. Post-treatment had no deleterious effect on adhesion of coating as no new interface was formed after aluminizing.

Recently, heat treating of NiCrBSiFe/Al system was investigated at temperature range of 500 to 700 °C for 3 h. $NiAl_3$ phase was formed gradually based on the temperature. Ni-islands were firstly formed which then enriched in Al to form Ni_3Al. The treated coatings showed superior oxidation resistant at 700 and 800 °C due to formation of dense Al_2O_3 layer. In the case of as-sprayed coatings, iron oxides were detected at substrate-coating interface, which reveals the high porosity results in decrease in protectiveness of as-sprayed coatings.[40]

Several attempts have been also made to diffuse Al into thermally sprayed MCrAlY coatings using chemical vapor deposition (CVD),[41] pack cementation,[42–46] or cathodic arc deposition.[47] This process is called 'over aluminizing.' Over aluminizing is often used to control the thermally grown oxide when MCrAlY used as a bond coat for TBCs. It can be also used to improve oxidation and hot corrosion resistance of MCrAlY top coats. Pt–Al coatings were also deposited on CoNiCrAlY coating by applying PVD Pt coating and subsequent aluminizing.[46] The results showed that the adhesion of Pt-aluminized coating during cyclic oxidation was better than that of as-sprayed and aluminized coating.

The pack cementation process has been used to densify plasma sprayed $NiCr/Cr_2C_3$. The results showed that the hardness increases after post-treatment.[48]

3.13.4 Sealing

3.13.4.1 The Basics

The porosity is one of characteristics of thermal spray coatings. The pores may be interconnected. The presence of such defects may results in penetration of corrosives medium or other unwanted materials through the coating body. In some applications, sealing enhances dielectric constant of coatings. The application of sealer can be useful were leakage is important in mechanical processes.[1–4] Anodic coatings like Zn and Al may be sealed to increase life time. Cathodic coatings like stainless steel or copper must be sealed if open pore is present. Ceramic coatings are also sealed for corrosion applications.

The conventional sealing involves penetrating a liquid sealer through the coating via capillary effect. Then, the sealer is cured to be solidified. A sealer must have low viscosity to penetrate through the coating. The chemical and thermal resistance of the sealer in service condition as well as safe and health aspects must be considered. Atmospheric sealing is performed by spraying, brushing, and immersion. The efficiency of this method depends on sealer wettability. But it can be performed on large parts. The sealing can be performed under vacuum (low pressure) or high pressures. Both methods are suitable only for small parts. High pressure method enhances the penetration of sealer. Low pressure method can remove air and moisture from the pores.[1–4] The sealer may be organic or inorganic which is discussed below.

3.13.4.2 Organic Sealers

The main organic sealers are used for post-treatment of thermal spray coatings are[1–4]:

- Paints which are water or solvent soluble. They are air dried.
- Waxes, greases, and oils.
- Phenolics (including epoxy phenolics) which must be air dried or heat cured.
- Epoxy resins which have one part as catalyst.
- Polyesters which have one part as catalyst or must be heat cured.
- Polyurethans which have one part as catalyst or must be air dried.
- Linseed oils which must be air dried.
- Polyimides which are heat cured.
- Coal tars which are air dried. They are used for submerged parts in salt or fresh water.
- Silicon resins which are air dried. Aluminum–silicon resins can be used at service temperatures up to 480 °C.
- Vinyls which are air dried for use in temperatures lower than 65 °C.
- Anaerobics which are cured in absence of air.

3.13.4.3 Inorganic Sealers

Inorganic sealing are used usually for high-temperature applications where organic sealer are not applicable. Various techniques such as aluminum phosphate, Cr diffusion, sol–gel, impregnation, electroplating, and other chemical processes can be used to seal the coatings.

3.13.4.3.1 Aluminum–phosphate

An aqueous solution containing aluminum hydroxide and phosphoric acid is applied to the surface. The subsequent heat

treatment is often performed at 100, 200, and 400 °C, respectively, to complete the dehydration process and to form aluminum phosphate. This process has been used to seal Al_2O_3, Cr_2O_3,[49,50] and YSZ coatings.[51]

It has been shown that the application of alumina/aluminum phosphate sealer can improve hot corrosion resistance of HVOF NiCr–Cr_2C_3 coatings. The sealer was applied by nylon brushing and air curing at room temperature.[52]

3.13.4.3.2 Enameling

HVOF CoNiCrAlY coatings were subjected to enamel coating using SiO_2-based feedstock. The results showed that the hot corrosion resistance and oxidation resistance at 900 °C improved after the post-treatment.[53] After vacuum annealing, enamel powders were place on coated samples and then heated to 1000 °C.

3.13.4.3.3 Electroplating

Ni electroplating has been used to seal arc sprayed hastelloy[54] and APS Al_2O_3[55] coatings. The electrodeposition seals the open pores and a forms top Ni coat as a barrier. In the case of hastelloy coating, the corrosion resistance improved after sealing. In the case of Al_2O_3 coating, the wear resistance and hardness improved.

3.13.4.3.4 Sealing using glass formers

Glass forming agents such as SiO_2 were used for sealing. The agent is applied and then the softening heat treatment is performed.[56] This process was used to seal YSZ coatings for solid oxide fuel cell applications.

3.13.4.3.5 Sol–gel

In sol–gel process an organic precursor and a metal ion containing liquid (sol) is used. The precursor penetrates through the open pores and forms a gel then. Finally, calcination process can be used. Sol–gel alumina process has been used to seal ceramic and cermet coatings.[57]

3.13.4.3.6 Chemical treatment

Nitrate solution has been used for sealing of YSZ coating for solid oxide fuel cell application. The densification was performed using aqueous solution of zirconium and yttrium. After sealing procedure, the coated samples were dried at 500 °C for 30 min to decompose nitrate. The post-treatment improved the electrical resistance by 30%.[58]

Hydroxide solutions were used for improvement in bioactivity of vacuum plasma sprayed Ti coating on carbon fiber-reinforced PEEK (CF-PEEK) substrate. The coated samples were immerged in 10 M NaOH solution. It was found that the mentioned procedure was effective to fabricate bioactive coatings for texture engineering applications.[59]

HVOF HAp–TiO_2 coatings were chemically treated using different processes. Using the alkaline treatment, a nanostructured sodium hydroxycarbonate was formed on the surface and biocompability improved. The collagen-treated coatings also showed better biological response.[60]

3.13.4.3.7 Chemical vapor deposition

CVD process has been used to seal the Al_2O_3–TiO_2 and Al_2O_3 coatings. H_2–$AlCl_3$–CO_2 gas mixture was used to react at 1000 °C. CVD coating with the phase structure of α-Al_2O_3 and thickness of 10–20 μm were produced. The corrosion resistance of Al_2O_3–TiO_2 improved after CVD process. However, Al_2O_3 were cracked during CVD cycle treatment due to mismatch between thermal expansion coefficient Cu substrate and Al_2O_3 coating. The CVD was not able to close these cracks.[61]

A duplex HVOF-sprayed WC–Co–Cr/CVD DLC coatings were deposited on aluminum substrate. DLC coating was composed of an interlayer of (Cr), a graded intermediate Cr–W/C and WC/C layers. The application of thin top coated decreased friction and wear but the corrosion resistance was not changed due to low thickness and presence of defects (pores) in CVD layer. Cermet layer had no effect of microstructure and properties of CVD layer but load carrying ability of the cermet layer (due to higher thickness) resulted in better scratch resistance. However, due to limited adhesion of CVD and sprayed layers spallation occurred at interfacial region.[62]

3.13.4.3.8 Molten metal or oxide penetration

Molten metals can be used for sealing. It penetrates through the coating. The melting point the sealer metal must be lower than that of coating. The process was used for cermet and ceramic coatings. In this regard, liquid Mn was used to seal YSZ coatings.[63,64] Cu infiltration has been also used for Ti–Mo coatings.[65]

Molten oxide infiltration is a novel sealing process. A multicomponent oxide with relatively low melting point is used a plate on the coated surface. The components are then heat treated in a furnace to melt the oxide and to perform the penetration process.[66,67] The penetration temperature depends on the melting point of oxide. It has been reported that sealing of APS 316 L coating using MnO–SiO_2 oxides improves the corrosion resistance of the coatings in salt spray procedure.[66,67]

3.13.5 Other Processes

3.13.5.1 Friction Stir Processing

Friction stir processing (FSP) is a solid state thermomechanical surfacing process. In this process, a rotating pin (**Figure 8**) is traversed along the specific path on the surface of component. The friction between the part and the tool results in heat generation. Simultaneously, the superficial layer deforms plastically in the front of pin. It is like a thermomechanical process. As a result, microstructural and grain refinement and homogenization occur at the surface.[68]

In recent years, efforts have been made to improve microstructure and mechanical properties of thermally sprayed coatings using FSP. However, the utilization of this post-spray technique has not been extensive.

HVOF WC–CrC–Ni coatings were modified by FSP using a sintered WC–Co tool.[69] Scanning electron microscope (SEM) micrograph of as-sprayed coating is shown in **Figure 9**. The thickness of coating was 300 μm. In macroscopic scale, no visible damage was detected, but the porosity is present in the coating. After FSP (**Figure 10**), the thickness decreased to about 150 μm due to stirring and compressive stresses. Under the coating layer, stir zone and heat affected zone are observed.

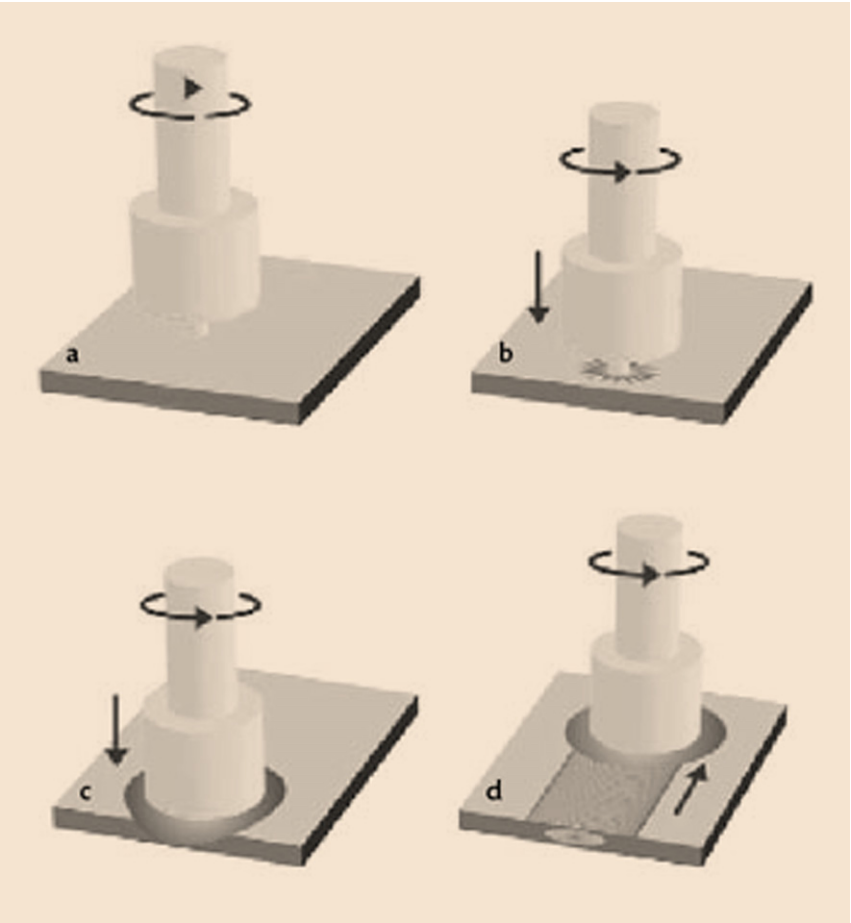

Figure 8 Schematics of friction stir processing.[68]

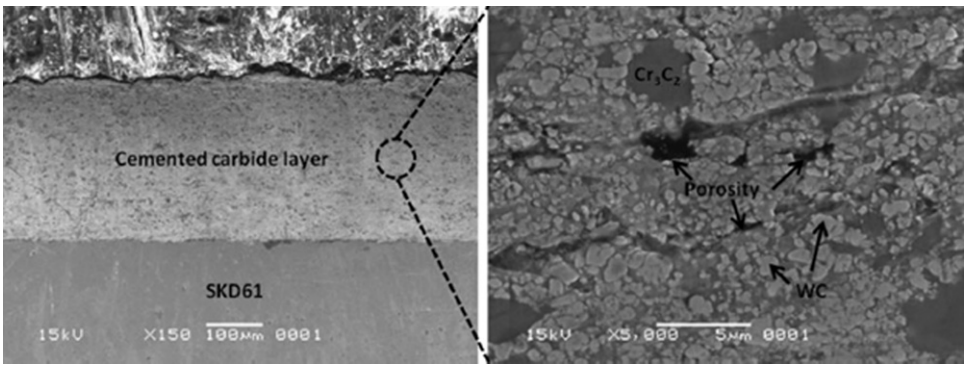

Figure 9 Scanning electron microscope micrograph of the cross-section of as-sprayed WC–CrC–Ni coating.[69]

SEM micrograph of the modified coating layer is shown in Figure 11. The pores disappeared and WC rearranged after FSP due to plastic deformation of Ni binder and an irregular interface was formed after FSP. Although the fracture toughness was not significantly after FSP, but the hardness of coatings increased from 1200 to 2000 HV.

In 2014, Mazaheri *et al.*[70] investigated the effect of FSP on microstructure and tribological properties of HVOF-sprayed A356/Al_2O_3 composite coating. A 200 μm thick coating was subjected to FSP. After FSP, a uniform distribution of Al_2O_3 particles was observed. The hardness and wear resistance increased after FSP. The effect of FSP on microstructure of arc sprayed high-Cr steel coatings was also evaluated. After FSP, the porosity was significantly decreased the microstructure was refined. It was shown that hardness and wear resistance of FSPed layer were two and seven times higher than that of

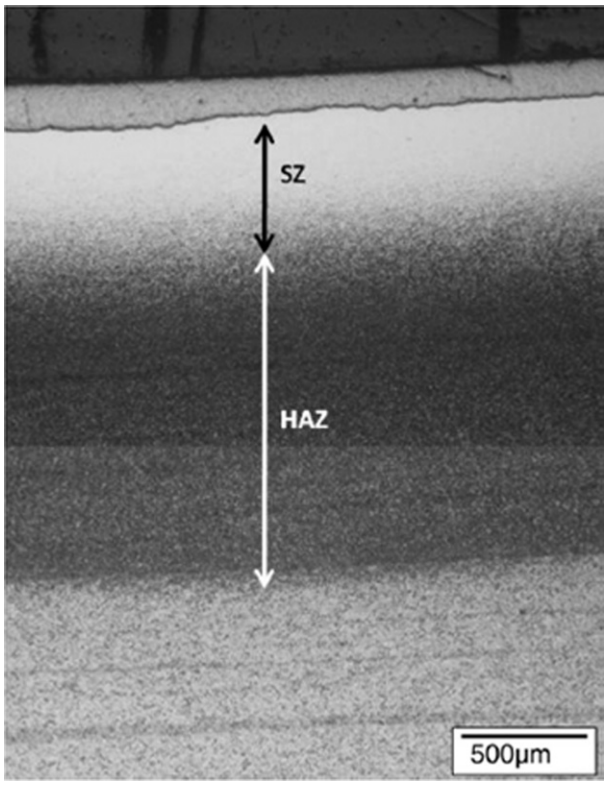

Figure 10 Scanning electron microscope micrograph of the cross-section of WC–CrC–Ni coating after friction stir processing.[69]

as-sprayed coating.[71] Flame sprayed Ni–Cr–Al Coating was also modified by FSP.[72] Grain size refinement occurred after FSP while a composite layer with good density was formed.

3.13.5.2 Plasma Electrolytic Oxidation

Plasma electrolytic oxidation (PEO) is a conversion surface treatment usually applied to light alloys like aluminum, titanium, and magnesium. The substrate is immerged in a liquid electrolyte as an anode. The electrical potential is applied to oxidize the surface of substrate. The voltage is so high (100–1000 V) to modify the structure of the coatings.[73,74] PEO process has been performed on arc sprayed aluminum coatings on carbon steel substrate in a liquid composed of KOH and liquid glass. Dense and uniform layers were formed in optimum conditions (**Figure 11**). The wear resistance was significantly improved wile high hardness (up to 2000 HV) was observed. Micro-arc oxidation (MEO) of arc sprayed Al, Al–6Mg, and Al–12Si coatings on low alloy steel were investigated. Ceramic coatings mainly composed of Al_2O_3 were obtained after MEO. The coatings showed high hardness.[74]

3.13.5.3 Sol Infiltration

Plasma sprayed Al_2O_3–Cr_2O_3 coatings deposited on Al_2O_3 were subjected to sol-infiltration and heat treatment.[75] The goal was to investigate effects of sintering stresses on cracking behavior of coatings for high-temperature applications. Fine microcracks were observed at coating/substrate interface in the

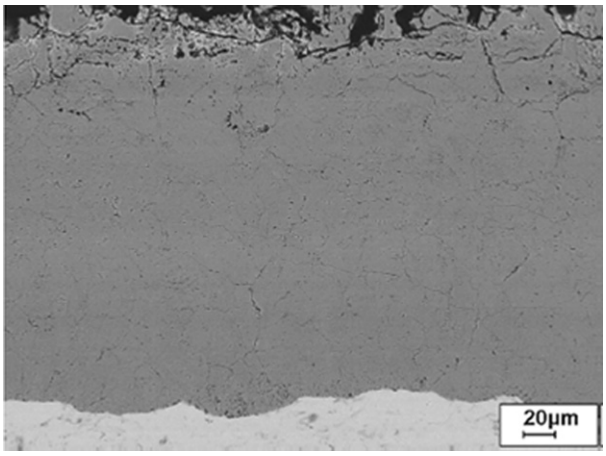

Figure 11 Scanning electron microscope micrograph of the cross-section of plasma electrolytic oxidation coating on arc sprayed aluminum.[74]

case of as-sprayed coating while after heat treated at 1550 °C severe delamination of coating was seen. The SiO_2 sol-infiltration (by immersing the coated specimen in ethyl silicate solution containing 25% SiO_2) was performed before heat treatment.

3.13.5.4 Physical Vapor Deposition

The use of PVD coatings as a post-treatment is not widespread. Ti–TiN_x coating was deposited on Ti6Al4V alloy using reactive plasma spraying process. The coatings were 50 μm thick. Then, a 2 μm TiN coating was applied by PVD. The friction coefficient of thermal spray coating was not significantly changed by application of TiN (at loads of 10, 20, and 30 N applied in wear tests). The weight loss of duplex coatings decreased by one order of magnitude at load of 10 N in comparison to that of as-sprayed coatings. At higher loads, the changes were not significant.[76]

3.13.5.5 Ion Implantation

Ion implantation is a surface modification technology in which accelerated ions (with the 10–200 keV energy) impact into a solid surface. The process can change chemical or tribological properties of the surface although the infected layers are too thin (less than 100 nm).[77,78]

Vacuum plasma sprayed CoNiCrAlY coatings implanted with Nb and N ions.[77] The oxidation resistance of coatings was evaluated at 1150 °C in air for 50 and 100 h was investigated. Ion implantation resulted in broadening of diffraction lines in X-ray diffractogram. The thickness of TGO reduced in the case of implanted coatings. This improves the service life of thermal barrier top coat. Another study was performed to investigate the effect of Al and Nb ion implantation on oxidation behavior of vacuum plasma sprayed CoNiCrAlY coatings at 1100 °C.[78] Nb-implanted coatings showed superior resistance due to formation of a dense Al_2O_3 scale. In the case of Al implantation, a non-protective spinel layer was formed during oxidation.

Ion implantation has been also used to improve tribological properties of coatings. It has been reported that N-ion implantation improve wear resistance of flame sprayed iron-base coatings.[79] Similar results were obtained for plasma sprayed Cr_2O_3 coatings.[80] In this regard, CrN and β-Cr_2N precipitates were formed in the N-ion implanted surface layer.

3.13.5.6 Shot Peening and Rolling

Shot peening is controlled impingement of metallic spheres stream in to a substrate to produce compressive stress. Shot peening can be used to improve fatigue resistance of coatings by introducing compressive stresses onto surface. In addition, the surface pores may be closed upon peening. Peening has been used for aircraft turbine parts. It was also shown the cavitation resistance of zinc coating improved after post-spray rolling.[1–4]

Shot peening has been performed to improve surface condition and oxidation resistance of CoCrAlY bond coat on Ni-based superalloys. YSZ top coat was deposited using EB-PVD, which showed good thermal cycling behavior (1643 cycles at 1020 °C).[81]

The fatigue strength of WC–10Ni coated AISI 4340 steel increased from 750 to 850 MPa after peening.[82] The fretting wear resistance of WC–17% Co coating on 30NiCrMo steel was not changed by shot peening but friction coefficient decreased. Such a coating was deposited on Al7050-T7451 alloy by HVOF process.[83] The fatigue strength of substrate increased after coating application. However, the resistance decreased after peening due to local roughening of coating which accelerated crack nucleation.

3.13.5.7 Laser Engraving

Laser engraving is formerly used for manufacturing Anilox rolls in printing industry.[84] The precise amount of ink is transferred by these rolls (in the flexographic printing machine). In the engraving process, fine patterns are produced on plasma sprayed ceramic coatings (like Figure 12) by local vaporizing the surface. CO_2 laser are mostly used but Nd-doped YAG laser were used too. Cr_2O_3, Al_2O_3, and Al_2O_3–TiO_2 coating were laser engraved.

3.13.5.8 Thermochemical Processing

Plasma nitriding (PN) and nitrocarburizing were performed on HVOF stainless steel coating.[85] In that work, the effects of PN and nitrocarburizing on HVOF-sprayed stainless steel. 17–4 PH (as a precipitation hardening grade), 316 (as an austenitic grade), and 410 (as a martensitic grade) were investigated. All coatings showed low porosity. After nitriding in $N_2 + H_2$ environment, a thick nitrided layer composed of a compound layer and a diffusion layer were formed. The thinnest nitride layer was corresponded to 316 coating with FCC structure while the thickest layers was formed on 410 coating with BCC structure (Figure 13). Plasma nitrocarburizing in C_2H_2 environment resulted in thicker nitride layers in comparison to those formed after nitriding. The thickest layer was formed on 410 coating like that in nitrided specimens.

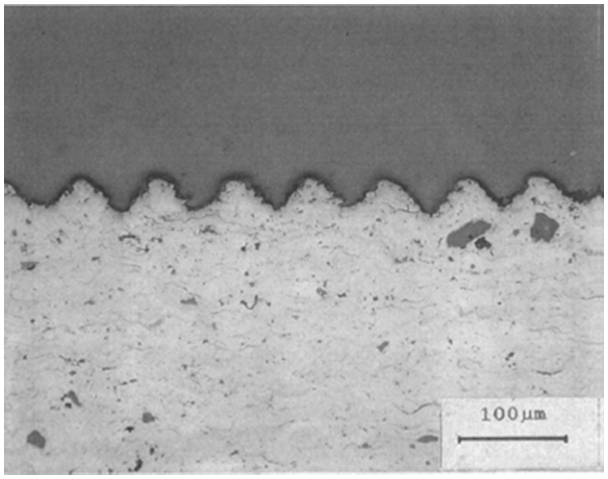

Figure 12 Scanning electron microscope micrograph of the cross-section of laser-engraved coating.[84]

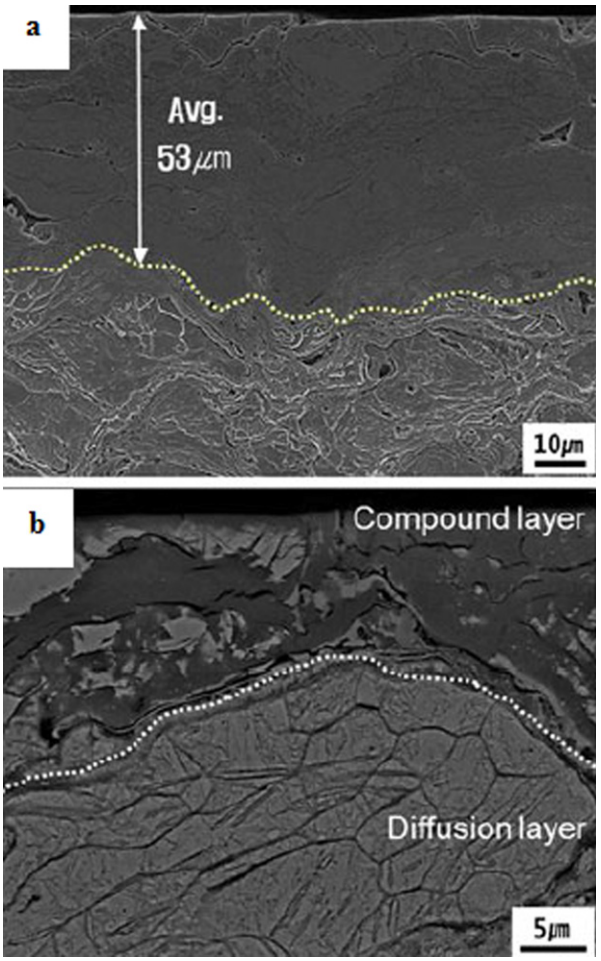

Figure 13 Cross-section of plasma nitride 410 stainless steel coating.[85]

The surface hardness of nitrided and nitrocarburized coatings were greater than 1300 HV 0.01 (three times higher than those of as-sprayed coatings) due to the presence of hard nitride

precipitates such as CrN, Fe_3N, and Fe_4N. The highest microhardness was observed in the case of 410 coating (above 1450 HV) due to formation of Cr23C6. 410 coating after thermochemical treatment, showed the best load bearing capacity due to the high thickness of nitrided or nitorcarburized layer.

3.13.6 Summary and Conclusion

Thermal spray coatings are widely used for various applications such as wear, corrosion, thermal and electrical insulation, and other applications. The nature of thermal spray coatings is different from that of bulk materials and even from other types of coatings. The lamella structure, porosity, oxides, and rough as-sprayed surface are the main characteristics of these coatings. In many applications, as-sprayed coatings cannot be used and additional treatment is necessary. Finishing and grinding is needed where smooth surfaces must be produced. Sealing procedures are applied to seal the open pores to improve corrosion resistance. Remelting and solid state heat treatment can be also performed to improve impact resistance and fracture resistance as well as corrosion behavior. Using remelting procedures, the microstructure of coatings changes completely and a rapidly solidified structure is attained. During solid-state heat treatment, the microstructure is partially changed to form a sintered structure. Some post-treatments were performed in recent years to obtain unique microstructures. In this regard, PEO, FSP, PVD, ion implantation, and thermochemical processing can be mentioned. These processes have not found widespread industrial applications but seem to be promising. It should be noted that the application of post-treatment is not always beneficial. Economic and technical limitations must be considered. In addition, as-sprayed coatings can be satisfactorily used in many industrial applications. The main challenges regarding post-treatments may be summarized as:

- investigating the effect of post-treatment on characteristics and properties using experimental or modeling procedures;
- development of cost-effective and environmentally friendly post-treatments with less technical limitations;
- the combination of thermal spray procures with other coating or surface modification technologies.

3.14.1 Introduction

Thermal spraying was mentioned for the first time in the patents of Swiss engineer Max Ulrich Schoop (1870–1956) at the beginning of the twentieth century.[1] It is a group of coating techniques, in which a jet of combustion products along with the injected powder particles are directed toward substrate material to form surface coating. Various thermal spraying techniques include arc spraying (AS), plasma spraying (PS), high velocity oxy-fuel (HVOF) spraying, detonation-gun (D-gun) spraying, and cold spraying (CS). Among these techniques, HVOF spraying offers the possibility to develop high-quality coatings, with several advantages such as increased hardness, lower value of porosity, low-oxide content, and good corrosion and wear resistance. That is why; HVOF spraying has attracted worldwide attention within the field of surface engineering. This chapter describes HVOF spray technology and its applications in relation to surface finishing. Some literature studies have been included to explain the role of HVOF spraying to achieve surface finish for some specific applications.

3.14.2 HVOF Spray Process

3.14.2.1 History

Thorpe *et al.*[2] reported that HVOF spray technology was invented in 1958 by Union Carbide, which is currently known as Praxair Surface Technologies, Inc. The technique was first introduced commercially in 1974 by Browning. Bick and Jürgens[3] and Kreye *et al.*[4] among others agreed that the initial work was conducted at the Thayer School of Engineering, Hanover, USA. According to Pawlowski,[5] HVOF spray torch to be used was developed at the end of the 1970s and at the beginning of the 1980s.[5]

3.14.2.2 Principle

To formulate a desired coating, HVOF spray process utilizes a blend of thermal and kinetic energy transfer. The melting and acceleration of powder particles take place.[6] The gases which can be used for this process are propane, acetylene, oxygen, propylene, methyl acetylene propadiene (MAPP-stabilized gas), hydrogen, methane, ethylene, SPRAL 29 kerosene, and LPG. The chosen gases are injected into the combustion chamber of the spray torch at high pressure, and are ignited. The resulting gas jet achieves supersonic speeds with Mach number greater than one. The selected coating powder to be deposited is fed axially into a spray gun, where it interacts with hot gas stream and gets melted, and propelled toward the workpiece surface to be coated (Tan *et al.*[6]). This process results in dense thermal spray coatings on the substrates. Voyer and Marple[7] stated that owing to high kinetic energy of the powder particles striking the substrate surface, the particles need not to be completely molten to form good quality HVOF coatings. Furthermore, improved gas heating and acceleration permit better heat/momentum transfer to the particles.[8]

3.14.2.3 Process Technical Details and Spray Parameters

Different HVOF spray systems have been manufactured by several companies in various designs and process-capabilities. For instance, a cross-section of a commercial Sulzer Metco

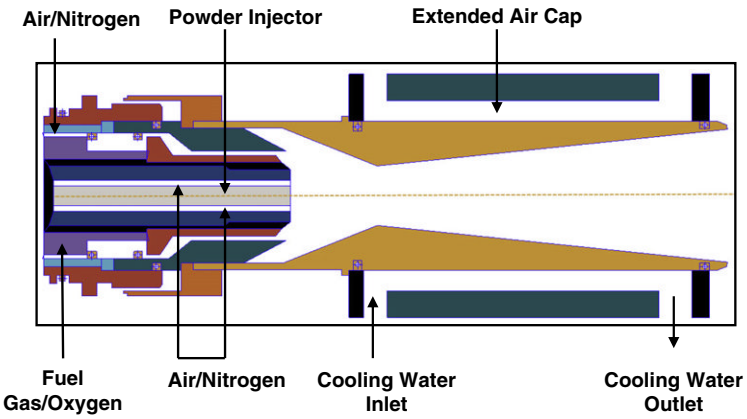

Figure 1 The high velocity oxy-fuel (HVOF) process (Lugscheider *et al.*[9]).

Diamond Jet Hybrid (DJ) HVOF system is shown in Figure 1.[9] The system comprises a spray torch, flow meter unit, powder feed unit, and an air and gas supply unit. To obtain good quality coatings and depending upon the requirement of the user, the mixture of oxygen and fuel gas or hydrogen (H_2) is used.[10] The fuel gases are mixed in the combustion chamber of the gun. Afterwards, these thoroughly mixed gases are expelled out from the nozzle and ignited in the exterior to gun. Ignited gases form a round flame configuration that surrounds the powdered material as it flows through the gun. Ignition temperatures in the range of 2760–3315 °C can be achieved depending on the fuel. The value of flame velocity reaches above 1200 m s^{-1}. In this way, the powder stream is provided with uniform heating, melting, and acceleration by the circular flame.[10] In the HVOF process, the powder particles attain supersonic velocities with a Mach number in the range of 1.5–2.0.[11]

HVOF spray apparatus is available with various gun designs and capacities in the market. Every system is different in design but are based on same fundamental principles. The supersonic gas velocities are achieved by the combination of high pressure (over 3 bar) and gas flow rates of several hundred liters per minute.[12] The HVOF systems are roughly divided into the first, second, and third generation systems. In the first two generations guns, the pressurized burning of gaseous fuel with oxygen is used to generate an exhaust jet traveling at a speed of about 2000 m s^{-1}.[12]

The primary difference between the first and second generation is the design of the nozzle. Oksa *et al.*[12] reported that in the first generation HVOF systems, there is relatively large combustion chamber and a straight nozzle.[12] Maximum of one Mach velocities can be achieved with this design. In the second generation there is de Laval nozzle, which enables over Mach 1 velocities at the diverging part of the nozzle. For instance, about 2–3 kg h^{-1} of WC–Co is sprayed under standard spray conditions in these systems with the power level of about 100 kW.[12] The third generation systems are designed with higher combustion chamber pressures from 8 bar up to as far as 25 bar and for power levels ranging from 100–300 kW. These systems are capable of having spray rates up to about 10 kg h^{-1}. The key differences between all these generations are summarized in Table 1.[12]

Table 1 The key differences between three generations of HVOF systems[12]

	Nozzle type	*Power level (kW)*[a]	*Combustion chamber pressure (bar)*	*Kg h^{-1} (WC–Co)*
1st generation	Straight	80	3–5	2–6
2nd generation	De laval	80–120	5–10	2–10
3rd generation	De laval	100–300	up to 25	10–12

[a]Total heat output.

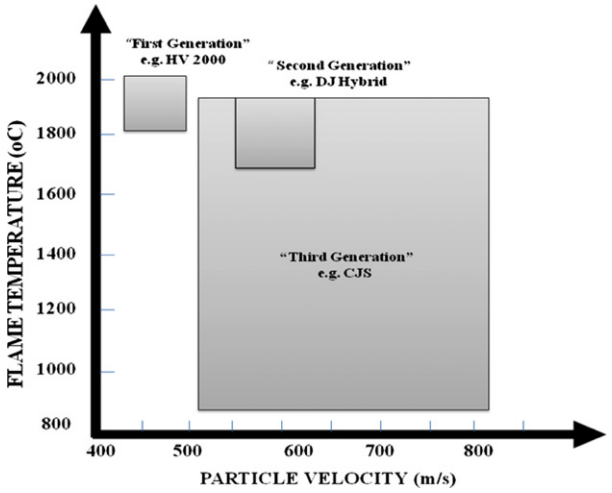

Figure 2 Flame temperature vs. particle velocity for the first, second, and third generation HVOF spray systems.[12]

Scientifically, the main parameters affecting the coating formation are particle velocity (v) and particle temperature (T) together with substrate characteristics.[12] These parameters decide the coating buildup process and the coating deposit formation. Particle velocity and particle temperature both affect the deposit microstructure and the deposit efficiency. Figure 2 schematically shows the trend in HVOF spray process development.[12] The trend has been toward faster particle velocities, higher gas pressures, and lower particle temperatures.

3.14.2.4 Mechanism of Coating

According to Pawlowski,[13] when a particle strikes substrate or grit blasted surface, it may be molten, semi-molten or solid. It all depends upon the melting temperatures of the particle relative to the flame temperature. The final microstructure of the deposit results from the state of the particle when it exits the combustion zone (Pawlowski[13]). At high velocities, rapid solidification of small globules gives rise to lamellar grain structure of the HVOF coatings, which flatten upon striking a colder substrate surface (Stokes[14]). Fantassi *et al.*[15] and Moreau *et al.*[16] reported that at first, the particle is melted and expelled out from the spray gun. It impacts the substrate and the impact creates a shock wave inside the lamella and in the substrate. Post-impact makes the particle into a 'pancake' shape lamella or splat (with reasonable particle velocities and reasonable heat contents) or a flower type lamella (connected with a higher velocity of the particle and a higher heat content) when the solidification process takes place as represented in **Figure 3**. Spreading of the splat is restrained by surface tension when a molten droplet reaches at a surface at high velocity. Else the extremities of the splat will either become weak, and break off or form small spherical drops (Stokes[14]). Kanouff *et al.*[17] in their studies made clear that the substrate surface roughness has a great influence on the splat formation and adherence loss occurs if an insufficient amount of surface roughness is present whilst spraying.

Stokes[14] explained the coating buildup for the HVOF spraying process. According to him, a coating is developed by the buildup of individual particles which strike a substrate. In one pass of the spray gun, a layer of 5–15 lamellae thickness is formed, however, it all depends upon the various processing parameters such as spray distance, powder feed rate, particle size, and the torch's linear speed.[14] Therefore, to build up a coating across the workpiece, several passes of spray gun are needed. In the meantime, the coating layer deposited by the first pass may be subjected to oxidation and cooling. Due to the difference in temperatures between the first and second layer, on the second pass, the temperature of earlier layer, which may be partially solidified, cools the second layer. The final coating may contain 5–200 passes of deposited material. Further, the coating is cooled down to room temperature. During this period the thermal stresses generate, often leading to crack formation in the coating or separation from the substrate.[14] As per the opinion of Stokes,[14] when a molten or semi-molten particle strikes the substrate or previously deposited material, solidification starts and a columnar deposit structure is developed. Moreover, Pawlowski[13] reported that the deposit structure may transform to a brick wall type structure where a low rate of heat removal is experienced between the particle and the adjoining material interface, due to substrate oxidation and/or surface roughness. In either case the solidification within each lamella will repeat itself as the coating builds up to the required thickness.[13]

3.14.2.5 HVOF Coating Characteristics

The key to the success of HVOF is the extremely high kinetic energy that is produced and transferred from the HVOF unit to the substrate using space-age rocket propulsion technology.[18,19] Typical velocities approach 1500 m s^{-1} to over 2200 m s^{-1}, depending on the hardware selected. With both thermal and kinetic energy, the high velocity particles are almost embedded into the substrate to form a superior coating with the following characteristics:[18]

- High density
- High bond strengths (in excess of 8.27×10^7 N m^{-2})
- Negligible porosity (with no interconnecting porosity)
- Metal working capabilities
- Essentially stress free
- Greater hardness
- Greater thickness
- Low thermal input (substrate temperature less than 149 °C which ensures that the original mechanical properties are preserved and no stress relieving is required).

Therefore, the HVOF coatings have high density, increased thickness capability, smoother surface finish, lower oxide levels, low porosities, less effect of the environment during the spray process and better corrosion and wear resistance properties (Kinos[18] and Khor and Leh[19]).

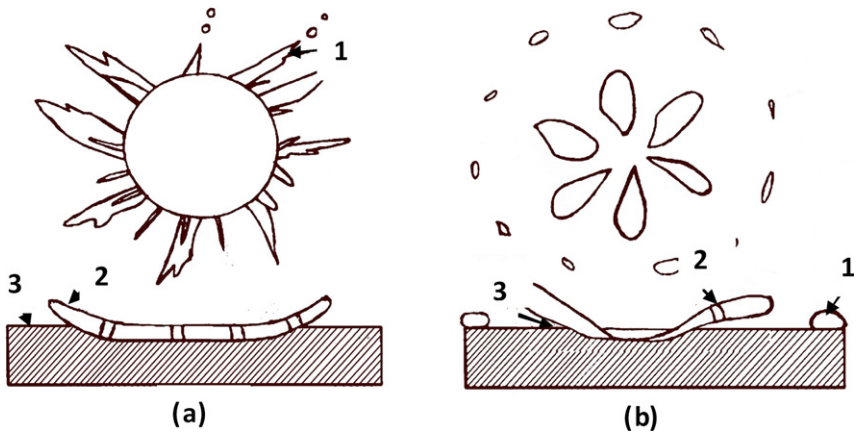

Figure 3 Primary morphologies of lamellae/splat obtained from sprayed particles: (a) pancake; (b) flower; (1) corona; (2) crack; (3) deformed substrate (Fantassi *et al.*[15] and Moreau *et al.*[16]).

3.14.3 Comparison with Other Thermal Spray Techniques

Pawlowski[5] presented a comparison of HVOF spraying with the other thermal spray processes and concluded that the principles of this technique are similar with a variation in the way of burning the fuel medium in oxygen.[5] This is done to attain a relatively lower temperature supersonic gas jet for the deposition of heat sensitive materials in facilities that function at ambient pressures and temperatures. It has been mentioned that the burning is continuous for HVOF, whereas repetitive for D-gun spray process. The HVOF spray process is a low-temperature process compared with other techniques. Moreover, the procedure requires minimal base metal preparation and can be directly applied to the working tools. These benefits enable HVOF to be a promising and popular process.[20–22] Jacobs *et al.*[23] suggested that in terms of particle condition, the HVOF spraying has many advantages over the other thermal spray processes including:

- More uniform and efficient particle heating, due to the high turbulence experienced by the particles within the combustion chamber.
- Much shorter exposure time in flight due to the high particle velocities.
- Lower surface oxidation due to short particle exposure time compared to other thermal spraying techniques.
- Reduced mixing with ambient air once jet and particles leave the gun.
- Lower ultimate particle temperatures compared to other processes such as plasma or arc guns, as these processes operate at temperatures of 16 000 and 6000 °C as opposed to 3000 °C in the HVOF (oxygen/propylene mixture) process.

The literature indicates that HVOF spray technique is a rapidly developing thermal spray technology for depositing surface coatings to combat high-temperature corrosion and wear. Even this technique has challenged vacuum PS technique, which is comparatively expensive to set up (capital costs approximately $2 000 000).[23] In addition, with the availability of handy HVOF spraying equipments, the process provides the possibility of on-site applications in the real boiler and other heavy-duty installations, which are not possible with other techniques such as PS, D-gun, chemical vapor deposition (CVD), physical vapor deposition (PVD), carbonization, and laser cladding. In high-temperature applications, the HVOF coatings possess relatively low porosity and high degradation characteristics.[24] Kirsten *et al.*[25] established experimentally that HVOF spray technique is a flexible dry-coating technology with less environmental impact. It covers many applications with a variety of possible coating materials. Table 2 presents a comparison of the typical parameters of various thermal spray techniques.[25]

3.14.4 Surface Finish Guidelines for HVOF Spraying

Based upon their research work, Greene Tweed,[27] established the optimum surface finish for the HVOF coatings. HVOF coatings are now replacing hard chrome plating in the aerospace industry; therefore the definition of optimum surface finish for the coatings has been modified. For instance, the interesting feature to notice is that how the chrome and HVOF interact with seals and bearings in dynamic applications. It has been reported that with growing time in service, the chrome surface finish will 'polish' and become smoother. On the other hand in spite of the accumulation of dynamic cycles with seals and bearings, the HVOF surfaces have been found to remain relatively uniform. Greene Tweed,[27] recognized separate recommendations for chrome-plated and HVOF-coated surfaces. The definitions of the surface roughness parameters as found in ISO 4287 for finished HVOF-coated surfaces are reproduced here[27]:

Ra: The arithmetic means of a surface finish profile within a sampling length.[27]

Rp: The largest peak height of a surface finish profile within a sampling length measured from the mean line (Figure 4). This parameter can be used to measure the potential aggression of the surface. A lower value of Rp is recommended for HVOF spray tungsten and carbide particles, to assure that no irregularly high peaks are present that could act to slice the seals and bearings.[27]

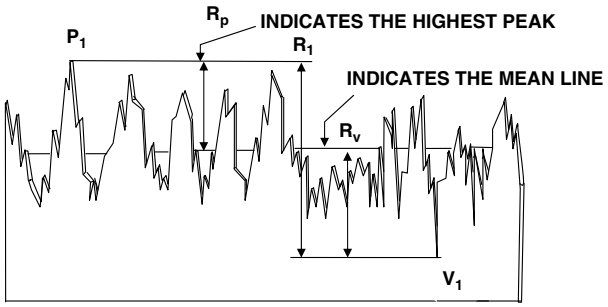

Figure 4 Surface roughness parameter Rp.[27]

Table 2 Characteristic parameters of several thermal spray techniques (Karthikeyan[25])

Parameter	*Wire arc*	*Plasma*	*HVOF*	*Cold spray*
Jet temperature (K)	~6000	~13 000	~5500	300–900
Jet velocity ($m\,s^{-1}$)	50–100	800–1500	1000–2000	1000–2500
Gas	Air, N_2, Ar	Ar, H_2, N_2, He	CH_4, C_3H_6, H_2	Air, N_2, He
Gas flow rates ($N\,m^{-1}$)	500–3000	40–150	400–1100	1000–3300
Power (KW)	2–5	40–200	150–300	5–10
Feedstock ($g\,min^{-1}$)	150–2000	10–80	15–50	20–80

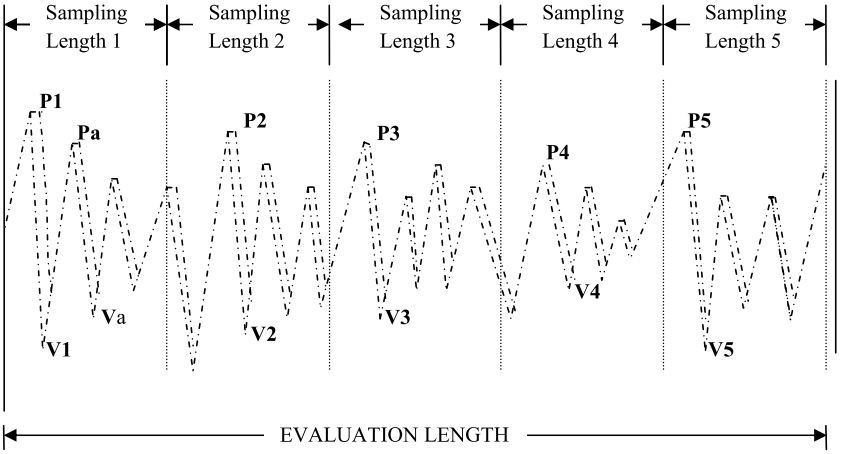

Figure 5 Surface roughness parameter Rz.[27]

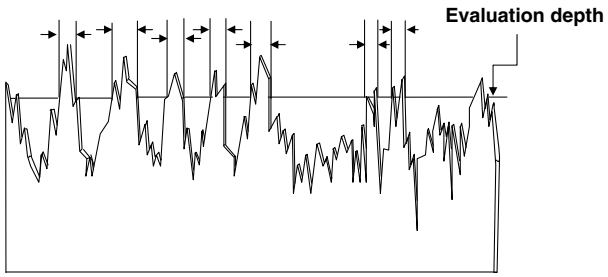

Figure 6 Surface roughness parameter Rmr.[27]

Rz: As reported by Greene Tweed,[26] the Rz surface roughness parameter is the average of the sum of the largest valley depth to the highest peak of a surface finish profile within a sampling length (Figure 5). The Rz value provides an indication of the surface's potential to maintain the desired lubrication to the seal as boundary layer lubrication present on the surface can be beneficial to decrease the friction and wear on the seal.

Rmr (tp): It is defined as the ratios of the material length at a specific depth for a surface finish profile. The parameter provides information on the relative material ratio at a specific evaluation depth (Figure 6).

Values for the surface finish parameters for HVOF as recommended by Greene Tweed[27] are as follows:

Ra = Maximum 4 μin (0.1 μm)
Rp = Maximum 8 μin (0.2 μm)
Rz = Maximum 40 μin (1.0 μm).

Since HVOF spray process utilizes hard, dense particles such as tungsten and carbides, the literature recommends that greater care in the preparation of the runout is required as compared to traditional chrome coatings. The following common criteria have been suggested in the preparation of HVOF runout[27]:

1. Long fade out is preferred – For HVOF coatings it is preferred to have much longer blending of the coating. The amount of the blend is to be determined by the manufacturing methodology and hardware geometry.
2. Hardware geometry – To create a more reliable, benign runout, the HVOF coating can be feathered along the tapered geometry (Figure 7). The termination of HVOF in advance of a chamfer or radius makes it more hard to fade out the coating, therefore increasing the possibility of the runout being aggressive to seals during installation.[27]

3.14.5 HVOF Spray and Surface Finish

In this section, surface finish issues related to the development of high quality HVOF-sprayed coatings have been discussed. Some specific studies have also been added so as to elaborate the issues with the help of experimental data.

3.14.5.1 Pre-Deposition Surface Finish

Thermal spray process requires adequate surface preparation in order to have good coating adhesion/substrate adhesion. For wear and erosion applications the adhesion of the coating to the substrate plays a vital role. If adequate bonding of a coating is required then the substrate has to be prepared properly. First and foremost is the cleanliness of the substrate surface followed by roughening the substrate using grit blasting or any other technique.[28] Surface preparation is most of the time necessary before the coating elaboration to ensure the best contact between the molten particles and the surface. The coating/substrate interfacial adhesion can then be improved. Various mechanisms related to the bonding of coating-substrate constitute an important aspect of the theory of thermal spray technology. Therefore, the investigations related to this aspect have attracted a great deal of attention in the past few decades.[29–32] For a thermal spraying process the different mechanisms of the coating-substrate adhesion can be classified as given[33]:

1. Mechanical interlocking effect,
2. Physical bond, and
3. Chemical–metallurgical bond.[33]

In case of a conventional spray process where particle velocity is comparatively low, the bonding between the coating and

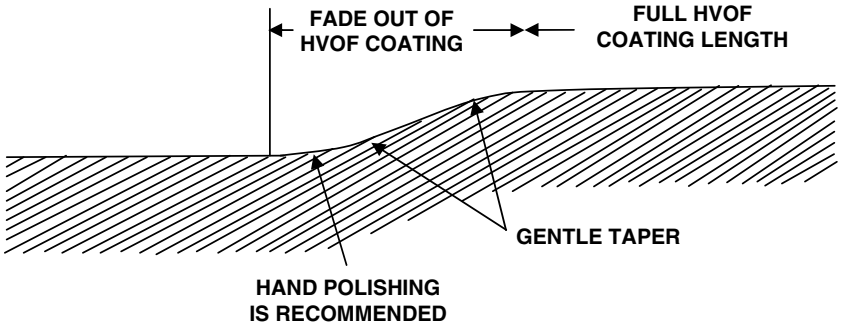

Figure 7 HVOF coating runout.[27]

the substrate is mainly dependent on the mechanical interlocking. The mechanical interlocking is further dependent on the substrate surface roughness and the solidification of the impacting particles, which are in the form of droplets. Investigations show that in case of conventional thermal spraying processes an increase in the roughness of the substrate surface as well as an improvement in the melting state of spray particle leads to an improvement in the adhesive strength of the coating.[34–38]

Wang *et al.*[39] conducted experiments in order to study how the substrate roughness affects the adhesive strength of HVOF-sprayed coatings. NiCrBSi coatings were deposited using HVOF spraying on the mild steel substrate surfaces of different roughness. The spraying gun used for the purpose was CH-2000 HVOF system in which propane gas was used as a fuel gas. The pressures of the propane and oxygen were 0.35 and 0.55 MPa, respectively. The flow of oxygen was set to 439 l min^{-1}, whereas that of propane 45 l min^{-1}. For the powder feed gas nitrogen at a pressure of 0.35 MPa was used. Throughout the spraying process the spray distance from the gun exit to the substrate surface was kept at 210 mm. In order to obtain different roughness, the substrates were prepared before the spraying; which was done by sandblasting or grinding with different sizes of grits. The surface of one set of samples was polished. Profilometer (TR240, Shidai) was used to measure the surface roughness and also to record the surface profile. For each sample, the calculated roughness Ra was the average of surface roughness measured at six different positions. The following conclusions were made:[39]

- For the recorded value of the substrate surface (Ra) less than 1.7 μm, similar adhesive characteristic were obtained for the HVOF NiCrBSi coatings to that of those coatings that were deposited on a polished substrate. Ineffective adhesion was observed at the substrate/coating interface.
- For the substrate surface roughness value more than Ra 5.8 μm, there was an increase in adhesive strength with an increase in the surface roughness. The adhesive strength of the coating was increased with the increase in the roughness of the substrate surface.
- For a practical rough substrate the coating reached a limited adhesive strength of about 40 MPa. The result was in accordance with the general observations about the effects of surface roughness on the adhesion of thermally sprayed coatings.
- For the coating deposited with completely melted alloy particles no improvement in the adhesive strength was observed with the increase in the substrate roughness when the adhesion reached to 40–50 MPa.[39]

The impact of roughness on the fatigue behavior was studied by Gonzalez-Hermosilla *et al.*[40] For this they deposited WC-10 Co–Cr cermet coating on SAE 1045 steel by HVOF spray technique. For conducting the fatigue tests rotating bending conditions ($R = -1$) were employed. Specimens were prepared having different surface roughness, including as-polished, fine grinding (abrasive paper grit 400), grit blasted with alumina particles of two different sizes (<1 and <3 mm, respectively), as-grit blasted specimens employing alumina particles of 3 mm in size. It was concluded that initiation of fatigue crack was delayed at deep notches because of presence of cermet coating and grit blasting lead to embedment of alumina particles at the steel substrate. In comparison with the as-polished specimens this led to an inconsequential fatigue strength debit of the coated one. On the other hand, fine grinding weakened the mechanical bonding of the coating, which lead to the delamination of the coating from the substrate at raised maximum alternating stresses. It was observed that though grit blasting improved the adhesion of coating, it also introduced flaws that initiated the formation of fatigue cracks.[40]

To explore the influence of varying surface roughness and chemistry on the formation of polyether ether ketone (PEEK) coatings on ANSI stainless steel 304 was subjected to various substrate pretreatments.[41] HVOF and assisted combustion high velocity air fuel (AC-HVAF) thermal spray techniques were used to deposit single splats and coatings of PEEK respectively. The three substrate pretreatments used for the work were as received degreased, etched, and steel grit blasted. X-ray photoelectron spectroscopy (XPS) analysis was done and the results showed that the etched substrate had the most chemically clean surface. This was confirmed by contact angle measurement which showed that the etched substrate had the lowest contact angle which indicated good wetting properties. This was followed by the degreased and the steel grit blasted substrates. Along with the Ra value the skewness parameter was also used for the description of the surface profile. As indicated by the roughness and skewness values of the treated substrates the steel grit blasted surface possessed the maximum roughness value in comparison to the etched and degreased substrates. The roughness value of etched and degreased substrates were found to be an order of magnitude lower than the roughness values of the steel grit blasted surface. While the skewness was found to be positive on the etched substrate, it

was found to be slightly negative on the steel grit and negative on the degreased substrate. Splats per mm^2 were highest on the steel grit blasted substrate followed by degreased and etched surface as depicted by PEEK single splat image analysis. From these results it was concluded that for ANSI304 stainless steel surface a positive skewness can be obtained using an etching process. For surfaces possessing appropriate topography the mechanical interlocking factor predominates than surface chemistry for room temperature substrates. Hence it may be established that PEEK coatings deposited by HVOF and AC-HVAF thermal spraying onto stainless steel surfaces and for ANSI304 stainless steel surfaces with comparable roughness and PEEK coatings on surfaces with positive skewness showed a better coating adhesion in comparison to similar surfaces with negative skewness.[41]

3.14.5.2 As-Sprayed Surface Finish

HVOF spray technique is best recommended for carbide matrix coatings.[42] Carbide coatings sprayed by HVOF render good hardness, wear, and abrasion resistance characteristics and have perfect alternative for hard chrome plating.[42] Harvey[43] mentioned in his study that adhesive strength at the coating and substrate interface for a typical HVOF-sprayed coating can be 10 times higher than that obtainable from other thermal spraying processes. HVOF spraying is considered a valid process to deposit cermet coatings (WC–Co and Cr_3C_2–NiCr) of low porosity content (about 1%) due to the high particle velocity and low flame temperature. Specifically HVOF spraying allows creating denser and less oxidized coatings than conventional thermal spray technologies. Perry *et al.*[44] reported that during the development of the HVOF coatings, no significant thermal and mechanical alterations of the substrate are usually observed. Moreover, Kaur *et al.*[10] mentioned that the HVOF coatings are used in applications requiring the highest density and strength that are not available from most other thermal spray processes. New applications that previously were not suitable for thermal spray coatings are now becoming viable. In the aeronautical industry, the HVOF coatings are considered as a standard for spraying of carbides and many applications. These industries were previously using electrolytic chromium and have now been replaced by carbides and alloys sprayed by the HVOF process.[45]

3.14.5.2.1 Automobile industry

Nowadays, automobile industry is a growing market for thermal spraying and number of coating applications is increasing steadily.[5] A few examples of HVOF coatings' applications are mentioned in **Table 3**. Picas *et al.*[42] studied the behavior of HVOF CrC75 (NiCr20) 25 coatings deposited on a steel substrate with a thickness of approximately 150 μm. In order to achieve very fine surface finish, dense, and coherent microstructure of the coating, they sprayed the HVOF carbide coatings from three different agglomerated feedstock powders with various powder size distributions. Taylor–Hobson rugosimeter–profilometer was used to measure the surface roughness values with a cut-off of 0.8 mm. With fine powder size distribution and optimized HVOF spray parameters, they succeeded in developing the as-sprayed HVOF CrC75 (NiCr20) 25 coatings with the lower value of surface roughness Ra as 2.0 μm (**Table 3**). The authors recommended the use of efficient and economic 'clean' HVOF technology to coat different type of critical mechanical components like valves, pistons, piston rings, rods, hydraulic components thereby considered to replace the hazardous hard chromium plating technology.

3.14.5.2.2 Power generation industry

Slurry erosion of turbine components is a very serious problem in the hydraulic power plants all around the globe, for instance in those situated in Himalayan regions of India.[46–47] The hydraulic turbine components such as guide vanes, top and bottom ring liners, labyrinths, runner blades, inlet valve seals, etc. are mainly affected by slurry erosion, which are usually protected by surface coatings. Therefore, Goyal *et al.*[48] deposited WC–10Co–4Cr and Al_2O_3–13(TiO_2) coatings on CF8M turbine steel by HVOF spray process and studied their performance under slurry erosion conditions. The coatings were developed at M/S Metallizing Equipment Company Private Limited, Jodhpur, India, by using commercial HVOF thermal spray system (HIPOJET2700). Surface roughness tester (SurftestSJ301, Mitutoyo) was used to measure the surface roughness values on the uncoated and coated specimens. The spray parameters and the Ra values are reported in **Table 3**. The authors observed higher erosion rates in the early cycles of experimentation. The authors reported that the initial roughness of the specimens could be the possible reason for this behavior. The higher material removal rate during the initial period might have resulted due to the micropeaks and valleys which exist on the surface of the specimens. However, once the surfaces became smooth, the erosion rate became, by and large, steady. The HVOF-sprayed WC–10Co–4Cr coating was found to be protective against the slurry erosion of the base steel.

3.14.5.2.3 Surface roughness of bondcoats in thermal barrier coatings

Thermal barrier coatings (TBCs) have been widely used in order to obtain more efficient and durable hot section components in gas turbine engines.[49,50] TBCs normally consist of a thermally insulating ceramic topcoat and an oxidation-resistant metallic bondcoat on the substrate.[51,52] MCrAlY (M¼Ni, and/or Co) is typically used as a bondcoat as it offers a good thermal expansion match between the substrate and the topcoat. In addition to that it also protect the substrate from oxidation and hot corrosion. A thermally grown oxide (TGO) formation takes place at the bondcoat/topcoat interface when in service at high temperatures. This TGO is responsible for the durability and failure of TBCs.[53–55] The roughness of the bondcoat is a critical factor which is responsible for the effective lifetime of TBCs. Bondcoat roughness depends on the technique used for deposition of coating. In addition to that it has been noticed that the properties of feedstock powders and spraying parameters also influence the microstructure and roughness of the bondcoats.[55,56] Studies done by various researchers proved that the condition of the bondcoat surface had a substantial effect on the lifetime of TBCs.[56–59]

In the work done by Ni and Zhou[60] HVOF spray technique was used to deposit NiCrAlY bondcoat with an aim to investigate the effect of three different types of surface modifications namely grit blasting, shot-peening, and vacuum treatment on

Table 3 Typical applications of HVOF spraying[42,48]

Component	*Coating material*	*Coating function and requirements*	*HVOF gun details*	*Spray parameters*		*Coating characterization results*
Valves, pistons, piston rings, rods, and hydraulic critical mechanical components	CrC75 (NiCr20) 25	Friction and wear properties	C-CJS HVOF gun (nozzle configuration k5.2 (Thermico, Germany)	Hydrogen flow rate taken ($m^3\ h^{-1}$) Fuel (kerosene) flow rate ($l\ h^{-1}$) Oxygen flow rate ($m^3\ h^{-1}$) N_2 powder feeding ($m^3\ h^{-1}$) Powder feed rate ($kg\ h^{-1}$) Deposit efficiency (%) Density taken in ($g\ cm^{-3}$)	0.8 8–12 6 45 4 55 6.6	• Surface roughness value with very fine powder size particles <5 μm (Ra-2.0 μm) • Dense and coherent microstructure obtained[42]
Hydro turbine components	WC–10Co–4Cr; $Al_2O_3 + 13TiO_2$; $Cr_3C_2 + 25$NiCr, Cr_2O_3; CoNiCrAlY	Slurry erosion	HVOF thermal spray system (HIPOJET2700)	Air pressure ($kg\ cm^{-2}$) Oxygen flow rate (slpm) Fuel (LPG) flow rate (slpm) Air-flow rate (slpm) Powder feed rate ($g\ min^{-1}$) Fuel pressure ($kg\ cm^{-2}$) Oxygen pressure ($kg\ cm^{-2}$) Spray distance (cm)	5.5 270 60–65 650 28 6.5 10.0 20	• Surface roughness values for WC–10Co–4Cr coating, Ra-4.27 μm and for $Al_2O_3 + 13TiO_2$ Coating, Ra-4.55 μm • Surface roughness values for $Cr_3C_2 + 25$NiCr coating, Ra-3.34 μm and for Cr_2O_3 coating, Ra-2.83 μm • Surface roughness values for CoNiCrAlY coating, Ra-4.58 μm[48]

the thermal cycling lifetime of TBCs. The main objective of the investigation was to study the morphology and composition of TGO, and also to explore the failure mechanism of the coating. NiCrAlY bondcoat was prepared by HVOF spray on nickel-based superalloy using a commercial Met Jet III (metallization) gun. The fuel used for the deposition was kerosene and carrier gas was nitrogen. After the successful deposition of the coating three different types of surface finishing modifications were employed as given below[60]:

- Grit blasting of the specimens by using alumina grit of 250 mm size,
- Shot-peening of the specimens by using glass grit of 250 mm size, and
- Preoxidation heat treatment under vacuum conditions using working pressure of $3–7 \times 10^{-3}$ Pa for 2 h at 1050 °C to obtain different surface morphologies of the coatings.

After the above mentioned procedure 8 wt% Y_2O_3–ZrO_2 powders were deposited by air plasma spray (APS) onto the surfaces of the HVOF-sprayed NiCrAlY coating. The results exhibited better thermal shock resistance in case of surface-modified TBCs. In case of TBCs with the as-sprayed bondcoat, failure took place within the topcoat as well as at the interface between spinels and the topcoat. For the shot-peening, grit blasting, and vacuum treatment TBC systems the failure was noticed mostly within the topcoat. TGO observed on as-sprayed bondcoat was found to consist of $Ni(Al,Cr)_2O_4$ spinels on the outer layer and a Al_2O_3 phase in the inner layer. A continuous and uniform Al_2O_3 was observed after surface modification. It was noticed that the presence of mixed oxides (spinels) on the as-sprayed bondcoat enhanced the failure of TBCs. It was concluded that the formation of a continuous and uniform Al_2O_3 after surface modifications was instrumental in the enhancement of the thermal cycling life of TBCs.[60]

The influence of processing parameters on the microstructure of overlay coatings has been studied by several authors. Rajasekaran *et al.*[61] observed that MCrAlY overlay coatings sprayed by HVOF process had considerable variations in the microstructure and roughness subject to powder grain size and spraying parameters, such as spray distance and/or

powder flow rate. Pant *et al.*[62] found that the microstructural properties of the MCrAlY overlay coating sprayed by high-energy HVOF were dependent on the type of gun used for the spraying process. An investigation of Perez[63] showed that the intersplat porosity can be greatly reduced by optimization of APS spray parameters, and the MCrAlY overlay coating density becomes similar to that sprayed by HVOF. All the above results showed that even in the frame of one spraying method, it is possible to produce bondcoats with large differences in microstructures and roughness profiles using different powder particles sizes, spraying parameters, or spraying guns.

Nowak *et al.*[64] investigated the influence of change in morphology and roughness profile on the lifetime of APS–TBC systems. For this purpose bondcoats of the same chemical composition were deposited using different thermal-sprayed techniques namely HVOF, VPS, and two kinds of a double-layered bondcoat having a base coating of HVOF and a thin outer layer 'flashcoat'sprayed by APS. The lifetime evaluation was done using cyclic oxidation testing at 1120 °C. The bondcoat roughness profile was correlated with the lifetime of APS–TBC systems using standard bondcoat roughness parameters, which included arithmetic average height (Ra) and maximum height of the profile (Ry), of the as-received TBC systems. Apart from the standard Ra and Ry calculations, fractal analysis of the bondcoat roughness profiles was also executed using the commercially available software Sfrax 1.0.[65] The three TBC systems chosen for the quantitative roughness evaluation were HVOF bondcoat, VPS bondcoat, and APS-flashcoat. Initially a standard roughness evaluation was done by calculating the Ra and Ry values. The results of the evaluated roughness values are reproduced in **Table 4**.

The arithmetic mean roughness (Ra) values of the evaluated bondcoats were found to vary between 11.2 μm for the HVOF bondcoat and 13.2 μm for the system with optimized APS-flashcoat. The TBC system which possessed the smallest bondcoat roughness, i.e., HVOF bondcoat showed the shortest lifetime. Further, the system possessing the highest roughness had the longest lifetime. It was observed that the parameters which were used for the APS-flashcoat spraying strongly effected the lifetime of the TBC system. It was noticed that a slight variation in spraying parameters for the APS-flashcoat led to formation of a porous and discontinuous layer. This led to shortening of lifetime of the respective TBC-system (which was even shorter than that of the system with flat HVOF bondcoat) as a result of rapid breakaway oxidation of the flashcoat.[64]

The performance of TBC specimens having NiCoCrAlYHfSi bond coatings deposited by HVOF spraying technique on superalloy 1483 and X4 substrates was assessed in dry and wet air in 1 h furnace cycles at 1100 °C.[66] Specimens of 1483 and X4 superalloys having size 16 mm diameter and 2 mm thickness were prepared by machining followed by grit blasting. Finally, the prepared specimens were coated using ~125 μm NiCoCrAlYHfSi (Amdry 386) by the HVOF process in two stages. In the first stage a finer (−44/+16 μm) powder was used and the second stage consisted of coarser (−90/+38 μm) powder in order to attain a higher roughness. After the deposition of the coatings, these were annealed in a vacuum of 10^{-4} Pa (10^{-6} Torr) for 4 h at 1080 °C. APS technique was utilized for the top coatings of 8 wt% Y_2O_3-stabilized ZrO_2 (YSZ) on one side of the coupons in thickness range of 190–240 μm. Cyclic oxidation test were conducted in a groups of four specimens at each condition. In order to characterize the thermally grown alumina scale three were coated with an APS YSZ topcoat and the fourth was tested without YSZ. Compared to an earlier study of NiCoCrAlYHfSi bond coatings, the HVOF bond coatings were found to be rougher having a value of Ra = 8 μm, which was nearer to commercial HVOF coatings.[66] It was observed that for the TBC coatings deposited on the X4 substrates cycled in air with 10% water vapor, the increase in the roughness value from Ra = 5 to 8 μm did not have much effect on the average TBC lifetime. The presence of 10% water vapor decreased the average TBC lifetime for 1483 by 13%, however, in both wet and dry conditions, the lifetimes for this substrate were 30–50% below those observed for X4 substrates. The main cause of this behavior was the lower Al content and higher Ti content in 1483. Roughness and residual stress in the alumina scale were measured on specimens without a ceramic top coating and it was concluded that the change in substrate or the addition of water vapor had no effect on the same. **Figure 8** summarizes the average TBC lifetimes measured in this study and compares these results to those obtained earlier on the same X4 substrate, but with a lower roughness HVOF bond coating.[67]

Table 4 Results of bondcoat roughness evaluation using conventional procedures combined with TBC lifetimes during thermal cycling[64]

Bondcoat	*HVOF bondcoat*	*VPS bondcoat*	*APS-flashcoat*
Ra (μm)	11.3	12.9	13.2
Ry (μm)	65	91	90
Lifetime at 1120 °C	108 h	252 h	344 h

3.14.5.3 Post-Deposition Surface Finish

HVOF spraying enables deposition of relatively thick coatings which are suitable for engineering applications including

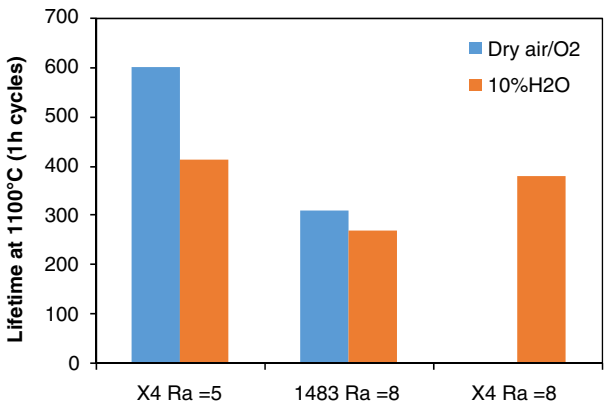

Figure 8 Average lifetimes for air plasma spray Y_2O_3-stabilized ZrO_2 coated X4 and 1483 specimens with high velocity oxy-fuel NiCoCrAlYHfSi type bond coatings exposed in 1-h cycles at 1100 °C in dry and wet environments: The data with the lower roughness is from a previous study.[66]

resistant to wear. The resultant coatings are economical, easy-to-achieve and offer excellent protection. As a result, these coatings have found applications in various industrial fields.[68,69] Though many coatings are deposited near-net shape but still their finishing is mostly required. For coatings that exhibit such a grade of protection, the finishing process can be troublesome. It can be time consuming and expensive, accounting for up to 50% of the manufacturing cost. Moreover, wrong finishing operations may lead to the deterioration of the coating precision and surface integrity.[70] It has been stated that grinding is the most commonly adopted method for finishing of hard materials[71,72] such as that of thermal-sprayed coatings. However, grinding can be comparatively costly and may occasionally reduce the performance of the coating.[72]

Abrasive fluidized bed (AFB) technology was proposed by Barletta *et al.*[73] to finish high speed axial-symmetric components coated by HVOF. The changes in the coating morphology according to the operational parameters and the related material removal mechanisms were investigated. Further, the closest conformity of the processed coatings with the dimensional tolerances were also evaluated. **Figure 9** shows that the trend of roughness parameters versus abrasive size at 12 000 rpm. Ra and Rz improved after the first finishing step with the biggest abrasive (mesh size 46) and improved slightly when smaller abrasives (mesh size 80 and 120) were used. Ra and Rz improved from approximately 7 and 35 µm to approximately 2 and 10 µm. Rdq (i.e., slope), related to the local coarseness of the surface and, therefore, to its capability to reflect the incident light, decreased after the first finishing step from 22 to 10 µm. RSm increased from 0.2 to approximately 0.26 mm as the morphology changed from the initial micro-corrugated topography of the partially melted or unmolten Stellite 6.[74]

It was concluded from the study that Al_2O_3 abrasives are suitable to finish the coatings leading to a satisfying morphology and the process does not have a significant impact on

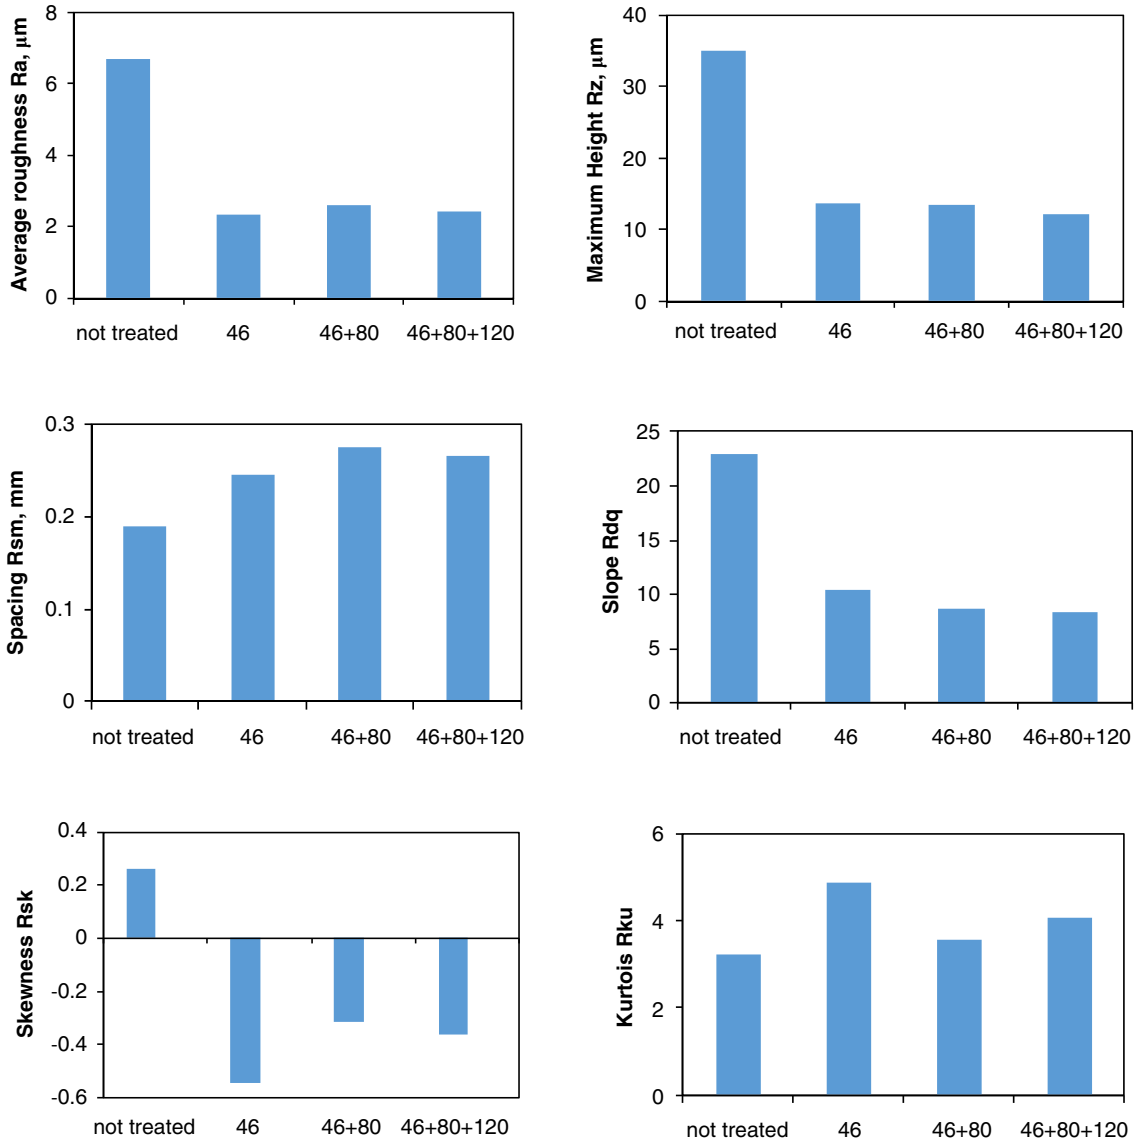

Figure 9 Trend of roughness parameters vs. abrasive size at 12 000 rpm.[73]

the dimensional properties with moderate material removal (−0.3% in the starting radius). Hence, the study demonstrated the feasibility of AFB to machine hard coatings. The technique has been suggested to be flexible and suitable to wider industrial applications. Moreover, this process permits to obtain end-products with a high standard. Furthermore, it is low cost, safe, easy to automate and eco-friendly process.[73]

Surface roughness characterization of thermally sprayed and precision machined WC–Co and Alloy-625 coatings was carried out by Zhong *et al.*[75] It was established that commercial machines and tools could be used for the machining of difficult-to-machine coating surfaces. The surface finish of the machined coatings was also characterized. The thermal spraying processes used for depositing the coating were AS and HVOF spraying. Optimization of the surface finishing of the coatings was done on the basis of surface finish and time required using different machining techniques. Machined samples were then examined using stylus roughness testers. Surface roughness parameters (Ra and Rq) were measured using different cut-off lengths, sampling lengths, and numbers of sampling in order to characterize the scaling behavior of the surfaces. Whereas the diamond turning process of WC–Co lead to high material removal rates, on the other hand diamond grinding of WC–Co resulted in good surface finish with relatively high material removal rates.[75] It was found that the surface roughness heights of the machined surfaces were dependent on the scale of cut-off length as a power law. For WC–Co coatings deposited by the HVOF process mirror like surfaces were achieved by fine grinding operation using a fine diamond wheel. When cubic boron nitride (CBN) grinding was done on the HVOF-sprayed WC–Co coatings some problems with loading of grinding wheels were observed. However no such loading problem was observed when diamond grinding was conducted.[75]

3.14.6 Concluding Remarks

In this chapter, HVOF thermal spray technique, its comparison with other thermal spray processes and its applications in relation to the surface finishing have been reviewed. HVOF techniques have developed extensively over the last two decades from the first generation HVOF systems to the third generation HVOF systems. New modifications and improvements of the technology have been introduced. Nowadays, HVOF thermal spray process is being accepted by many industries due to the advantage of being applied on-site on the surface of the components and superior coating properties. The HVOF spray process retains the composition of the coating material to a greater extent and has been shown to produce coatings with low porosity, low-oxide content, better density, better coating cohesive strength and bond strength in comparison with other thermal spray processes. Furthermore, it is evident from literature studies that with increasing time in service, the HVOF-coated surfaces have been found to remain relatively constant regardless of the accumulation of dynamic cycles with seals and bearings in dynamic applications. Surface preparation is vital before the coating deposition process in order to improve the coating/substrate interfacial adhesion. Certain preprocessing techniques are utilized to remove grease and other contaminants from the surface which also help to change the physicochemical properties and/or surface morphology for better adhesion of the same. Among the commonly used techniques, degreasing and sandblasting are used in most cases. Investigations done by various researchers prove that for TBCs the condition of the bondcoat surface roughness had a significant effect on the overall lifetime of the same. The bondcoat can be subjected to grit blasting, shot-peening or certain preoxidation heat treatment processes in order to obtain different surface finish. For optimizing the surface finish after the coating deposition different machining techniques like grinding, diamond turning and AFB technology have been recommended.

3.15.1 Introduction to Surface Finish Systems

The flip chip is a type of interconnection used in electronic packaging. The main components of the flip chip consist of thin layers of metal called under bump metallurgy (UBM) on the die bond pads, layers of metal called top-surface metallurgy (TSM) on the substrate bond pads, and solder bumps on the UBM, as shown in Figure 1. The term 'surface finish' refers to the TSM layers.

The decision to use a surface finish is based on the premise that the desired level of solderability could not be realized with the conditions of the substrate surface at the time of soldering.[1] Inadequate substrate solderability can arise during the course of one of two general pretexts:

1. Similar to the case of glasses, ceramics, or refractory metals, the underlying base metal is isolated from the molten solder by a finish that provides the solderable layer to which the solder wets and over which it spreads to form the joint.
2. The applied finish simply coats the base metal to seal it against excessive oxidation. The surface finish is either dissolved into the solder, as is typically the case with metal coatings, or dissipated by the heat process just before the solder starts spreading, like those associated with several organic coatings.

Other than solderability protection, the application of this one-layer or multi-layer thin film on the metallization pads is also needed to provide adhesion and to act as a solder diffusion barrier, a solder wetting layer, and a corrosion-resistant layer.[2,3] Usually, the solder used contains a high percentage of tin (Sn). Because of Sn's high diffusivity and reactivity with copper (Cu; the metallization pad), this will result in rapid Cu–Sn intermetallic growth. Intermetallics, although needed to form a good bond, may reduce the solder's thermal fatigue life, if present in excessive quantities, due to their brittle nature.[4] This is one of the reasons why surface finishes are very important. Figure 2 illustrates the effect of a surface finish on the solderability and the process of solder joint formation.

It is also of great importance that the thicknesses of the solderable and protective layers (surface finish system) are closely controlled. If the solderable layer (which is usually the diffusion barrier layer) is too thin, then it might be fully consumed during soldering, thus exposing the liquid solder to the underlying base metal surface and, in the process, defeating the purpose of acting as a diffusion barrier. If dissolution of the

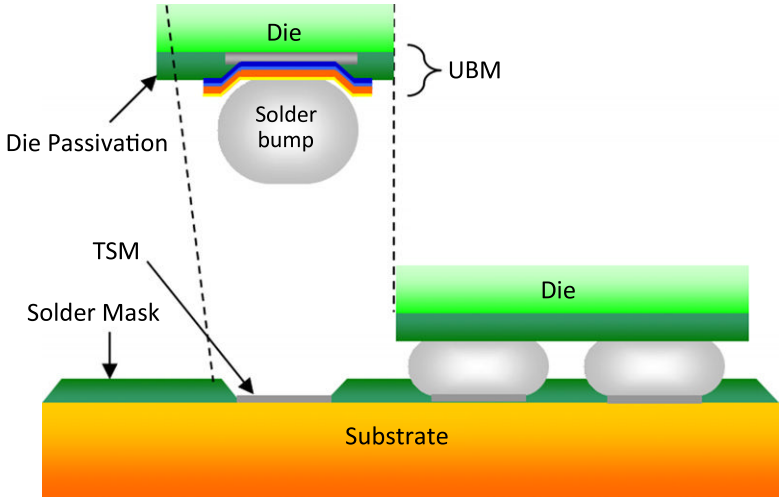

Figure 1 Flip chip solder joint.

 doi:10.1016/B978-0-12-803581-8.09177-3

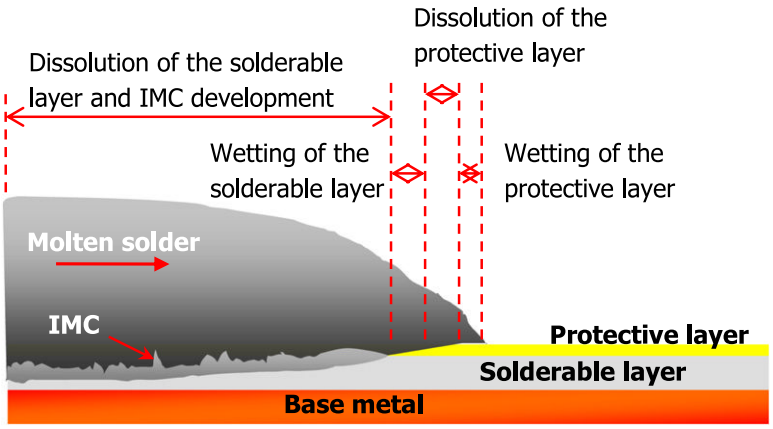

Figure 2 Schematic diagram of the phenomena that occurs in the solderable and protective finishes during the wetting and spreading of liquid solder.[1]

solderable layer occurs, then it may lead to the degradation of the solder joint's properties. If it is too thick, then it is not only undesirable from an economic view point but also detrimental to the solder joint's reliability. Thick coatings are always associated with high residual stress and contaminants from the plating bath. High residual stresses will lead to delamination of the solderable layer from the base metal surface.[1,5]

As the world moves forward toward adapting to stricter environmental standards, the entire electronics industry needs to re-evaluate its manufacturing practices. Implementation of restriction of the use of hazardous substances in countries around the world has moved innovation forward by leaps and bounds to determine new lead-free products that meet these requirements. In addition, the package also has to be able to withstand the higher assembly temperatures of lead-free solder alternatives.[6] In summary, it can be said that a good surface finish must be able to produce the following: acceptable metallurgical properties between the substrate and the solder; an inert property at ambient and/or reflow conditions over time; excellent wetting properties with the solder; and flat with controllable thickness.[7]

For the manufacturers of electronic packaging, hot-air solder leveling (HASL) has been the dominant final finish for the majority of printed circuit boards. However, it is the largest source of lead used in the industry. In addition to the need for lead-free materials, the other drivers that are pushing the electronics industry to consider HASL alternatives are cost and technology. Thus, as technology has evolved, a series of alternate surface finishes has been created, tested, and implemented for use throughout the printed circuit industry. Some finishes are widely used and others are used for very specific applications.

Regardless of the material type used for the surface finishing, electroless, and immersion plating seem to be the available methods for surface finish deposition in electronic packaging. This is due to the fact that electroless and immersion plating allow the fabrication of isolated metal patterns on insulating substrates.[8] Some of the surface finish systems available for electronic packaging using the electroless and immersion processes are:

1. Electroless nickel (EN)/immersion gold
2. EN/electroless gold
3. EN/electroless palladium/immersion gold
4. Immersion silver
5. Immersion tin
6. Direct immersion gold.

In the process in which metal is deposited from an aqueous solution, both electroless and immersion plating meet the requirements of chemical deposition. However, the electroless and immersion techniques differ in terms of their deposition mechanisms and the final results. Electroless plating is basically a chemical reduction process depending on the catalytic reduction of a metallic ion in an aqueous solution containing a reducing agent, with subsequent deposition of the metal without the use of electrical energy. The substrate itself can be catalytic or activated by the use of displacement deposits of palladium compounds or galvanic coupling with a catalytic metal. After the reaction is initiated, the metal deposited serves as the catalyst, ensuring the continuous build-up of the metal. For immersion, however, the more noble material will be deposited on the less noble through displacement. The process will stop as soon as the substrate is completely covered by the metal coating. The immersion process requires no reducing agents in the bath solutions.[9–11] In this research article, attention is focused on electroless plating solutions.

3.15.1.1 Surface Treatment

Electroless plating, like any other process, has its own advantages and weaknesses, as listed in **Table 1**.[8,12]

In electroless plating, the surface preparation of the substrate is a very important procedure. The solderability of the surface finish can deteriorate due to the exposure of the surfaces to deposited air-borne contaminants such as dust, 'acid rain' components, lubricant aerosols, or even tarnishing chemicals. The nature and magnitude of these contaminants will depend on the localized plant environment, as well as on any nearby industrial and agricultural operations. For example, in EN deposition, not all substrates are catalytic and could initiate plating without requiring additional activation steps. Nickel, steel, and aluminum substrates can initiate electroless

Table 1 Advantages and weaknesses of electroless plating

No.	*Advantages*	*Weaknesses*
1.	Capability to deposit thin films of metal on nonconducting surfaces (e.g., glass, ceramics, polymers)	Complex plating bath solution containing metal complex ions, reducing agents, pH adjustments, buffering components, and additives that may age, by-product reaction affecting the deposition, homogenous nucleation of the plating solution, nucleation on defects or nonselected surfaces, or failure to nucleate due to contamination or problems with the catalytic surface
2.	Requires relatively simple tools; plating bath and plating bath solution	Most of the plating solutions are hazardous to the environment (e.g., gold plating solution containing cyanide, nickel plating solution with thiourea as a stabilizing agent); need a proper method to dispose of the solution after plating
3.	Constant thickness of plated layer regardless of shape	Stringent control of the chemicals, temperature, and pH is needed according to each plating solution's specification

deposition with standard preparation cycles. However, copper and brass are not catalytic and require additional activation steps to ensure plate initiation.[1]

Alkaline soak cleaning is the traditional first step in the preparation cycle. The type of soils to be cleaned and the type of substrate determine the step or approach to solving the potential cleaning problem. The variety of soils commonly found in a plating facility includes machine drawing lubricants, buffing compounds, chlorinated oils, and waxes.[13] There are many more types of material that can be categorized as soils, including dirt, smut, oxides, rust, and heat scale. These types of soils are primarily handled during the activation process. Once a specific cleaning strategy has been chosen, factors such as operating temperature, concentration, and agitation become important considerations.[13]

Rinsing is the most critical part of the pretreatment process. According to Durkin,[13] increasing the rinsing time effectively removes these materials at the surface interface, although the films remaining contain minimal wetting agent or surfactant. In most cases, this condition is not harmful to the next process stage. It is also easy to visualize that a simple rinsing scheme, moving the substrate up and down as one wishes, is not likely to be very effective. Increasing the time (up to 2 min) of the rinses following the alkaline cleaning processes is recommended to ensure that the films remaining on the surface interface area are adequately removed.

After rinsing, activation is the most critical step in the preparation process. After cleaning the oils from the surface, all oxides need to be removed to allow proper atomic bonding of the plate to the substrate. The activation process can be broken down into different types or groups. The most common types are acid activation based on acid salts, mineral acids such as sulfuric acid or hydrochloric acid, and activators based on citric acid. The choice of which acids to use and their strength depend on the type and condition of the metal to be plated. Hydrochloric acid should not be used because chlorides may be detrimental to the EN deposit if corrosion resistance of the deposit is an important requirement. Other activators in the cleaning line include electro-cleaners, electrolytic acids, and nickel copper strikes. For nonconductive substrates, activators based on palladium chloride are commonly used.[13]

Immediately after the activation process, the substrate is immersed inside the plating solution, following the respective plating solution requirements such as temperature and pH. The actual deposition and its kinetics are defined in the following way:[8]

1. Transport of the constituents (i.e., metal complexes, reducing agents, other ions, additives) in the electrolyte toward the catalytic surface.
2. Adsorption of the constituents onto the surface.
3. Intermediate reactions involved in metal complex reduction and decomposition and the absorbed reducing agent oxidation. There are many possible intermediate reactions, and the rate depends on the catalytic seed as well as the absorbed species concentration.
4. Desorption of unreacted species, intermediates, and products.
5. Transport of the unreacted species, intermediates, and products away from the substrate.

After the initial step of nucleation, the metals grow following the deposition reaction as long as there is no significant depletion of any electrolyte compound or loss of the substrate catalytic properties.[8] The understanding of the process, stability, precision, and cost reduction in the electroless plating process has improved according to the technology evolution.

3.15.2 Electroless Plating Baths in Electronic Packaging

When selecting an alternative surface finish, the key parameters to consider are solderability, ambient stability, high-temperature stability, suitability for use with lead-free solders, solder joint integrity, and cost.[14] Currently, there are several alternative surface finishes using the electroless and/or immersion deposition techniques, which are used or are being explored for future use in the lead-free industry. The surface finishes are[5,12,15]:

1. EN/immersion gold
2. EN/electroless gold
3. EN/electroless palladium/immersion gold
4. Immersion silver
5. Immersion tin
6. EN/immersion silver

Based on this list, commonly there are only three types of electroless baths involved. These are EN, electroless palladium, and electroless gold solutions.

3.15.2.1 EN Plating

EN plating is undoubtedly the most important catalytic plating process that results in uniform deposits in use today. Several advantages, like its low cost, the easy formation of a continuous and uniform coating on the surface of a substrate with a complex shape, and the capability of depositing on either conductive or nonconductive parts, have attracted great interest from academia and industry. EN plating has unique chemical and mechanical properties and therefore is increasingly being used.[16] Some of these properties are:

1. Uniformity
2. Excellent corrosion resistance
3. Wear and abrasion resistance
4. Solderability
5. High hardness
6. Amorphous and microcrystalline deposits.

The chemical and physical properties of an EN coating depend on its composition, which, in turn, depends on the formulation and operating conditions of the EN plating bath. Typically, the constituents of an EN solution are[17–19]:

1. A source of nickel ions, usually nickel sulfate or nickel chloride; the nickel concentration is normally between 5 and 11 g l^{-1}.
2. A reducing agent to supply electrons for the reduction of the nickel. Several reducing agents are used in EN plating, including sodium hypophosphite, amineboranes, sodium borohydrite, and hydrazine. However, approximately 70% of EN is deposited from solutions reduced by sodium hypophosphite. This reduces the nickel ions and reacts with water at catalytic surfaces to form orthophosphite, which accumulates in solution and eventually precipitates as nickel phosphate. Because hydrogen ions are a by-product of these reactions, the pH of electroless solutions will decrease during normal operations.

The electrochemical mechanism, whereby catalytic oxidation of the hypophosphite yields electrons at the catalytic surface, which, in turn, reduces the nickel and hydrogen ions, is illustrated as follows[20]:

$$H_2PO_2^- + H_2O \rightarrow H_2PO_3^- + 2H^+ + 2e^- \quad [I]$$

$$Ni^{2+} + 2e^- \rightarrow Ni \quad [II]$$

$$2H^+ + 2e^- \rightarrow H_2 \quad [III]$$

$$H_2PO_2^- + 2H^+ + e^- \rightarrow P + 2H_2O \quad [IV]$$

The atomic hydrogen mechanism, whereby atomic hydrogen is released as a result of the catalytic dehydrogenation of the hypophosphite molecules adsorbed at the surface, is illustrated as follows:

$$H_2PO_2^- + H_2O \rightarrow HPO_3^{2-} + H^+ 2H_{ads} \quad [V]$$

$$2H_{ads} + Ni^{2+} \rightarrow Ni + 2H^+ \quad [VI]$$

$$H_2PO_2 + H_{ads} \rightarrow H_2O + OH^- + P \quad [VII]$$

The adsorbed active hydrogen [VI] then reduces the nickel at the surface of the catalyst:

$$(H_2PO_2)^{2-} + H_2O \rightarrow H^+ + (HPO_3)^{2-} + H_2 \quad [VIII]$$

Simultaneously, some of the absorbed hydrogen reduces a small amount of the hypophosphite at the catalytic surface to water, hydroxyl ions, and phosphorus [VII]. Most of the hypophosphite present is catalytic, which is oxidized to orthophosphite and gaseous hydrogen [VIII], causing low efficiency of EN solutions for the alloy coating while the deposition of nickel and phosphorus continues. Usually, 5 kg of sodium hypophosphite is required to reduce 1 kg of nickel, for an average efficiency of 37%.[21,22] The coefficient of utilization of the hypophosphite varies with the nature of the buffer additive; the highest degree of utilization of the hypophosphite was observed in the solution containing sodium acetate, and the lowest was observed with sodium citrate. The main characteristic of the process is the change in the composition of the solution. The concentration of nickel salt and hypophosphite is decreased and the concentration of the acid is increased during the process of deposition. This causes lowering of the deposition rate.[22]

3. Suitable complexing agents: added to control nickel ion activity that will, if too high, result in the complete decomposition of the solution when the sodium hypophosphite is added. The complexing agents also function as buffers and suppress the tendency for nickel to precipitate as hydroxide. Complexing agents control the rate of the deposition reaction, the rate of change of pH, the phosphorus content of the deposit, the bath stability, the tendency to form insoluble nickel phosphate, and the ease of solution control.
4. Stabilizers/inhibitors: used in minute quantities to completely eliminate the tendency for spontaneous decomposition of the plating solution and the deposition of metal on the walls of the plating tank, pipes, and other equipment.
5. Energy: catalytic reactions, such as EN plating, require energy that is supplied in the form of heat to proceed. The quantity of energy required by the system or added to it is one of the most important factors affecting the kinetics and the rate of the deposition reaction.

The major factor affecting EN plating is the bath composition. **Table 2** shows typical EN bath formulations, both acidic and alkaline. However, other factors such as pH, temperature, and the surface area of the substrate also affect the plating process.[16] Nickel deposits obtained from acid solutions have a very bright and smooth surface. As the pH increases to become more alkaline, the nickel content of the deposit increases or phosphorus decreases. Temperature also has a significant effect on the rate of the plating process. The plating rate increases with the increase in temperature and, after a certain point, the quality of the plating deteriorates because it will be difficult to

Table 2 Typical electroless nickel bath formulations[23]

	Acid	*Alkaline*
Temperature	77–93 °C	26–95 °C
pH	4.4–5.2	8.5–14
Deposition in 1 h	12.7–25.4 μm	10–12.7 μm
Metal salt	Nickel sulfate Nickel chloride	Nickel sulfate Nickel chloride
Reducing agent	Sodium borohydride Sodium hypophosphite Dimethylamine borane (DMAB) Hydrazine	Sodium borohydride Sodium hypophosphite Dimethylamine borane (DMAB) Hydrazine Diethylamine borane (DEAB)
Complexing agent	Citric acid Sodium citrate Succinic acid Proprinic acid Glycolic acid Sodium acetate	Citric acid Sodium citrate Succinic acid Lactic acid Glycolic acid Sodium acetate Sodium pyrophosphate
Stabilizer	Fluoride compounds Heavy metal salts Thiourea Thioorganic compounds (i.e., mercaptobenzothiazole, MBT) Oxy anions (i.e., iodates)	Thiourea Heavy metal salts Thioorganic compound Triethanolamine Thallium salts Selenium salts
pH adjustment	Ammonium hydroxide Sulfuric acid	Ammonium hydroxide Sulfuric acid Caustic soda Sodium hydroxide

maintain the pH of the solution. This temperature depends on each solution used.

Generally, there are three main types of EN coatings: nickel–phosphorus, nickel–boron, and poly-alloys. Nickel–boron is very often used in industrial applications for its as-plated hardness, which is higher than that of nickel–phosphorus. The boron content can vary from 0.1 to 10%. The reducing agent used is dimethylamine boron or sodium borohydride, depending on the desired alloy composition. Poly-alloys are a combination of nickel, boron, or phosphorus and other metals such as cobalt, iron, tungsten, rhenium, or molybdenum. Composite deposits such as EN–polytetrafluoroethylene and EN–diamond have been developed for special applications.[23] **Figure 3** shows the general categories of the EN coatings.[19]

EN–phosphorous is by far the most widely used in electronics applications. It is a barrier type of coating and has an autocatalytic chemical reduction process in which the reducing agent is oxidized and Ni^{2+} ions are deposited on the substrate surface. Once the first layer is deposited, it acts as a catalyst for the process. EN–phosphorous coatings are binary alloys of nickel and phosphorous. They are classified as low phosphorous (<6 wt% P), medium phosphorous (6–10 wt% P), and high phosphorous (>10 wt% P) according to Henry[23] and Jothi *et al.*[19]

The phosphorus content of the deposit varies with the bath pH and has a significant influence on the deposit's chemical and physical properties in both the as-plated condition and after heat treatment. Electroless deposits with high phosphorous are obtained in acidic solutions and are either crystalline or amorphous, whereas alkaline solutions have low phosphorous content and are generally crystalline. **Table 3** illustrates the differences in properties between the various nickel–phosphorous coatings.

Because the surface finish will have to go through an elevated temperature for the soldering process, some research has been conducted to study the effect of heating on the EN phosphorus layer. A study by Tomlinson and Wilson[24] found that the nickel–phosphorous layer will start to oxidize at approximately 400 °C; at above 800 °C, the phosphorous will decompose and evaporate from the coating. At above 600 °C, the phosphorous migrates to the surface and the formation of phosphorus oxide has been observed. A kinetic study performed in the same research article at 800–1000 °C showed that the nickel–phosphorus deposit oxidized approximately 100-times faster than pure nickel. The addition of even a small amount of boron to the deposit helps to decrease the amount of oxidation. This finding basically shows that the phosphorus in the nickel–phosphorus layer is the cause of the poor oxidation resistance of the plated layer. Because in electronic packaging the solderability of the surface finishes is one of the most important aspects for consideration, the EN layer will be covered by another plated layer like electroless palladium, electroless gold, or immersion gold to prevent oxidation.

3.15.2.2 Electroless Palladium Plating

Among platinum group metals, palladium is the most inexpensive and is expected to have extensive industrial applications. An example of an electroless palladium plating bath solution is an aqueous solution containing a bivalent palladium salt as a metal source, ammonia as a complexing agent, ethylenediaminetetraacetic acid (EDTA; or a salt thereof) as a stabilizing agent, and hydrazine as a reducing agent.[25] Electroless palladium plating baths can be classified by the reducing agent used. **Table 4** summarizes a few of the bath formulae for two different reducing agents.[26]

Rhoda and Mari[27] developed several electroless palladium plating solutions using hydrazine as a reducing agent. The palladium tetramine complex used in the baths was prepared by the careful addition of ammonium hydroxide to a palladium chloride solution. The solution was then heated to dissolve possible precipitates. EDTA was found to be an effective stabilizer against the spontaneous decomposition of the solution. Bath 1 in **Table 4** was recommended for barrel plating.[27] The hardness of the deposits ranged from 150 to 350 Knoop (25 g load), whereas softer deposits were formed at higher deposition rates. The deposits consisted of a minimum of 99.4% palladium and exhibited a density of 11.96 g cm^{-3}.[27] However, the disadvantage of the hydrazine baths is that the deposition rate decreases drastically after several hours of use, before any significant consumption of the bath constituents

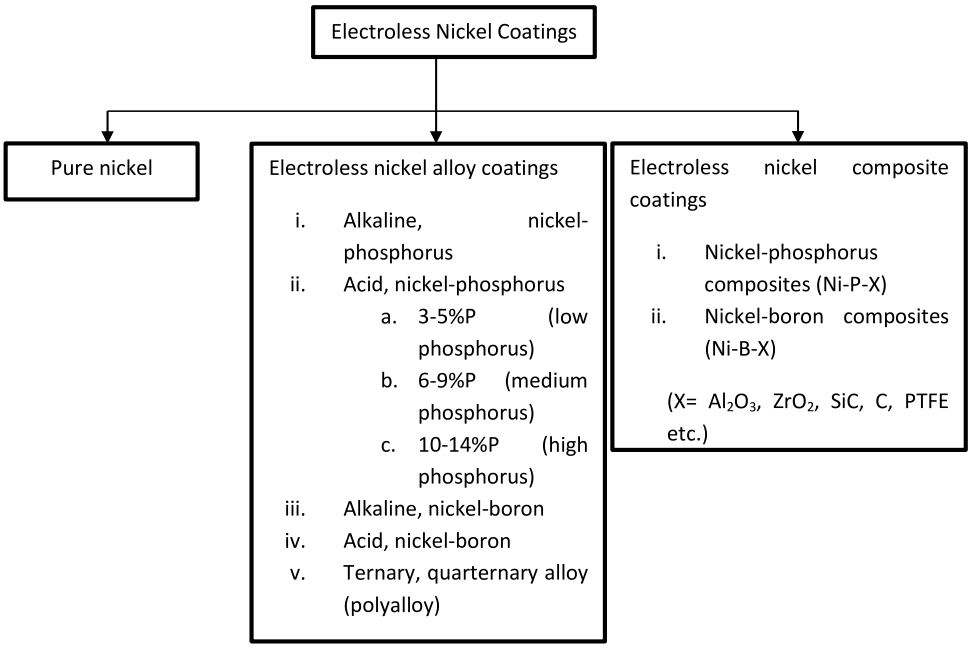

Figure 3 General categories of electroless nickel coatings.[19]

Table 3 The detail of various electroless nickel–phosphorus platings[23]

Phosphorus level	*Phosphorus content*	*Depositions quality*
High	10% or higher	• Excellent corrosion • Easily soldered • Excellent ductility • Nonmagnetic • Excellent diffusion barrier
Medium	6–10%	• Good corrosion resistance in both alkaline and acidic environments • Excellent lubricity • Heat-treatable to 65 RC • Bright, decorative appearance • Mixture of amorphous and microcrystalline phases
Low	Less than 6%	• High as-plated hardness • Excellent wear resistance • Very resistant to corrosion in alkaline environments • High melting point (1200 °C) • Easily soldered • Microcrystalline phase (consisting of many small grains, approximately 2–6 nm in size)

has taken place.[26] Several modified electroless palladium solutions have been designed to solve this problem.[28–30]

The electrochemical aspect of the electroless palladium depositions of baths 3 and 5 in **Table 4** has been studied by Ting *et al.*[29] They reported that the exchange current density for hydrazine (7.8×10^{-5} A cm^{-2}) is higher than that for hypophosphite (2.6×10^{-5} A cm^{-2}). Using electrochemical polarization measurements, Shu *et al.*[28] studied the autocatalytic effect during electroless palladium plating deposition in an alkaline bath containing the palladium–ammine complex, EDTA, and hydrazine. The tetravalent palladium species in the bath may be stabilized through interaction with the co-existing tin oxide in palladium–tin activated substrates.

In most practical electroless palladium plating baths, the palladium–ammine complex is used together with ammonium chloride and hypophosphite as the stabilizer and the reducing agent, respectively.[29,31] A representative make-up for this type of bath, as represented by Pearlstein and Weightman,[31] is shown in **Table 4** as bath 4. The palladium deposits in this bath contained approximately 1.5% phosphorus, and approximately 3 g of sodium hypophosphite monohydrate was consumed to produce 1 g of the electroless palladium

Table 4 Palladium plating bath formula using hydrazine and hypophosphite reducing agents[26]

Bath	*Hydrazine type*			*Hypophosphite type*	
	1	*2*	*3*	*4*	*5*
Palladium (as ammine complex), $[Pd(NH_3)_4]^{2+}$	5.4 g l^{-1}	7.5 g l^{-1}	–	–	–

DI water	100 ml

deposit.[31] Sergienko[32] developed a stable electroless palladium plating bath containing EDTA and hypophosphite.

Other than these two types of reducing agents, Stremsdoerfer *et al.*[33] proposed a new type of electroless deposition of palladium and gold–palladium alloys on a bare n-GaAs surface using hydroxylamine as a reducing agent. The plating bath is composed of two solutions, as shown in Table 5.

Hydrofluoride and potassium chloride, in solutions A and B, respectively, act as stabilizers. The autocatalytic bath for electroless palladium plating on bare n-GaAs as a substrate is prepared by adding a small quantity of solution A to 40 ml of solution B. The bath exhibited a deposition rate of 0.5 μm h^{-1} in the acidic media at 20 °C. The deposits obtained from this bath were well structured and adherent. In addition, Stremsdoerfer *et al.*[34] also reported that the palladium deposited using this bath formed a good metal–semiconductor junction (Pd/n-GaAs junction) by subsequent annealing up to 550 °C. Chepuri and Trivedi[35] reported on the electroless plating of pure palladium from palladium–ethylenediamine complex baths using formic acid as a reducing agent. Electroless pure palladium was deposited using the following basic bath composition: 0.01 M palladium chloride, 0.08 M ethylenediamine, 0.2 M formic acid, and pH 6 at 60 °C. When phosphite or trimethylamine borane was used as a reducing agent, the content of phosphorus in the deposit was reduced.[35]

For application in electronic packaging, palladium and its alloys have also been developed as an economic alternative to gold plating. Even though palladium and gold differ in some of their properties, as listed in Table 6, both materials share the noble character of being highly oxidation-resistant. Electroless palladium shares the desirable attributes of electroless plating in general. However, the soldering process will be easier with a very thin layer of gold on the palladium layer (0.025–0.05 μm).[36] For some applications, even without the gold layer, the solderability of electroless palladium is good enough for electronic packaging.[37]

Other than the applications mentioned, palladium can be used as a soldering preservative and as a barrier inner layer in applications where it is plated directly onto copper circuitry. Palladium, like thin deposits of gold, also can be used as a soldering preservative for electroless nickel-plated copper. Palladium is well known for its catalytic properties in the chemical and automotive industries. Although high cost and application difficulties have limited its use, it is suggested that thin films of electroless plated palladium on a ceramic sponge or other support materials could be used effectively as reaction or auto-emission catalysts.[37]

3.15.2.3 Electroless Gold Plating

The advantages of gold deposition by electroless means are the same as those of EN and electroless palladium. There are a number of formulations available. Many of these have been used in commercial applications, with careful attention being given to bath monitoring and control. Several of the gold salt sources used are potassium gold cyanide, gold chloride, and gold sulfite. By far, potassium gold cyanide is the most common source.[37] Because the gold solution normally contains cyanide compounds, extra precaution is needed in the process and waste treatment of the plating solutions.[12,19] The reducing agents used are also as diverse as the gold source, such as sodium hypophosphite, dimethylamine borane, sodium borohydride, hydrazine, and benzyl alcohol.[37] The formula in Table 7 is reported to plate at a rate of 12–17 μin h^{-1} at 70 °C. The rate is dependent on the benzyl alcohol concentration. A gold film of approximately 35 μin (0.87 μm) requires 2 h immersion in the bath.[38]

Table 6 Comparison of properties, gold versus palladium[37]

Property	*Gold*	*Palladium*
Color	Yellow	Silver/white
Crystal	Face-centered cubic	Face-centered cubic
Resistivity	$2.2 \times 10^8\ \Omega$ m	$10.5 \times 10^8\ \Omega$ m
Magnetic	Diamagnetic	Paramagnetic
Density	19.3 g ml^{-1}	12.0 g ml^{-1}

Table 10 Effect of palladium acetate on deposition rate and purity[9]

Bath	*Palladium acetate (g l^{-1})*	*Deposition rate (μm h^{-1})*	*Deposited Pd content (wt%)*
1	0.1	0.2	0.04
2	0.5	0.4	0.04
3	1.0	1.0	0.08

When the substrate is immersed in the plating solution, the first reaction is immersion; then, once the substrate is covered with gold, autocatalytic reduction takes place. The electroless gold is deposited as the benzyl alcohol is oxidized. Most electroless gold plating processes require a separate gold immersion deposit, which provides adhesion for the subsequent gold layer and avoids contamination of the gold plating bath, particularly by nickel.[37] In a study conducted by Ikuhiro *et al.*,[15] the plating process of gold consists of two steps. The first step is immersion gold to produce a gold thickness from 0.05 to 0.1 μm, followed by electroless gold plating to produce a gold thickness more than 0.1 μm. Table 8 lists the formula for immersion gold and electroless gold, as used by Ikuhiro *et al.*[15]

Hassan and Ian[9] listed various types of electroless gold plating recipes based on publications at that point in time. From their findings, they developed three formulations for an electroless gold plating bath with minimal agitation requirements because it is not possible to apply vigorous agitation during electroless plating on the complex geometries

needed by some of the available formulations. The first two formulae could deposit up to 2 μm h^{-1} of gold. The substrate used was gold film produced either by electroplating or by vacuum deposition. Table 9 lists the formulations.

The first formula explores the use of the palladium complex as a reductant. Palladium acetate was considered in this study. Table 10 lists the deposition rates of formula I with variable amounts of palladium acetate.

The deposition rate for formula I increases with higher palladium concentration. However, the high cost of palladium acetate mitigates against the use of higher palladium contents. The deposit obtained from this solution was smooth, reflecting the substrate contours, and had a matte, lemon-yellow appearance. However, the bath was not completely stable and decomposition started within approximately 3 h of operating temperatures. Nevertheless, on a small scale, the plating was successful prior to the decomposition process.[9]

Formulas II and III were based on Okinaka's research.[39,40] In formula II, it was found that the decomposition commenced within 1 h of the solution's working life. The initial deposition of 2 μm h^{-1} rapidly decreased with decomposition. It was found that the cyanide increase would help to reduce the rate of decomposition. However, the increase of cyanide also reduces the deposition rate. In formula III, modifications have been made by adding another two stabilizers, EDTA, and ethanolamine. This helps to increase the deposition rate without decreasing the bath stability. The formula was able to produce a consistent deposition rate of 1.5 μm h^{-1} over the course of the 8 h working day. Studies indicated that depletion of the gold content in the bath of up to 50% could be tolerated with no significant reduction in the gold deposition rate.[9]

In the electronics industry, the selection of either electroless or immersion gold plating depends on the final thickness of the gold layer needed for the surface finish application. There are also cases, as mentioned, in which the immersion and electroless solutions were used consecutively. For example, in the EN/immersion gold surface finishes, the three most common failure modes are porous gold, gold embrittlement, and black pad.[41] All of the three mentioned issues are highly related to the mechanisms of gold plating. Therefore, stringent selection of the gold plating solution and the option of immersion or electroless are important and will determine the quality of the surface finish produced.

3.15.3 Conclusion

The literature review indicates that numerous attempts have been made to identify the best formulations and parameters that affect the performance of the three main electroless solution types used in the electronics industry, which are EN, electroless palladium, and electroless gold. The benefits of electroless plating are well understood and discussed; just like any type of processing, it has its own advantages and disadvantages. One type of plating bath may not be suitable for all applications, even in the same field of electronic packaging. Further investigation needs to be conducted to modify, fine-tune, and stabilize the formulations to obtain the necessary final product.

3.16.1 Introduction

Machining has become main shaping process used in manufacturing of engineering components throughout history. In any machining technology, there is a need for the tools to last long, operate smoothly, and ensure the requested quality of the product (smooth surface, dimensional stability). Thus cutting tools are essential in any machining operation. Due to high competitiveness, tool users are forced to increase tool lifetime, productivity, product quality, and to decrease lubricant consumption. These goals can be partly achieved by modified tool geometry, machining parameters, or tool material improvements. The latter approach has quite strong limitations. Namely, the tool has to be ductile to prevent fracture and hard to decrease tool wear. However, high ductility and high hardness are basically contradictory demands – a material is either hard and with poor ductility, or vice versa. A solution of this problem is to protect the tool made of ductile material (e.g., tool steel) with hard coating. The former ensures resistance to fracture, while hard coating protects the cutting edge against abrasive and mild adhesive wear. Hard coating also reduces the tool temperature by reducing the friction between chip and rake face of a tool. Additionally a relatively low chemical reactivity of coating with workpiece materials ensures protection against welding and thus reduces the adhesive wear. The result of all these effects is that coated tool can operate at higher cutting speed and higher feed rate. Thus hard coating expands the safe zone of cutting tools by minimizing the builtup formation (BUE) and crater wear. Hard protective coatings with high hardness, good resistance to wear, and oxidation, are predominantly transition-metal nitrides with a coating thickness of a few micrometers. Hard protective coatings, deposited by physical vapor deposition (PVD) and chemical vapor deposition (CVD) are the subject of this chapter.

The progress in cutting tool materials, coating techniques, and machine tools has paved the way for machining of materials at higher cutting speeds, higher feed rates or in hardened state. Hard machining operations have potential to be an alternative to grinding and electrical discharge method (EDM) due to their high productivity and flexibility and low environmental waste formation.[1,2] It is important that a workpiece material has good machinability. A workpiece material with high machinability would be described by its low cutting forces, high material removal rate, good surface integrity, precise workpiece dimensions, and low tool wear rate.[3] Hard coatings contribute improvement of these characteristics of machinability.

Carbide tools among other cutting tool materials are frequently preferred in many metal cutting processes owing to their high toughness and satisfactory hardness. However, due to high cutting forces, high contact pressures, high temperatures, and intensive chemical attack at cutting zone in machining process of difficult-to-cut materials[4] (such as hardened steels or nickel and titanium based aviation materials), it is difficult to keep the wear of carbide cutting tools at low level. Notwithstanding that carbide tools have relatively lower cost and higher toughness than Cubic boron nitride (cBN) tools, very often cutting tool change as a result of early tool wear leads to an increase of machine tool run-down time, which affects productivity and manufacturing costs.[5] Therefore, carbide tools need to have high hardness and high oxidation resistance to obtain long lifetime in hard machining, high speed machining, and dry cutting applications. One of the methods used to increase lifetime and thereby machinability of hard materials is deposition of hard coatings on cutting tools. In order to assure performance increase in carbide tools, first TiN, and then TiAlN based thin films, which have high wear resistance and high performance under corrosion or high temperature conditions, was developed.[4,6–8] TiAlN based coatings have frequently been used in dry cutting operations due to the fact that they keep their one phase cubic structure and have high oxidation resistance at cutting processes where temperatures higher than 800 °C comes out.[9,10] In recent years, with

 doi:10.1016/B978-0-12-803581-8.09178-5

development of nanolayer and nanocomposite coatings, superior properties in hard coatings has been obtained.[11–14] Basic characteristics of these advanced hard coatings are high microhardness and toughness together with high adhesion to substrate.

In this chapter, hard coatings deposited on cutting tools will be introduced. After design and production methods are summarized, the effect of hard coatings on surface roughness, cutting forces, and residual stresses will be explained.

3.16.2 Hard Coatings

Hard coatings are thin films which are deposited on tool substrates in order to improve their desired properties such as hardness, friction, wear resistance, and corrosion resistance, while not changing properties of the bulk material.[14] From a functional point of view the most important coating properties are hot hardness, good adhesion to the substrate, and chemical stability. The coating performance can be further improved by optimum coating thickness, fine microstructure, and compressive residual stresses. These properties can essentially be fulfilled only by ceramic materials. In practice, the choice is limited to transition metal nitrides and partly carbides and oxides. Such materials can be reliably deposited in a thin film form by CVD or PVD techniques. In contrast to the CVD methods, the starting material for PVD process is a solid (e.g., titanium), while the volatile elements are usually added as a gas (e.g., nitrogen). The PVD hard coatings have a certain advantages: low deposition temperature preserves cemented carbide toughness, they can be applied to sharp cutting edges, compressive residual stress inhibits microcracks, they have finer grains (smoother surface), higher microhardness, non-equilibrium compositions which are not possible with CVD, their deposition is environmentally clean process.[15,16] The limitations of PVD hard coatings are: thickness limitation due to residual stress, worse adhesion in some cases. Additional drawback is that PVD deposition process is line of sight and hence very complex geometries cannot be coated evenly. In its basic concept a homogeneous (single layer) coating is deposited on the substrate (**Figure 1(a)**). In some cases double layer coating is recommended to be used (**Figure 1(b)**). Thus we can combine for instance the bottom layer having a high hardness (high wear resistance) and the relatively soft top layer with a low friction coefficient. A gradient coating can also be used instead of two discrete layers (**Figure 1(c)**). As an example is TiCN coating, in which the ratio between carbon and nitrogen atoms changes during deposition process. The double layer structure can be repeated several times to achieve a multilayer coating (**Figure 1(d)**). The individual layer thickness can be lowered below 10 nm (while increasing the total number of layers to several hundred). Such a structure is called a nanolayer coating (**Figure 1(e)**). Yet another concept is possible, where during deposition process a two-phase structure (nanocomposite) is formed (**Figure 1(f)**). In these coatings, one phase segregates to the grain boundary of the second phase, where the size of the grains is in the nanometer range. Nanocrystalline TiN embedded in amorphous SiN_x can be given as an example to nanocomposite coatings.[14] Nanostructured coatings generally have higher hardness when compared to conventional coatings.

In the end of 1950s, high speed machine tools started to be used in order to increase machining productivity. However, high cutting speeds or high depths of cut led to the increase of forces at cutting zone and the increase of temperature together with friction and therefore a decrease of cutting tool lifetime. In consequence of researches performed to obtain higher tool life, higher cutting performance, and lower machine tool run-down time, hard coatings such as TiN and TiC started to be deposited on cutting tools by CVD method in the end of 1960s. The CVD coating process is still highly efficient on cemented carbide cutting tools. Due to high deposition temperature (higher than 800 °C) and thermal stresses occurring at coating-substrate interface, CVD technology was unable to transfer to high speed steel (HSS) or other common engineering alloys.[15,17] In the beginning of 1970s, this obstacle was overcome by development of PVD method which provides deposition of hard coatings at temperatures lower than 500 °C.

The first hard coating deposited by PVD method successfully was TiN. Soon after, it was noticed that addition of other elements to the TiN provides enhancement in mechanical and oxidation properties of this coating. As high wear and oxidation resistance, TiAlN coating was used in protection of cutting tools in high temperature cutting applications and today it is still the most commonly used hard coating. PVD process proved to be very flexible due to the fact that it allows deposition of three or more ingradient material at various stoichiometry.[14]

Historical development of hard coatings can be summarized as below:

- In the early 1970s the first CVD hard coatings (TiC) were applied to cemented carbide tools.
- 1975 – first CVD multilayer hard coating combining TiC, TiN, and TiCN layers.
- 1980 – CVD multilayer coating, combining TiC, TiCN, Al_2O_3, and TiN layers.

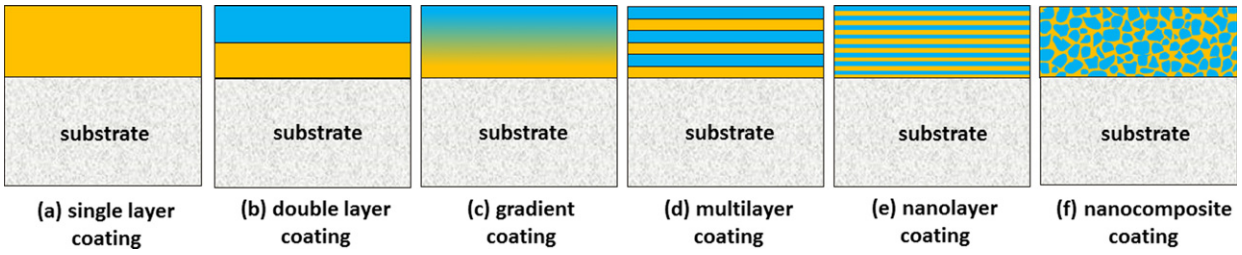

Figure 1 Design of hard coatings.

- 1980 – first low temperature PVD TiN hard coating was first proven on HSS tools.
- 1985 – low temperature PVD TiCN hard coating with gradient composition.
- 1990 – low temperature PVD TiAlN hard coating.
- 1995 – CVD diamond coating multilayer PVD hard coatings (ml–TiN/TiAlN) PVD TiB_2 coating TiAlN/WC–C low frictional PVD hard coating.
- 2000 – first nanolayer coatings (the individual layer thickness can be lowered down to only a few nanometer.
- 2005 – PVD AlCrN first nanocomposite coatings PVD Al_2O_3 coatings.
- 2010 – PVD oxynitride coatings.

Hard coatings are deposited on tools (such as cutting or forming tools[18]) and machine components (such as gears, bearings). Here the goals are to extend their lifetime, to decrease lubricant consumption, to increase productivity and/or to provide machining of new materials. Thus, hard coatings have become an integral part of modern tool technology, and many researches have been dedicated to development of better coating materials and new deposition techniques. The contact between cutting tool-workpiece pair determines the wear resistance of a coating. There is no coating which is universal for each tribological situation. Therefore, various coatings have been improved for certain applications. Nowadays, researches focus on diamond-like carbon (DLC) and oxynitride coatings together with nanocomposite and nanolayer coatings which are applied in industrial manufacturing. Researches continue for coating materials giving better performance in a wide application field.

3.16.2.1 Hard Coating Materials and Design

Production of hard coatings has been carried out using various materials and material combinations until today. As hard coating material, generally, nitrides, carbides, borides, and oxides of transition metals are used. The nitrides used as cutting tool coating material are TiN, TiAlN, CrN, ZrN, TiSiN, TiAlSiN, CrAlN, TiAlCrN, and cBN; carbides are TiC, CrC, and WC.[14,19] TiB_2, is used due to its high hardness and chemical inertness, can be given an example to boride coatings.[20] Al_2O_3 of oxide coatings is among widely used coatings today. DLC, MoS_2, and WC–C are the other coatings used on cutting tools due to their low friction characteristics and they are preferred in other tribological conditions such as gears and bearings.[21,22]

According to the used cutting tool material, workpiece material, and machining method, the ingredients to be used in a coating are determined with the aim of increasing the performance of the cutting tool. Common hard coating properties which should be fulfilled at the cutting edge under operating conditions (high stress and temperature) are[14]

- Good adhesion to the substrate, and between the layers in the case of multilayers (good adhesion to the substrate is a necessary condition for satisfactory performance of the coated tools),
- High hardness at working temperature (hot hardness) of the tool (hard coatings contribute to increased abrasive wear resistance),
- High toughness (coating fracture toughness is as important as hardness),
- Chemical stability and inertness against workpiece material (low solubility of coating material in workpiece material at temperatures encountered during machining),
- Fine-grained microstructure (grain size, grain structure, and grain- and phase boundaries affects the mechanical properties),
- Good oxidation resistance,
- Low coefficient of thermal conductivity for heat to dissipate into the workpiece,
- Coating morphology (relatively smooth PVD hard coatings provide lower cutting forces and ensures better surface finish on the machined part),
- Low friction coefficient,
- Crack retardation by compressive stress,
- Optimal thickness (If it is too thick, then we lose the sharpness of the cutting edge, while thin coating means low wear volume).

There is no hard coating which has all of these properties. Depending on application conditions, some properties of the coating is provided to come to the fore.[23] The early generation of PVD coatings (TiN, TiCN) is still effective at normal machining conditions for carbon and alloys steels. But as speed is increased TiAlN type coatings should be applied due to its better stability at high temperature.[22] TiAlN coating has high oxidation resistance and thermal stability[24] and optimum properties were obtained at 60–70% Al content.[25] As AlTiN coatings are in tendency to transform to cubic hexagonal phase at Al concentrations of higher than 65%, those coatings become metastable.[26] Therefore, with Cr addition, the TiAlN coatings maintain cubic B1 structure at 70% Al concentration and the coating shows high oxidation resistance.[27,28] Cr and Y provide enhancement in oxidation and corrosion resistance. Y also leads decreasing of residual stress, contributing formation of a fine grained structure. CrN has high thermal stability and reduces buildup formation in machining of Ti alloys using Ti based coatings.[22] Zr is useful to increase wear resistance. V addition up to a certain value results in the increase of hardness of TiN. Hardness and chemical inertness of TiAlN increases with Si addition. B addition leads to an increase of wear resistance of Ti–Al based coatings and reduces friction coefficient due to its lubricating property. Hf based nitride and carbide coatings provide improvement in flank and crater wear resistance of cutting tools.[24]

3.16.2.2 Deposition of Hard Coatings

Coatings are deposited by three types of processes which compose of gaseous state, solution state, molten, or semi-molten state processes. Two important characteristic parameters for the coating processes are the thickness of the coatings that can be achieved (from 0.1 μm to 10 mm) and the deposition temperature (from room temperature up to 1000 °C). Two basic deposition processes used in application of hard coatings on cutting tools are CVD and PVD. CVD process is a chemical process which is based on introduction of the material to be deposited in gaseous state into a reaction chamber and then condensation of these gases on to the substrate to form a coating at deposition temperatures in the range of 800–1200 °C.

In PVD process, material is vaporized or sputtered from a solid source (target) and that material is deposited on to the substrate to form a coating.[5] The basic idea of PVD is to transfer the material from the source onto the surface of the substrate. One of the basic requirements is a vacuum environment which ensures that the main free path of evaporated species should be comparable to the source–substrate distance. At the same time the vacuum conditions ensures that the coating contains predominantly the target material, with as few as possible impurities from the ambient atmosphere.

There are many methods, how to release the atoms from the solid target. In evaporation, the atoms are released from the target by heating. In vaporization process, target material is vaporized by one of these methods; resistance evaporation, induction heating, electron beam evaporation, cathodic arc evaporation, or laser beam evaporation. Thereby it is not necessary to reach the target material boiling point. Instead, the target material vapor pressure should be high enough to enable a vapor pressure of about one, which is in standard metals mostly achieved below the melting point. The process is called 'evaporation.' PVD is a line-of-sight process, thus only the surfaces directly exposed toward the source are coated. Due to the geometrical shadowing effect the shaded areas are generally not coated.

In sputtering process, target material is vaporized by bombardment of inert gas ions such as argon. The target atoms can be ejected from the target surface by an elastic collision. General sputtering methods are diode, magnetron, and ion beam sputtering.[5] In the case of diode configuration we ignite plasma between anode (substrate) and cathode (target). This is done by supplying a suitable voltage between the cathode and the anode (about 1 kV) at a suitable pressure (about 1 Pa) of a working gas (typically argon). At these conditions, argon is ionized and these ions bombard the cathode surface with energy of up to 1 keV in our case. Each collision ensures that a few target atoms are ejected from the surface; they reach the substrate surface where they grow as a coating. This process is called 'sputtering.' Diode sputtering is simple but not technologically useful due to low deposition rate ($\sim \mu m\ min^{-1}$) and high temperature of substrates. There are several methods to enhance the ionization of the plasma and thus increase the deposition rate. The most common option is the magnetron sputtering. A magnetron is a device with circularly arranged magnets which form a closed loop of magnetic field, a kind of a magnetic bottle. If a magnetron is placed as a cathode behind the target, this configuration traps the electrons within the closed loop, just above the target. This ensures strongly ionized plasma, which causes heavy bombardment of the target, which in turn provides a high deposition rate. One of the main advantages of magnetron system is the very wide range of materials that can be deposited. PVD processes are also classified according to power sources used in deposition process. In its basic form it is supplied by direct current (DC), at a constant voltage, which is used for deposition of conductive materials. For insulators, an AC power supply is necessary, usually in the radio-frequency (RF) or medium-frequency (MF) regimes. For thermally sensitive materials, a useful compromise is a pulsed-DC mode. It enables a relatively high ionization during the pulse-on phase, and a relatively long pulse-off time allowing the material not to overheat. Recently, short or high power pulsed power sources have been developed. Very high ionization can be obtained with this kind of power sources.[29]

Magnetron sputtering of PVD methods has shown a rapid development. As a result of demand on very quality functional coatings in various sectors and especially in manufacturing processes such as high speed machining and hard metal cutting, recently, magnetron sputtering method is widely preferred in production of many coatings used in industry. The most common coatings deposited by magnetron sputtering method are hard, wear resistant coatings, low friction coefficient coatings, corrosion resistant coatings, decorative coatings, and special optical or electrical property coating.[30] In many cases, the coatings deposited by magnetron sputtering have superior properties than coatings deposited by other PVD processes and have the same function with thicker coatings produced with other surface coating techniques.

3.16.2.3 Multilayer Hard Coatings

Multilayer protective CVD coatings have been deposited on cemented carbide cutting tools for many years. The first multilayer hard coatings were composed from TiC, TiCN, and TiN. Later Al_2O_3 layer was added in such structure. The layers in PVD processes are formed by deposition of coating materials sequentially from different targets. Three different principles are applied for deposition of layered coatings in PVD techniques: (1) sequential switching between two or more sources, (2) rotation of substrates along different spatially separated sources, and (3) changing reactive gas flow.[31] Nowadays, changing output voltage of plasma generator in high power pulsed magnetron sputtering method, the layered structures of the same material can be obtained.[32]

With deposition of multilayer coatings by creating proper material combinations, wear, corrosion, and oxidation resistance of hard coatings have been improved. The first multilayer coating was produced by CVD and then PVD method. Nowadays, multilayer structure is used in most of coatings used industrially.[33,34] The goal of multilayer coatings is to enhance properties and performance of the coating by combining positive characteristics of different coatings. As multilayered sandwich structure provides an increase in coating toughness by means of deflection and branching of the crack energy between layers,[35] the usage of this structure has been useful in cutting processes, for example, milling, where high dynamic loads exist. TEM image of a multilayer CrN/TiAlN coating deposited by magnetron sputtering is given in **Figure 2**. Using a multilayer structure, the columnar structure forming in single layer coatings can be prevented.

Main advantages of multilayer coatings are: (1) Adhesion of a coating to the substrate can be increased[36] and interface layers can be used to provide a gentle transition from coating properties to substrate properties. (2) Sequentially depositing several thin layers with various mechanical properties, stress concentration, and crack propagation conditions can be changed. In the case of a crack formation on coating surface, the crack energy is decreased by deviation and branching of the crack. Conversely, single layer coatings show less resistance to the crack growth. As shown in **Figure 3**, the crack propagates easily onto substrate/cutting tool surface and wide coating

zones are damaged. (3) With deposition of coating layers on the surface, which have individually different properties, for example, corrosion resistance, wear resistance, thermal insulation, electrical conductivity, diffusion barrier, and adhesion to the substrate, the properties of diverse property layer can be improved.[31]

3.16.2.4 Nanolayer Hard Coatings

Nanolayered coatings have excited researchers interest after very high hardness increment obtained in nanolayer TiN/VN coatings.[37] Main reason of the increase in hardness and strength of a nanolayer coating was found to be a large number of interfaces between layers. The change of coating hardness with layer thickness is shown in Figure 4. Maximum hardness was obtained at 5–10 nm bilayer period thickness. In addition, in this bilayer thickness range, the columnar structure seen in single layer coatings was found to change in multilayer superlattice coatings, for example, nanolayer TiAlN coating.[24]

In literature, the difference between multilayer coatings and nanolayer coatings is not described definitely. Generally, high hardness (superhardness) values obtained in nanolayer coating configurations distinguish them from multilayer coatings. The hardness of nanolayer coatings is not equal to average hardness of materials constituting the coating, while the hardness of a multilayer coating is equal to average hardness of materials constituting the coating. Superhardness is commonly seen at layer thickness of 3–10 nm and typically not seen at thickness values higher than 10 nm. An example of the typical nanolayer coating is shown in Figure 5.

The hardness increase in nanolayer coatings is provided by means of interfaces as stated above. Several theories for the

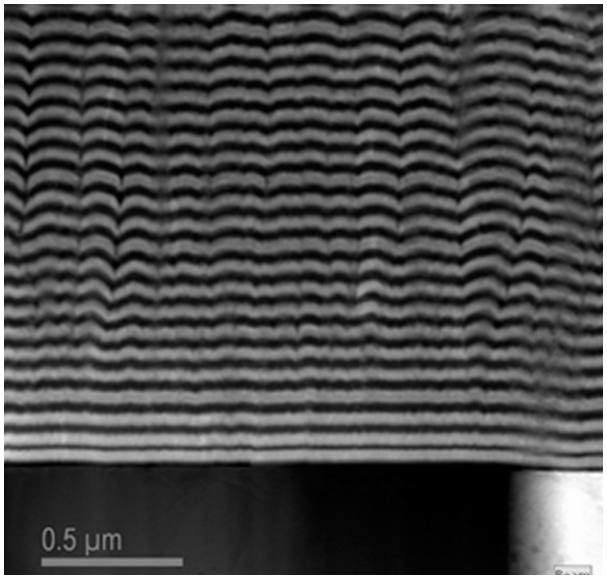

Figure 2 SEM image of CrN/TiAlN layers deposited on a steel substrate.

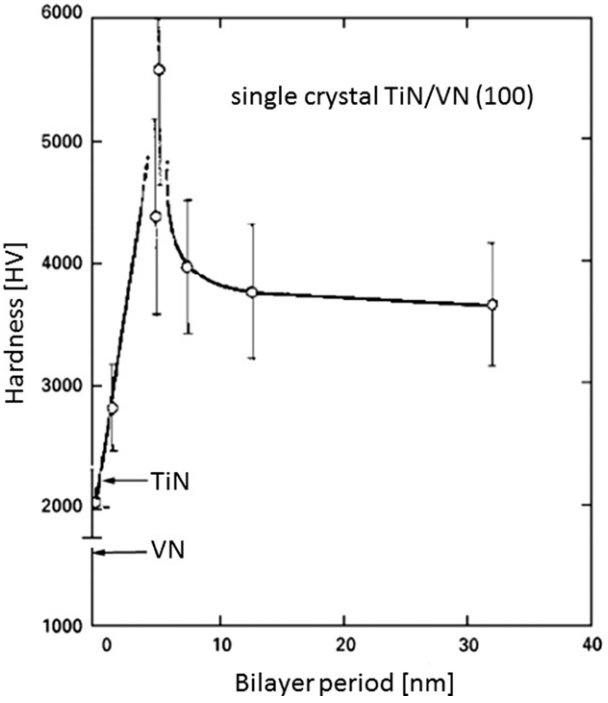

Figure 4 Hardness change of nanolayer TiN/VN coating as a function of bilayer period.[37]

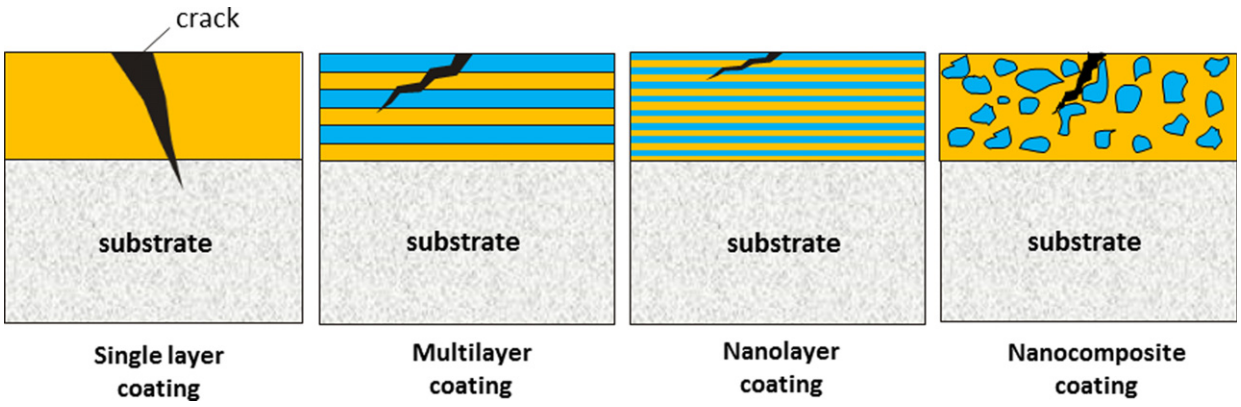

Figure 3 Different crack growths on single layer, multilayer, nanolayer, and nanocomposite coatings.

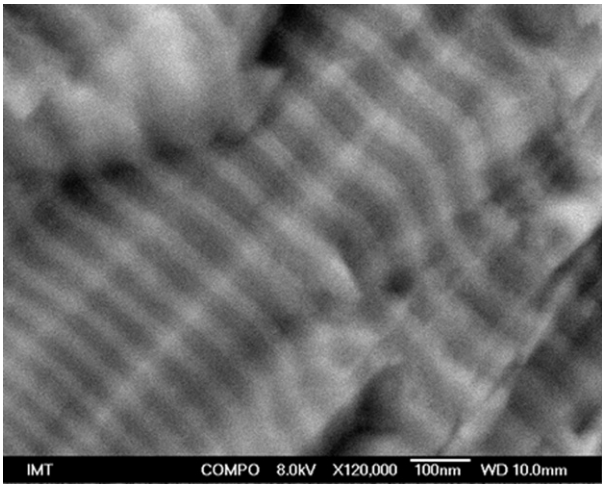

Figure 5 TEM cross sectional image of nanolayer TiN/TiAlN coating.

increase in hardness have been proposed: dislocation blocking by layer interfaces,[38] the Hall–Petch strengthening,[39] the strain effects at layer interfaces[40] and the supermodulus effect.[41] Among these, dislocation blocking has been commonly accepted as a dominant factor in large increase in hardness.[35]

Coating structure plays an important role on fracture toughness of a coating. Nano-multilayer or superlattice coatings are found to show more resistance against microchipping and crack propagation than single layer coatings as shown in **Figure 3**.[24] Moreover, these layers assist to transfer of elements to the surface, which maintains tribo-film formation process in the cutting tool/chip contact region.[42]

3.16.2.5 Nanocomposite Hard Coatings

Nanocomposite coatings are a new generation of materials. A nanocomposite coating composes of at least two phases: a nanocrystalline phase and an amorphous phase, or two nanocrystalline phases.[43] The nanocomposite materials show improved properties due to smaller ($\leq$10 nm) grain sizes compared to those of the conventional materials ($\geq$100 nm). The main property of nanocomposite coatings is an increased hardness. In general more than two times greater hardness can be obtained in a nanocomposite coating compared to that of its harder component. The main reasons of the hardness increase are the dislocation-induced plastic deformation, the nanostructure of materials, and cohesive forces between atoms of neighboring grains.[44]

3.16.3 The Effect of Hard Coatings on Workpiece Surface Finish

In this section, the effect of hard coating application on a cutting tool's performance and the surface finish will be discussed. The relation between hard coatings and cutting process variables and wear mechanisms between tool and workpiece will be explained using experimental results.

The main effects of hard coatings are on surface integrity of the machined material. The term 'surface integrity' is used to describe the attributes of a machined surface (surface topography and properties of subsurface layer) and its relationship to functional performance. Performance characteristics that are most often determined by surface integrity are: fatigue strength, fracture strength, corrosion rate, and tribological behavior (such as friction, wear and lubrication, and dimensional accuracy).[45] A good performance with the machined component can be obtained under service conditions if its surface integrity is high. Thereby, it is highly significant to control the surface integrity in machining processes.[46] Topography, microstructure, texture, surface roughness, metallurgy, hardness, and residual stresses constitute the surface integrity of a machined material.[47] In the following sections, the effect of hard coating on mainly surface roughness and residual stress will be explained.

As stated repeatedly, performance of cutting tools can be enhanced by deposition of a hard coating on tool surfaces. Main reasons for this enhancement are the reduction of adhesion effects between coated tool and workpiece materials, an improvement of abrasive wear resistance, the reduction of the cutting temperature[48,49] and an improvement of the inertness against tribo-oxidation. In addition, an improvement of chip flow can be obtained by a coating with low friction coefficient. The sum of the protective effects provides several times longer tool life than that of uncoated tools and also an increase of machining parameters.[16] The hard coatings enable higher cutting speed and increased tool life, while keeping other cutting conditions the same as with uncoated tools.

Cutting tool dimensions are quite important in terms of workpiece surface finish. The dimensions of component must be maintained during machining to produce accurate parts and to carry out an economically viable process.[48] The tool geometry have been reported to have influence on performance parameters such as surface finish, tool wear, residual stress, white/dark layer, chip form, heat generation, cutting forces, and microhardness variations.[50] Cutting edge profiles of a cemented carbide inserts in turning of Ti6Al4V alloy at cutting speed of 150 m min^{-1} after removal of different volume of material are given in **Figure 6**. It is clearly seen from the figure that the geometry of the cutting edge changes as a result of tool wear on flank and rake faces of the tool due to the mechanisms of abrasion, adhesion, and dissolution–diffusion. Such a geometrical change on the tool results in the increase in cutting temperature and cutting forces, leading to further diffusion wear and buildup edge formation.[51] The most important functions of the hard coating are the separation of the tool material from the counter-face workpiece material (lower diffusion wear) and to reduce wear by hardening the top layer of the surface. Protection of cutting tool with hard coating provides better surface integrity as well as longer tool life when compared to uncoated tools.

To achieve maximum metal cutting productivity, the thickness of the coating has to be optimized. Typical thickness of CVD coatings are 10 μm, while the thickness of PVD coatings are usually less than 5 μm. The thickness of a coating deposited on cutting tools has an influence on the cutting performance. Thickness of a coating, deposited by magnetron sputtering, on the rake and flank face of a cutting tool can be seen on cross-sectional image of the coated tool in **Figure 7**. According to the figure, nose radius of the uncoated tool can be seen to increase

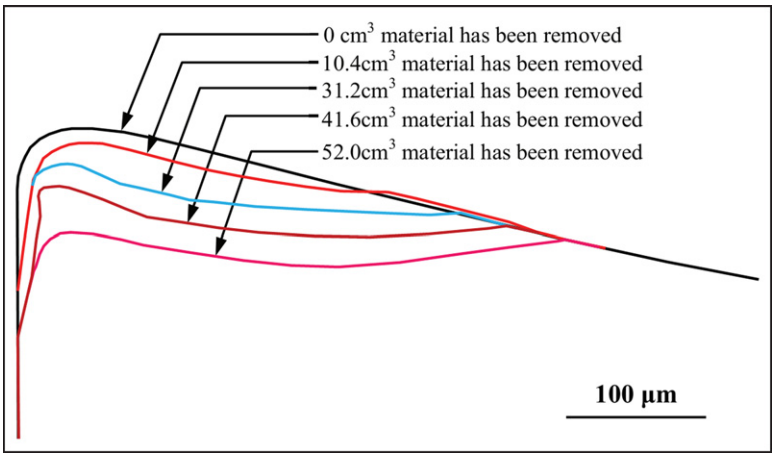

Figure 6 Cutting edge profiles of cemented carbide inserts after different volume of material (Ti6Al4V) have been removed by turning (cutting speed: 150 m min^{-1}).[51]

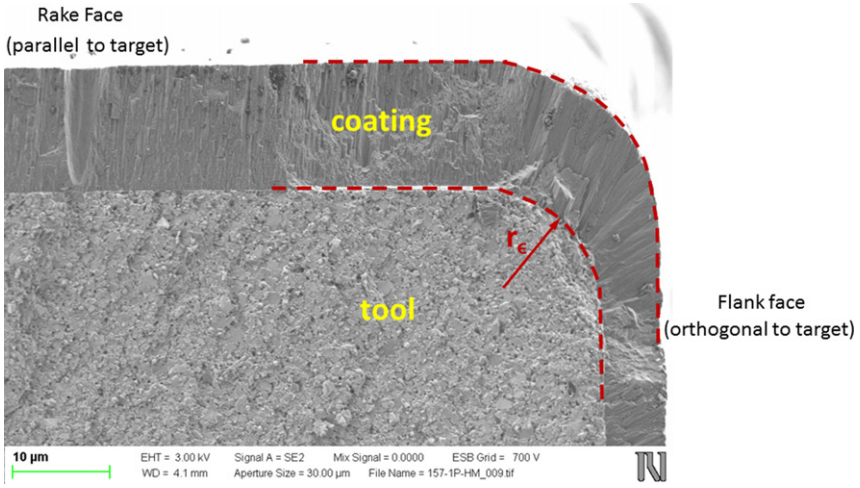

Figure 7 SEM micrograph of cross-sections from a coating grown by magnetron sputtering.

after coating deposition process. This means a geometrical change on the cutting edge. The increase in nose radius of the tool makes cutting tool motion in workpiece difficult, leading to higher cutting forces and temperatures. The higher cutting temperature is the shorter tool life. On the other hand, the extent of the effect of nose radius on cutting forces depends upon the machining condition.[52] If the nose radius is smaller than uncut depth of cut, chip formation occurs easily; otherwise surface roughness may worsen as a result of vibrations.

Besides its effect on nose radius, the thickness of hard coating on cutting tool's rake and flank surfaces are also significant. Due to the configuration of magnetron sputtering process, coating deposition rate is higher on the rake face, which is parallel to target, than the flank face which is orthogonal to target. As well known, thicker coating provide longer lifetime to cutting tools. The thickness value on each tool face should be taken into account to obtain expected tool performance and surface finish. Recently, with developments in magnetron sputtering technique, for example, high power pulse magnetron sputtering, uniform coating thickness can be obtained on tool surfaces.[53]

In addition to the effect of coating thickness on cutting forces and chip formation, the relation between coating's strength and thickness has great significance. Qin *et al.* reported that the residual stresses at the coating–substrate interface will increase with increasing coating thickness. On the other hand, they stated that the increase in coating thickness will commonly raise the resistance of coating cracking and delamination. They obtained longer tool life with diamond coated tools with coating thickness for the thickness range tested due to delay of coating delamination.[52]

Performance of a coated tool is also affected by roughness of the hard coating. The surface topography of hard coatings depends on the topography of bare substrate and the topography induced by the coating deposition process. When tool surface is covered by a hard coating, the surface roughness alters to some extent, depending on the deposition method. During machining scratching of the hard asperities in the

counter-face often occurs and this has the effect of increasing friction and wear. Therefore, the heat generating between the rake face and chip, and between the flank face and finishing face as a result of friction during cutting increases when surface roughness of a coating is high. The highest cutting temperature was obtained with TiAlN/AlCrN among four kinds of coating films, for example, TiN, TiCN, TiAlN, and multilayer TiAlN/AlCrN in milling of hardened steel.[54]

The BUE is one of the principal factors adversely affecting surface finish. It is commonly observed at relatively low cutting speeds. The gradual growth and rapid decay of the size of the BUE causes a saw toothed surface, which is characteristic of the BUE component of surface roughness. In addition, the cutting tip becomes larger and the desirable diameter of the workpiece changes when a builtup-edge is present.[55] The hard coatings with lower friction coefficient prevent sticking of workpiece material on cutting tool edge and provide enhancement in surface quality of machined parts. Due to the fact that DLC coated tools have an excellent smooth surface of $R_a = 0.01$ μm, a low friction coefficient ($\mu = 0.1$) and an excellent anti-adhering property, the formation of builtup edge were prevented in machining of aluminum alloys. Thus, the sharpness of the cutting edge could be maintained, which reduces cutting resistance approximately 50%, and improves the machinability.[56] According to FEM simulations for milling of AlMg2.5 alloy given in **Figure 8**, it seen that chip formation and cutting temperature is affected by DLC coating. In case of DLC coating, a higher chip flow speed was obtained as a result of low friction coefficient of such coating, which produces a large shearing angle, a decreased thickness of chip, and a smaller curl diameter. On the other hand, in case of uncoated cemented carbide tool, the chips were observed to be not susceptible to curl due to higher friction coefficient of the tool.[56]

It was reported many times that hard coatings reduce cutting forces and power consumption due to lower friction coefficients on the rake face of the cutting tools.[57] **Figure 9** clearly designate the influence of hard coating on average cutting force during milling test with CrTiAlN coated and uncoated tools. The cutting forces of uncoated tool increase drastically with the increase of cutting distance, especially at earlier cutting distances. When compared to cutting forces obtained with uncoated tool, that of CrTiAlN coated tool was seen to be much lower and remains stable after a certain cutting distance. It is clearly understood that main reason of reduction in cutting forces and stable milling process is low friction coefficient of CrTiAlN coating.[58]

The influence of DLC coating on cutting forces in machining of AlMg2.5 alloy is shown in **Figure 10**. The principal force, the feed force, and the back force were found to be less for the DLC coated tools than the uncoated ones in all

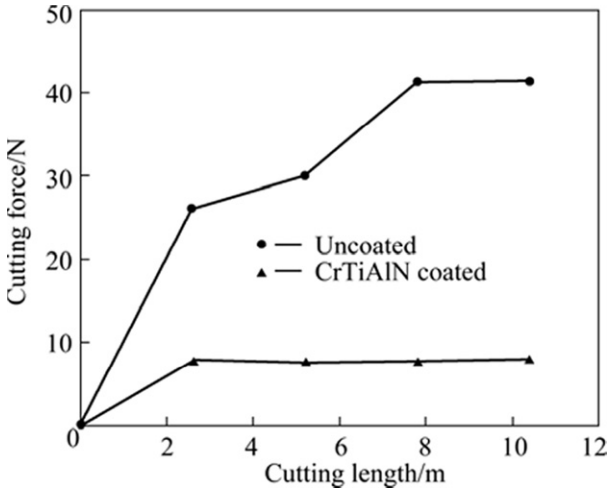

Figure 9 A comparison of cutting force as a function of cutting length during milling test with CrTiAlN coated and uncoated tools.[58]

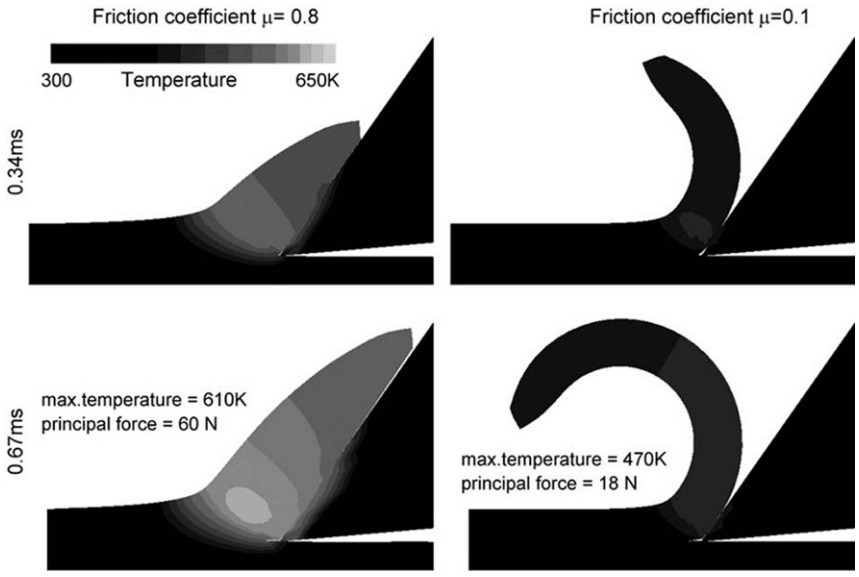

Figure 8 FEM simulation results of types of chip and contours of temperature for AlMg2.5 alloy milling test ($V = 300$ m min^{-1}, $f = 0.15$ mm rev^{-1}, depth of cut 1 mm, lubrication: dry).[56]

cutting tests. In addition, the cutting resistances of DLC coated tools under dry conditions were less than uncoated tools under wet conditions.[56]

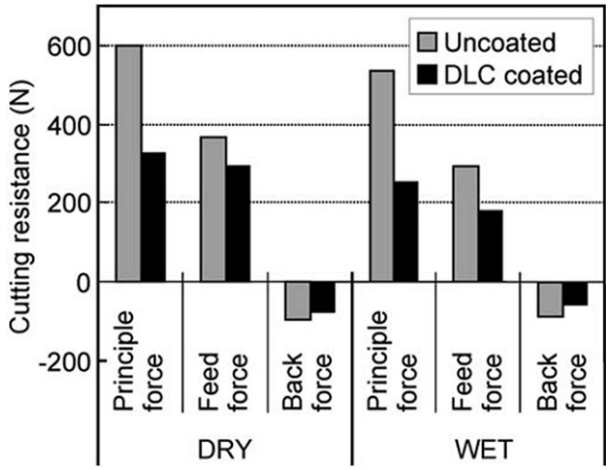

Figure 10 Cutting forces were obtained by averaging the cutting force signals for three teeth during AlMg2.5 alloy machining ($V=300$ m min^{-1}, $f=0.15$ mm rev^{-1}, $a_p=a_e=5$ mm, lubrication: dry).[56]

3.16.3.1 Surface Roughness of Machined Parts

Effect of machining conditions on surface roughness of machined parts is presented in fishbone diagram in **Figure 11**. Surface roughness is affected by many of parameters (nose radius, tool shape, tool material, chip formation, friction in the cutting zone, cutting force variation) and hard coating can be regarded as one of the most important due to its effect on all these parameters. As explained in previous sections, hard coatings as a surface part of a cutting tool material provide improvement in wear resistance and friction characteristics. When considering nose radius, the nose radius increases with the increase of hard coating thickness, resulting in a decrease of surface roughness and an increase of cutting forces. On the other hand, a hard coating protects the shape of cutting tool with higher wear resistance and provides regular chip formation and lower cutting forces as a result of low friction coefficient on the surface.

A better surface roughness with a TiN (PVD) coated cutting tool was obtained in machining of cold-formed carbon steel C15 E4 steel.[60] In face milling of hardened AISI O2 steel using nanolayer AlTiN/TiN and multilayer nanocomposite TiAlSiN/TiSiN/TiAlN coated tools, it was seen that optimum surface roughness changed depending on coating type.[61] A better surface finish was obtained with a-CN/TiAlN coatings after first

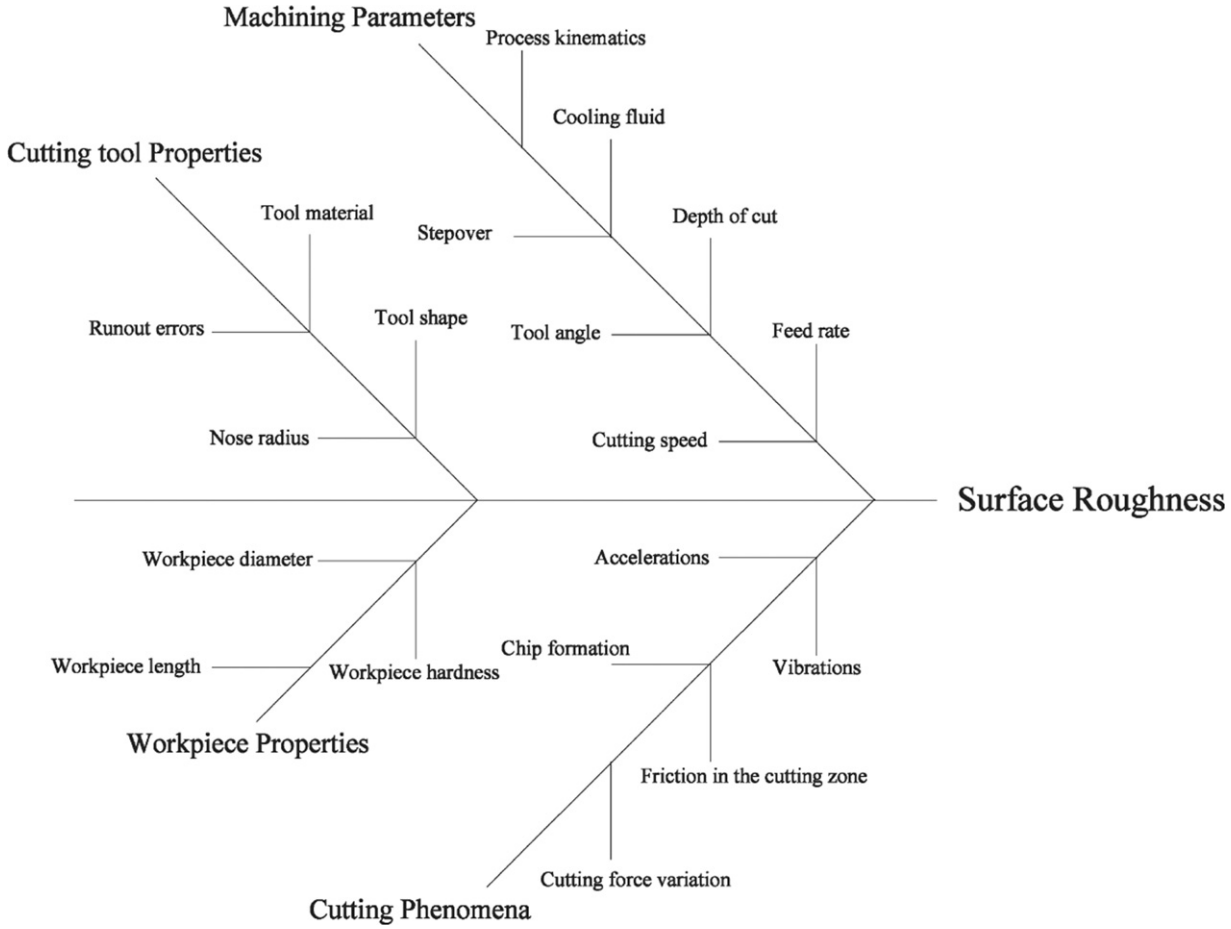

Figure 11 The parameters that affect surface roughness.[59]

pass in face milling of Ti6Al4V alloy. After removal of softer a-CN layer, surface roughness was observed to be similar to that of commercial TiN/TiAlN coated tools.[62]

DLC coatings have excited researchers due to its low friction coefficient and high wear resistance. Under dry conditions, the machined surface roughness of $AlMg_{2.5}$ and $AlCu_{4.5}Si_{12}$ alloys was decreased to about one half using DLC coating as presented in Figure 12.[56]

According to turning test results on the gray cast iron workpiece (260 HB), a lower surface roughness and a higher surface quality were obtained with the coated ceramic tools deposited by PVD or CVD methods, especially in the finish machining process. The uncoated tool gave the highest surface roughness (sample 0). In the case of coating systems (TiN + TiAlSiN + TiN), sample B, and TiCN + TiN (sample F) (Figure 13), a minimum roughness of $R_a = 2.3$ μm was obtained at finish turning. The roughness parameter R_a lower than 2.5 μm was obtained at finish turning for all coating systems, except TiAlN (sample E) and $TiN + Al_2O_3$ (sample G).[63]

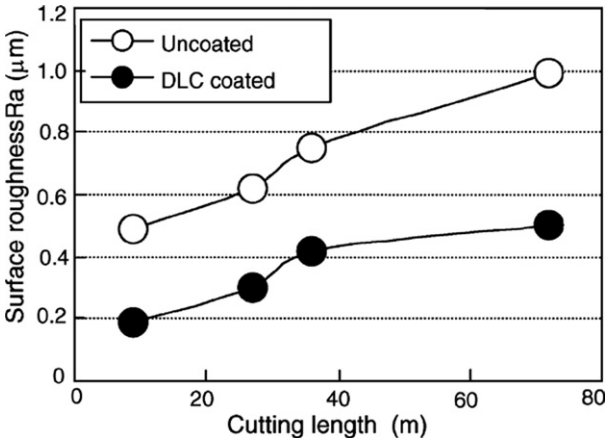

Figure 12 Surface roughness as a function of cutting length during dry machining[56] of workpiece material (AlCu2.5Si18 alloy) using uncoated and DLC coated inserts.

cBN is also a promising coating material due to its higher hardness and wear resistance. Uhlmann *et al.*[64] deposited cBN coating (1.4 μm thickness) on carbide tools. TiAlN was used as interlayer. During machining of Inconel 718 with TiAlN monolayer and TiAlN + cBN coated carbide tools at cutting parameters given in Figure 14, lower roughness and lower resultant cutting force components was obtained with latter ones.[64]

A comparison of cBN tool and coated carbide tools was performed by Okada *et al.*[54] In the case of milling of hardened steel with coated carbide tools, rougher surfaces were generated than those with cBN tools. This was attributed to the difference in roughness of the cutting tool surfaces. Accordingly, smaller workpiece roughness values were obtained with TiN- and TiCN-coated tools than TiAlN- and TiAlN/AlCrN-coated ones. Such behavior was affected with the coated tool's original surface roughness.[54]

3.16.3.2 Residual Stress and Microstructure

The amount of wear on a tool's flank face has critical importance to avoid excessive surface and subsurface damages on the machined components.[65] Especially in hard machining operations on hardened steels, sharpness of a cutting tool considerably effect white layer and residual stress formation on the machined component surface. When sharp tools are used, the surface microstructure remains the same as the bulk material and the surface residual stresses tend to be compressive. Residual stress profiles produced after turning of hardened steel with sharp and worn tools are given in Figure 15. It is seen that in case of the sharp cutting tool, the residual

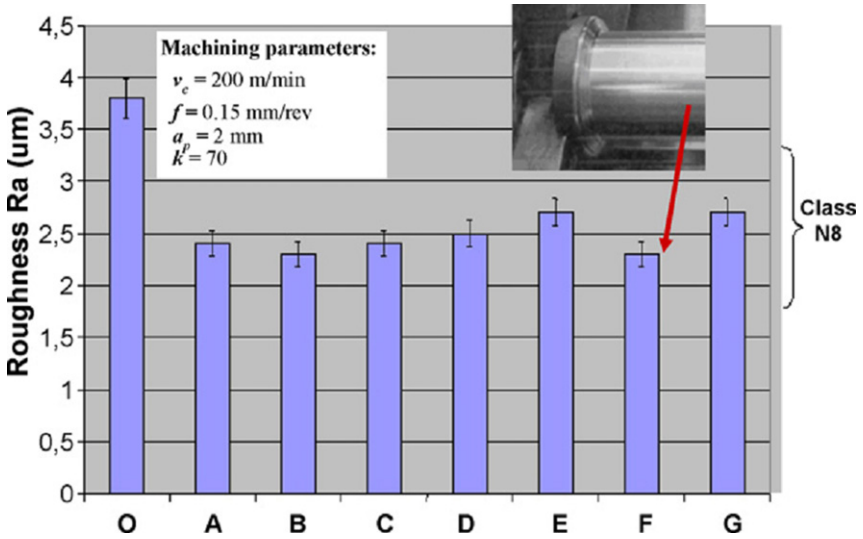

Figure 13 Comparison of the roughness parameter R_a of gray cast iron machined surface with uncoated (sample 0) and different PVD and CVD-coated tools (samples A–G).[63]

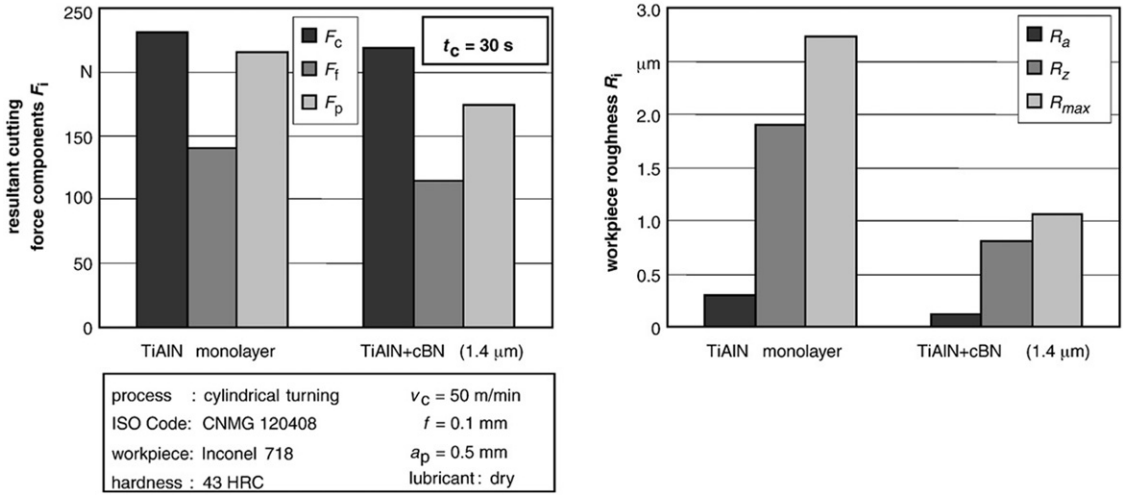

Figure 14 Resultant cutting force components and workpiece roughnesses of cBN coating and TiAlN coating during machining of Inconel 718.[64]

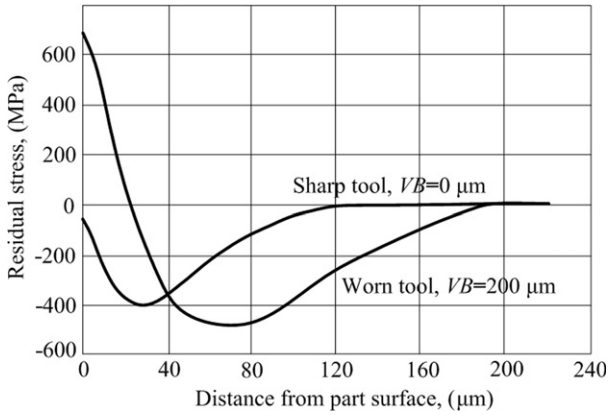

Figure 15 Residual stress depth profiles produced after turning of hardened steel with sharp and worn tools.[55]

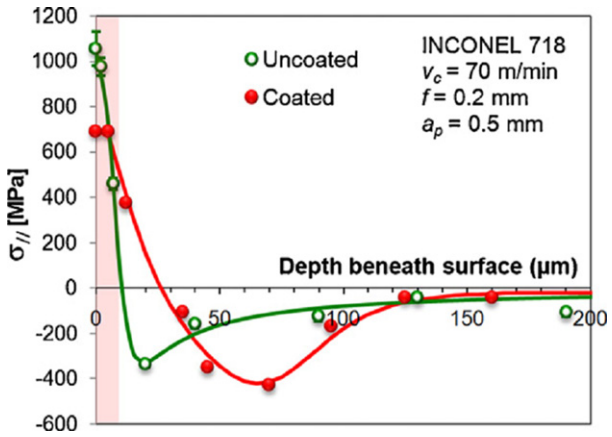

Figure 16 In-depth $\sigma_{//}$ residual stress distribution in machining Inconel 718.[66]

stress at the surface is zero and it becomes compressive below the surface. On the contrary, in case of the worn cutting tool, tensile residual stress occurs at the surface and it becomes compressive at greater distances from the part surface. The residual stress formation with the worn tool was explained in such a way that, with the increase of the tool flank wear, friction between tool flank face/the machine surface increases, leading to higher thermal loads on the surface layer. High cutting temperatures cause to the formation of white layers and a greater tendency to induce tensile residual stresses in the surface layer of the hard machined part.[55]

Figure 16 shows the depth profiles of residual stress induced by machining of Inconel 718 with coated and uncoated cutting tools. Differently from residual stress profiles obtained on hardened steel depicted in Figure 15, residual stresses are tensile at the surface machined with both coated and uncoated tools and the stresses gradually change to compressive values beneath the surface, and then they become equal to the values before machining (around zero MPa). When compared with the coated tools, uncoated tools resulted in higher tensile residual stresses at the surface, lower thickness of tensile layer and lower residual stresses (maximum) in the subsurface.[66]

Figure 17 shows the change of the workpiece surface roughness and of the external tangential residual stress as a function of the cutting speed in hard turning of 27MnCr5 alloy with uncoated cBN tools and TiN coated cBN tools. It is seen that TiN coating provides better surface finish at higher cutting speeds (Figure 17(a)). It can be observed in Figure 17(b) that a TiN coating provides a decrease in the external residual stress between 150 and 350 MPa. A more benefit from TiN coating in terms of residual stress level was obtained at high cutting speeds. The reason of lower residual stress with the TiN coated tools was attributed to the good tribological behavior of TiN coating, which reduces the friction and thereby the mean cutting temperature at the tool/chip interface.[67]

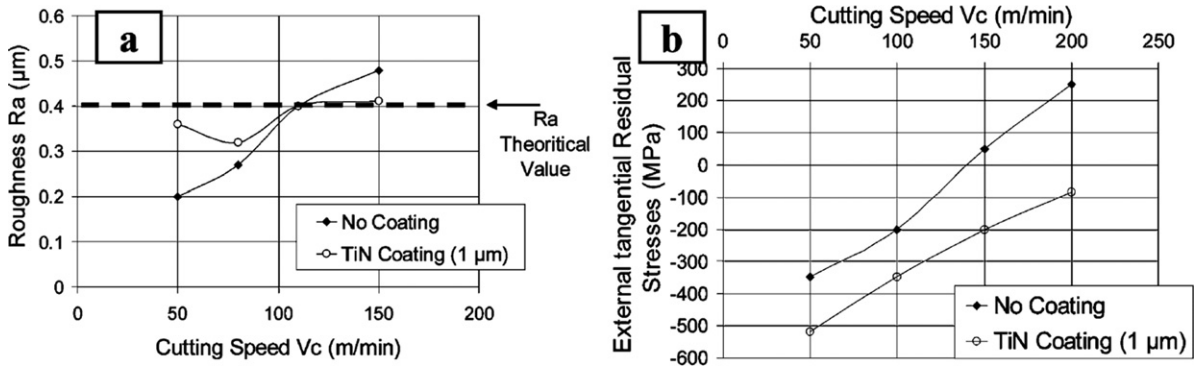

Figure 17 Influence of the TiN coating on external residual stress and roughness after hard turning-27MnCr5, 850 HV0.3, $a_p = 0.15$ mm, TNGA 160408S, f = 0.1 mm rev^{-1}.[67]

3.16.4 Conclusions

In this chapter an outline of the effect of hard coatings on surface finish in machining applications is presented. Main hard coatings designs were introduced and the required properties from a hard coating were summarized. It was shown that cutting performance of cutting tools and surface finish can be significantly improved by deposition of a hard coating on cutting tool materials. The relation of hard coatings with tool wear, cutting temperature, chip formation, surface roughness, and residual stress was discussed in detail.

3.17.1 Topological Evaluation Methods

Topological characterization methods are divided into two categories. These are contact and noncontact measurement and evaluation methods. These methods have pros and cons in different aspects. The technological developments are bringing new approaches and solutions. Therefore, evaluation methods for surface characterization should be revised and adapted to new approaching or emerging technologies.

3.17.1.1 Contact Surface Measurement Techniques

In the twentieth century, the attempts for development of the surface instrumentation were initiated by industry and academia. Surface topographical characterization was assessed by the judgment of the inspector either by eye or fingernail. The simplest way to characterize surface structure is visual inspection. The mere eye can tell quite much about larger scale features. The resolution of the human eye is limited to slightly under 100 μm.[1] Because of this reason, it is necessary to have higher spatial resolution measurement systems, which can be used for the surface topographical assessment.

The first contact type stylus profilometer (SP) was developed for the surface topographical characterization by Schmaltz in 1929.[2] After G. Schmaltz, Abbott in 1936[3] and Hobson in 1939[4] advanced the surface inspection and measurement know-how. Early stage evaluation methods were insufficient in order to put a numerical value to the surface texture. Contact type SPs advanced the evaluation methodologies and gave an opportunity to measure the surface parameters for finer and smoother surfaces quantitatively.

3.17.1.1.1 Portable handheld surface finish instrument

Portable handheld surface finish instruments measure multiple roughness parameters using diamond tip drawn across a sample part with motorized traverse mechanism. These instruments produce a set of traceable measurement results including detailed profile graph with one-button operation. Most common types of instruments use standard cutoff values (0.8 mm), accuracy (ranges from 0.1 to 40 μm in R_a), diamond tip with a radius of 5 μm, and traverse length of 5 mm.[5]

There are two common types of surface finish measuring systems as skidded and nonskidded (can be called as skidless). These testers with skidded can measure roughness only (**Figure 1(a)**), whereas skidless testers can evaluate the surface components as form, waviness, and roughness (**Figure 1(b)**). Workpiece belonging to surface being measured is used as a reference surface by skidded instruments, while skidless instruments can use an internal precision surface as a reference. Skid can be used as a mechanical filtering in the measurements. Skid radius is a key factor that determines the obtained results from a tester.

3.17.1.1.2 SP

SPs are supported with the most of the surface finish standards for the prerequisites of the engineering communities and academia (**Figure 2**).[6] A stylus with diamond tip with different

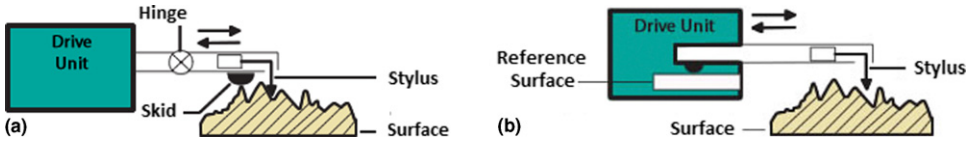

Figure 1 Portable handheld surface finish instrument. (a) with skid and (b) skidless.

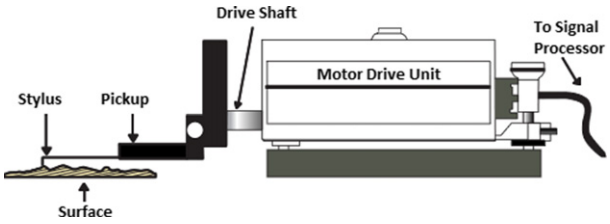

Figure 2 Working principle of stylus profilometer.

sizes (ranges from 20 nm to 50 μm) is moved in vertical stylus displacement on the surface being measured, while the tip is moved laterally across the sample for a predetermined contact force (range from less than 1–50 mg). Measuring range for a typical SP is between 10 nm and 1 mm. An analog signal is produced, as diamond moves mechanically up and down in vertical direction. Generated analog signals by transducer are converted into digital signals, and then this digital information is stored, analyzed, and displayed.

The SPs have pros and cons in different aspects. Software used by these profilometers is compatible with the world's surface finish standards. Stylus instruments are the only instrument types that are fully covered by ISO specification standards and there is good practice guidance available.[7] Obtained measurement results from the SPs are reliable. SPs are more preferable since they have an ability to measure the surface properties of a material with dirty layer, while noncontact measurement systems can measure material surface properties plus surface contaminants. Vertical resolution of these profilometers is usually sub-nanometer level.

The contact type stylus measurement technique has considerable drawbacks that the loaded stylus can damage or scratch the surface being measured, particularly the situation for soft surfaces. The transducer and stylus tips are often fragile, the measurements with these instrument should be applied in a fairly vibration free environment. Consequently, this direct contact measurement method may not be appropriate to be used on a test object undergoing a machining process simultaneously.[8]

3.17.1.1.3 Atomic force microscopy (contact mode)

Atomic Force Microscopy (AFM) is one of the scanning probe microscopy (SPM) techniques. The AFM[9] was developed for imaging the insulating surfaces at atomic resolution levels. For the working principle of AFM, the samples are scanned in 2-axes under the force-sensing probe with tip attached to a cantilever. The interaction between the tip and sample occurs, when the tip is approached to the sample surface with proximity. Therefore, forces between the tip and the sample results in a deflection for the cantilever. The light from a laser is sent to the cantilever, and then reflected light from back of the cantilever is focused on a position sensitive photodetector.[10] Such an optical beam deflection system is sensitive to subnanometer deflections of the cantilever.[11] The AFM performs raster scanning and produces a topographic map of the sample surface (Figure 3(a)). The imaging with contact mode AFM can damage or distort some biological samples (Figure 3(b)).

AFM has abilities to measure the parameters in nanoscale level (Figure 4). These parameters can be:

1. Nanomechanical properties such as elastic modulus, hardness, stiffness, viscoelastic, frictional, etc.
2. Nanochemical properties such as chemical composition of surface features, etc.
3. Nanoelectrical properties such as work function, conductivity, etc.
4. Nanomagnetic properties, for example, magnetostatic field, field gradient above ferromagnets, etc.
5. Texture parameters such as average roughness, maximum peak to valley height, root mean square roughness, 10-point mean height roughness, surface skewness, surface kurtosis, etc.
6. Particle characterization such as parameters, volume, size, shape, and particle surface morphology, etc.

3.17.1.2 Noncontact Surface Measurement Techniques

The invention of noncontact optical techniques is in a sense due to the drawbacks of the contact type stylus measurement techniques. These noncontact measurement methods have ability to measure in-process and the different types of materials. The optical systems and the SPs are two complementary methods.[12] This noncontact environment can also result in much faster measurement times for the optical scanning instruments in the characterization of technical and nontechnical surfaces, while the SPs take more operation time in an aerial scanning mode. 3D noncontact optical surface inspection and measurement methods work with sensor-based approach by being placed at a certain distance from the object. Since optical measurement systems contains many drawbacks such as objective properties, spot size, numerical aperture (NA), field of view (FOV), surface slopes and discontinuities, and multiple scattering, surface finish evaluation results seems to have higher values in other words overestimation of the values of surface texture parameters occurs.

In this section, confocal microscopy, focus variation microscopy, coherence scanning interferometry (CSI), SPM, and electron microscopy as the noncontact methods for measuring surface topography is mentioned.

3.17.1.2.1 Confocal microscopy

The fundamental working principle of confocal microscopy is that only focused-light is sent to detector by means of a spatial

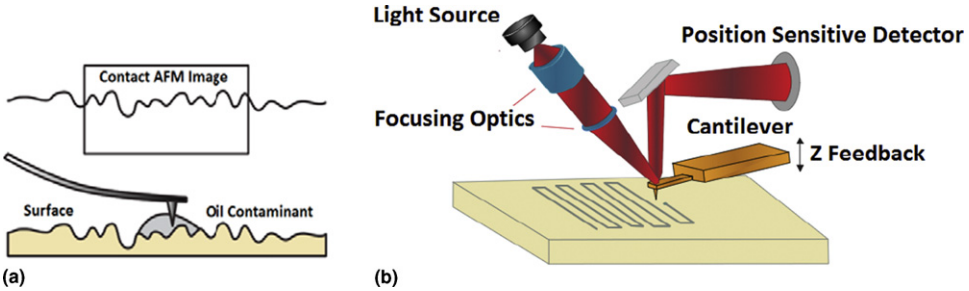

Figure 3 (a) Contact mode AFM imaging and (b) Atomic force microscope (AFM).

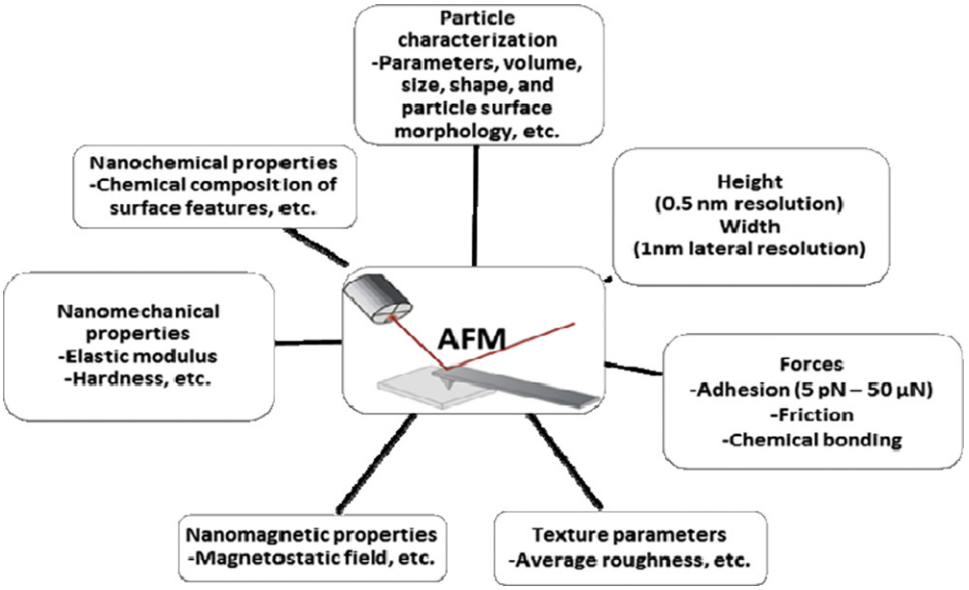

Figure 4 Measurement parameters with AFM.

pinhole placed at the confocal plane of the lens to remove out of focus light. In the late 1800s, Ernst Abbe (The Abbe Criterion) first enlightened that these traditional type fluorescence microscopes have the limits to spatial resolution. The principle of confocal imaging was patented (US patent 3013467) in 1957 by Minsky[13] with the purpose of surpassing the limitations of widefield fluorescence microscopes, since the resolution in confocal microscopy is augmented by eliminating out of focus light. In recent technologies, the confocal microscopy has three main different types of working principles. These principles are named as confocal laser scanning microscopy (CLSM or LSCM) (Figure 5(a)), disk scanning confocal microscopy (DSCM) (Figure 5(b)) and programmable array scanning confocal microscopy (PACM) (Figure 5(c)).

The main differences among confocal microscopes are beam scanning system, motorized scanning disk system, and programmable array scanning system for CLSM, DSCM, and PACM, respectively. In CLSM, beam scanner provides the raster scan of illumination to generate the confocal image. This is obtained by using two mirrors that move in perpendicular directions in order to bend the beam of the light. In DSCM, three different motorized disks are available in the market, these are called as Nipkow disks, parallel slits, and point rotating slit disks. Scanning disk turns and captures light that represents a slice of image from sample surface. In PACM, programmable array takes the roles of beam scanning system in CLSM and motorized disk in DSCM. Programmable array works in a way that only desired lights are taken into account. This each pixel of micro display acts as an illumination and detection element at the same time. Light from out of focus regions falls into neighboring pixels and the signals on the correlated pixels are used to reconstruct confocal image. The array of apertures can be opened or closed.

3.17.1.2.2 Focus variation microscopy

The principle of focus variation was first published by von Helmholtz in 1924.[14] The working principle of these instruments is based on focus variation. The visible light sends through a lens and to a beam splitter, then light goes through objective lens, finally to a sample. The driving unit connected to sample compartment moves vertically to provide in focus, lateral movement of the sample compartment enables the scanning of the sample. Reflected light from the sample goes through objective lens, and passes through semitransparent mirror and tube lenses to the Charge–Coupled Device (CCD) array. In an array, the status of focusing such as out of focus,

almost in focus, and in focus is evaluated, calculating the focus information (standard deviation) by 5×5 neighboring pixel values with the pixel values for the point of interest. Working principle of focus variation microscopy is depicted in Figure 6.

3.17.1.2.3 CSI

CSI (Figure 7) is often referred to as vertical scanning white-light interferometry. The light goes through beam splitter to an objective lens and internal reference mirror driven by a piezo-system, finally through the object to be measured. From here, the light is reflected back to the objective, goes through beam splitter, and finally reaches to the digital image sensor. The upper beam splitter directs light from the light source toward the objective lens. The lower beam splitter in the objective lens splits the light into two separate beams. One beam is directed toward the sample and one beam is directed toward an internal reference mirror. The two beams recombine and the recombined light is sent to the detector. Due to the low coherence of the white light source, the optical path length to

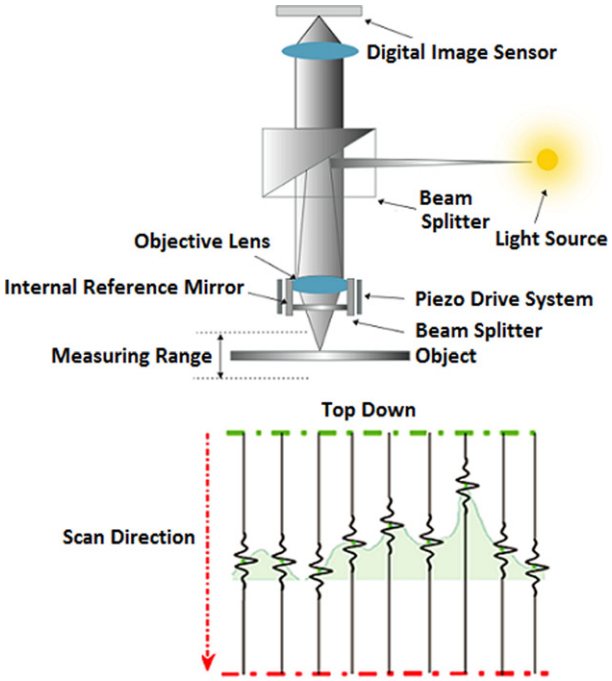

Figure 7 Working principle of coherence scanning interferometry design (upper) with schema of how to build up an interferogram on a surface using CSI. The vertical lines are intensity profiles at the image sensor (lower).[17]

the sample and the reference must be almost identical, for interference to be observed.[16] This characterizes how well a wave can interfere with itself at a different time. The detector measures the intensity of the light as the interferometric objective is actuated in the vertical direction (z-axis) and finds the maximum interference. Each pixel of the sensor measures the intensity of the light and the fringe envelope obtained can be used to calculate the position of the surface.

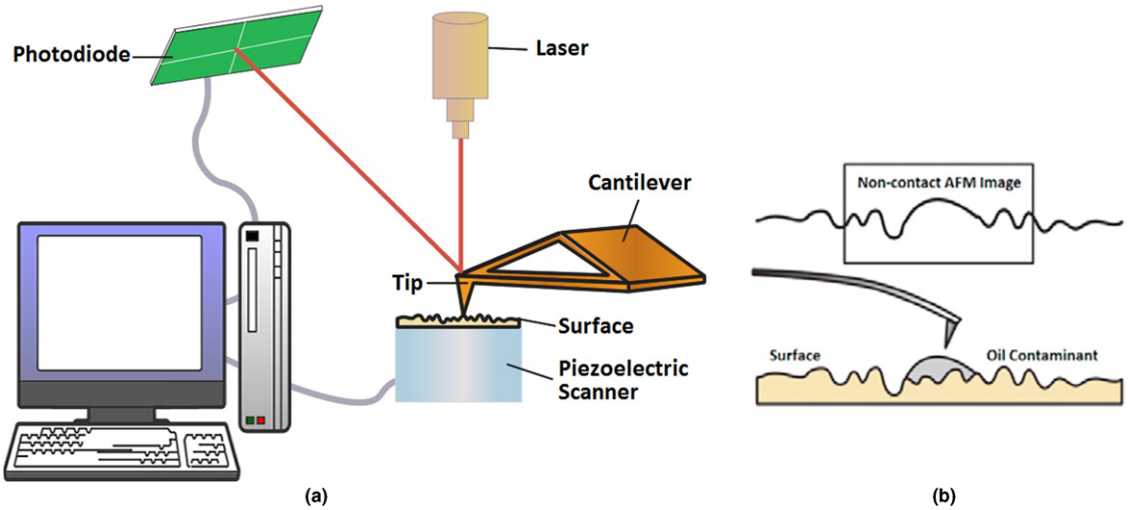

Figure 8 (a) Atomic force microscope and (b) Noncontact mode AFM imaging mode.

3.17.1.2.4 SPM

The Scanning Probe Microscopes (SPMs) represent the fundamental instrumentations for Nanotechnology. Basic principle of SPM has two distinct functions. These are scanning and probing. Scanning is performed by piezo raster 2D (X–Y) scanning, while probing is achieved by a sharp tip mounted to a z-scanner. The most common types of SPMs are noncontact AFM and scanning tunneling microscopy (STM).

3.17.1.2.4.1 AFM (Noncontact mode)

The first Noncontact AFM (NC-AFM) was designed by Martin *et al.* in 1987.[18] Tapping mode or NC-AFM (Figure 8(b)) can be classified in this section, since tip of the instrument does not have contact with sample surface. These types of instruments measure surface topography by utilizing attractive forces (interatomic force) between the tip and the sample surface. NC-AFM uses piezoelectric modulator to obtain the information regarding the surface topography. Piezoelectric modulator enables to keep minimum distance to the sample surface by van der Waals forces between the tip and the sample surface. Therefore, all the time the distance between the tip and the sample surface remains in the same level by z-servo feedback loop control system. The light sends to the cantilever, and then reflected back to photodetector. In photodetector, surface topography information is monitored (Figure 8(a)).

3.17.1.2.4.2 STM

The STM is based on the quantum mechanical tunneling effect (Figure 9). Binnig and Rohrer developed this system in 1981 (at IBM Zürich) and earned the Nobel Prize in Physics in 1986.[19] For an STM, average lateral and depth resolutions are considered to be 0.1 and 0.01 nm, respectively. With this resolution, individual atoms within materials are routinely imaged and manipulated. STM performs well for all conductive materials. However, it is possible to measure even biological materials such as DNA. Working principle of these instruments is that extremely fine conducting material creates tunneling effect with conductive samples. In theory, when a quantum object is sent on a material with a thick barrier, this quantum object bounces off. If the barrier is thinner, it has the ability to pass through the object. Metals are made of atoms and electrons. Electrons come off the metal surface, when electric current passes through the tip. This produces a tunnel effect. Low current is amplified by a current amplifier. Distance control and scanning unit enable to control the voltage goes to the piezoelectric tube. Thus, the tip is moved, and then finally data is recorded and displayed.

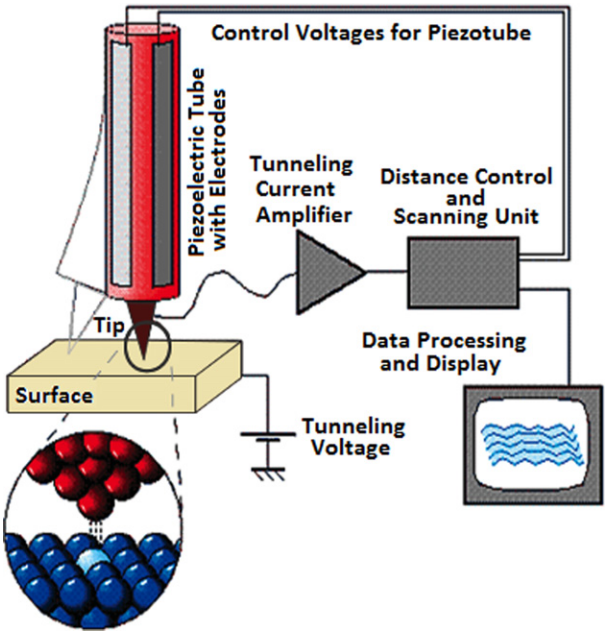

Figure 9 Working principle of scanning tunneling microscopy.[20]

3.17.1.2.5 Electron microscopy

The working principle of electron microscopes is that the system uses a beam of electrons instead of the light to produce an image of the sample specimen. There are two types of

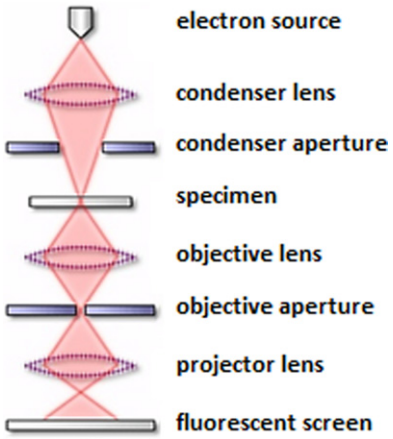

Figure 10 Schematic representation of transmission electron microscopy.

electron microscopes. These are Transmission Electron Microscopy (TEM) and Scanning Electron Microscopy (SEM). Generally, TEM and SEM utilize electromagnetic and/or electrostatic lenses to keep up the path of electrons. The resolution of these systems depends upon the wavelength of the irradiation used to create an image. Reducing the wavelength increases the resolution. Thus, the resolution of the image obtained from the microscope can be increased if the accelerating voltage of the electron beam is increased. Hans Busch was a pioneer of electron optics and laid the theoretical basis for the electron microscopy in 1920s. Knoll and Ruska[21] succeeded in magnifying an electron image. The first prototype of electron microscopy was actually built by Ruska in 1933 and was capable of resolving to 50 nm. In this section, the working principles of TEM and SEM are explicitly depicted.

3.17.1.2.5.1 TEM

In these instruments (Figure 10), instead of using light, electrons are produced and transmitted through an ultrathin specimen (semitransparent for electrons) as an electron beam. Like in spectroscopy, electrons passing through a specimen interact with the atoms in sample. As a result of the specimen characteristics, the properties of transmitted electron beam changes. The transmitted electron beam is projected on a fluorescent screen, and then the information is captured from fluorescent surface to create the TEM image. In other words, TEM contains a high voltage electron beam emitted by a cathode and formed by magnetic lenses. The electron beam partly transmitted through the ultrathin specimen carries information about the structure of the specimen. The spatial information is magnified by a series of magnetic lenses, and finally the image formed on a fluorescent screen. The image detected by a CCD camera played and recorded in real time.

3.17.1.2.5.2 SEM

In contrast to the TEM, SEM (Figure 11) produces the images using secondary electrons which are emitted from a specimen hit by the electrons of the primary beam. In SEM, the electron beam is scanned across the surface being measured in a raster scan with the detectors for building up an image by mapping the detected signals with the beam position. Since primary

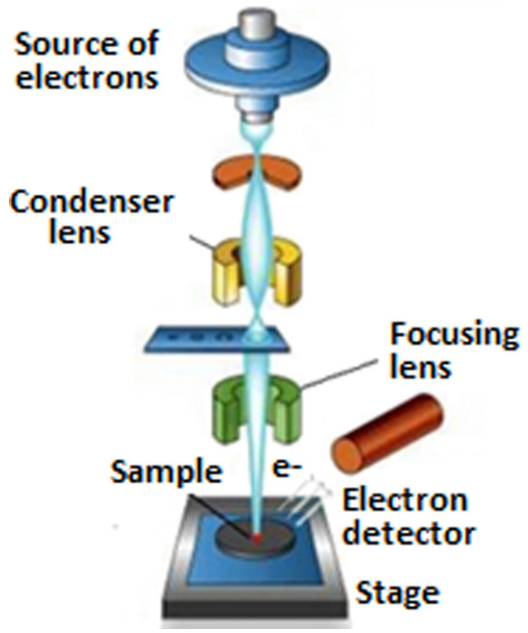

Figure 11 Schematic representation of scanning electron microscopy.

beam electrons have more energy than secondary electrons, secondary electrons from the atoms are kicked away by primary electrons and scattered electrons carry information regarding the surface properties of the specimen. Therefore, SEM is a vital measurement technique for the surface finish studies.

3.17.1.2.6 Comparison

Table 1 gives the comparison of the measurement and inspection techniques.

The sensitivity of instruments using cantilever beam with tip are affected by stiffness, size, and material type of the tip. TEM requires a special environmental conditioning such as vacuum, while SEM and others does not require. When compared in terms of cost and complexity, TEM and SEM require special lenses and optics, and have the highest cost among others in investment. STM tip should be conducting, can be simply cut freshly by normal wire cutter. STM works with the very top atom at the freshly cut tip, providing to atomic resolution. AFM tip should be sharp enough to get good resolution (fat-tip effect), and also AFM tip should be stiff enough to sense the atomic interaction with sample surface. AFM tip is not necessary to be conducting, but STM tip should be conductive.

From coarse to very fine surface finishes, it is important to test a specimen with proper instruments and to make decision with above mentioned measurement and inspection methods. Therefore, surface finishing and quality measurements can be done using above instruments. In surface finish measurement studies or in industry, crucial task is that the selection of proper measurement methods according to surface finish.

3.17.2 Characterization of Parameters

Surface texture refers to the surface irregularities such as peaks and valleys, produced on a surface by any forming processes.

Table 1 Comparison of the measurement and inspection techniques

Criteria	*Contact stylus*	*Noncontact optical*	*AFM*	*STM*	*TEM*	*SEM*
Type of probe	Tip	Light beam	Tip	Tip	Electron beam	Electron beam
Type of contact	Contact	Noncontact	Contact and Noncontact	Noncontact	Noncontact	Noncontact
Source	Mechanical-electrical energy	Photons	Mechanical-electrical energy/Photons	Atomic forces	Electrons	Electrons
Detection	Transducer	Photodetector	Photodetector	Photodetector	Fluorescent scene	CCD
Sample preparation	Little/Not required	Little/Not required	Required	Required	Required	Required

Z-Resolution	0.3 nm	0.1 μm	Sub-nanometer/ Angstrom	0.2 nm	100 nm	2 nm
Z-Range	50 μm	20 μm	5 μm	100 nm	2 μm	2 μm
Output	2D/3D	2D/3D	3D	3D	2D	3D

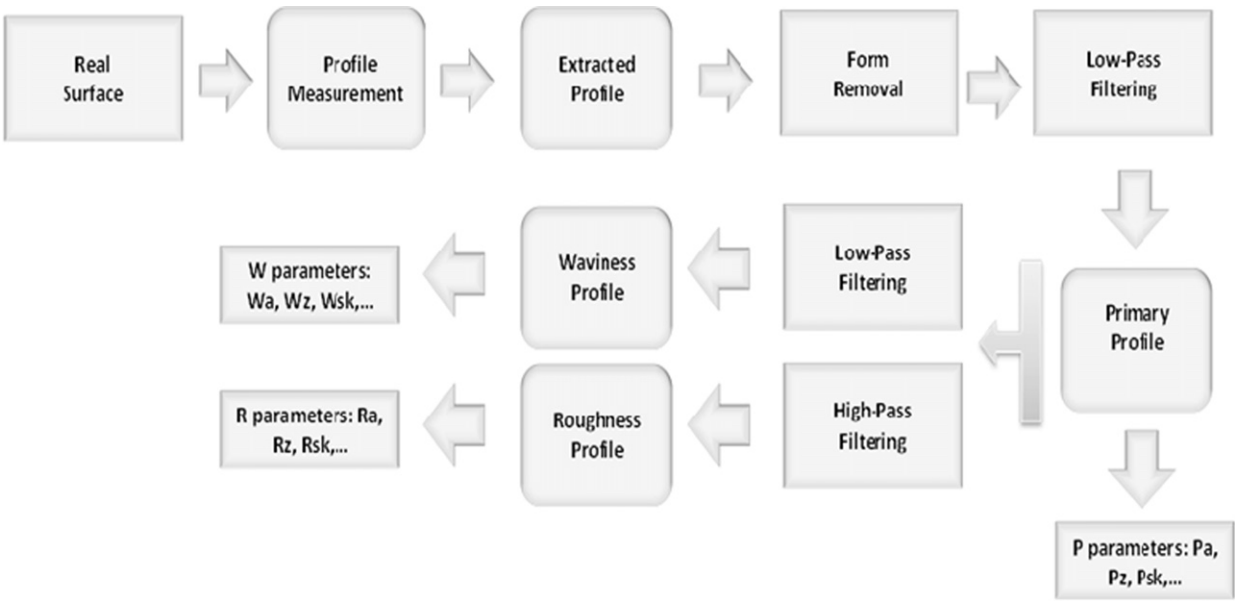

Figure 12 Surface topography evaluation schema.

Form, waviness, and roughness are basic components of a surface texture, which is much more associated with the roughness, since in practice surface roughness is most commonly used and measured. Forms typically appear due to the errors occurring from machining. This is commonly known as straightness errors. Waviness is a result of various vibrations during machining process related to both machine tool and outside sources like work deflection, vibration, heat treatment, and other similar factors. Roughness occurs as a result of feed-rate tool geometry, tool condition, the process used, and hardness and other variations in material characteristics. Since form, waviness, and roughness appears due to different factors mentioned above, it is possible to remove these errors with analyses. The removal of errors can be accomplished using selected filters or cutoff values. In this section, primary profile, waviness, and roughness are detailed explicitly.

Surface parameters are obtained using two types of profiling techniques. These techniques are based upon height measurements. These height measurements are made along a line (profile method) or over an area (raster area methods). Both types of techniques develop quantitative knowledge of the surface peaks and valleys by point measurement using high resolution probe. Surface topography evaluation schema (Figure 12) indicates how primary profile, waviness, and roughness are obtained using digital filters. Firstly, a profile signal is extracted from a surface using any profilometer such as with mechanical/optical probe. The extracted profile refers to the sampled and digitized signal. Then, form removal process is applied to the extracted profile signal. This refers to removal of errors caused by geometry of sample part/measurand. After the removal of form type, low-pass filter is applied to the obtained signal. The result is the primary profile signal. The primary profile parameters such as P_a, P_z, P_{sk}, etc.,

are obtained from primary profile signals. Low-pass filtering is applied to the primary profile signal and therefore, waviness profile signal is obtained. Parameters obtained from these signals are W_a, W_z, W_{sk}, etc. High-pass filter is applied to the primary profile signal. Then the roughness profile signal is obtained. Roughness parameters are R_a, R_z, R_{sk}, etc.

3.17.2.1 Primary Profile

The primary profile is acronym as *P*, which is the profile after low-pass filtering the measuring values using the cutoff wavelength λ_s. The short-wave profile parts in the signal are cutoff and evaluated within the sampling length (cutoff). This equals to the measured length or the length of the measured surface profile.[22] The primary profile signal obtained from a surface texture using low-pass filter is shown in **Figure 13(a)**. The profile is a superimposed image of roughness, waviness, and profile. **Figure 13(a)** shows the surface texture profile signal for a surface while **Figure 13(b)** illustrates the signals for original signal plus primary profile signal.

3.17.2.2 Waviness Profile

The waviness profile is acronym as *W*, which results from low-pass filtering the primary profile with the cutoff wavelength λ_c and high-pass filtering with the cutoff wavelength λ_f. Waviness profile is evaluated over the measured length l_n, which is composed of several sampling lengths l_w. The single measured length l_w corresponds to the cutoff wavelength λ_f of the high-pass filter. The original signal is illustrated in **Figure 14(a)**. The waviness profile signal obtained from a primary profile signal using low-pass filter is shown in **Figure 14(b)**.

3.17.2.3 Roughness Profile

The roughness profile is acronym as *R*, which results from high-pass filtering the primary profile with the cutoff wavelength λ_c. Roughness profile is evaluated over the measured length l_n, which is composed of five single measured lengths l_r. The single measured length l_r corresponds to the cutoff wavelength λ_c of the primary profile filter. The original signal is illustrated in **Figure 15(a)**. The roughness profile signal (**Figure 15(b)**) is obtained from a primary profile signal using high-pass filter.

Table 2 shows the 2D surface profile parameters, their corresponding equations, and graphical representations. Here, for each 2D parameter, definitions are given with their equations in order to use in surface topological calculation and evaluations. Furthermore, graphical representations for each surface parameter are depicted so as to illustrate the phenomena how 2D surface parameters are withdrawn for the best comprehension.

Hybrid Parameters Root mean square slope of the assessed profile $R\Delta q$, $W\Delta q$, and $P\Delta q$	$R\Delta q = \sqrt{\frac{1}{l}\int_0^l \left[\frac{d}{dx}Z(x)\right]^2 dx}$ Root mean square value of the ordinate slopes dZ/dx within a sampling length.	
Curves Related Parameters Material ratio of the profile $Rmr(c)$, $Wmr(c)$ and $Pmr(c)$	$Rmr(c) = \frac{1}{ln}\sum_{i=1}^{m} Ml(c)i$ Ratio of the material length of the profile elements $Ml(c)$ at a given level c to the evaluation length.	
Profile section height difference $R\delta c$, $W\delta c$, and $P\delta c$	$R\delta c = c(Rmr1) - c(Rmr2)$ $: Rmr1 < Rmr2$ Vertical distance between two section levels of given material ratio.	
Relative material ratio Rmr, Wmr and Pmr	$Rmr = Rmr(c_1)$ $C_1 = C_0 - R\delta c$ $C_0 = C(Rmr0)$ Material ratio determined at a profile section level $R\delta c$, related to a reference C_0.	

3D surface profile parameters are listed with their corresponding equations in Table 3. Here, for each 3D parameter, definitions are given with their equations in order to use in surface topological calculation and evaluations. This areal information is needed to have better results for surface evaluation since 3D parameters contain more information than information obtained from profiling.

3.17.3 Surface Finishing

All machining processes leave characteristic topographic features on the surfaces of components. Surface finishing is a very wide range of industrial processes. These processes change and modify the surface of produced sample to reach the desired properties. From deburring processes to a variety of technological processes,

Table 3 3D surface profile parameters[25]

3D surface profile parameters	*Equation with description*
Amplitude characterization	$Sa = \iint_a \lvert Z(x,y)\rvert \, dxdy$
	Sa: The average deviation of the surface
	$Sq = \sqrt{\iint_a (Z(x,y))^2 dxdy}$
	Sq: The root mean square deviation of the surface
	$Ssk = \frac{1}{Sq^3} \iint_a (Z(x,y))^3 dxdy$
	Ssk: Skewness of surface height distribution
	$Sku = \frac{1}{Sq^4} \iint_a (Z(x,y))^4 dxdy$
	Sku: Kurtosis of surface height distribution
	$Sz = \frac{\sum_1^5 \lvert \text{Peak Heights}\rvert + \sum_1^5 \lvert \text{Valley Depths}\rvert}{5}$
	Sz: Ten point height of the surface
Spatial characterization	$Sds = \frac{\text{Number of Peaks}}{\text{Area}}$
	Sds: Density of summits
	$Str = \frac{\text{Length of fastest decay}(0.2) \text{ of ACF in any direction}}{\text{Length of slowest decay}(0.2) \text{ of ACF in any direction}}$
	Str: Texture aspect ratio; ACF = Auto correlation function
	Sal = Length of fastest decay of ACF to 0.2 in any direction
	Sal: Fastest decay auto correlation length
	Std = Major direction of lay derived from APSDF
	Std: Texture direction of surface; APSDF = Angular power spectral density function
Hybrid characterization	$Sdq = \sqrt{\frac{1}{A}\int_0^{Lx}\int_0^{Ly} \left(\frac{\partial Z(x,y)}{\partial x}\right)^2 + \left(\frac{\partial Z(x,y)}{\partial y}\right)^2 dydx}$
	Sdq: Root-mean square surface slope
	$Ssc = \frac{1}{A}\int_0^{Lx}\int_0^{Ly} \left(\frac{\partial^2 Z(x,y)}{\partial x^2}\right) + \left(\frac{\partial^2 Z(x,y)}{\partial y^2}\right) dydx$
	Ssc: Mean summit curvature
	$Sdr = \frac{(\text{Total surface area}) - (\text{Cross sectional area})}{\text{Cross sectional area}}$
	Sdr: Developed surface area ratio
Functional characterization	$Sbi = \frac{Sq}{\text{True height}(0.05)} = \frac{1}{h(0.05)}$
	Sbi: Surface bearing index
	$Sci = \left(\frac{Vv(h_{0.05}) - Vv(h_{0.80})}{A}\right) \div Sq$
	Sci: Core fluid retention index; smoother = Smaller sci
	$Svi = \left(\frac{Vv(h_{0.80})}{A}\right) \div Sq$
	Svi: Valley fluid retention Index; good fluid retention = larger *Svi*

	Sc: Core void volume – Volume enclosed 10–80% bearing area
	$Sv = \left(\frac{Vv(h_{0.80}) - Vv(h_{1.00})}{A}\right)$
	Sv: Surface void volume – Volume from 80 to 100% bearing area

Table 4 Adding and altering methods

Adding and altering methods	*Working principle*	*Topological evaluation of surface finish*	*Applications*
Blanching	Whitening of a surface using acid or coating with tin.	0.4–0.8 μm	Tin based productions, etc.
Case hardening	Hardening of surface such as flame and induction hardening, carburizing, nitriding, cyaniding, carbonitriding, ferritic nitrocarburizing.	0.3–0.5 μm	Screws, firing pins and rifle bolt faces, or engine camshafts, etc.
Ceramic glaze	Coating of vitreous materials to fuse with ceramic using fire.	0.3–0.5 μm	Coloring, water-proofing, and decorating purposes, etc.
Cladding	Bonding of two different metals by pressing/extruding two metals through a die/rolling two metal sheets with high pressure.	0.5–1 μm	Heat exchangers, coins productions, etc.
Corona treatment	Modificating surface using electrically discharge plasma.	0.5–1 μm	Polyethylene, polypropylene, vinyl, PVC, PET, metalized surfaces, etc.
Diffusion processes	Diffusing carbon or nitrogen to a metal surface.	0.5–1 μm	Gears, crankshafts, valve parts, extruder screws, die-casting tools, forging and extrusion dies, injectors, and plastic-mold tools, etc.
→Carburizing	Diffusing carbon to a metal surface.		
→Nitriding	Diffusing nitrogen to a metal surface.		
Electroplating	Coating metal objects with a thin layer of a different metal.	0.5–1 μm	Circuits of cell phones, computers, and other electronic devices, etc.
Galvanizing	Coating steel with zinc to provide long term corrosion protection and abrasion resistance with hot metal bath or Electro-deposition.	150 μm	Building and construction, etc.
Gilding	Coating metals and nonmetals with gold leaf, gold flakes, brass, etc.	NA	Hand application and glueing, electroplating, etc.
Glazing	Glazing by spraying, dipping, pouring, and painting etc.	NA	Ceramic glaze, insulated glazing, etc.
Knurling	Producing indentations on a part of a workpiece.	NA	Tool handles, mechanical pencils, and the control knobs on electronic equipment, etc.
Painting	Applying paint, pigment, color, or other medium to a surface.	NA	Knives, sponges, and airbrushes, etc.
Passivation/Conversion coating	Coating with a chemical or electro-chemical process.	NA	Microelectronics, photovoltaics, etc.
→Anodizing	Increasing thickness of the natural oxide layer on metal surface by forming the anode electrode of an electrical circuit.	Usually, the higher the anodizing voltage, the more roughening occurs.	Baseball bats, signs, furniture, surgical trays, motorcycle, architectural molding, etc.
→Bluing	Heating the steel until a blue oxide film appears without chemicals.	NA	Guns, firearms, razor blades, etc.
→Chromate conversion coating	Applying chromate conversion coating to substrate to passivate steel, aluminum alloys.	NA	Aircraft industry, everyday items such hardware, tools, etc.

Adding and altering methods	*Working principle*	*Topological evaluation of surface finish*	*Applications*
Phosphate conversion coating	Spraying to the surface with dilute solution of phosphoric acid and phosphate salts to form phosphates layer.	NA	Application of supplemental coatings: lubricants, sealers, oil, etc.
◆◆ Parkerizing	The process involves submerging the metal part into a phosphoric acid solution.	NA	Automobiles, firearms, etc.
→Plasma electrolytic oxidation	Producing oxide coatings on metals, using higher potentials, so that discharges occur, resulting plasma modifies structure of the oxide layer.	NA	Aerospace and defense (gearboxes, gear bearing carriers, etc.).
Plasma spraying	Producing coatings on structural materials into the plasma jet, emanating from a plasma torch.	NA	Corrosion protection, medical implants, etc.
Powder coating	Producing thicker coatings without sagging, and producing minimal appearance differences between horizontally coated surfaces and vertically coated surfaces.	NA	Automobile parts, bicycle frames and parts, etc.
Thin-film deposition	Depositing a thin film of material onto a substrate or onto previously deposited layers.	Sub-micrometer and nanometer	Electronic semiconductor devices and optical coatings, etc.
→Chemical vapor deposition (CVD)	Depositing thin films of materials on wafers or other substrates.		
→Electroplating/ Electrodeposition	Using electrical current to reduce metal cations in an electrolytic solution in order to coat a conductive object with a thin adherent layer, modifying the surface properties.		Car parts, bath taps, kitchen gas burners, wheel rims, and coins such as pennies, etc.
→Electrophoretic deposition (EPD)	Suspending colloidal particles in a liquid under the electric field, depositing onto an electrode.		Automobile bodies and parts, tractors and heavy equipment, electrical switch gear, industrial products, etc.
→Mechanical plating/ Peen plating/ Mechanical deposition/Cold welding	Descaling and removing soil from the workpiece in tumbler without electrical charge passing through the plating medium.		Nails, screws, nuts, washers, stampings, springs, clips, and sintered iron components, etc.
→Sputter deposition	Removing atoms from a solid target's surface, projecting them into gas phase from condensing on another surface.		Photovoltaics, flat panel display, etc.
→Physical vapor deposition (PVD)	Depositing thin films by the condensation of a vaporized form of the desired film material onto workpiece surfaces.		Aerospace, Dies, and molds, Automotive, Surgical/Medical, Cutting tools, Fire arms, etc.
→Vacuum plating	Depositing layers of material atom-by-atom/ molecule-by-molecule on a solid surface at below atmospheric pressure (i.e., vacuum).		Metallic films, semiconductor films, solar cells, automotive applications, etc.
Vitreous enamel/ Porcelain enamel	Fusing a thin layer of glass at high temperature on to the surface of a metal.	NA	Jewelry and decorative art, housing and interior walls of major kitchen appliances, chemical reactors and pharmaceutical process tanks, etc.

surface finishing covers a wide-ranging of industries and applications. The main functions of the surface finishing are the improvement of the surface appearance, the enhancement of the corrosion resistance and the impartment of the required surface properties. Surface finishing processes can be categorized by how they affect the workpiece as adding or altering finishing (**Table 4**) and removing or reshaping finishing (**Table 5**).

Table 6 represents the general characteristics of machining processes.[26] This table gives detail information regarding the process, their characteristics, tolerances, and roughness values. Here, it is clear that each machining process produce different surface topography. Average roughness values for each machining process prove that each machining process results in different surface texture.

Table 7 explicitly indicates the general characteristics of advanced machining processes.[26] Information regarding the process, their characteristics, tolerances and roughness values are detailed.

Table 5 Removing and reshaping methods

Removing and reshaping methods	*Working principle*	*Topological evaluation range*	*Applications*
Abrasive blasting	Propelling a stream of abrasive material against a surface under high pressure to smooth a rough surface.	NA	The lettering and engraving on most modern cemetery monuments and markers, etc.
→Sandblasting	Producing 3D-signage. These signs often incorporate gold leaf overlay and crushed smalts.		Refurbish buildings, cleaning boat hulls, brick, stone, concrete work, etc.
Burnishing	Burnishing smears the texture of a rough surface and makes it shinier.	0.125–0.5 μm	The inner ring of the ball bearing, burnishing tools, etc.
Chemical-mechanical planarization (CMP)	Using abrasive chemical slurry, to remove material and making any irregular topography the wafer flat.	Sub-micrometer and nanometer	Semiconductor devices, photolithographic applications, etc.
Electropolishing	Removing surface imperfections from a sample to polish, passivate, deburr metal parts using chemicals and electrical current.	Sub-micrometer and nanometer	Drums of washing machines, surgical devices, etc.
Flame polishing	Exposing the material to a flame smooths tension of the surface out.	Sub-micrometer	Glass pipettes, electronic industry, IC encapsulation, etc.
Gas cluster ion beam	Bombarding to a surface by a beam of high energy nano cluster ions using gas cluster ion beam.	Sub-nanometer	Semiconductor devices, optical thin films, fixed disk memory systems.
Grinding	Using a rotating abrasive wheel to smooth the flat surface of materials to reach an ideal surface for a functional purpose.	0.1–1.6 μm	Sealing surfaces between cylinder head and cylinder liner and between cylinder liner and engine frame, etc.
Industrial etching/ Chemical milling	Using baths of temperature-regulated etching chemicals to remove material to attain the desired shape.	Sub-micrometer and nanometer	Printed circuit board, semiconductor, integrated circuits and microelectromechanical systems etc.
Linishing	Using grinding or belt sanding techniques to improve the flatness of a surface and produces a matt finish.	0.1–3.2 μm	Profiles with square and rectangular section, etc.
Mass finishing processes/Vibratory finishing	Deburring, radiusing, smoothing, polishing and degreasing the mass produced parts by mechanical/chemical means.	Sub-micrometer and nanometer	Metal parts, etc.
Pickling	Remove impurities from ferrous metals with a solution called pickle liquor containing strong acids.	Pickled surfacing increases roughness range (2–6 μm)	Jewelry, sheet steel, plate, coil, etc.
Polishing	Rubbing the surface or using a chemical action in order to create a smooth and shiny surface.	0.05–0.5 μm	Household cleaners, car polish, stone polishing, jewelry, plastics, brake linings, ball bearings, aerospace, etc.
→Buffing	Smoothing the surface using an abrasive and a work wheel or a leather strop.		Automotive, aviation, composite, marine, etc.
→Lapping	Rubbing two surfaces together with an abrasive by hand movement or using a machine.		Aircraft and motor manufacturers, electronics companies, clockmakers, toolmakers, etc.
Peening/Shot peening	Bombarding to a metal part by tiny balls of steel, stainless steel, cut-wire, glass, or ceramic shot.	Shot peening treatment increases roughness range (1–6 μm)	Crankshafts, gears, torsion bars, springs, valves, exhaust manifolds, blades, disks, turbines, etc.
Superfinishing	Using bonded abrasive stick moved with a reciprocating motion and pressed against the surface to be finished (similar to honing).	0.025–0.2 μm	Computer memory drums, sewing machine parts, automotive cylinders, bearing components, pistons rods, axles, shafts, clutch plates, etc.
Magnetic field-assisted finishing	Using a magnetic field to force abrasive particles against the target surface.	Sub-micrometer and nanometer	Medical components, fluid systems, optics, dies and molds, microelectromechanical systems, etc.

Table 6 General characteristics of machining processes

Process	*Characteristics*	*Commercial tolerances (± mm)*	*Roughness average,* R_a *(μm)*
Turning	Turning and facing operations are performed on all types of materials; requires skilled labor; low production rate, but medium to high rates can be achieved with turret lathes and automatic machines, requiring less skilled labor.	Fine: 0.05–0.13, Rough: 0.13, Skiving: 0.025–0.05	0.4–6.3
Boring	Internal surfaces or profiles, with characteristics similar to those produced by turning; stiffness of boring bar is important to avoid chatter.	0.025	0.4–6.3
Drilling	Round holes of various sizes and depths; requires boring and reaming for improved accuracy; high production rate; labor skill required depends on hole location and accuracy specified.	0.075	1.6–6.3
Milling	Variety of shapes involving contours, flat surfaces, and slots; wide variety of tooling; versatile; low to medium production rate; requires skilled labor.	0.13–0.25	0.8–6.3
Planing	Flat surfaces and straight contour profiles on large surfaces; suitable for low-quantity production; labor skill required depends on part shape.	0.08–0.13	1.6–12.5
Shaping	Flat surfaces and straight contour profiles on relatively small workpieces; suitable for low-quantity production; labor skill required depends on part shape.	0.05–0.13	1.6–12.5
Broaching	External and internal flat surfaces, slots, and contours with good surface finish; costly tooling; high production rate; labor skill required depends on part shape.	0.025–0.15	0.8–3.2
Sawing	Straight and contour cuts on flats or structural shapes; not suitable for hard materials unless the saw has carbide teeth or is coated with diamond; low production rate; requires only low skilled labor.	0.8	1.6–25

Table 7 General characteristics of advanced machining processes

Process	*Characteristics*	*Commercial tolerances (± mm)*	*Roughness average,* R_a *(μm)*
Chemical machining	Shallow removal (up to 12 mm) on large flat or curved surfaces; blanking of thin sheets; low tooling and equipment cost; suitable for low production runs.	0.025–0.1 mm min^{-1}	1.6–6.3
Electrochemical machining	Complex shapes with deep cavities; highest rate of material removal; expensive tooling and equipment; high power consumption; medium to high production quantity.	V: 5–25 DC; A: 2.5–12 mm min^{-1}, depending on current density	0.2–3.2
Electrochemical grinding	Cutting off and sharpening hard materials, such as tungsten–carbide tools; also used as a honing process; higher material removal rate than grinding.	A: 1–3 A mm^{-2}; typically 1500 mm^3 m^{-1} in per 1000 A	0.1–1.6
Electrical-discharge machining (EDM)	Shaping and cutting complex parts made of hard materials; some surface damage may result; also used for grinding and cutting; versatile; expensive tooling and equipment.	V: 50–380; A: 0.1–500; typically 300 mm^3 min^{-1}	0.05–6.3
Wire EDM	Contour cutting of flat or curved surfaces; expensive equipment.	Varies with workpiece material and its thickness	0.8–1.6
Laser-beam machining	Cutting and hole making on thin materials; heat-affected zone; does not require a vacuum; expensive equipment; consumes much energy; extreme caution required in use.	0.50–7.5 m min^{-1}	0.2–6.3
Electron-beam machining	Cutting and hole making on thin materials; very small holes and slots; heat-affected zone; requires a vacuum; expensive equipment.	1–2 mm^3 min^{-1}	0.2–6.3
Water-jet machining	Cutting all types of nonmetallic materials to 25 mm and greater in thickness; suitable for contour cutting of flexible materials; no thermal damage; environmentally safe process	Varies considerably with workpiece material	0.1–3.2

(*Continued*)

Table 7 Continued

Process	*Characteristics*	*Commercial tolerances (± mm)*	*Roughness average, R_a (μm)*
Abrasive water-jet machining	Single or multilayer cutting of metallic and nonmetallic materials.	Up to 7.5 m min^{-1}	0.1–1.6
Abrasive-jet machining	Cutting, slotting, deburring, flash removal, etching, and cleaning of metallic and nonmetallic materials; tends to round off sharp edges; some hazard because of airborne particulates.	Varies considerably with workpiece material	0.1–1.6

3.17.4 Conclusion

In this chapter, topological evaluations with regard to surface finish were discussed in three subsections. These subsections were so vital in order to comprehend the relationships among topological parameters and evaluation methods, instruments and surface finish, which is the outcome from the machining process. It is so significantly meaningful that knowing the weaknesses of measurement tools and instrumentation can enlighten and enrich the topological evaluation methods for surface finish evaluation. Today's topological evaluation methods are using the product surface finish evaluations after machining process. However, tomorrow's topological evaluation methods will have data from the instruments during machining process. It is hoped that for further future evaluations, multisensory approaches integrated with experimental models will provide advance information for surface finishes.

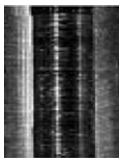
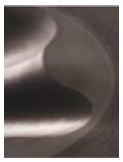
3.18.1 Surface Finish Quality

Surface finish occurs during the manufacturing process. For precise manufacturing, surface finish topological characterization methods are divided into two categories. These are contact and noncontact measurement and evaluation methods. These methods have pros and cons in different aspects. The technological developments are bringing new approaches and solutions. Therefore, evaluation methods for surface characterization should be revised and adapted to new approaching or emerging technologies.

Table 1 lists the machining processes corresponding to surface roughness value and their tolerances.[1] Each machining process produces a variety of surface finish, which has a range of roughness values (R_a). Also, each process consists of tolerance limits for manufacturing.

In order to achieve the desired surface finish, the evaluation of the surface parameters should be determined properly. With the development of novel and recent measurement techniques, the introduction and the usage of new materials and coating technologies has enabled us to evaluate and verify different characteristics of surface parameters in two- (2D) and three dimensions (3D). The measurement of surface texture can be used to determine the surface roughness in which some parameters such as R_a, the area between the roughness profile and its central line, and R_z, the average maximum height of roughness profile, etc. describe the roughness in values. These surface roughness parameters are generally measured and evaluated by a diamond stylus profilometer (SP).[2–4] These contact type profilometers are supported with the most of the surface finish standards for the needs of the engineering and research communities.[5–9] The verification of computer vision (CV)-based surface parameters determinations are generally performed using the values obtained from the contact stylus type profilometers.





3.18.2 Imaging Systems for Surface Characterization

3.18.2.1 Imaging Systems

There are numbers of imaging methods in order to characterize surfaces (Table 2).[10–14] These methods use the photons, electron beam, atomic forces, and mechanical–electrical energy in order to produce the image of a specimen. The different energy sources are used. The main idea here is to obtain information regarding the surface/specimen. Light/energy source, optics, detectors, and software are the main components of these imaging systems. Images are the output of these systems. Hardware and drivers for capturing images are used to form images. Depending upon the software specifications, there are available image processing and analyses algorithms in the software. Some of the below mentioned imaging systems require sample preparation. The resolutions of these systems vary in micron to nano levels.

The sensitivity of instruments using cantilever beam with tip are affected by stiffness, size, and material type of the tip. Transmission Electron Microscopy (TEM) requires a special environmental conditioning such as vacuum, while Scanning Electron Microscopy (SEM) and others does not require. When compared in terms of cost and complexity, TEM and SEM require special lenses and optics, and have the highest cost among others in investment. Scanning Tunneling Microscopy (STM) tip should be conducting, and it can be simply cut freshly by normal wire cutter. STM works with the very top atom at the freshly cut tip, providing to atomic resolution. Atomic Force Microscopy (AFM) tip should be sharp enough to get good resolution (fat-tip effect), and also AFM tip should be stiff enough to sense the atomic interaction with sample surface. AFM tip is not necessary to be conducting, but STM tip should be conductive. Computed tomography (CT) instruments for conventional medical applications provide

Table 1 Machining processes related to surface finish quality

Process	*Images*	*Commercial tolerances (± mm)*	*Roughness average, R_a (μm)*
Turning		Fine: 0.05–0.13; Rough: 0.13; Skiving: 0.025–0.05;	0.4–6.3
Boring		0.025	0.4–6.3

Shaping		0.05–0.13	1.6–12.5
Broaching		0.025–0.15	0.8–3.2
Sawing		0.8	1.6–25

resolution of 1–2 mm for meter–decimeter-scale objects. Common industrial CT systems have high-resolution instruments. These instruments provide resolution of 100–200 μm for decimeter–centimeter-scale objects. Microfocal ultrahigh-resolution instruments provide resolution of a few tens of microns for centimeter–millimeter-scale objects.

X-ray based CT is a noncontact and nondestructive technique for visualizing interior features within solid objects, and for obtaining digital information from their 3D geometries and properties. CT is dependent upon X-ray absorption of the elemental composition and the density of the sample and the distance the X-rays traverse through the sample. Tomography with X-ray tubes has a spatial resolution of about 10 μm within an object size of a few millimeters for industrial and materials science applications.

X-ray tomographic microscopy (XTM) is a noncontact and nondeformative technique for visualizing the material structures by utilizing intense, highly collimated synchrotron radiation. XTM can be used for the characterization of surface topography.

Table 2 Imaging systems for surface characterization

Criteria	*Noncontact optical*	*AFM*	*STM*	*TEM*	*SEM*	*CT/XTM*	*CV*
Type of probe	Light beam	Tip	Tip	Electron beam	Electron beam	Electron beam	Light beam
Type of contact	Noncontact	Contact and noncontact	Noncontact	Noncontact	Noncontact	Noncontact	Noncontact
Source	Photons	Mechanical–electrical energy/Photons	Atomic forces	Electrons	Electrons	Electrons	Photons
Detection	Photodetector	Photodetector	Photodetector	Fluorescent scene	CCD	CCD	Photodetector/ CCD
Sample preparation	Little/Not required	Required	Required	Required	Required	Not required	Not required
Spatial Resolution	0.5 μm	20 nm	2.5 nm	2 nm–1 μm	10 nm	0.37 μm	<1 μm
Z-Resolution	0.1 μm	Sub-nanometer/ Angstrom	0.2 nm	100 nm	2 nm	–	–
Z Range	20 μm	5 μm	100 nm	2 μm	2 μm	–	–
Output	2D/3D	3D	3D	2D	3D	2D/3D	2D/3D

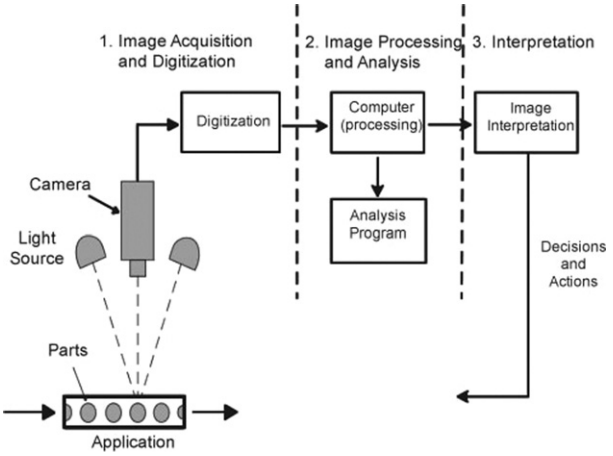

Figure 1 A typical computer vision application.[15]

From coarse to very fine surface finishes, it is important to test a specimen with proper instruments and to make decision with above mentioned measurement and inspection methods. Therefore, surface finishing and quality measurements can be done using above instruments. In surface finish measurement studies or in industry, crucial task is that the selection of proper measurement methods according to surface finish.

A typical CV system consists of image acquisition and digitization, image processing and analysis, and interpretation, decision and action (**Figure 1**). In image acquisition part, light source, frame grabbers, and camera are essential components. The selection of each unit and combining them to have working CV system require specialty. However, it can be learnt. In image processing and analysis part, a computer and commercial image processing packages/user developed codes using Matlab, Visual C++, OpenCV, Matrox Library etc., are necessary components. In image interpretation part, the derivation of useful spatial information from images is the task of image interpretation. The detection (searching for objects), identification (recognition of certain target), delineation (outlining the recognized target for mapping purposes), enumeration (counting certain phenomena from the image),

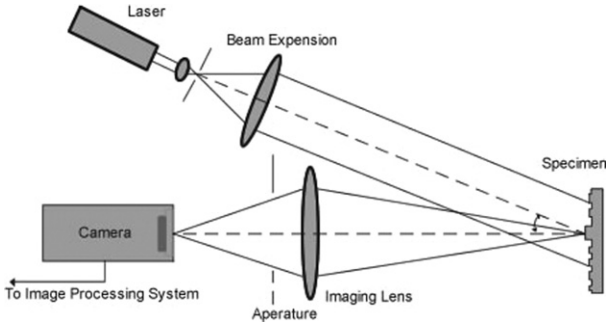

Figure 2 Surface measurement by computer vision.[15]

mensuration (measuring the area, the volume, the amount, and the length of certain target from an image) are pillar of image interpretation. Image interpretations are based upon some elements. These are listed here:

1. Image tone, gray level, or multispectral gray-level vector,
2. Image texture,
3. Pattern,
4. Association,
5. Shadow,
6. Shape,
7. Size,
8. Site.

In decision and action part, the desired action is properly selected using the results or information derived from image processing, analysis, and interpretations. Here, an expert system/decision support system/user developed codes of criteria can be used to start or to give commands to execute the required action.

Figure 2 demonstrates the surface measurement by CV. Here, a camera, a laser light source, apertures, and lenses are used for surface measurement. Light from laser is sent through aperture and beam expansion lens to the surface of the sample. The reflected light from the sample goes through imaging lens and aperture to the camera. The image is then obtained.

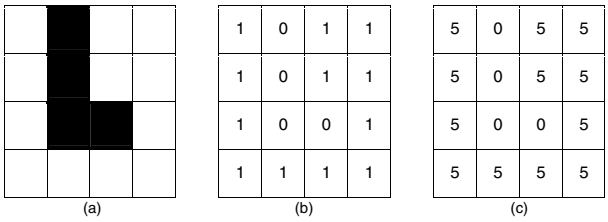

Figure 3 Binary imaging representation of 4 by 4 pixel array: (a) image, (b) DN values, and (c) voltages (volt).[16]

3.18.2.2 Basics of Image Acquisition for CV

Imaging is the creation of images from a physical scene using a camera or similar device. Imaging can be studied by dividing the area into two as analog and digital imaging. Currently, digital imaging is dominating the imaging world. A digital image may be created directly from a physical scene by a camera or similar devices. Alternatively, it may be obtained from another image in an analog medium, such as photographs, photographic film, or printed paper, by an image scanner or similar device.

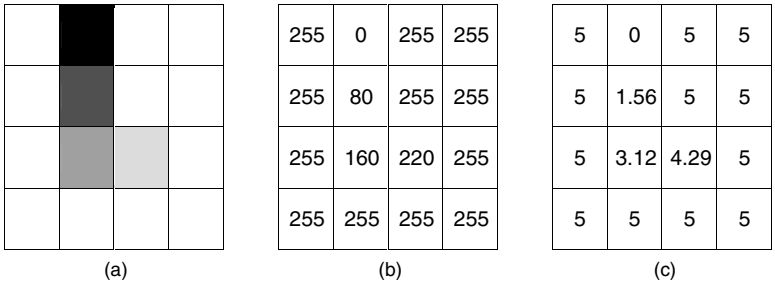

Figure 4 Gray level imaging representation of 4 by 4 pixel array: (a) image, (b) DN values, and (c) voltages (volt).[16]

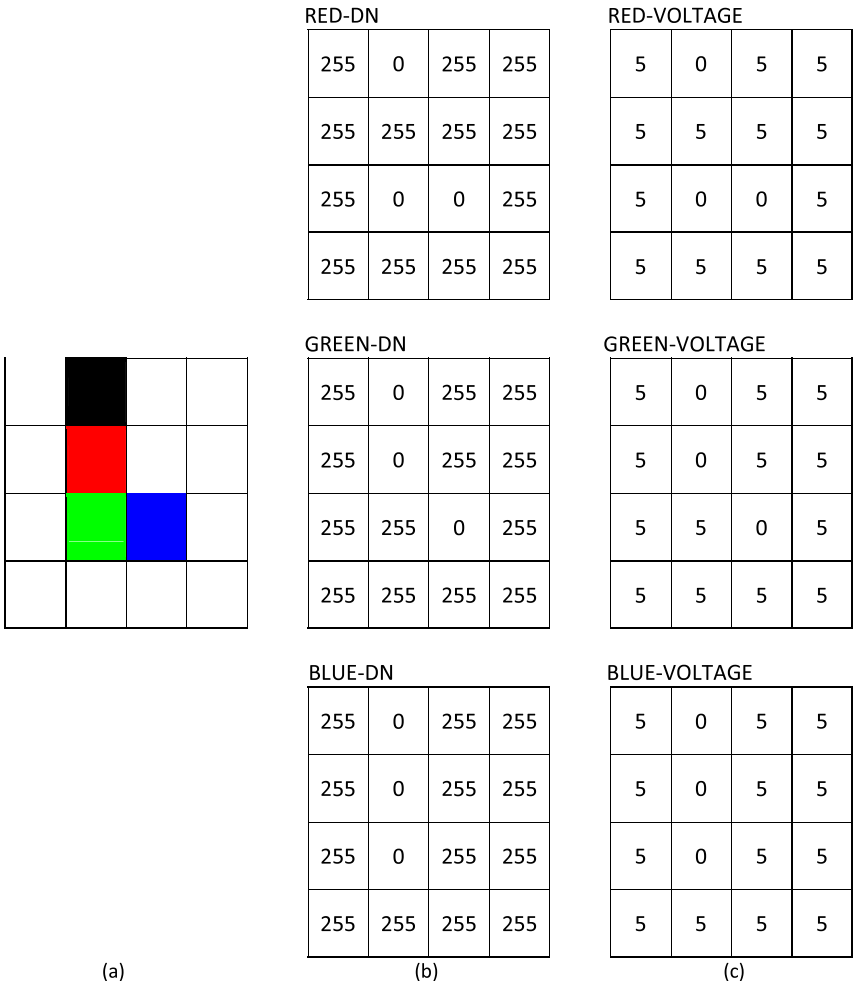

Figure 5 Color imaging representation of 4 by 4 pixel array: (a) image, (b) DN values, and (c) voltages (volt).[16]

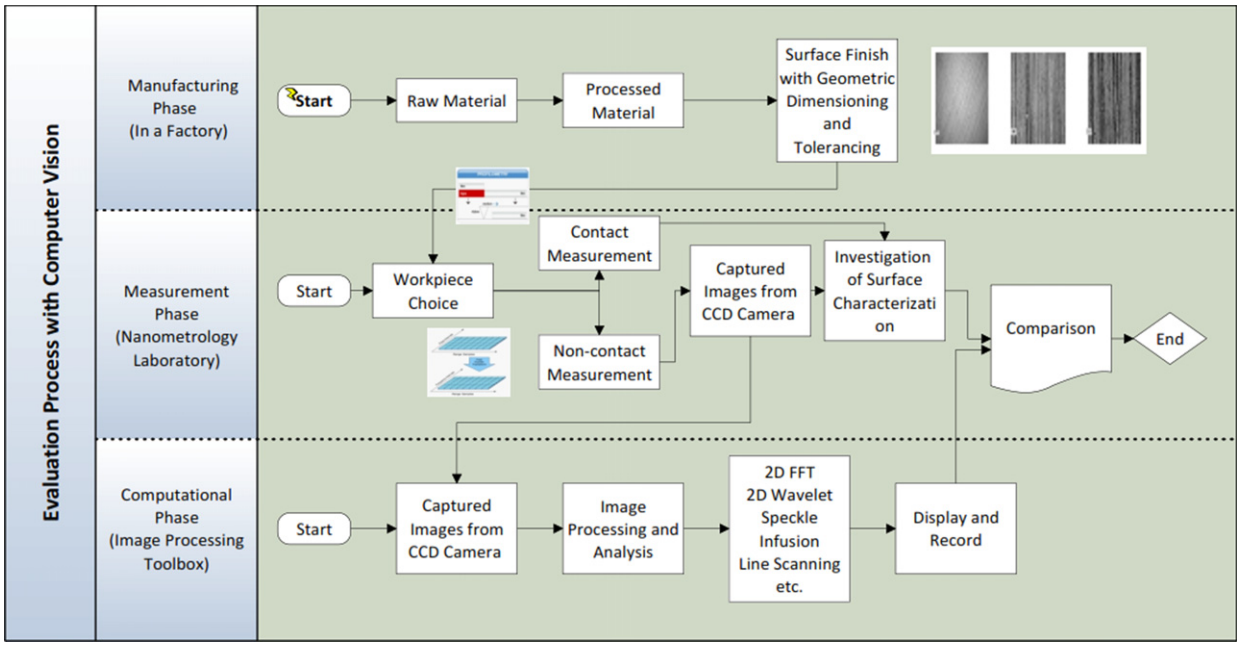

Figure 6 Evaluation process with computer vision.

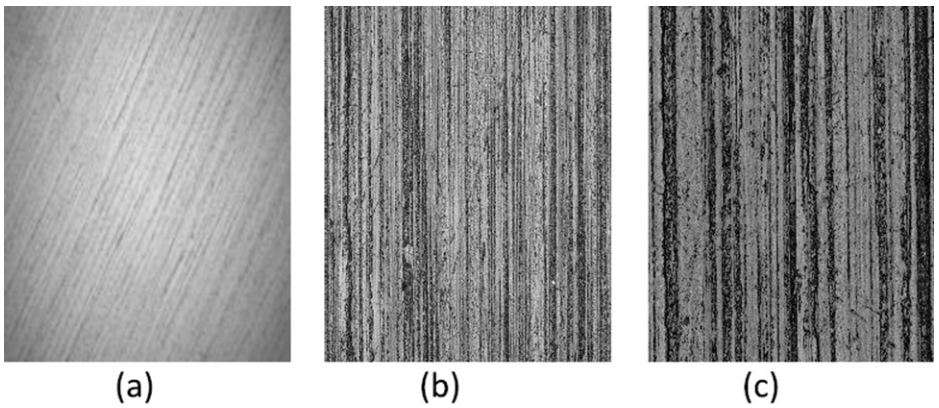

Figure 7 The images taken from the workpieces: (a) Ground surface (R_a=0.498 μm), (b) Front milled surface (R_a=2.382 μm), and (c) Face turned surface (R_a=3.984 μm).[17]

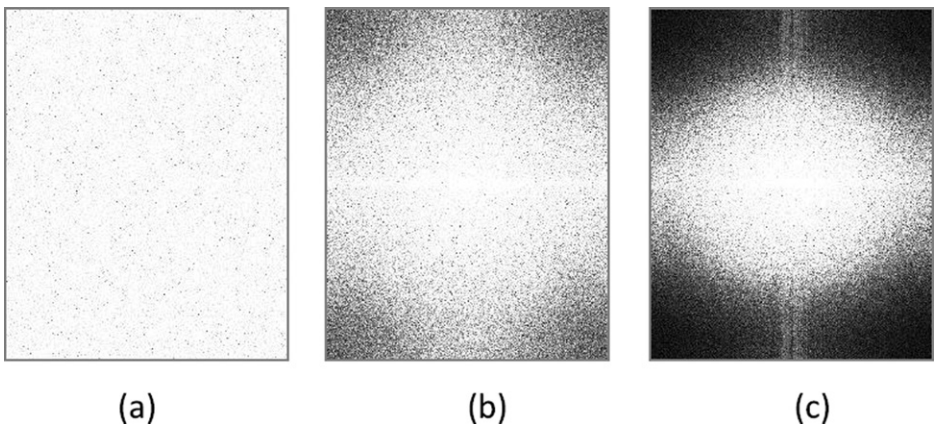

Figure 8 The images after FFT analysis: (a) Ground surface (R_a=0.498 μm), (b) Front milled surface (R_a=2.382 μm), and (c) Face turned surface (R_a=3.984 μm).[17]

There have been so called imaging practices in science without using a camera or similar device. Ultrasound images can be given as an example. Many technical images; such as those acquired with tomographic equipment, side-scan sonar, or radio telescopes are actually obtained by complex processing of nonimage data. This digitalization of analog real-world data is known as digitizing, and involves sampling (discretization) and quantization.

Figure 3 illustrates the binary imaging representation of L shaped-item. Digital numbers (DNs) are given in Figure 3(b) and array voltage representation is shown in Figure 3(c). An example of 4 by 4 pixel array detector is given here. It is assumed that minimum voltage level is 0 V while the maximum voltage level is 5 V. When L shaped black colored item is fixed to the white board, the image appears as seen in Figure 3(a). The voltage levels of each detector are observed as in Figure 3(c). Finally DN values of the image matrix would be as Figure 3(b) for 2 bit representation.

Figure 4 illustrates the monochrome imaging representation of L shaped-item colored with black and different tones of grays for 8 bit imaging system. DNs are given in Figure 4(b) and array voltage representation is shown in Figure 4(c). An example of 4 by 4 pixel array detector is given here. It is assumed that minimum voltage level is 0 V while the maximum voltage level is 5 V. When L shaped black and gray colored item is fixed to the white board, the image appears as seen in Figure 4(a). The voltage levels of each sensor are observed as in Figure 4(c). Finally DN values of the image matrix would be as Figure 4(b) for 8 bit representation.

Up to now non-spectral imaging is explained, in this approach, the light from the physical scene comes to the detector via optics with no spectral fragmentations. The detector sensitivity and digitalization of frame grabber/AD converter are main factors in non-spectral imaging. The light intensity/the amount of the reflection is the essential determinant factor in sensing. When we come to the color imaging, sort of fragmentations of the light into different wavelengths occurs.

Figure 5 illustrates the color imaging representation of L shaped-item colored with black, red, green, and blue for 8 bit imaging system. DNs are given in Figure 5(b) for red, green, and blue (RGB). The array voltage representations are shown in Figure 5(c) for RGB. An example of 4 by 4 pixel array detector is given here. It is assumed that minimum voltage level is 0 V while the maximum voltage level is 5 V. When L shaped black, red, green, and blue colored item is fixed to the white board; the image appears as seen in Figure 5(a). The voltage levels of each sensor are observed as in Figure 5(c) for RGB. Finally DN values of the image matrix would be as Figure 5(b) for 8 bit representation. For imaging, there are few significant factors that affect the quality of the image. These can be explained as stated below:

1. CCD/CMOS detector pixel size,
2. f-value (focal length) for focusing optics,
3. The distance between the object and the camera,
4. Light intensity,
5. Aperture size,
6. Shutter speed,
7. ADC digitization resolution (8, 16, 24 bit).

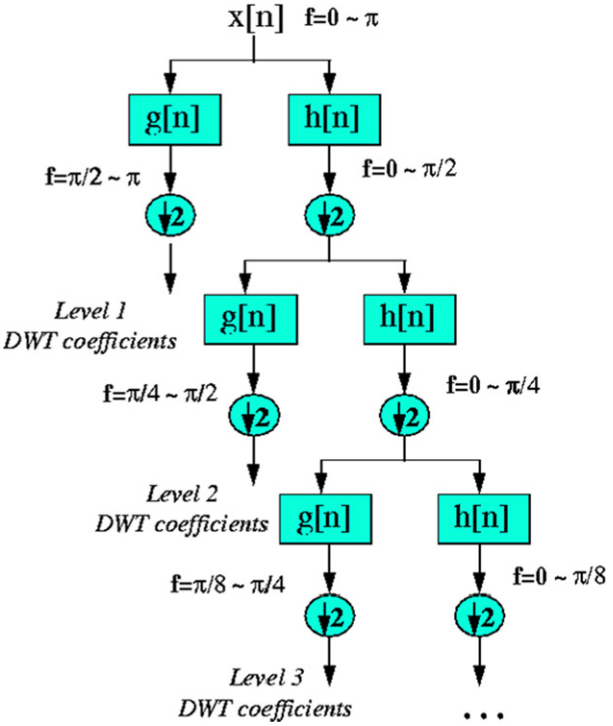

Figure 10 Application of wavelet transform using low-pass and high-pass filters.[20]

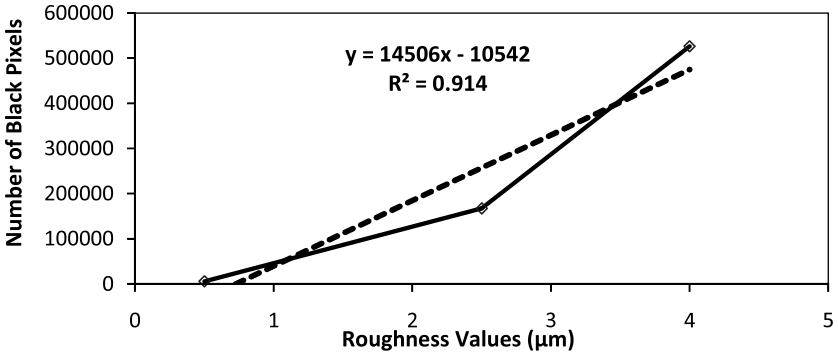

Figure 9 The number of black (dark) pixels from FFT images taken from images of workpieces: (a) Ground surface (R_a=0.498 μm), (b) Front milled surface (R_a=2.382 μm), and (c) Face turned surface (R_a=3.984 μm).[17]

3.18.2.3 Basics of Image Processing and Analysis for CV

The parameters stated above are the main factors which defines the quality of images. Spatial resolution is one of the most important key factors. Imaging mostly involves alteration, subtraction, addition, multiplication, and division etc., of DNs at 2D matrix within or with other 1D/2D matrix or constant. In imaging, some of image processing techniques can be stated below:

1. Resampling,
2. Resizing,
3. Color space processing,
4. Filtering (low pass, high pass, band pass, edge filtering etc.),
5. Pattern recognition,
6. Blob analysis,
7. Contrast enhancement,
8. Geometric corrections/calibrations/enhancements,
9. Transformations (Fourier, wavelet etc.).

Above mentioned techniques are some of the commonly used techniques. However, there are many more image processing techniques used for image processing.[16]

3.18.3 Surface Evaluation Methods with CV

All machining processes leave characteristic topographic features on the surfaces of components. Surface finishing is a very wide range of industrial processes. These processes change and modify the surface of produced sample to reach the desired properties. From deburring processes to a variety of technological processes, surface finishing covers a wide-ranging of industries and applications. The main functions of the surface finishing are the improvement of the surface appearance, the enhancement of the corrosion resistance and the impartment of the required surface properties.

Surface finishing processes can be categorized by how they affect the workpiece as removing or reshaping finishing and adding or altering finishing.

The main objective here for surface evaluation with CV is that rapid, cost-effective, real-time measurements of surfaces can be easily conducted. In order to perform better measurements, a calibration for the camera is necessary. If the sample size is fixed for CV measurement, a calibration without any object/marker can be performed. In CV surface characterization, μm–nm/pixel should be determined before any further evaluation is conducted. Spatial resolution in this case is very important parameter in order to classify the instruments. Higher spatial resolution cameras can give out more information. Spatial resolution in a way can be arranged by the distance between a camera and an object.

Evaluation process with CV can be categorized into two sections apart from manufacturing phase before calibration. A part is manufactured using conventional, additive, precision etc., manufacturing techniques. The obtained workpiece is then scanned using 2D/3D surface measurement instruments. The profile, waviness, and roughness parameters are then computed.

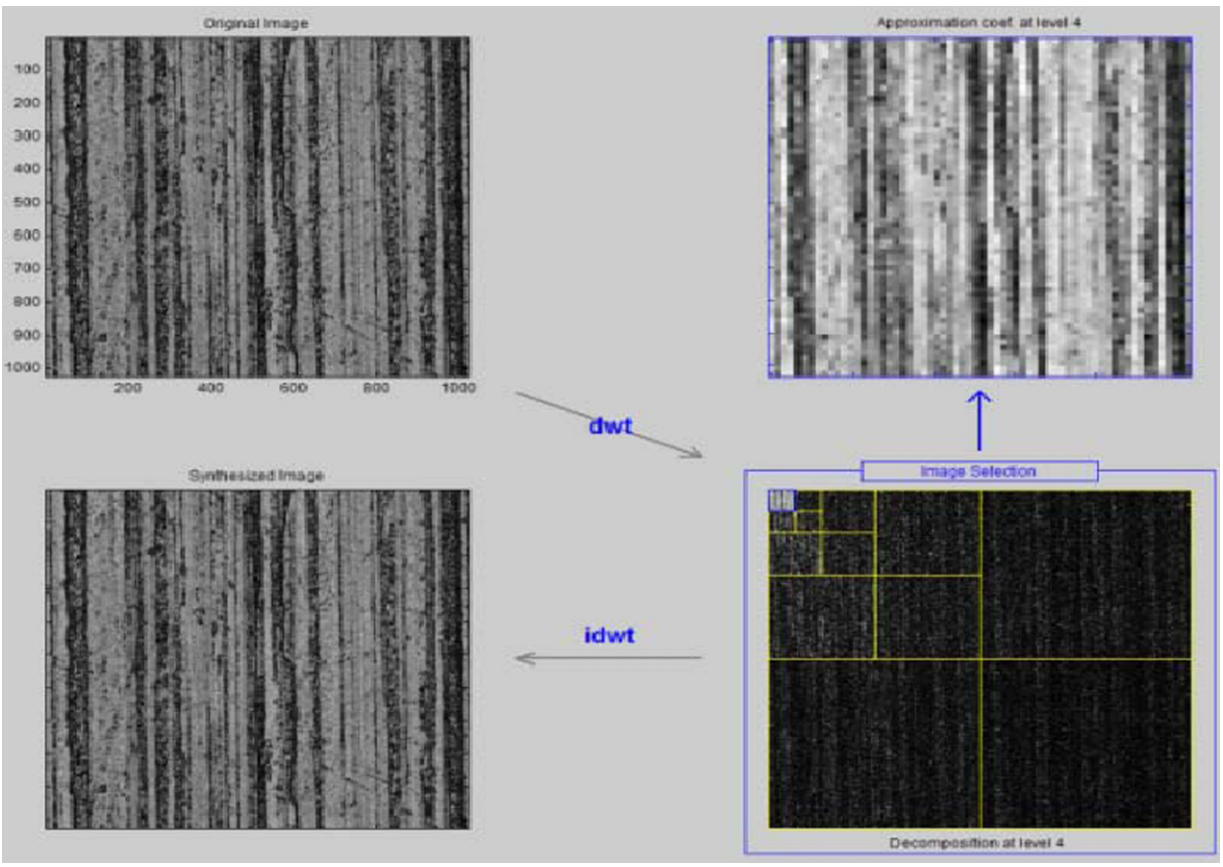

Figure 11 Wavelet transform procedure.[21]

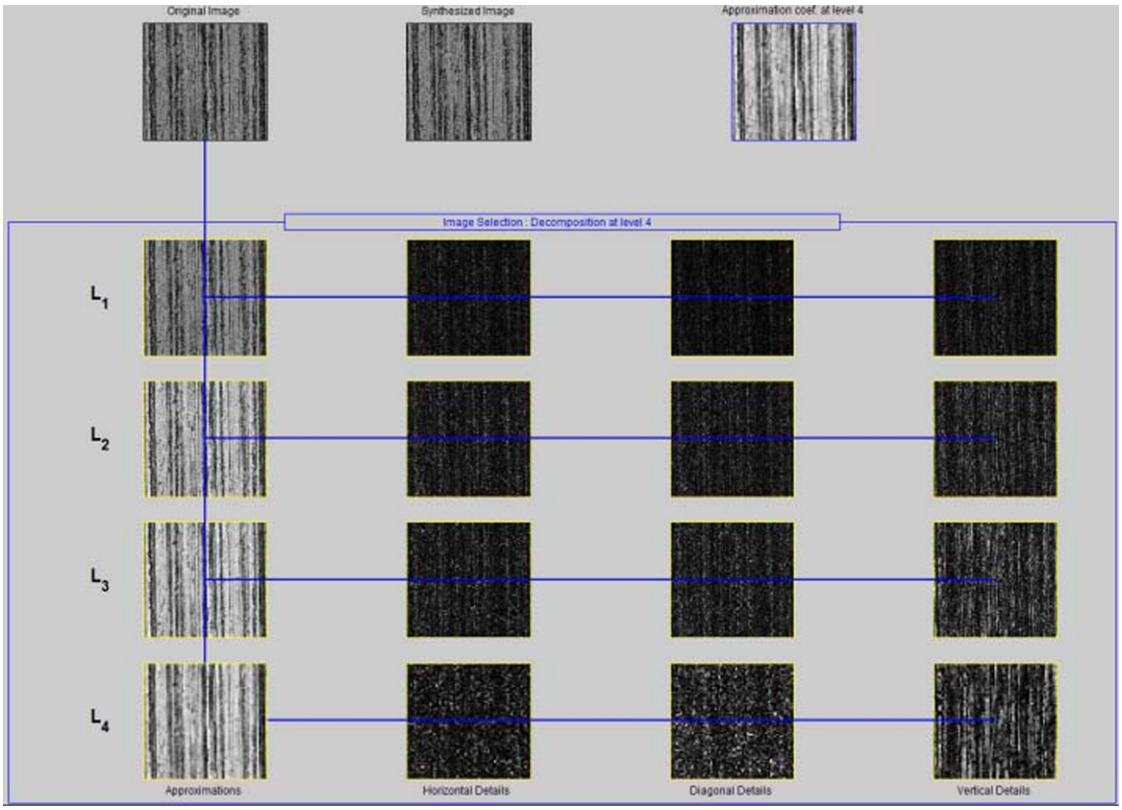

Figure 13 Wavelet transform for the front milled surface.[21]

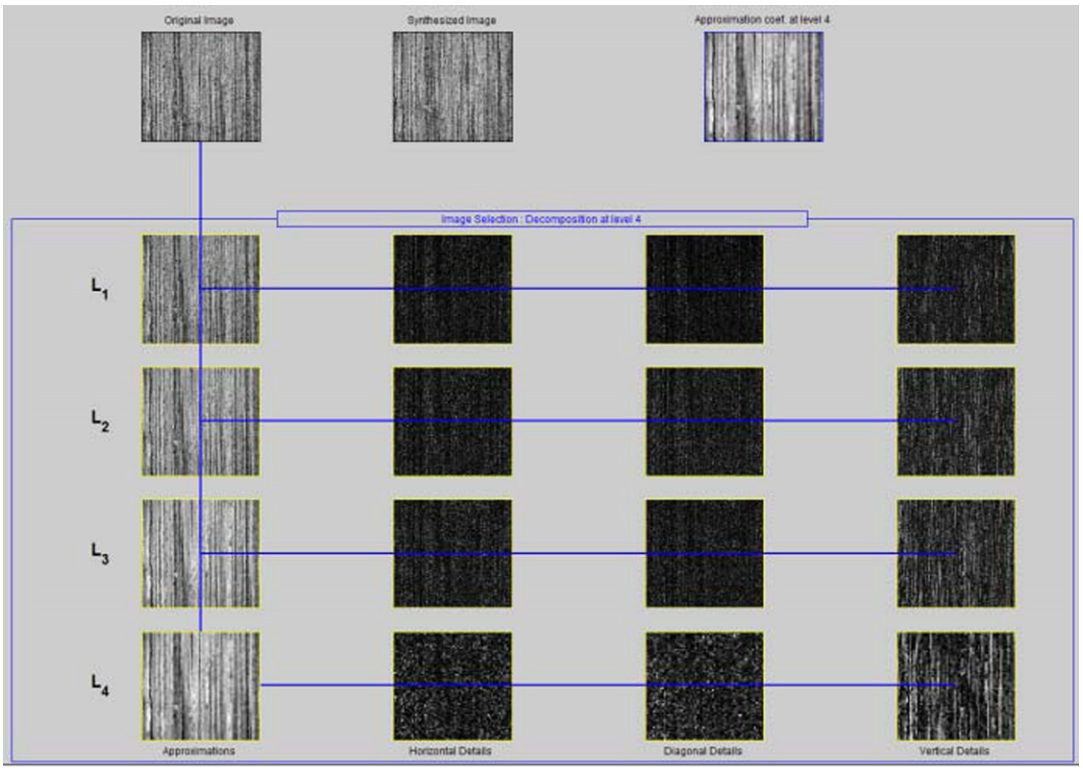

Figure 14 Wavelet transform for the face turned surface.[21]

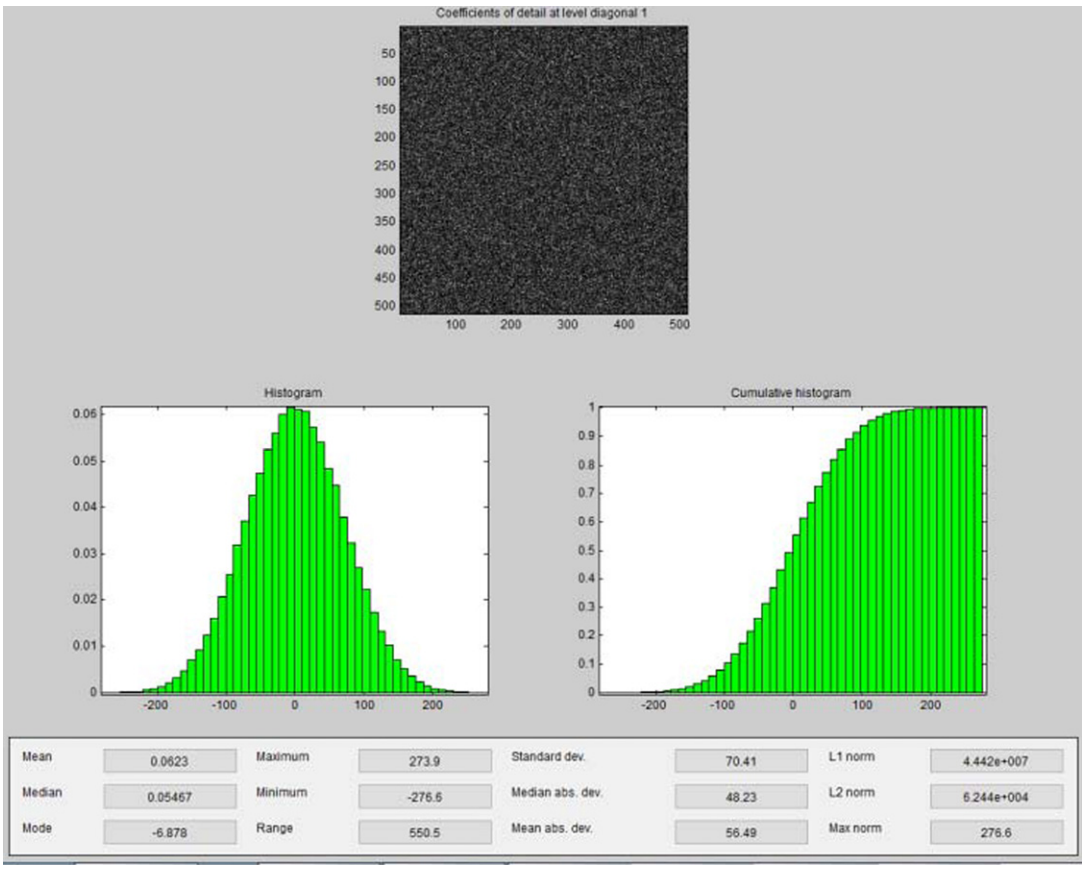

Figure 15 Statistical results from wavelet transform for the grounded surface.[21]

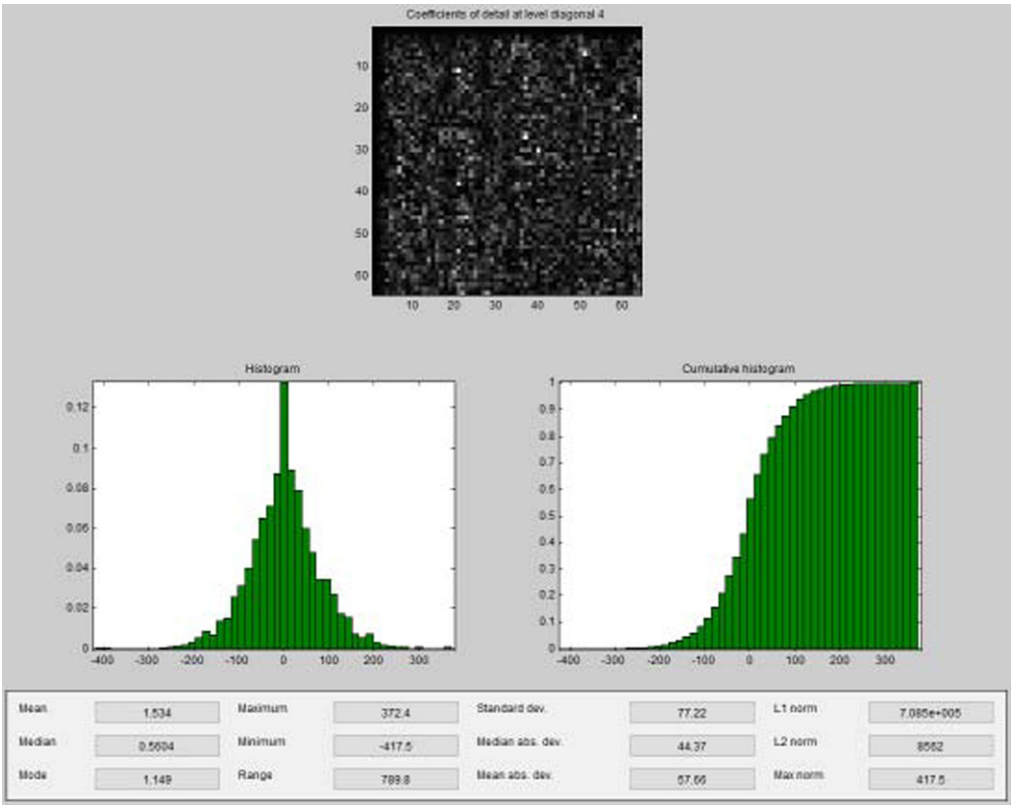

Figure 16 Statistical results from wavelet transform for the front milled surface.[21]

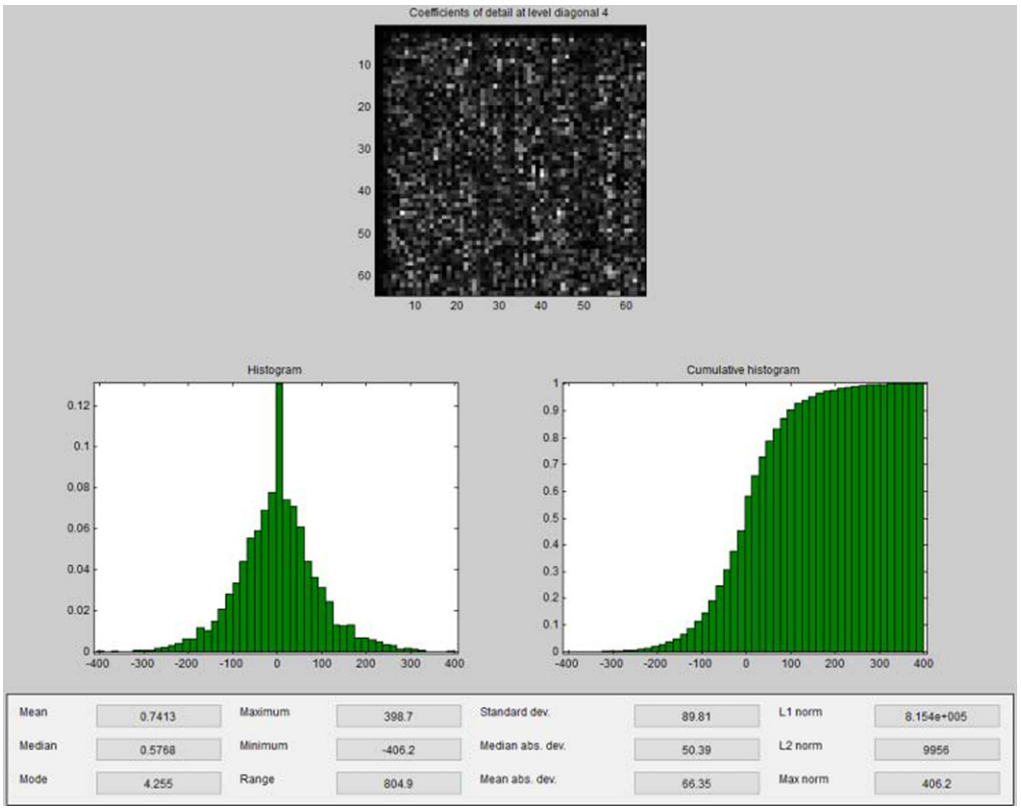

Figure 17 Statistical results from wavelet transform for the face turned surface.[21]

In computational phase, image processing, and analyses algorithms are applied to find out the surface parameters (Figure 6).

In recent years, there have been many researches regarding the surface characterization using CV. CV studies focus on image acquisition, processing, and analysis. Each phase is so vital in order to perform right measurement. In image acquisition phase, camera specifications such as the field of view (FOV), aperture size, focal length, shutter speed, pixel size, zooming, ADC type (x bit), lighting specifications; light type (Led, laser, ambient, fluorescent lamp, incandescent etc.), the position of lighting (rear, front, side, structured etc.), intensity variation by the time, scattering, and environmental conditions; temperature, dust, and moisture can affect the performance of measurements.

Several investigations have been performed to inspect surface roughness of a workpiece by using image processing techniques. The same location of each captured image as shown is processed and analyzed using image processing software. Mostly, the names of the techniques carried out are Line scanning, Speckle, 2D Fast Fourier Transform (FFT), 2D Wavelet Transform (WT) image processing techniques.

In this chapter, for better comprehension, three parts with three different surface roughness parameters are taken as a case study. Then, each image analysis technique is applied to these images. The distinction of surface roughness parameters are observed after the application of these algorithms to these images.

Figure 7 shows the images taken from workpieces manufactured by conventional manufacturing processes such as grinding, milling, and turning. Surface parameters are measured and calculated using standard instruments and their software. The computed surface parameters in this study are a variety of surface parameters such as R_z, R_a, R_q, R_t, taken as R_a values.[18] These values are the average values from ten measurement points. The results from analysis are as follows: R_a values are 0.498, 2.382, and 3.984 μm for ground, front milled, and face turned surfaces, respectively.

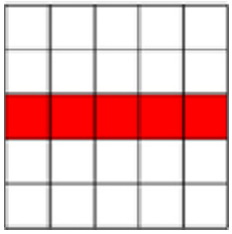

Figure 18 Line scanning representation.[20]

3.18.3.1 FFT

The Fourier Transform is used if the geometric characteristics of a spatial domain image are desired.[19] Because the image in the Fourier domain is decomposed into its sinusoidal components, it is easy to process certain frequencies of the image. The 2D FFT algorithms transform the spatial domain image into the frequency domain image to identify the major influencing factors. The captured color images of samples produced by different manufacturing techniques are transformed into gray level 8 bit images. Eight bit gray images are binarised using different threshold level such as 0.2 threshold level. Binarised images are analysed using FFT. The percentages of black and white pixel numbers of the transformed images are then computed in order to validate with other surface parameter determination methods. Here is the example how the number of white and black pixels are computed.

Calculation of the percentage of black pixels (PBP) is presented below:

$$\mathrm{PBP} = \frac{\mathrm{TNBP}}{\mathrm{TNP}} \times 100 \qquad [1]$$

where,

PBP is the percentage of black pixels (%),

TNBP is the total number of black pixels in the image,

TNP is the total number of pixels in the image.

Calculation of the percentage of white pixels (PWP) is presented as follows:

$$\mathrm{PWP} = \frac{\mathrm{TNWP}}{\mathrm{TNP}} \times 100 \qquad [2]$$

where,

PWP is the percentage of white pixels (%),

TNWP is the total number of white pixels in the image,

TNP is the total number of pixels in the image. Then, the comparison between the images taken from different surface topographical structures is conducted.

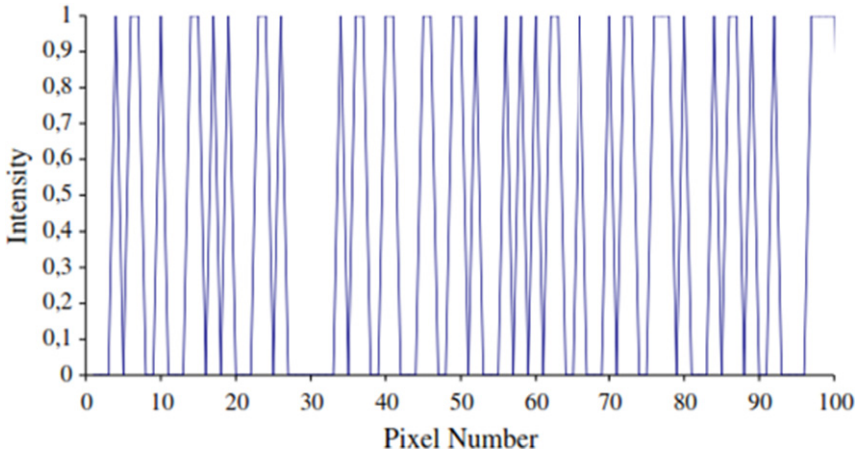

Figure 19 The signal taken from the image workpiece manufactured by grinding (R_a=0.498 μm).[17]

Figure 8 illustrates the results of 2D FFT analyses. Figures 8(a)–8(c) clearly indicates that as the roughness increases the diameter of white pixels blob decreases. Additionally, the number of black pixels increases as the roughness of surface increases.

Figure 9 shows the relationship between the number of black pixels and surface roughness values obtained from standard measurement methods.[6–9] The number of black pixels in the image increases with increase in surface roughness values. Also, as the surface roughness values increases, the

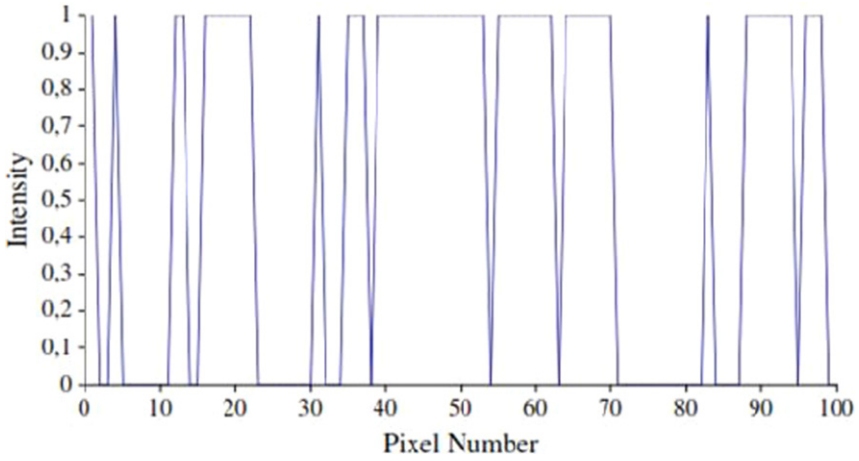

Figure 20 The signal taken from the image workpiece manufactured by milling (R_a=2.382 μm).[17]

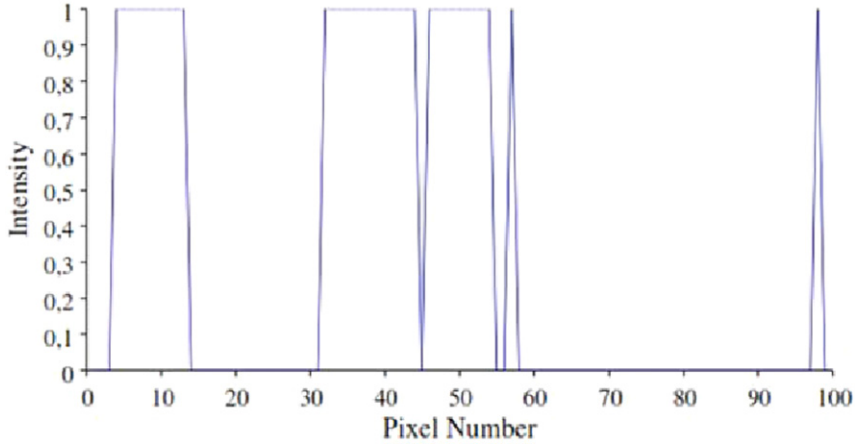

Figure 21 The signal taken from the image workpiece manufactured by turning (R_a=3.984 μm).[17]

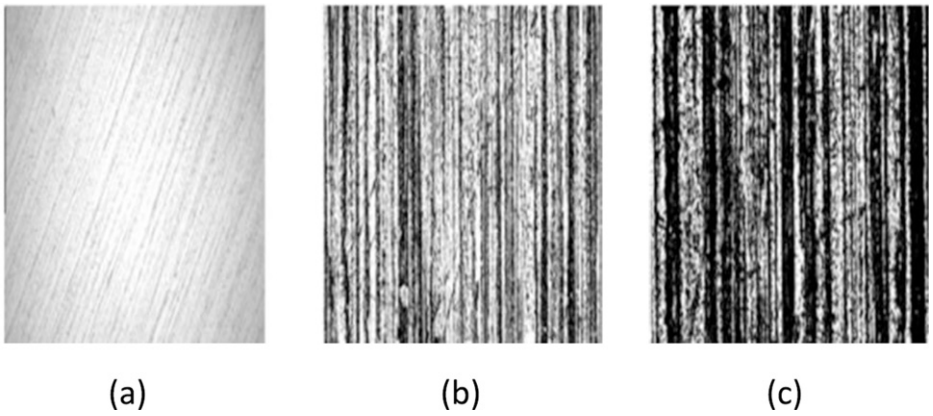

Figure 22 The speckle images added to binarised images of workpieces (a) Ground surface (R_a=0.498 μm), (b) Front milled surface (R_a=2.382 μm) and (c) Face turned surface (R_a=3.984 μm).[17]

number of white pixels in the image decreases. The regression equation and the coefficient of determination for the relationship between black pixels and surface roughness values are given at eqn [3].

$$Y_{bp} = 145\ 061 * R_a - 105\ 427 \quad (R^2 = 0.91) \qquad [3]$$

where,

Y_{bp} is the number of black pixels

R_a is surface roughness.

3.18.3.2 WT

WT works as decomposing the image into its frequencies but preserving the information coming from spatial domain. Decomposition can be explained as the application of filtering. The filtering here is the implementation of low-pass and high-pass filters, accordingly (**Figure 10**).

Figure 11 indicates the WT procedure. **Figures 12–14** demonstrate the WT results for the surface images captured from workpieces manufactured by conventional techniques such as grinding, front milling, and face turning.

The statistical results from WTs for the surface images captured from workpieces manufactured by conventional techniques such as grinding (**Figure 15**), front milling (**Figure 16**), and face turning (**Figure 17**) are illustrated.

Statistical results from discrete wavelet transform analysis indicate that standard deviations derived from the images decomposed at level 4 have significant relationship with R_a values for ground, front milled, and face turned surfaces, respectively (*Stdv*: 70.41, 77.22, 89.81, and R_a: 0.498, 2.382 and 3.984 μm).[21]

3.18.3.3 Line Scanning

True color images are binarised. DN values of binarised images are collected from the selected lines using line scanning technique. **Figure 18** illustrates how information is picked up from the image for further analysis by line scanning.[20]

The results of line scanning as an image processing techniques from **Figures 19–21** clearly indicate that pulse numbers are different for each surface. The number of pulses is 28, 11, and 5 respectively for ground, front milled, and face turned surfaces. Also pulse widths of signals confirm that pulse widths increase with increase in surface roughness.

3.18.3.4 Speckle Infusion

Speckle is the random pattern of bright (white pixels) and dark (black pixels) regions that is observed when a surface is illuminated with a highly coherent light beam. When the illuminating beam is reflected from a surface, the optical path difference between various wavelets with different wavelength would result in interference showing up as a granular pattern of intensity termed as speckle. The properties of this speckle pattern are used for estimation/quantification of roughness parameters. The spatial properties of the speckle pattern can be related to the surface characteristics. For example, surface roughness may be extracted from the information provided by speckle pattern.[17,22] For example, when Matlab is used for image processing, the function in image processing toolbox is presented as 'J=imnoise (I,'speckle',v).'

The function adds multiplicative noise to the image I, using the eqn [4] below,

$$J = I + n * I \qquad [4]$$

where, n is uniformly distributed random noise with mean 0 and variance v. The default value in the toolbox for v is 0.04.

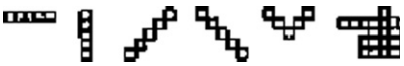

Figure 23 Image particle-finding method.[20]

Table 3 Blob analysis description

Color	*Description*
Green	All the particles found in an image
Blue	The smallest particles
Yellow	Small particles
Red	Big particles
Pink	The biggest particles

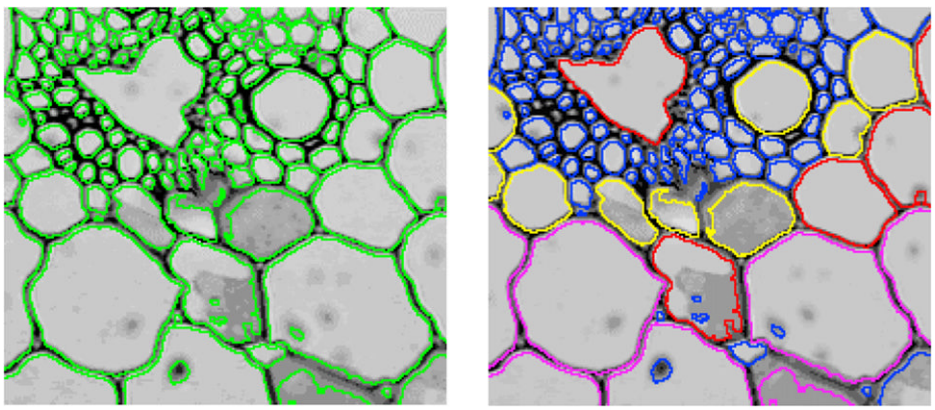

Figure 24 Visual (Blob) sieving: (a) Found particles and (b) Classified particles.[20]

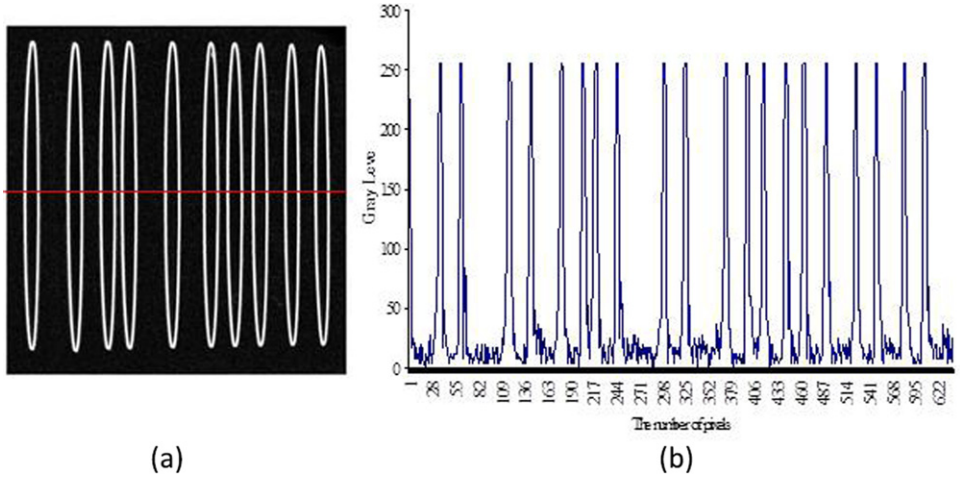

Figure 25 Signal extraction with line scanning method from an (a) edge-detected image and (b) extracted signal.[23]

This technique adds multiplicative noise to the image. The variance of the added random noise in this study is 0.05.

Speckle analyses results are shown in **Figure 22**. **Figures 22(a)–22(c)** clearly indicate that as the roughness increases the both sharpness and color distinctions increase. Also, surface texture becomes more recognized.

3.18.3.5 Morphological Evaluations

3.18.3.5.1 Blob analyses

In the image sieving method, images are resampled to the X by X pixel frames. Then the Color level is decreased to the 16 gray (4 bit) and the image particles are found. This is shown pictorially in **Figure 23**. In particle finding method, decision is made whether neighboring pixel is the part of the same particle with the selected pixel or not. The criteria can be standard deviation of the selected pixel.

In particle finding procedure, a particle is defined as a number of connected pixels within a particular grayscale range, specified by low and high threshold values. After finding the particles in an image the software is trained by picking up the same size particles for each class. In this case, the four classes are determined. The mean, minimum, maximum numbers of area and perimeter and also particle numbers of each class in the images are computed. The results are shown as the found particles (**Figure 24(a)**) and the classified particles (**Figure 24(b)**). **Table 3** also explains the description for blob analysis results. Blue, yellow, red, and pink refer to particle size range from small to large.[20]

3.18.3.5.2 Edge enhancement and detection

Obtaining accurate size information is not easy task. **Figure 25** illustrates how size information from an image was obtained. Red line shows that data is retrieved from the image (see **Figure 25(a)**). Extracted signal which represents gray level values for pixel positions is illustrated in **Figure 25(b)**. DN values over 250 suggest that there is an edge in that pixel location. In theory, the more the frequency of signal extracted from across the images the more the particle number in that axis, because each peak value represents the one edge in the image.

3.18.4 Concluding Remarks

In this chapter, surface finish quality evaluations with CV/Machine Vision are discussed in three subsections. These subsections are surface finish quality, imaging systems for surface characterization, and surface evaluation methods by CV. These subsections are so vital in order to comprehend the relationships among surface quality parameters, imaging instruments, and surface finish. With the advance of new technologies, machine vision techniques would be used widely in the industry for the characterization of surface finish quality. Rapid and real-time measurement capability of machine vision systems could improve and develop the technique for the characterization of surface parameters in the future.

3.19.1 Introduction

Each substance ends at a point or place. This point or place is the surface and it is not an actual end point, but rather a point to distinguish two states or physical concepts. On the surface of a liquid, the molecules have fewer neighbors in comparison with the bulk volume. As a result, the energy interaction is evident in the surface tension, γ_{LV}, a force that is applied to decrease the area of the free surface of the liquid. Traditionally, the surface tension can be assumed as a force in the unit of the length, which can be counted in Newtons per meter squared or in energy for the units of the surface (Joule per meter squared).[1] The surface tension, γ_{LV}, implies an interface between liquid and vapor, which is an example of surface tensions. Two other interfaces, including solid–liquid and solid–vapor, create the surface tensions of γ_{SV} and γ_{SL}. The equilibrium between these surface tensions decides that a droplet on a solid surface will have a droplet form or will change to a layer form.[2] As shown in recently published work, the lexicology of the word 'wettability' has not been clearly paraphrased. So, we aim to elucidate it here.

The words 'hydro,' 'phobic,' and 'philic' are derived from Greek and mean water, fear, and adoration, respectively. These words are used to define the interaction of water and other materials. As an example, these words are used to classify liquids and solids based on their solubility in water and based on their wettability.[3] Many surfaces in the nature have superhydrophobic and self-cleaning properties. For example, the wings of the butterfly and the leave of some plants (including cabbage and Indian cress) have the aforementioned properties. The best example is the lotus leaf.

The electron microscope pictures of the lotus leaf show some protrusion parts that are 20–40 μm away from each other and are covered with a rough surface with a waxy structure. Numerous studies confirm that this coarsened structure is a combination of micrometer and nanometer scale, with low surface energy; this combination causes a contact angle higher than 150°, low slide angle, and self-cleaning effect. Surfaces with such properties are called 'superhydrophobic.' Some natural examples do not show this two-scaled structure, and there are some questions about the necessity of this two-scaled structure, which is discussed in Section 3.19.2 from the wettability point of view.[4] Before 1996, little attention was given to the superhydrophobic surfaces that were based on the connection of the static contact angle of the water and the geometry of the rough surface. In 1997, two German botanists, Neinhuis and Barthlott, using scanning electron microscope (SEM) discovered the two-scaled structure of the lotus leaf and investigated its chemical composition. That study revealed two important guidelines for researchers who study superhydrophobic surfaces: the roughening of the surface of materials with low surface energy and the modification and creation of the rough surfaces using materials with low surface energy. Therefore, the unusual surface wettability in nature can be created by controlling the microstructure of the geometry of the surface and low surface energy. After that discovery (by German scientists), much research and many review articles related to the superhydrophobic surfaces were published, which explained the applications of the superhydrophobic surface. These applications include self-cleaning windshields of cars, optical equipment, windowpanes, and anti-fog and anti-corrosion coatings. In many reviews and research articles, the 'lotus effect' was investigated and the microscaled/nanoscaled structure was suggested to create and develop superhydrophobic surfaces (Figure 1).[5]

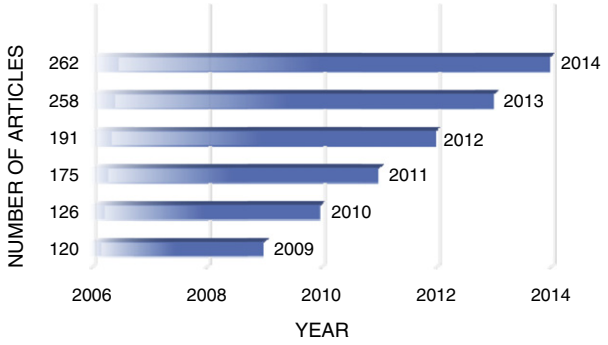

Figure 1 The bar chart of the articles in the past 6 years. Cao, L. *Superhydrophobic Surface: Design, Fabrication, and Applications*; University of Pittsburgh: Pittsburgh, PA, 2011.

3.19.2 Surface Wettability

3.19.2.1 Wettability on a Flat Surface

When a liquid droplet is on a physically and chemically homogeneous surface (Figure 2), wettability of the surface is determined by the chemical composition of the surface. The contact angle of a flat surface (or inherent contact angle θ_{flat}) can be related to three free surface energies in the Young equation: free surface energy of the intersections of solid–vapor (γ_{SV}), solid–liquid (γ_{SL}), and liquid–vapor (γ_{LV}) (Figure 2).[6]

$$\text{Cos}\,\theta_{flat} = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \quad [1]$$

In which the γ_{SL} is approximated using the following equation:[6]

$$\gamma_{SL} = \gamma_{SV} + \gamma_{LV} - 2\sqrt{\gamma_{SV} * \gamma_{LV}} \quad [2]$$

According to eqns [1] and [2], by increasing the free surface energy of solid–vapor (γ_{SV}), the hydrophobia increases. It has been reported that the intersection with the lowest surface energy belongs to the trifluoromethyl group (6 mN m^{-1}), which with a contact angle of 120° has the highest surface contact angle of water on the flat surface. Increasing the hydrophobicity requires manipulation of surface topography.

Modifying the contact angle of samples, with the aim of hydrophobizing the hydrophilic surface, requires reduction of surface energy, with different methods, of low-energy materials that are placed on the surface. The most common and most popular of them are silanes[8,9] and fluoropolymers.[10,11]

3.19.2.2 Wettability on Rough Surfaces

The effect of surface roughness on wettability was discussed by Wenzel in 1936, and later by Cassie and Baxter in 1944. Wenzel suggested that when a surface becomes rough, the area of the affected surface increases, resulting in more of a tendency for

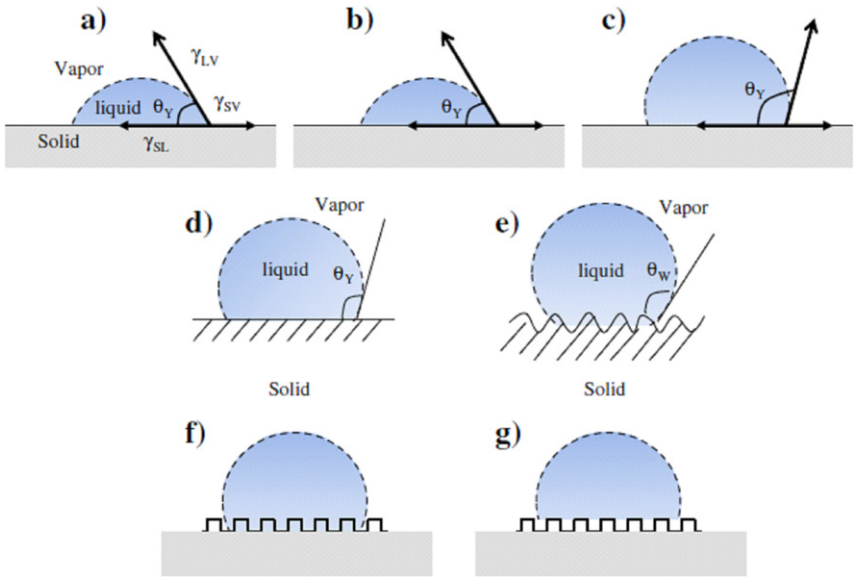

Figure 2 Schematic illustration of contact angle: (a) contact angle of Young's equation; (b) hydrophilic surface; (c) hydrophobic surface; (d) a smooth solid surface; (e) a rough solid surface; (f) homogeneous (Wenzel state) wetting regime; and (g) heterogeneous (Cassie–Baxter state) wetting regime.[7]

water to be more widespread on the hydrophilic surface and in the increased contact of liquid and the surface; spreading on the rough hydrophobic surface decreases to decrease the contact angle. These two states are more favorable from a thermodynamic point of view. A key assumption is that the water is completely in contact with the surface, which is named the Wenzel state (**Figure 2(f)**). The relation between superficial contact angles (θ_{rough}) in the coarse surface and inherent contact angle (θ_{flat}) can be explained by the Wenzel equation.[6]

$$\cos\theta_{rough} = r\cos\theta_{flat} \quad [3]$$

Where r is the roughness factor and is defined as a ratio of the real surface to the horizontal surface. Because r is always higher than 1 for a rough surface, the equation predicts that if $\theta_{flat} > 90$, then $\theta_{rough} > \theta_{flat}$, and if $\theta_{flat} < 90$, then $\theta_{rough} > \theta_{flat}$. So, in the Wenzel state, the surface roughness increases the hydrophobia of the hydrophobic surface and also increases the hydrophilicity of the hydrophilic surface.[6]

It seems impossible for the water to follow surface bumps of the hydrophobic substrate to keep complete contact with the solid surface. That is because in this state, the energy of complete contact is higher than that of partial contact with the surface. It is possible that air gets trapped between the water and the texture of the surface. As a result, the water contacts the surface of the solid–vapor composite and shapes the droplet. This is called the Cassie state (**Figure 2(g)**). The superficial contact angle is explained in the Cassie state with the Cassie–Baxter equation. $\text{Cos}\theta_{LV}$ is the fraction of surfaces that are in contact with the air.

$$\cos\theta_{rough} = \varphi_s * \cos\theta_{flat} + \varphi_v * \cos\theta_{LV} = \varphi_s * \cos\theta_{flat} - (1 - \varphi_s) \quad [4]$$

Where φ_s and φ_v are the fraction of solid in contact with water ($\varphi_s + \varphi_v = 1$). Because the contact angle of water in the air is 180°, the trapped air significantly increases the superficial hydrophobicity of the surface. According to eqn [4], reduction of φ_s, increases the θ_{rough} and results in hydrophobicity. In the Cassie equation, surface roughness has no effect that can be obtained using the roughness number of eqn [5].[12]

$$\cos\theta = r\cos\theta_{flat} - \varphi_v * (r\cos\theta_{flat} + 1) \quad [5]$$

For a system in which the water is in contact with the coarse solid surface, one of the two states can happen. Equations of Wenzel and Cassie cross-over at the critical point of θ_c.[6]

$$\cos\theta_c = -\frac{1 - \varphi_s}{r - \varphi_s} \quad [6]$$

When $\cos\theta_{rough}$ increases, the energy of the system reduces linearly. So, when the water is in contact with the surface of the solid and $\theta_c > \theta_{flat}$, the Wenzel thermodynamic state is more stable. Because $r > 1$ and $\varphi_s < 1$, Q_c is always higher than 90°. With this kind of roughness, when $\theta_c < \theta_{flat}$, the Cassie state occurs on hydrophobic surfaces. All the aforementioned equations are for homogeneous or uniform roughness. So, the general state for the Cassie surface contact angle is provided by eqn [7] (see **Figure 3**).

$$\cos\theta_{composite} = f_1(x,y) * \cos\theta_1 + f_2(x,y) * \cos\theta_2 \quad [7]$$

3.19.2.3 Contact Angle Hysteresis

Another parameter in addition to the contact angle, which is measured in the static state, is needed to specify the wettability.

The hysteresis of the contact angle is the difference between the advancing contact angle (θ_A) and receding contact angle (θ_R), which appears due to the roughness and the heterogeneity of the solid surface. 'Hysteresis' of the contact angle has been derived from the shape of the contact angle in the mobile surface method. In the mobile surface method, the intersection moves slowly and creates advancing and receding contact angles (**Figure 4**). If the roughness is the first agent to be

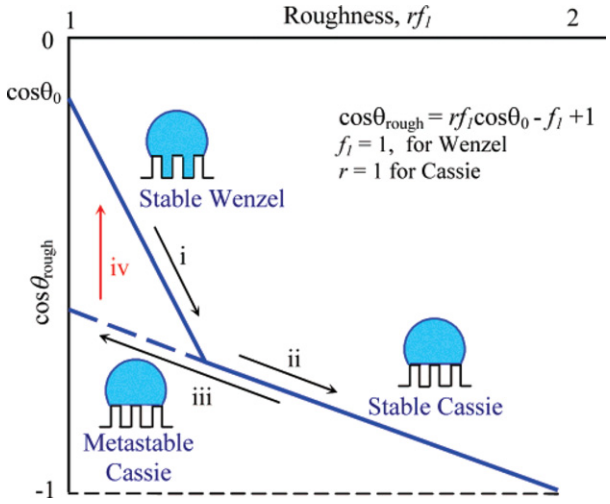

Figure 3 Wetting hysteresis for a superhydrophobic surface. Contact angle as a function of roughness. The stable Wenzel state (i) can transform into the stable Cassie state with increasing roughness (ii). The metastable Cassie state (iii) can abruptly transform (iv) into the stable Wenzel state. The transition from (i) to (ii) corresponds to equal Wenzel and Cassie states of free energies, whereas the transition in (iv) corresponds to significant energy dissipation and thus is irreversible.[13]

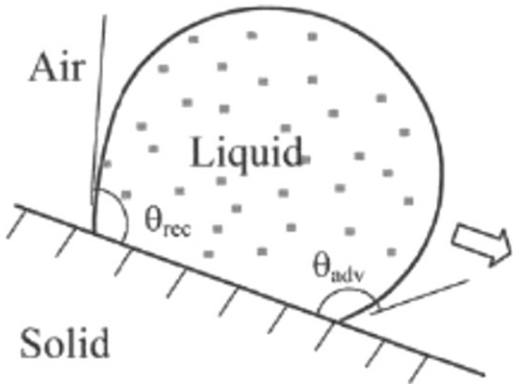

Figure 4 Schematic of a droplet on a tilted substrate showing advancing and receding contact angle.[13]

calculated, then the contact angle measured from the Young equation is meaningless.[14] The advancing and receding angles have the most and least Gibbs free energies, respectively. The barrier of energy for the surface to achieve the least energy is very high. This unstable energy level can be eliminated using vibration, but the least energy still cannot be achieved.

3.19.2.3.1 Film pressure contact angle hysteresis

In most of the intersection systems, it has been observed that the contact angle depends on this concept of how the liquid advances on the dry surface or how it recedes on a wet film surface. Because of the film pressure, free energy of the solid surface, γ_{sf}, changes, which can be determined with eqn [1], in which π is the film pressure. This equation cannot be applied to the Cassie state and is only calculated for the Wenzel state.

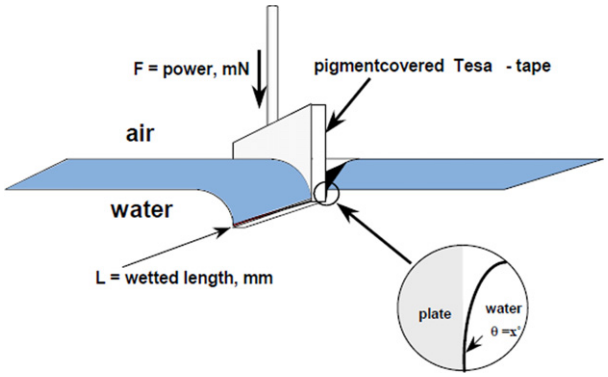

Figure 5 Modified 'Wilhelmy plate' technique.[16]

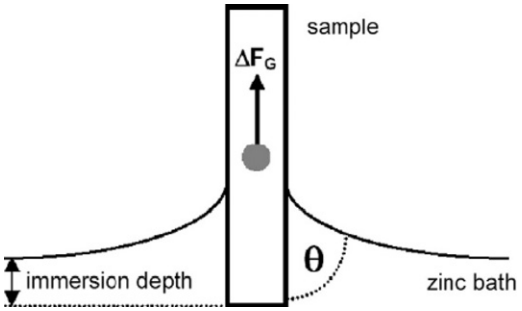

Figure 6 Applied Wilhelmy plate methodology with partially dipped sample.[18]

$$\gamma_{sf} = \gamma_{SV} + \pi = \gamma_{SV} + \gamma_{LV}(\cos\theta_R - \cos\theta_A) \quad [8]$$

Because the spreading of the droplet is not spontaneous, it is accompanied by increasing free energy of the solid surface in the territory of the receding droplet. As a result, π would be positive. If the liquid remains after receding of the droplet, then eqn [2] can be used.[15]

$$\gamma_{SV} = \frac{\pi*(1+\cos\theta_A)^2}{(1+\cos\theta_R)^2 - (1+\cos\theta_A)^2} \quad [9]$$

3.19.2.4 Methods of Contact Angle Hysteresis Measurement

3.19.2.4.1 The Wilhelmy method

In Figures 5 and 6, we can see the schematic of the Wilhelmy plate technique. The F force for partial soaking of a flat surface in a solution is as given in the equation, where P is the wetted perimeter of the surface, γ is the surface tension of the liquid, θ is the contact angle of the vapor–solid–liquid, ρ is density of the liquid, A is the area of the cross-section of the surface, h is the soaking depth, and g is the gravity constant.[14]

$$F(h) = P\gamma\cos B - pAhg \quad [10]$$

In the dynamic position, for capillary number, $Ca = \eta v/\gamma$ less than 10^{-15}, where η is the viscosity of the liquid and v is the speed of contact line movement of the air–solid–liquid; the dynamic contact angle is almost equal to the static contact angle. So, if the applied force on the surface, F, is recorded during the cycle of testing, slow soaking, and exiting of the test

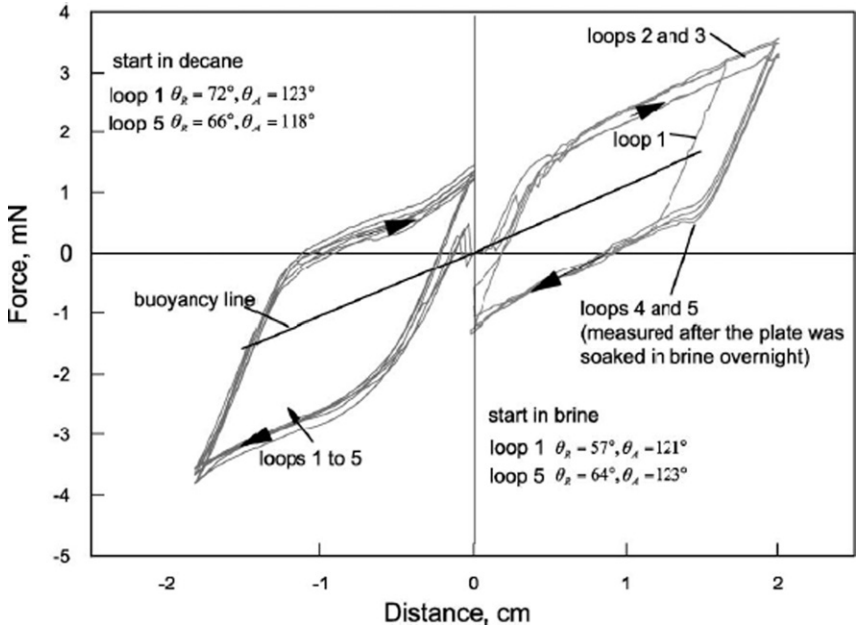

Figure 7 Force–distance diagrams for plates prewetted in 0.1 NaCl brine and aged in A95 crude oil for 10 days at 80 °C.[17]

liquid, then that diagram of F as a function of soaking depths, h, should be linear with the slope of $-\rho Ag$ and γ-intercept of $P\gamma\cos B$. For porous and hygroscopic materials, the weight of the surface might change during the cycle of the testing due to the absorption and desorption of the liquid. So, the measured force is in the form of eqn [11]. $F_w(t)$ is the weight of absorbed water during time.[14]

$$F(h,t) = P\gamma\cos\theta + F_W(t) + \rho Agh \qquad [11]$$

The results of the Wilhelmy test are shown in the diagrams in Figure 7. The hysteresis of the contact angle that results in a difference of force is clear in the results. As the distance of the two parallel lines increased, the more hysteresis of the contact angle that was recorded for the samples with different wettabilities. One of the advantages of this method is that it gives a mean value of different places on the sample, and its disadvantage is that it needs symmetry in the sample and indirect data that should be converted to the contact angle. In Figure 8, a real diagram of the Wilhelmy test results from the zinc samples with oxide coatings is shown. Shifting of the diagram to the more positive values shows a reduction in the contact angle. In fact, it is the distance between advancing and receding hysteresis of the contact angle that is reduced. The slope of the diagram shows the buoyancy force, which has a direct relation with the width of the sample, and these variations occur because of the physical heterogeneity of the sample.

The results of the Wilhelmy diagrams are dependent on the surface of the solid sample, and the condition of the solution also has an effect.

Figure 9(a) shows the profile of force and soaking depths for a wetted sample with no buoyancy effect detected. Figure 9(b) shows the effect of buoyancy as the slope of the sample; this effect could be eliminated with measurement of hysteresis of the contact angle at the crossover point with the surface for these samples. In Figure 9(c), the weight of the sample increases with the process and absorbs the liquid. This method can be used for the porous materials that have a constant soaking rate and the absorbed weight changes. Figure 9(d) shows the required force for the sloping of the nonwetted sample into the liquid as a function of soaking depths. At first, the force does not increase because the contact angle is more than 90° and repels water, but the negative slope of the diagram still exists because of the buoyancy.

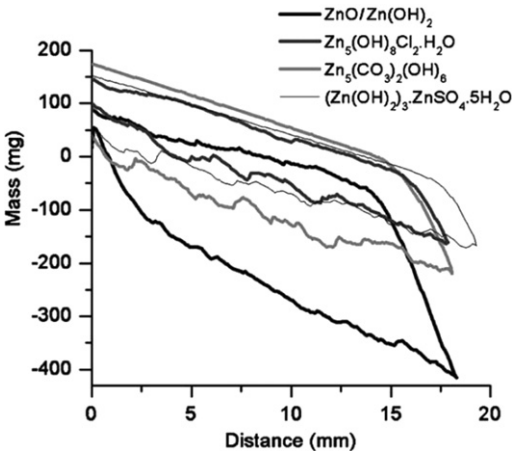

Figure 8 The Wilhelmy diagram showing the variation of the weight as a function of soaking distance in water for the zinc surfaces with oxide coating.[19]

3.19.2.4.2 The methods of suction and injection (sessile drop)

It is usually achieved with expansion and shrinkage of the droplet, using a needle to drag the droplet, and applying water to the droplet. This method is also known as slow dynamic contact angle. A droplet is poured on the surface and the

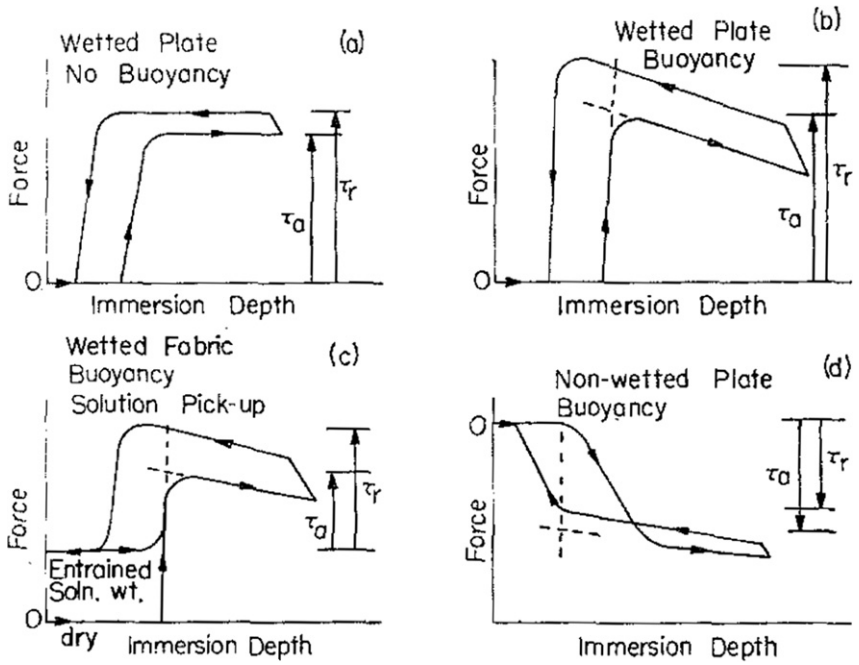

Figure 9 The profile of the ideal force and soaking depths for different solid samples. Each shows how the advancing and receding adhesive forces, T_a and T_r, are calculated.[20]

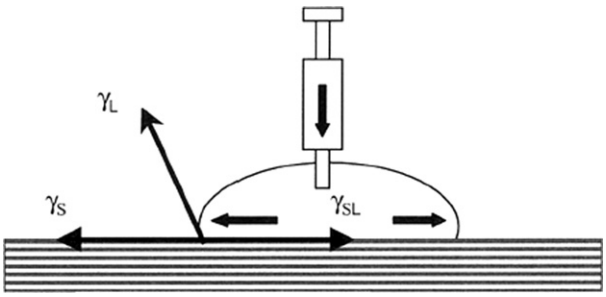

Figure 10 Schematic representation of the measurement of advancing contact angle.[21]

contact angle is measured. For the advancing contact angle, the liquid is injected into the droplet using a needle, and the volume of the droplet would increase continuously but the diameter of the droplet would remain steady (see **Figure 10**). The contact angle would also increase. In a second, the increased diameter and the contact angle would be at maximum value, and that value would be the advancing contact angle. For the receding contact angle, instead of injecting, the liquid would be suctioned; the minimum value during reduction of diameter is the receding contact angle. The limitation of this method is that several measurements of different areas of the sample should be performed and the mean value should be reported.

3.19.2.4.3 Tilted surface method

To investigate the hysteresis of the contact angle, a small droplet of approximately 5 µl should be placed on the flat surface. Then, up to the position that the droplet starts moving on the surface, the surface should be tilted. Then, the advancing and receding contact angles should be calculated using picturing and picture analysis. **Figure 11** shows some states of the droplet during this method. The limitation of this method is investigating the dynamic angle in the low velocities.

This method can be performed in a slightly different way: the droplet could be placed on the tilted surface, followed by blowing on the droplet (**Figure 12**). The droplet would grow in volume and, during moving of the droplet, the hysteresis of the contact angle should be calculated. As the droplet grows bigger, it should start sliding at a minor angle. Low contact angles are mostly in the Wenzel surface state and high contact angles are mostly in the Cassie state. When the hysteresis of the contact angle increases, it is possible that the advancing and receding contact angles are different from each other. Contact angle hysteresis could occur in the Wenzel or Cassie states at a constant value; the equilibrium contact angle requires prediction of the state of the surface (**Figure 13**).

The sliding angle is the least tilted angle of the substrate that causes the droplet to move. The connection between hysteresis of the contact angle with the sliding angle follows from eqn [12].[6]

$$\frac{Mg(\sin\alpha)}{W} = \gamma_{LV} * (\cos\theta_R - \cos\theta_A) \qquad [12]$$

Where α is the sliding angle, g is the gravity acceleration, M is the mass of the droplet, and w is the area of the wetting. From eqn [12], it seems that the sliding angle depends on the size and shape of the droplet. So, the smaller hysteresis of the contact angle results in a smaller sliding angle, and a constant droplet size could be used to compare the wettability.

3.19.2.5 Wetting Free Energies

To measure wetting free energies variations in a sessile droplet on a solid surface, a thermodynamic model with the assumption

Figure 11 The states of the liquid droplet (nonadhesive, adhesive, sliding) for the tilted droplet method.[22]

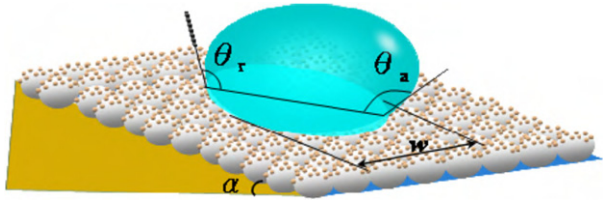

Figure 12 Schematic illustration of the liquid droplet that starts to slide down a tilted plate.[23]

of an adsorption mechanism has been identified. This model resulted in direct specification of the wetting free energies from contact angle data without any knowledge of solid–vapor–liquid interface tension. In this model, it has been assumed that the chemical potential of the surface of the solid is equal to the liquid droplet, the chemical potential of the liquid is dependent on the internal pressure of the droplet, the internal pressure of the droplet is dependent on the variation of the curvature of the droplet on the surface, and the droplet has a spherical shape at first but, after being placed on the surface, it becomes a part of wetting free energies.

Finally, a formula was achieved for wetting free energies as a function of the advancing contact angle (it is approximate to the equilibrium state in static position), which is mentioned in eqn [13]. **Figure 14** shows the wetting free energies as a function of advancing contact angle. With an increasing contact angle, the wetting free energies decrease exponentially and arrive at zero, which seems to be the tendency of the liquid when the wetting has been eliminated; according to eqn [5], liquid has no tendency to adhere to the surface.[24]

$$\Delta G = \left(\frac{1}{3}\right)(RT)*\ln\left[\left(\frac{1}{4}\right)(2+\cos\theta)(1-\cos\theta)^2\right] \qquad [13]$$

3.19.2.6 Contact Angle and Corrosion Resistance

Corrosion of metals in the electrolyte is dependent on the surface reactions, and any agent that repels corrosion agents or reduces the reaction rate can increase corrosion resistance, for example, inhibitors that reduce the contact surface or coatings that reduce the contact surface and increase the resistance. One of these agents is the contact angle of water on the surface. Many studies investigated the effect of the superhydrophobic contact angle on the corrosion rate.

The polarization test has been performed on anodized aluminum with modified surface energy using molten myristic acids (**Figure 15**). The superhydrophobic sample has more corrosion potential and less corrosion current; of course, it shows a passive state. The contact angle of the coating was 154° and the results of the electrochemical impedance show that the polarization resistance values for superhydrophobic and anodized surfaces were 337 and 27.94 kΩ, respectively.

3.19.2.7 Common Methods of Producing Superhydrophobic Surfaces

There are many physical and chemical methods for producing superhydrophobic surfaces that can be performed using two procedures. The first way is the modification of the rough hydrophilic surface with a hydrophobic layer. The second way is roughening of the hydrophobic surface. There are different physical and chemical methods to produce the hydrophobic surfaces, such as solution and laser etching, soaking, chemical vapor deposition (CVD), plasma vapor deposition (PVD), electroplating, electrospinning, anodizing, self-assembled monolayers (SAMs), synthesis, and sol-gel.

3.19.2.7.1 SAMs

SAMs are ordered molecule connections that are created on the surface of the solids with adsorption of a surfactant (**Figure 16**). This simple process has made the SAMs inherently producible, which are technologically attractive for superlattice production and surface engineering. In this 2D system, the ordering is produced by spontaneous chemical synthesis in an intersection as a system that is approaching equilibrium. Even though the surface is not limited to the long-chain molecules, SAMs of long-chain hydrocarbons are the most common complements for the supermolecular structures.

3.19.2.7.2 Fatty acid monolayers

Spontaneous absorption of long-chain *n*-alkanoic acid ($C_nH_{2n+1}COOH$) has been studied in recent years. This is an acid–base reaction and is the driving force for creation of the surface salt between the carboxylate anion and the surface cathode of the metal. These layers are placed on the oxides, but their chemical absorption on the amorphous oxides is not unique. It has been discovered that on the surface of AgO, two atoms of oxygen carboxylate connect to the surface symmetrically, whereas on the surfaces of CuO and Al_2O_3, the carboxylate, which has been connected to the surface asymmetrically, shows an angle approximating to zero (**Figure 17**).

3.19.2.7.3 Organosilicon-derivative monolayers

Monolayers of alkylchlorosilan, alkylalkoxysilanes, and alkylaminosilane need a hydroxylated surface as a substrate to be created. The driving force for this self-assembly is the creation of the connection with the position of polysiloxane that is to

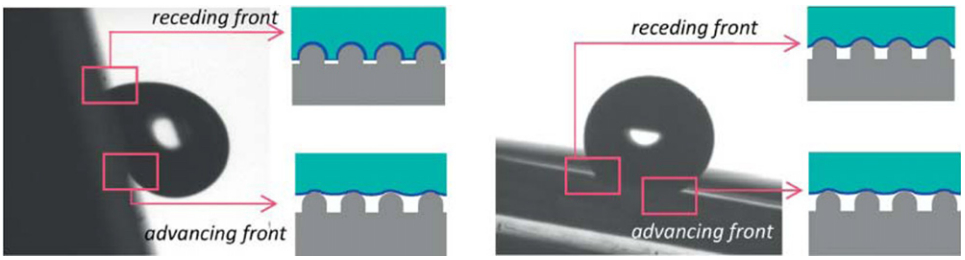

Figure 13 (Left) The droplets slides on the hydrophobic surface. Observed strong hysteresis (contact angle of 72°) can explain the difference in the wetting ability, which is due to the surface fraction of the liquid in contact with the air or the solid in the advancing and receding contact angles. (Right) The droplet moves on another surface with low contact angle hysteresis and with low surface energy. There is little difference between the fraction of solid in contact with the two sides.[22]

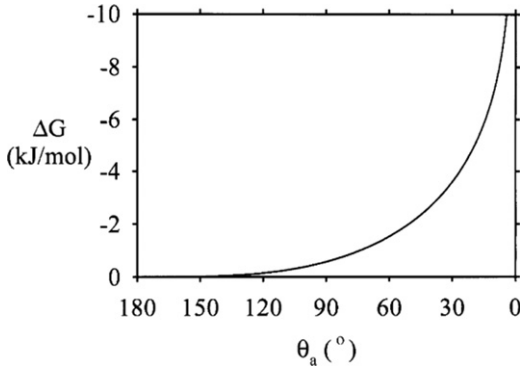

Figure 14 Variation of wetting free energies as a function of the advancing contact angle.[24]

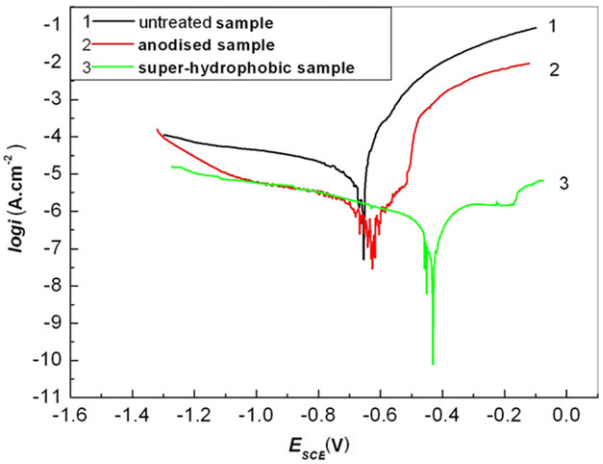

Figure 15 Polarization diagram of the untreated, anodized, and superhydrophobic samples in sterile sea water with 2 mVs^{-1}.[25]

connect with the surface of the silanol group with Si–O–Si bounds. The substrate, which was successfully prepared for these monolayers, includes silicon oxide, aluminum oxide, quartz, glass, mica, zinc selenide, germanium oxide, and gold. Because the substrates in the creation of SAMs are amorphous silanes, arrangement of alkyl chains in silane alkyl SAMs is specified below the structure of the polysiloxane chain. The recreating ability of the alkyltrichlorosilan is still a problem because the quality of the created monolayer is dependent on the reaction conditions. The coating time was different, from 90 min to 24 h. atomic-force microscopy (AFM) has proven the island structure of the partial monolayer. Researchers have discovered that the octadecyltrichlorosilane (OTS) of monolayers on mica is created with the nucleation of island hillsides with fractal dimensions that increase with the increase of the surface covering. In the OTS film, there are pinholes up to 100 nm wide.

3.19.2.7.4 Organic adsorbed sulfur on the metal

Sulfur and selenium complements have a high tendency to surface on transition metals. This is probably due to the creation of multiple bonds with the surface metal clusters. The kinetics of the alkanethiol absorption on the surface of gold (Au, 111) in relatively dilute solutions (millimolar) shows that there are two different absorption kinetics. First, there is a very fast step that results in a contact angle that reaches the value limit, and the thickness is 80–90% of the maximum value. Then, there is a slow step that takes hours, resulting in contact angle and thickness at the maximum values. The first step, which is explained by Longmire absorption under the control of diffusion, is highly dependent on the concentration of thiol. In a concentration of 1 mM, it takes approximately 1 min; in the concentration of 1 μM, it takes more than 100 min. The second step can be explained by crystallizing, which the alkyl chains avoid in their disordered manner and enter the unit cells. So, the first step of kinetics is dependent on the reaction of the head surface, and the activation energy might depend on the adsorbing sulfur electron density. In other words, the second step of kinetics is related to the disorder of the chain, different components of the chain–chain (bipolar–bipolar and others) reaction, and the movability of the chains.

3.19.2.7.5 Silanes

Silanes are a wide branch of materials that are used for these purposes, but they can be considered a subbranch of fluoroalkyksilanes (FAS). The synthesis of the silica fluor nanoparticles is performed by methods like spin coating. An agent in a group of fluorine particles is proven using the Fourier transform infrared spectroscopy (FTIR) method and indicating the presence of Si–O–Si and C–F bonds.

FAS can makes agents for silica particles using the sol-gel process. Fluorine silica can be produced with the Stober standard

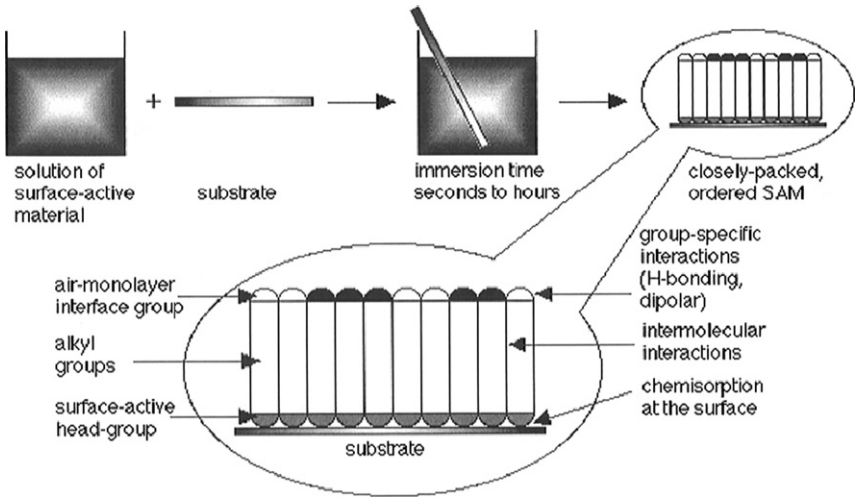

Figure 16 Self-assembled monolayers can be created by single soaking of the substrate in a solution of surface-activated material. The driving force for spontaneous creation of the 2D connection was the formation of a chemical connection of molecules with surface and intermolecular reactions.[26]

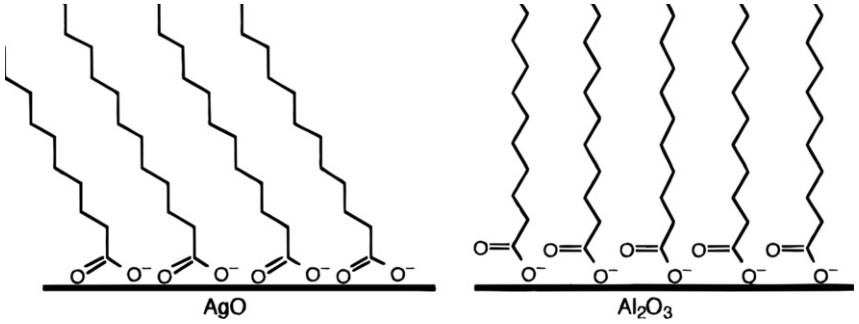

Figure 17 Monolayer of fatty acid on Al_2O_3 and AgO.[26]

process. Ethanol and ammonium hydroxide are mixed at 50° in a container. Tetraethoxysilane (Si $(OC_2H_5)_4$; TEOS) is added to the solution, droplet by droplet, while stirring. The transparent mixture is opaque because of the formation of silicon nanoparticles. The sensitized silica nanoparticles in a solution of ethanolic fluor alkyl silane or FAS 17 ($C_{16}H_{19}F_{17}O_3Si$) have more agents. With the spin-coating process, aluminum, glass, and silicon can be coated with fluorine silica nanoparticles. This coated film on a hot surface at 70° is too dry for vaporizing water and ethanol. The agented silica nanoparticles can be identified using infrared spectroscopy (Figure 18). With seven layers of coating, the contact angle is 150°. In one layer, the

roughness of the coating has not achieved the appropriate value and the contact angle is low. With the increasing layers, the roughness achieves the appropriate value and the contact angle increases (Figure 19).

3.19.2.7.6 Stearic acid ($CH_3(CH_2)_{16}CO_2H$)

Stearic acid is a saturated fatty acid that can deposit on the surface in special conditions. This acid is insoluble in water and soluble in ethanol. The copper substrate should be cleaned, pickled, and soaked in 10% volume HNO_3 for oxide elimination. The clean sample should be soaked in ethanolic stearic acid solution (0.01 M) and 30 V DC should be applied. The anode and cathode should be made of copper. Studying the X-ray powder diffractometer (XRD) peaks proves the existence of copper stearate components resulting from the reaction of stearic acid with copper. The resulting component was studied using SEM (Figure 20). These components provide the necessary roughness and low energy of hydrophobia so the contact angle arrives at 153° and so the hysteresis of the contact angle decreases. Other researchers created a self-assembled layer on porous alumina using stearic acid.[28] This method was performed on anodized aluminum in 0.01 volume of stearic acid solution in ethanol for 30 min without applying any potential and superhydrophobia was achieved.[29]

Due to the insolubility of stearic acid, it cannot be applied to sedimentation of magnesium stearate in an aqueous solution. With the addition of soda to stearic acid sodium, stearate would form, which is completely soluble in water. Magnesium stearate can be created by a reaction of magnesium sulfate, which is soluble in water, with sodium stearate, and the magnesium stearate would deposit in solution because it is insoluble in water. If magnesium chloride exists in solution other than magnesium stearate, then sodium chloride would also be produced. Of course, there is the possibility of its creation from a magnesium ion solution. The melting point of magnesium stearate is 85.5 °C, but the calcium stearate produced from the reaction of calcium oxide and stearic acid melts at 155 °C. Stearic acid was applied on the zinc oxide nanorods and the contact angle increased. The zinc oxide (Figure 21) produced was soaked in a solution of 0.002 M *n*-Hexane stearic acid and shows a contact angle of 151° and negligible hysteresis. The FTIR analysis shows that the bonding of the carboxyl group was broken and transformed to the carboxylate bidentate on the surface of zinc oxide.

Another method of creation of surfaces with high contact angles is hydrophobizing of particles, such as ceramics, and then depositing them on the surface.[32–34] Zinc oxide dry powder (0.209 g) and stearic acid (0.0595 g) in the ethanol solution (10 ml) should be mixed for 1 h with a constant speed at 75 °C. Then, the mixture should be aged for 2–3 h. The resulting suspension is used to create the thin film on the glass using the dip coating method. Then, it should be dried at 80 °C. To investigate the effect of stearic acid, samples were coated with different amounts. The researchers calculated an angle of 178° for the sample with an 8%M concentration of stearic acid and zinc oxide. This is because zinc oxide nanoparticles provide the required roughness and stearic acid provides low surface energy. In higher percentages, the contact angle decreases due to reduction of roughness. Hydrophobizing of the magnesium can be performed using a simple methods of soaking in a superhydrophobized ethanol solution with 0.05 mol l^{-1} stearic acid[35] (see Figure 22).

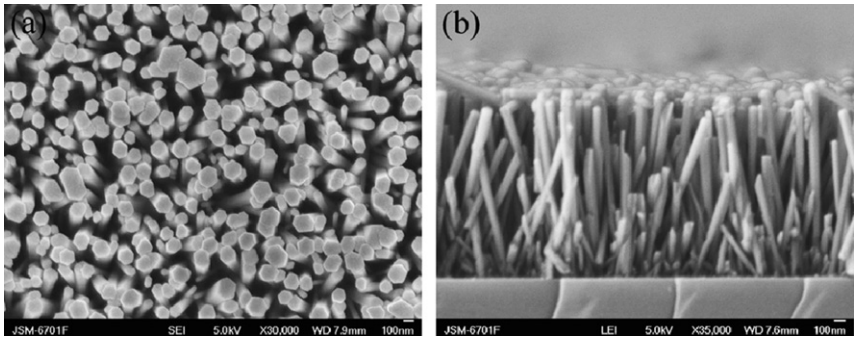

Figure 21 (a) Scanning electron microscope (SEM) tops and (b) cross-section of the zinc oxide nanorods after the first step.[31]

3.19.2.7.7 Tetradecanoic acid

Tetradecanoic is a hydrocarbon fatty acid like stearate that can react with metals and that creates a hydrophobic component on the surface. Copper (Figure 23) should be soaked in 0.01 M tetradeconoic acid solution in ethanol at room temperature for 3–5 days. Because of the oxygen in the environment, the copper will corrode, the copper ions react with the tetradecanoic, and the component is created. Finally, copper tetradecanoic can be created in cluster form and provides the hydrophobic condition of the copper specimen at 162°.

3.19.2.7.8 Benzoic acid ($C_7H_6O_2$ or C_6H_5COOH)

Benzoic acid is a colorless crystal solid that can reduce the energy of the surface in a reaction. This acid can be dissolved in water at less than 3 g per liter. A thin film of silver is created at room temperature on a clean copper substrate with simple soaking in blue silver nitrate solution with or without the presence of adequate concentrations of benzoic acid during a specified period of time. Silver attaches to the surface with a displacement reaction, the hydroxyl benzoic acid group attaches to the surface of copper and silver, and the superhydrophobic surface engenders an angle of 162° (Figure 24).

3.19.3 Topography of the Rough Surface

3.19.3.1 Characteristics of the Rough Surface

A rough surface (see Figure 25) (to be more specific, the intersection of liquid– solid, gas–solid, or solid–vacuum) has a complex structure and characteristics depending on the nature of the material and surface preparation. All the surfaces of solids, whether natural or artificial, regardless of production method, have disorders. No machine can produce a molecular flat surface for common materials. Even the flattest surfaces

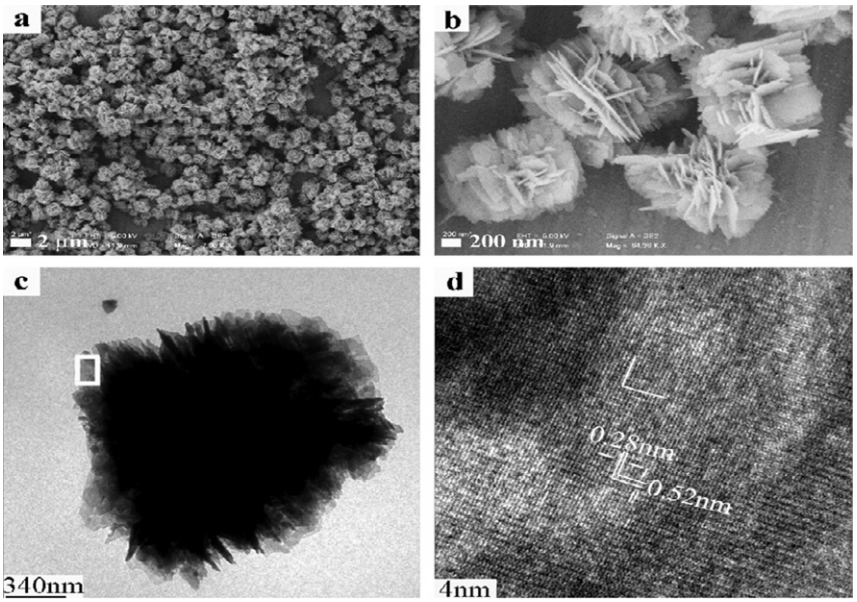

Figure 22 Field emission scanning electron microscope (FESEM) and transmission electron microscopy (TEM) images of the zinc oxide samples. (a) Panoramic FESEM image. (b) FESEM image with higher magnification. (c) TEM image of hierarchical microholes. (d) High-resolution transmission electron microscopy (HRTEM) image of a nanosheet with a distinct square.[32]

have disorders because of cleavage of some crystals (such as graphite or silica). Their height is on the atomic scale. Engineering surfaces usually contain the following:

- Wavy conditions
- Roughness
- Lay
- Imperfections

Wavy conditions are a result of vibrations from machine production or collision during production. These conditions involve disorders with relatively long wavelengths (usually some microns). Roughness is produced by surface vibration of the short wavelengths that are defined by the ledges (local maximum) or valley (local minimum). Lay is the main path of the main pattern that usually occurs during production. Undesirable and unexpected imperfections and unintentional discontinuities exist in texture.[38,39]

The difference between the properties of different kind of roughness is an issue that is related to the conditions, application, detachments limits, and measurement tools.

Generally, it is not possible for all properties to be measured simultaneously. The word 'hardness' has many meanings, and this can cause many problems. This is because of the concept that for one resolution, a value that is reported as a maximum on the surface profile might be reported as a minimum for another resolution.

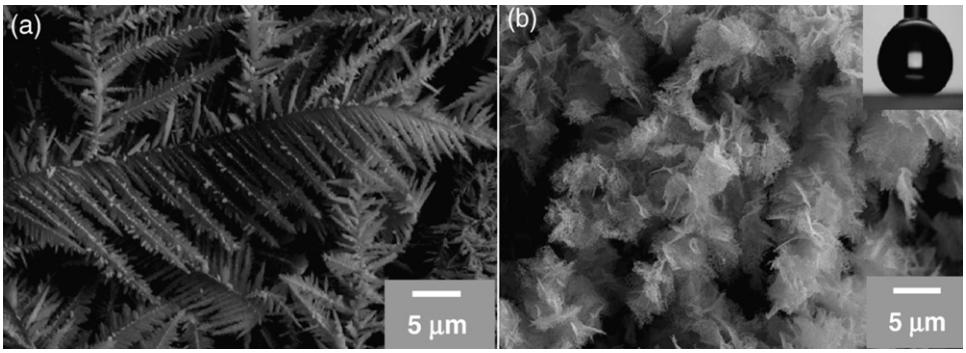

Figure 24 Scanning electron microscope (SEM) image of deposited silver on the copper substrate in the galvanic reaction exchange in silver nitrate solution (a) without benzoic acid and (b) with benzoic acid and an image of a water droplet on the surface.[37]

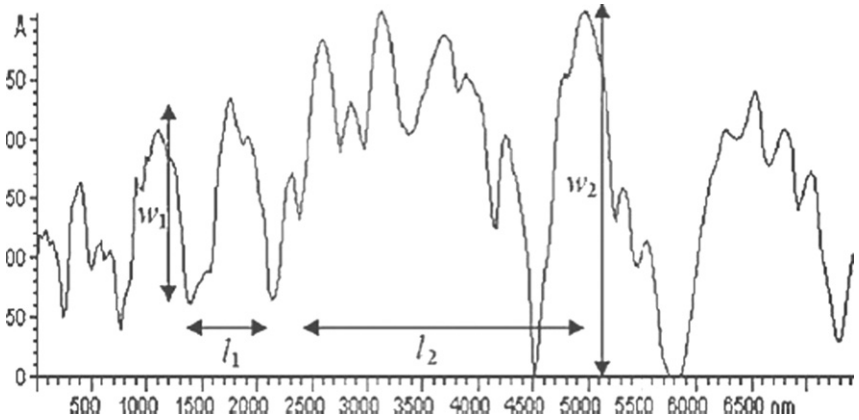

Figure 25 A rough surface.[40]

There are a variety of tools for measurement of surface roughness. Mechanical tools (contacting) and optical tools (not contacting) are applied for measurements of roughness on macroscales and microscales.[38,39]

The mechanical pen method includes amplifying and recording of the vertical movements of the tip of the pen, which moves with a constant speed on the surface. The pen is usually mechanically coupled with a capacitor sensor or linear indignant differential transformer. When the pen starts scanning the surface, the corresponding analog signal amplifies and converts to a digital signal. The detachment limit of the profile depends on the dimensions of the pen's tip. The sharper the tip, the more details of the profile that can be achieved.

Optical methods are based on the reflection of light from the surface. This method includes reflection methods that are dependent on the medical mirror. In the gloss meter method, measurements are performed by applying diffusion reflection and optical intersection methods, which are applied in many commercial methods. Using noncontact methods, there is the possibility of surface damage.

Many methods have been developed for measurements of roughness on microscales and macroscales. The family of instruments used based on scanning tunneling microscope (STM) and AFM are named scanning probe microscopy (SPM). For STM, which was developed in the 1980s, a small, sharp, metallic tip is placed near the surface (0.3–1 nm). As soon as the voltage is applied between the tip and the surface of the sample, the tunneling current is recorded, which is proportional to the distance between the tip and the surface. When the tip scans the sample, the profile of the height of the sample is recorded in nanometers up to the detachment limit.

AFM is a combination of STM principles and the measuring pen. For AFM, the tip of the pen (with diameter of a few nanometers) is placed at the end of a long (a few micrometers), strong cantilever. The deviance of the cantilever is measured by identifying the position of the reflected laser beam. During the contact mode, the tip of the pen scans the sample and the inequality map is achieved up to the detachment limit (in nanometers).

In the noncontact mode, the noncontact force of van der Waals in front of the tip of the pen causes deviation of the prop. When the hardness of the cantilever is identified, this deviation can be converted to the units of the force (with a detachment limit measured in nano-Newtons). AFM can be performed in normal environments as well as in a vacuum.[41,42]

SEM can also be applied to study the properties of the surface. This method has several limitations. First, it is difficult to achieve quantitative information from SEM. Second, the scope field of the SEM is limited. SEM requires a vacuum. In addition, a conductor is required for isolating the sample. For biological samples, there is a technique called environmental scanning electron microscopy (ESEM), which performs the measurements

in controlled conditions of humidity and pressure. Advanced methods of material analyses include X-ray spectroscopy, Raman spectroscopy, electron diffraction, and some other methods.

In addition to the surface disorders, the surfaces of the solids include different regions or different layers such as chemical absorption layers (0.03 nm), physical absorption layers (0.03–3 nm), and some layers that have reacted chemically (1–100 nm). In chemical absorption layers, the surface of the solid creates bonds with the absorbed species that are of the covalent type and share electrons. With increasing cell absorption layers, there is no chemical bond between the substrate and absorbed material, and the forces are van der Waals. The van der Waals forces are relatively weak (<10 kJ mol^{-1}) in long ranges in comparison with the strong forces (40–400 kJ mol^{-1}) in short ranges (in atomic ranges, which are approximately 0.3 nm). The common absorption agents include oxygen, water vapor, and hydrocarbons resulting from an environment that can be dense on the surface. Although the chemical absorption layer is a monolayer, the physical absorption layer can contain different layers of molecules. A layer that has bonded chemically is significantly thicker and includes many molecular layers. A common example of the chemically reacted layer is an oxide layer on metallic substrates.

3.19.3.2 Random Surface Roughness Static Analysis

There are many quantitative parameters for specifying random roughness properties of the surface (see Figure 26). This means that they are all derived from a specified form. These parameters include vibrating parameters and space parameters.[38,39,43] The most common vibrating parameter is root mean square (RMS) or standard deviation from the central mean line.

For a 2D roughness profile, $Z(x)$ is defined as the central mean line calculated from the mean of the absolute value of the vertical deviation from the profile mean line (see Figure 27).

$$R_a = 1/L \int_0^L |z - x| dx \quad [14]$$

where L is the length of the sample.

$$m = \int_0^L Z dx \quad [15]$$

and RMS-squared can be attained from eqn [16].

$$\sigma^2 = 1/L \int_0^L (z - x)^2 dx \quad [16]$$

Because the coarse surfaces profile can have the same RMS, the other parameters for identifying the details of the surface profile are needed. Two other statistic parameters are skewness and kurtosis, which can be represented using the following normalized forms:

$$SK = 1/\sigma^3 L \int_0^L (z - x)^3 dx \quad [17]$$

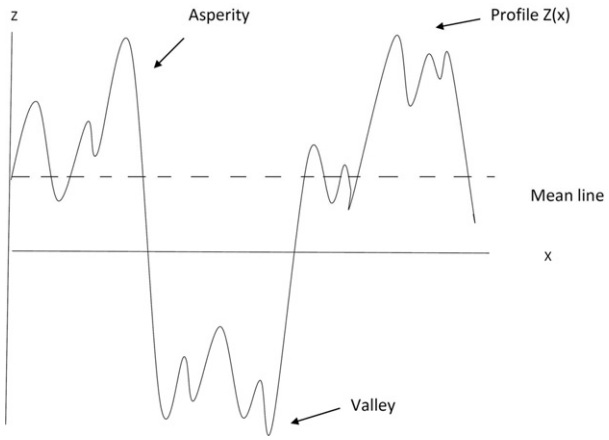

Figure 27 Schematic of the rough surface profile.

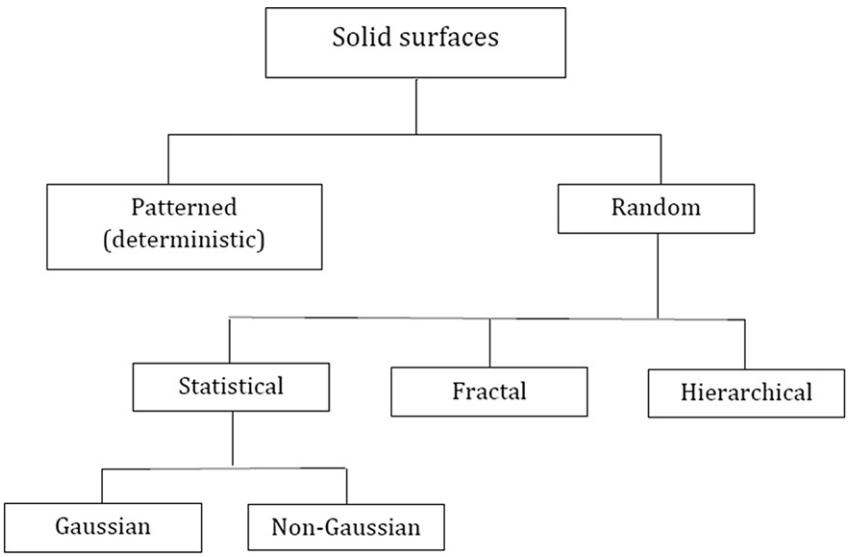

Figure 26 Typology of the rough surfaces.

$$k = 1/\sigma^4 L \int_0^L (z-x)^4 \mathrm{d}x \quad [18]$$

A surface with negative skewness has more local maximums above the mean line (Figure 28(a)), whereas for a positive skewness it is opposite (Figure 28(b)). Similarly, a surface with low kurtosis has more local maximums above the mean line in comparison with a high elongation surface. It is noticeable that although these parameters were defined for 2D surfaces, they can be easily generalized for 3D surfaces.[38,39]

The cumulative probability distribution function p (h) is connected to the random variable Z (h), which is defined as the possibility of the occurrence of $Z(x)<h$ and is written as:

$$p(h) = (z<k) \text{ Probability} \quad [19]$$

It is common for the structure of the random data to be defined as the slope of the distribution function, which is known as the probability density function (PDF) and is represented as:

$$p(z) = \mathrm{d}p(z)/\mathrm{d}z \quad [20]$$

The integral of PDF is equal to P (z), and the area under the curve of the PDF should continue.[38,39]

In many of the practical cases, random information tends to follow normal or Gaussian distribution that, in the case of PDF, is represented as follows:

$$p(z) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(z-m)^2}{2\sigma^2}\right) \quad [21]$$

where m is mean and σ is the standard deviation. For simplicity, the Gaussian function is usually pictured as a function of a normalized variable of $Z = \frac{z-m}{\sigma}$.

$$p(z^*) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{z^{*2}}{2}\right) \quad [22]$$

The Gaussian equation has SK=0 and K=3.[39]

Gaussian distribution is found in nature and practical applications when a random quantity is the sum of so many random agents that affect each other independently. When an engineering surface is formed, many random agents are related to the roughness, and in many of these cases the height of the roughness follows Gaussian distribution. Such surfaces are called Gaussian surfaces.

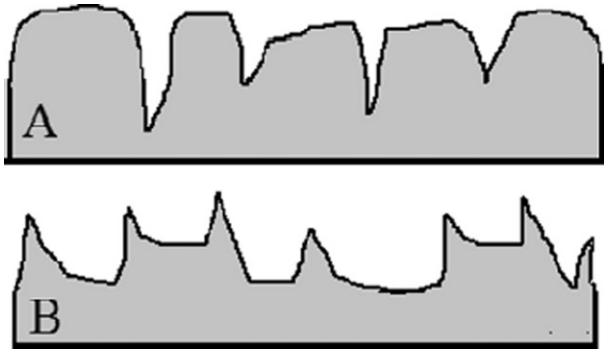

Figure 28 Surfaces with negative (a) and positive (b) skewness.[44]

To introduce spatial distribution of random roughness, the correlation function, defined here, is used.

$$c(\tau) = \lim_{L\to\infty} \frac{1}{L\sigma^2} \int_0^L [z(x)-m][z(x+z)-m]\mathrm{d}x \quad [23]$$

This function identifies the correlation between two measured variables in the distance of τ from each other, for example, $Z(x)$ and $Z(x+\tau)$.

This function can be attained from a comparison between the $Z(x)$ function with the same τ shifted function. The function c (τ) goes to zero if there is no static correlation between z values separated by the value of τ. In contrary, this function has values different than zero. There are several engineering surfaces that have an exponential self-correlated function.

$$c(\tau) = \exp\left(-\frac{\tau}{\beta}\right) \quad [24]$$

where β is the length of correlation and/or a length that the correlation function is reduced to by a small component of its primary value. In this β, the distance function is reduced to the value of $1/e$. In many cases, the value of β^*, which is equal to 2.3 β, is used as the correlation length, and the function is reduced to 10% of its main value.[38,39]

For a Gaussian surface with a self-correlated function, σ and β are two parameters with length dimensions that easily define the roughness. Although σ is a height parameter that determines the height of an inequality (hardness), β is a length parameter that determines the length of an inequality. The absolute mean value of the slope is proportionate to the σ/β^*, whereas the mean curve is proportionate to the β^*/σ. For a Gaussian surface, σ is related to the RMS because $\sigma = \sqrt{\pi/2}$.[38,39] The parameters σ and β^* are suitable parameters for specifying many random surfaces. It should be noted that a Gaussian surface has just one inherent length parameter, β^*, and one vertical parameter, σ. Thus, it cannot specify manifold scaled roughness.

3.19.3.3 Roughness of Fractal Surfaces

Roughness measurement parameters such as σ and β^* are sensitive to the scale; this is because of the measurement apparatus detachment limit (limits of the sample intervals or short wavelength) and the scan height (the limit of the long wavelength). Because the roughness is made of many overlapping wavelengths, all of them affect the cumulative values of σ and β^*. Wavelengths shorter or higher than the sample intervals have no effect on the roughness parameters. So, the measured roughness parameters are dependent on the limitations of the short and long wavelengths. These considerations are not just a result of the measurements or the limitations of the measurement apparatuses. In practical cases that are accompanied by contact, inequalities can be introduced as a component of the roughness that is formed during contact and forms a contact point. So, the height and length of the contact points for rough surfaces are important and might cause wavelength limitations during the contact.

A surface consists of a lot of roughness. The differences in the height of surfaces and other parameters of roughness

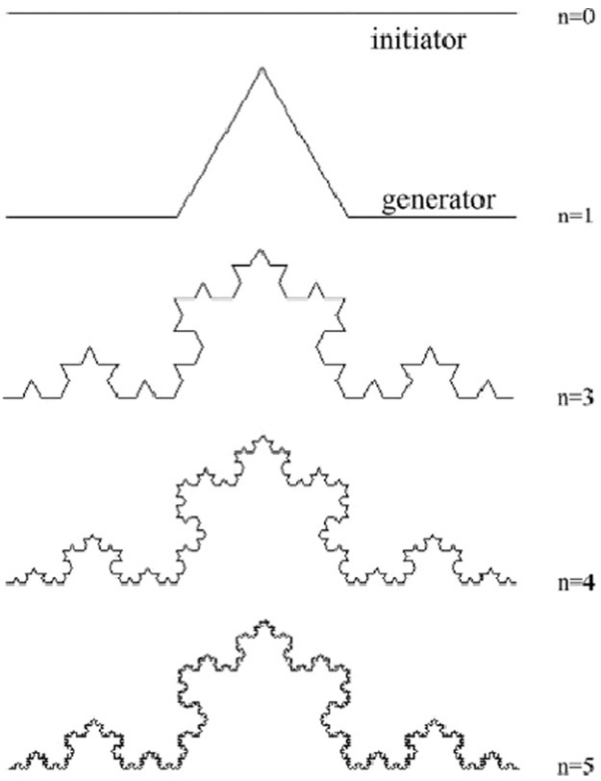

Figure 29 Construction of the triadic Koch curve.[46]

are dependent on the detachment limit of the roughness measurement tools. By increasing the detachment limit of the roughness measurement tools, smaller details can be observed. When a surface grows continuously, the roughness details can be observed in nanoscale. The roughness is structurally the same at all the magnifications. Self-affinity can be identified by fractal geometry.

Archad[45] suggested that a rough surface is covered with inequalities with specified extents, but few inequalities exist.

He proved that an elastic surface with a hierarchical structure, which is similar to fractal geometry, can result with approximately linear dependence on the actual contact surface with the normal force. This is in agreement with the linear dependence on the friction force of the contact surface, which is due to the adhesion and can confirm the coordination between friction force and normal applied force.

Self-similarity surfaces and diagrams were investigated in the early 1920s. An important property of these diagrams and surfaces is that they have small dimensions. When a linear scale is magnified using a specified factor of α, the size of the diagram or the area is altered proportionally to α^D. This is due to the possibility of more detailed observations at higher magnifications. When the Koch diagram (see **Figure 29**) with a length of L is magnified with an agent of $\alpha=3$, the length is $4L$. Therefore, the fractal scales would vary between $D=\frac{\ln(4)}{\ln(3)}=1.26$, 1, and 2. Even though the fractal curves provide the same self-similarity magnification in all directions, contrary to most mathematical functions applied in engineering, fractal curves have no intersection. The word self-affinity (see **Figure 30**) has little meaning.

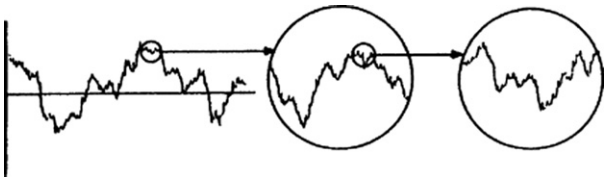

Figure 30 Qualitative description of statistical self-affinity for a surface profile.[53]

In the 1970s, there word fractal was introduced and self-similarity and self-affinity theories were widely popular. Fractal geometry can be applied in a wide scope of physical problems, from the beach line of the oceans to the turbulence of the fluids. Fractal geometry is a general tool that can be applied for noncontinuous behaviors that cannot be studied using traditional continuous functions calculations.

In the 1980s, it was suggested that fractal geometry can be applied to identify the properties of rough surfaces.[47–52] Majumdar and Bhushan (1990) suggested that the self-affinity function has important properties of a self-affinity surface profile.

$$z(x)=G^{(D-1)}\sum_{n=n_j}^{\infty}\frac{\cos 2\pi\gamma^n x}{\gamma^{(2-D)n}} \qquad [25]$$

$\Upsilon>1;\ 1<D<2$

where D is the fractal dimension, G is a dimensionless constant for scaling, and Y^n indicates the surface roughness frequency. D is dimensionless and G has the dimension of the length, and they both indicate a fractal profile. Ganti and Bhushan[48] developed this analysis and considered the side detachment power of the apparatus as an inherent length unit. This analysis considers the extended surface properties of the two parameters of fractal geometry – fractal scale and intensity coefficient – that are theatrically independent for each surface and apparatus. Ganti and Bhushan[48] presented a technique for simulation of fractal surface profiles.

Some engineering surfaces are measured to confirm the extended fractal analysis, especially for magnetic tapes, thin film hard disks, steel disks, plastic disks, and diamond films, which have different hardness. For a surface with different roughness, the fractal dimension stays steady. Although the constant of scaling varies with the variation of the height of the surface (σ^2) for an apparatus, the simulated σ has the same trend as the measured σ (equal up to small scanned lengths). The coefficient of friction for all surfaces has a logical relationship with the constant of scaling.

Almost no type of self-similarity can be found up to any specific length scale (e.g., molecular scale) or limited high-frequency (short wavelength), ω_h, with higher magnification of the profile. In the same conditions, there is limited low frequency (long wavelength), $\omega_{h.}$ in fractal behavior.[50] It should be noted that a fractal profile has no specific parameter on the length scale. Even though the limitations of short and long wavelengths significantly create these parameters of the length scale, $\frac{1}{\omega_l}$ and $\frac{1}{\omega_h}$, during the contact of two coarse surfaces, the parameters such as number of inequalities in contact and the real surface in contact are dependent on the limitations of short and long wavelengths as exponential functions, and the exponential functions are dependent on D and G.

3.19.3.4 Creation of a Rough Substrate and Its Modification Using Low Surface Energy Materials

The methods of creation of the superhydrophobic surfaces using materials with low surface energy are usually a single-step process that benefits from the ease of the process. However, they are always limited to a small group of materials. Here, the superhydrophobic surfaces are created using a completely different strategy with coarse substrates and modification of materials with low surface energy. The wettability divides the surface from the bulk properties and enhances the applicability of the superhydrophobic surfaces.

There several methods for fabrication of coarse surfaces, including laser with the plasma/chemical etching, lithography, sol-gel process, dissolution method, colloid accumulation method, layer method, reaction and electrical/chemical deposition, electrospinning, and CVD. Also, there are many methods for chemical edification of the surface. For example, a covalent bond can be created between gold and alkyltiol. Silanes are usually applied for reduction of surface energy. Absorption and coating can also change the chemistry of the surface.

3.19.3.4.1 Etching and lithography

Etching is a direct and effective method for fabrication of rough surfaces. Etching has many methods, including plasma etching,[54,55] laser etching,[56,57] and chemical etching.[58,59] All of these methods have been applied for the fabrication of superhydrophobic surfaces. For example, Teshima *et al.*[55] achieved a transparent superhydrophobic surface from a polymer substrate (poly(ethylene terephthalate) (PET)) using oxygen etching by means of plasma, which increased the CVD by using (tetramethylsilane (TMS)) an advancing agent. Qian and Shen[58] suggested a simple method for roughening the surface using chemical etching of the selected dislocation on polycrystalline metals including aluminum. After modification by flouroalkylosilanes, the metallic etched surface showed hydrophobicity.

Lithography (e.g., photolithography, lithography of electron beam, lithography of X-ray, soft lithography, nanolithography) is an accepted method for producing a large area with a periodic pattern in nanoscale and microscale.[60,61] Abdolsalam *et al.*[62] performed a systematic study of wettability of gold surfaces using a plating method for molds with submicron scales and investigated the role of the size of the holes and their shape in the wettability control. Matrin *et al.*[63] produced an ordered array of nanoholes and vertical nanorods using electron beam lithography and plasma lithography. They achieved a contact angle of 164° and hysteresis of 1° for the surface with vertical long rods with arc tips after hydrophobizing using octadecyl trichlorosilane. Using photolithography, complex surfaces with hydrophobic patterns and superhydrophilic properties were reported by Notsu *et al.*[64] (see **Figure 31**).

3.19.3.4.2 Sol-gel process

The sol-gel process is used for manufacturing superhydrophobic surfaces from many types of materials.[65–70] In many investigations, due to the presence of materials with low surface energy in the sol-gel process, there is no other hydrophobizing process. For example, Shirtcliff *et al.*[67] produced a porous sol-gel foam of Organo-trithoxysile that shows both superhydrophobic behavior and superhydrophilic behavior when exposed to high temperatures. Shang *et al.*[69] presented a method whereby transparent superhydrophobic surfaces were produced by modifying silicate-based films using fluorinated silanes instead of mixing low-energy materials in sol. In the same case, Wu

et al.[70] produced a ZnO-based surface in a microstructure using chemical processing; after coating, superhydrophobia was achieved using long-chain alkanoic acids (see Figure 32).

3.19.3.4.3 Colloid accumulation and layer method

This is a rich method for manufacturing thin coatings on a molecular scale on the film, and the chemistry used in this method involves static interaction and hydrogen bonding. Recently, the layer-by-layer (LBL) method has been used for manufacturing superhydrophobic rough surfaces.[71–74] For example, Zhai *et al.*[75] used LBL for manufacturing a pH-sensitive multilayer from poly allylamine hydrochloride and poly acrylic acid that forms a beehive structure on the surface after appropriate acid modification. As Zhang *et al.*[71,72,76] revealed, this method can be combined with electrochemical deposition to form superhydrophobic surfaces (Figure 33(a)).

Accumulation via colloid systems shows that the roughness creates an appropriate surface for superhydrophobicity.[77–79] Ming *et al.*[78] prepared a surface with two scales of roughness containing raspberry-shaped particles. These particles were formed from a covalent bond between silica particles in the amine agent group with a size of 70 nm and silica particles of an epoxy agent with a size of 700 nm. The reaction was between the amine groups and epoxy. The surface was superhydrophobic after modification by polydimethylsiloxane (Figure 33(b)).

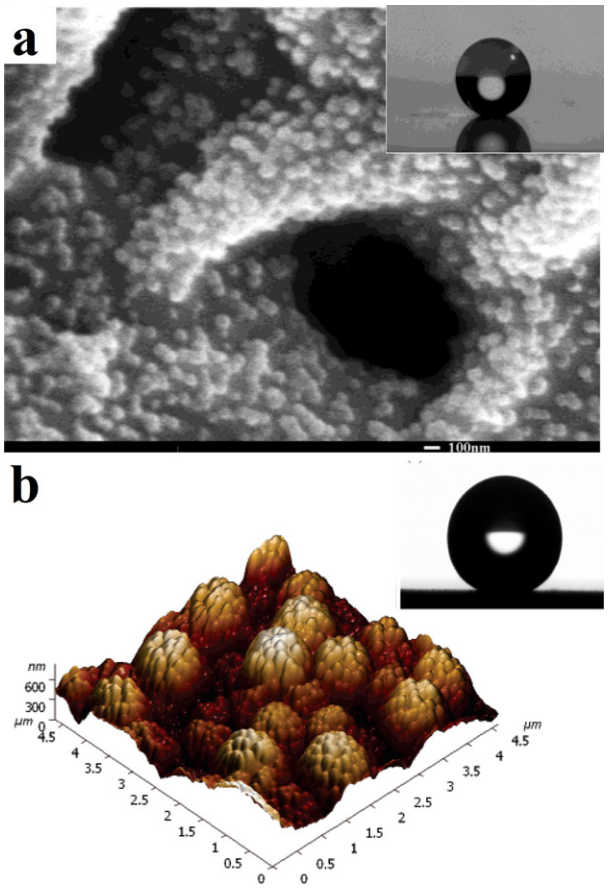

Figure 33 Superhydrophobic surfaces containing two scales of roughness produced by (a) the layer method[75] and (b) the colloid method.[78]

3.19.3.4.4 Electrochemical reaction and deposition method

This method is widely used for the preparation and creation of superhydrophobic surfaces. For example, Zhang *et al.*[76] showed that surfaces that have been coated using the electrochemical deposition method with gold dendritic clusters on an indium–tin oxide electrode and that have been modified using a multilayer poly-electrolyte show superhydrophobic properties after deposition of a single monolayer of *n*-dodecanethiol. Shirtcliff *et al.*[80] produced a copper piece with two scales of roughness using an electroplating and simulation technique. That piece of copper was similar to a 'chocolate with pieces of candy.' More hydrophobizing was performed using fluorocarbons; with superhydrophobizing, a contact angle of 160° was achieved. The Cho group[74] recently created a superhydrophobic surface similar to a lotus leaf using an electrochemical reaction of copper or copper–tin alloy on ferrous plates using sulfur gas and subsequent modification using perfluorosilanes. It should be noted that chemical bed deposition is applied for producing nanostructure surfaces. For example, Hosono *et al.*[81] applied this technique to manufacture a brucite cobalt hydroxide nano-pin, and a contact angle higher than 178° after modification and use of laric acid was achieved (see Figure 34).

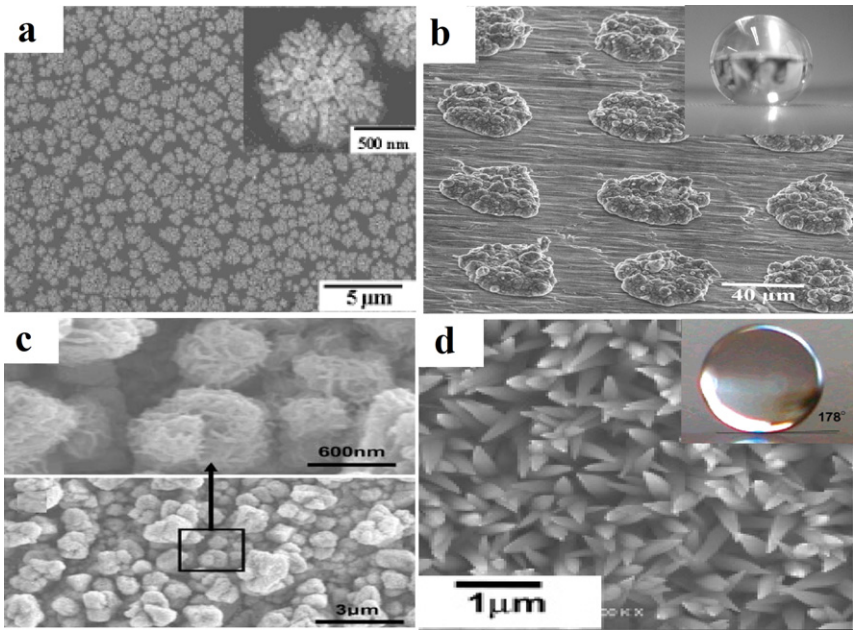

Figure 34 Scanning electron microscope (SEM) image of superhydrophobic surfaces manufactured using electrochemical deposition or chemical bed deposition. (a) Gold cluster produced on indium–tin oxide electrode and modified using a multilayer polyelectrolyte.[76] (b) The surface of copper with two roughness scales and the droplet on it (inset).[80] (c) The surface of the copper after the electrochemical reaction with sulfur gas.[74] (d) Nano-pin of brucite cobalt hydroxide-laric acid and its contact angle (inset).[81]

3.19.3.4.5 Other methods

Electrospinning is a powerful technique for manufacturing very small fibers and has been studied by many groups for its use in manufacturing superhydrophobic surfaces.[82–88] Electrospinning of a hydrophobic material promotes it to a superhydrophobic in one single step. Ma *et al.*[87] showed that superhydrophobia with a high contact angle of 170° can be achieved by applying a thin layer of compact fluorinated polymer coating to the electrospinned samples using incipient chemical vapor deposition. CVD and PVD have been widely used for chemical modification and creation of nanosurfaces. Haung *et al.*[89] created a stable hydrophobic surface that consists of carbon nanotubes that were created using CVD on a catalyst layer of Fe–N. Superhydrophobia was achieved after the creation of the thin layer of ZnO.

3.19.4 The Relationship between Roughness and Surface Wettability

A surface is considered a superhydrophobic surface if the contact angle is approximately 180°. The contact angle depends on many different factors, including surface roughness, preparation method, and cleanliness of the surface.[38,39,90] One of the methods for increasing the hydrophilic and hydrophobic properties is increasing the surface roughness. Wenzel[91] presented a model based on reduction of net energy during droplet extension on the rough surface. A rough surface has a bigger solid–liquid intersection, which results in higher net energy, and this concept will increase the contact angle for a hydrophobic surface and reduce the contact angle for a hydrophilic surface. Another model was represented by Cassie and Baxter[92] that uses a solid–liquid–air interface that can affect the contact angle of very rough surfaces. It has been proven in the laboratory that the roughness that alters the contact angle is in agreement with the Wenzel model. Yost *et al.*[93] found that roughness can increase the wettability of a copper sample with the eutectic weld of tin–lead. This system has a contact angle of 15–20° for flat surfaces. They concluded that the contact angle increases for wetting liquids. Erbil *et al.* measured the contact angle of polypropylene; they found that there is an increase of roughness when the contact angle increases.

In the past decade, scientists focused on natural hydrophobic materials. There are some plants leaves, including lotus, that have a high contact angle with water.[94,95] These leaves are covered with a range of different waxes that are a combination of large hydrocarbon molecules with a thickness of 1 nm and high hydrophobic properties. These surfaces are rough due to the existence of epidermis bump cells, which create inequalities (**Figure 35**). Other examples of biologic surfaces are the wings of a duck and of a butterfly. Their stripy surfaces create some air pockets that prevent complete contact with water. The study and simulation of biological substances are referred to 'biomimetics,' which is derived from the Greek word 'bio mimesis' and means biological imitation. Artificial hydrophobic surfaces can be achieved by chemical modification accompanied by materials with low surface energy, including polytetrafluorothilen, silicones, and waxes, and/or directly from roughening of hydrophobic surfaces.

When two solid materials make contact in the presence of a wetting material, surface tension is usually created. This surface tension results in normal surface tension force that can increase the tangential force of friction. The magnitude of the surface tension force is dependent on the contact inequalities

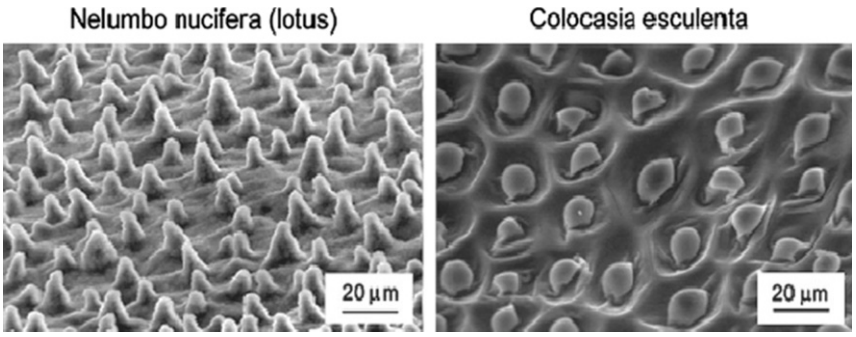

Figure 35 Micrographs of two hydrophobic leaves: *Nelumbo nucifera* (lotus) and *Colocasia esculenta*.[96]

and the diameter inequalities, and these are dependent on roughness, surface tension of the liquid, and the contact angle. The contact angle depends on surface roughness. So, roughness affects the wet friction force. This impact was previously neglected.

3.19.4.1 The Analysis of the Contact Angle

The dependence of the contact angle on the surface tension of the liquid contacting the surface of a rough solid and a flat surface has been considered. Also, the effects of the contact point and sharp edge on the contact angle have been discussed.

3.19.4.1.1 Flat surface

It is well known that the atoms and molecules of the surface of liquids or solids contain higher energy in comparison with bulk atoms or molecules; this results in surface tension or free surface energy and is considered an important surface property. This property can be claimed quantitatively by free surface energy or surface tension that is equal to the equivalent needed work for creation of unit cells at a constant volume and temperature. When a solid contacts a liquid, the molecular interaction decreases the energy to below the energy level for each individual surface. This is claimed by the Dupre equation.

$$W_{SL} = \gamma_{SA} + \gamma_{LA} - \gamma_{SL} \quad [26]$$

where W_{SL} is the work of adhesion in the unit of area between two surfaces, γ_{SL} and γ_{SA} are surface energy (surface tension) of solids against air and liquids, and γ_{LA} is the surface energy of liquid against air.[38,90]

If a droplet of liquid is on the surface of the solid, the surfaces of the liquid and solid maintain equilibrium, and a specific angle called the static contact angle is formed. The contact angle can be identified using the general energy of the system in the minimum state.[90] The total energy, E_{tot}, can be obtained from the following equation:

$$E_{tot} = \gamma_{LA} * (A_{LA} + A_{SL}) - W_{SL} * A_{SL} \quad [27]$$

where A_{LA} and A_{SL} are areas where liquid contacts solid and air. It has been assumed that the droplet is small enough to neglect the potential energy of gravity. In the equilibrium state, dE_{tot} is zero, resulting in the following equation:

$$\gamma_{LA} * (dA_{LA} + dA_{SL}) - W_{SL} * dA_{SL} \quad [28]$$

For a droplet in constant volume, geometrical considerations can be applied:

$$\frac{dA_{LA}}{dA_{SL}} = \cos\theta_0 \quad [29]$$

By combining eqns [26], [28], and [29], the contact angle can be determined with the famous Young equation (eqn [4]).

$$\cos\theta_0 = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \quad [30]$$

Using eqn [5], the static contact angle can be calculated if the surface tensions are clear.

3.19.4.1.2 Effect of surface area on the contact angle of a rough surface

The Young equation is only applicable for flat solid surfaces. If the surface is rough, then it affects the contact angle in two ways. The first is the increased contact area A_{SL}, and the second is the effect of sharp edges (see **Figure 36**).

If the droplet size is small in comparison with the normal roughness value, then the roughness distribution cannot affect the contact angle. We consider a rough solid surface with the normal value of roughness, which is smaller than the droplet (100 μ or bigger), guarantees the Young equation, and realizes that effective surface tension can be a complicated function of the surface roughness. For a droplet that is placed on the surface, eqn [29] can be modified as:[91]

$$\mathrm{Cos}\,\theta = \frac{dA_{LA}}{dA_F} = \frac{A_{SL}}{A_F} * \frac{dA_{LA}}{dA_{SL}} = R_F \mathrm{Cos}\,\theta_0 \quad [31]$$

where θ is the contact angle of the coarse surface, A_f is the flat contact point of solid–liquid and/or the reflection of the solid–liquid A_{SL} surface on the horizontal surface, and R_f is the roughness factor defined as:

$$R_F = \frac{A_{SL}}{A_F} \quad [32]$$

Equation 31 shows that if the liquid surface wets the solid surface, ($\mathrm{Cos}\theta_0 > 0$), then it can wet the surface with a contact angle of $\theta_0 > \theta$ because $R_f > 1$. In addition, for nonwetting liquids ($\mathrm{Cos}\theta_0 < 0$), the contact angle would be bigger for the rough surfaces in comparison with flat ones ($\theta_0 < \theta$). The

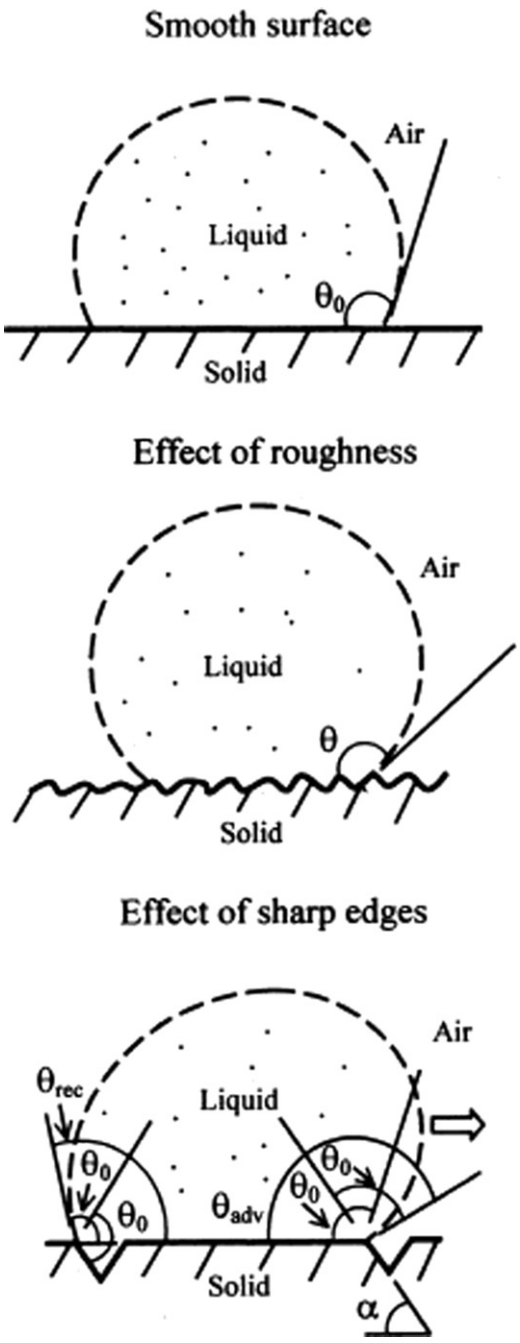

Figure 36 The liquid droplet in contact with a solid flat surface; the contact angle is θ_0. The rough surface, contact angle of θ, and a surface with sharp edges are also show. For a droplet moving on a sharp edge from left to right (declared with the arc), the contact angle on the sharp edge can have any value between the contact angle on the horizontal surface and the sloped surface. This effect can cause the difference in the advancing and receding contact angles.[96]

dependence of the contact angle on the roughness coefficient is represented in **Figure 37** for different values of the θ_0.

3.19.4.1.3 Composite solid–liquid–air interface

It is claimed that the eqn [31] is only qualified for the mean values of R_f when $-1 < R_f \mathrm{Cos}\theta < 1$. With high roughness, a

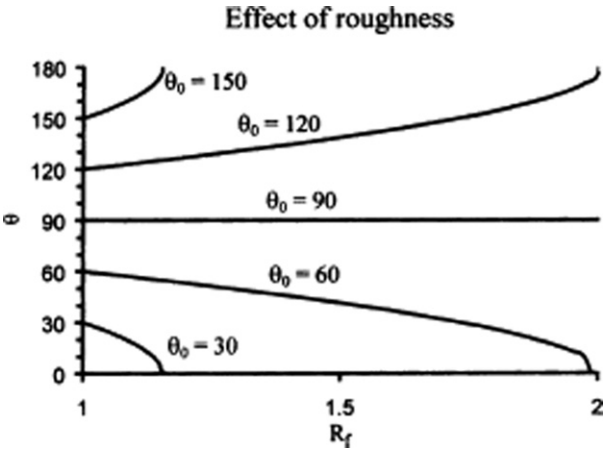

Figure 37 Contact angle for the rough surface (θ) as a function of the roughness factor (R_f) for the contact angles for a flat surface (θ_0).[97]

wetting liquid would be completely absorbed by the holes of the roughness. A nonwetting liquid cannot defuse in the holes with a high slope, which is due to the formation of the air pockets and will result in the creation of a combined intersection of solid–liquid–air, which is shown in **Figure 38(a)** for flat and saw-toothed profiles. The contact point's air–liquid will not increase with an increase of roughness.[98]

The creation of a composite interface of a saw-toothed profile with the slope of α for a flat profile is shown in **Figure 38(a)**. To determine whether the interface is liquid–solid or combined, the pure energy variation dE_{tot} should be considered, which is in agreement with the ds displacement of the liquid–air surface along the sloped wall of the groove. For the liquid–air interface, $dE_{tot} < 0$, from the energy point of view, liquid is most likely to fill the groove. Although for a composite interface, $dE_{tot} > 0$, from the energy point of view, liquid is most likely to leave the groove. The variation of energy is dependent on the α angle, and the critical value of this slope, called α_0, can be calculated using the equation $dE_{tot} = 0$.

$$dE_{tot} = dA_{SL} * \gamma_{SL} + dA_{LA} * \gamma_{LA} = -2\gamma_{LA} \cos\alpha_0 \, ds$$

$$+2(\gamma_{SL} - \gamma_{SA})ds = 0 \qquad [33]$$

By applying eqn [5] in eqn [8], the resulted can be $\mathrm{Cos}\alpha_0 = \mathrm{Cos}\theta_0$.

$$\alpha_0 = 180 - \theta_0 \qquad [34]$$

For small slopes ($\alpha < \alpha_0$), the total energy variation is negative and the intersection is solid. For high slopes ($\alpha > \alpha_0$), this variation is positive and the intersection is combined (as shown in **Figure 38(a)**).

Cassie and Baxter[92] developed the Wenzel equation. The Wenzel equation was developed for the homogenous solid–liquid interface and composite interface. For this purpose there are two interfaces: a liquid–air interface with the surrounding environment and a mixed interface under the droplet, which contains the solid–liquid, liquid–air, and air–solid interfaces. For the area of a geometrical component of a flat interface of solid–liquid and air–liquid under the droplet, φ_{SL} and φ_{LA}, the

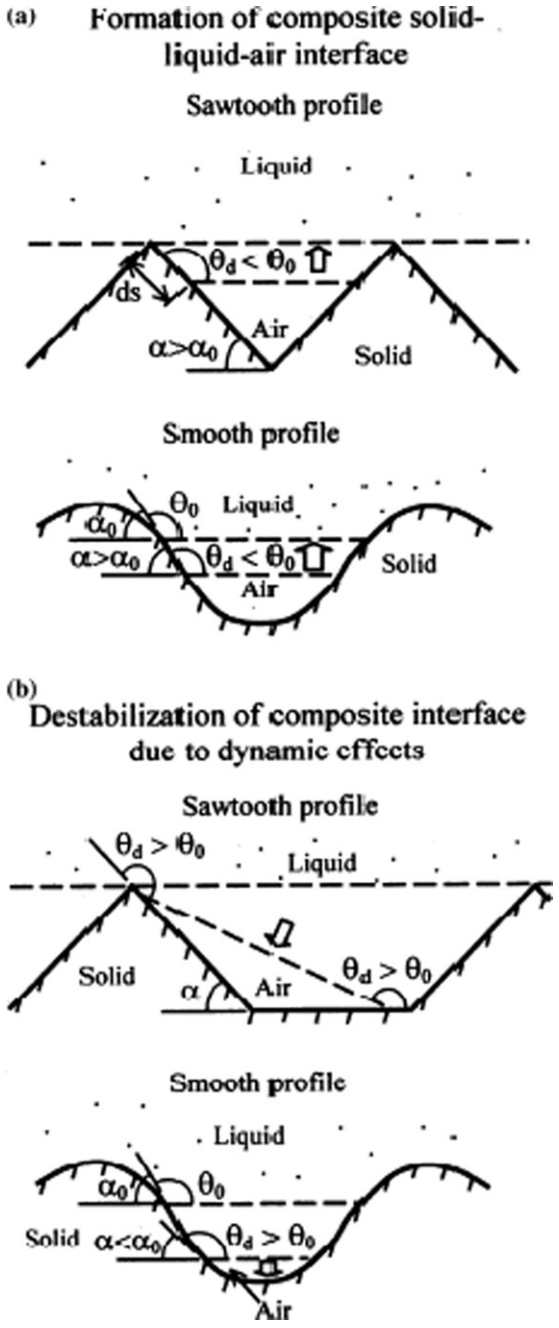

Figure 38 (a) Creation of a combined intersection of solid–liquid–air for saw-toothed and flat profiles. (b) Instability of composite interface for flat and saw-toothed profiles according to dynamic effects. The dynamic contact angle $\theta_d > \theta_0$ is proportional to the advancing liquid–air intersection, whereas $\theta_d < \theta_0$ is proportional to the receding interface.[97]

area of the composite flat interface is equal to:

$$A_C = \varphi_{SL} * A_C + \varphi_{LA} * A_C = R_F A_{SL} + \varphi_{LA} A_C \qquad [35]$$

To calculate the contact angle in a state similar to calculating eqn [31], the differential surfaces of the air–liquid interface under the droplet, $\varphi_{LA}\ dA_c$, should be subtracted from the total differential surface of liquid–air:

$$\cos\theta = R_F * \varphi_{SL} * \cos\theta_0 - \varphi_{LA} \qquad [36]$$

According to eqn [36], for the roughness factor limit, high φ_{SL} approaches zero while φ_{LA} tends toward 1, and as a result θ tends toward 180°. Although the Cassie–Baxter model explains no dependence of φ_{SL} and φ_{LA} on the roughness factor and does not explain under what condition the combined intersection can be created. Johnson and Dieter showed that the combined homogenous interface has a relationship with two semi-stable states of the droplet. Although it might be possible for a system to have a composite interface geometrically, from the energy point of view, it is more likely that liquid penetrates the inequalities and creates a homogenous interface. Marmur[99] formulized the geometrical conditions for a surface in which the energy of the system is comparatively minimum and a composite interface might exist. Patankar[100] suggested that the existence of the interface in a combined or homogenous form is dependent on the history of the system. For example, the droplet is created on the surface or is deposited there. The mentioned analyses are not in agreement with the concept that both homogenous and composite interfaces can exist simultaneously. To investigate the possibility of the creation of the composite interface, stability should be analyzed. It has been assumed that the composite interface is stable, as extracted from the equation. It was assumed that the advancing liquid–air interface stays horizontal. This assumption is difficult to justify when the distances between inequalities are long or when the slope changes are slowed. In these cases, the air–liquid interface can easily be unstable because of imperfections of the profile or dynamic effects such as surface waves. This can result in creation of the homogeneous solid–liquid interface. **Figure 38(b)** shows the instability of the combined interface when there is a long distance between inequalities and when there is a flat profile with liquid filling the groove. In a point of the liquid–air intersection, if the local angle of that point with the surface of solid is higher than θ_0, then eventually the liquid fills the groove. Equation [36] predicts the contact angle; because the possibility of instability has been neglected, development of a random approach with attention given to the probability of an unstable composite interface and other probabilities of semi-stable states has been suggested.

3.19.4.1.4 The effect of edge and variation of surface slope

A sharp edge can pin the interface of the air–liquid–solid (which is known as a triple line). In other words, it can place the interface in a contact angle different than θ_0. This effect has been shown in the discontinuous line of **Figure 36**, in which a droplet displaces among a grooved solid surface. On the edge, the contact angle is not specified and can hold any value between the contact angles of a flat surface or a sloped surface. For a droplet moving from left to right, this triple line is stuck on the edge point until it is able to cross the sloped surface. In **Figure 36**, the variation in the surface slope at the edge is the reason for this sticking. Because of this concept, the advancing contact angle (dynamic advancing contact angle or $\theta_{adv} = \theta_0 + \alpha$) is higher than θ_0, whereas the receding contact angle (dynamic receding contact angle or $\theta_{rec} = \theta_0 + \alpha$) is less than θ_0. This phenomenon is known as the hysteresis of the contact angle.[90,98] The amplitude of the hysteresis is defined as $\theta_{adv} - \theta_{rec}$. The liquid can

easily move along the surface if the hysteresis of the contact angle is a small. In the same conditions, the hysteresis of the contact angle can exist if the slope changes slowly. The transition to the composite interface can decrease the contact area of the liquid–solid. As a result, the liquid would be in contact with solid just during the peak of inequalities and where the slope variation is small and the triple line trapping is less. Therefore, the transition to the composite interface can reduce the hysteresis of the contact angle and the droplet would move easily.

3.19.4.2 Calculation of the Contact Angle for Selected Surfaces and Surface Modification

Figure 39 shows the different roughness profiles of the 2D and 3D surface profiles. According to this analysis, modification of roughness for the contact angle can be performed.

3.19.4.2.1 2D periodic profiles

3.19.4.2.1.1 Saw-toothed periodic profile

We assumed a saw-toothed profile surface with a tooth angle (or the overall slope) of α (see Figure 39). The roughness factor can be calculated by using eqn [7]:

$$R_F = \frac{A_{SL}}{A_F} = (\mathrm{Cos}\ \alpha)^{-1} \qquad [37]$$

By applying eqn [31], the contact angle can be achieved:

$$\mathrm{Cos}\ \theta = \frac{\mathrm{Cos}\ \theta_0}{\mathrm{Cos}\ \alpha} \qquad [38]$$

Increasing the value of α up to the critical value of α_0, represented using eqn [9], transfers the complete contact of liquid–air to the air–liquid–solid interface and eqn [38] can no longer be applied. Appling the value of $\alpha=\alpha_0$ obtained from eqn [34] in eqn [13], the value of θ, which is correlated to α_0, can be attained. The critical value of α_0 can be correlated to the contact angle of 180°. This means that by increasing the angle of the tooth up to the critical value, a surface with an approximate contact angle of 180° for a specific θ_0 can be created. The sharp edge can result in trapping the triple line and a lack of tendency for the creation of a saw-toothed profile. The saw-toothed profile can create the roughness in the direction of the grooves and open head capillary tubes can amplify the wettability, which is undesirable.

3.19.4.2.1.2 Periodic profile

Considering function, the Fourier equation, and the mathematical equations related to it, it can be concluded[101] that a combined intersection can be unstable and eqn [36] cannot be applied. So, the sinus intersection is not proposed for manufacturing superhydrophobic surfaces. In addition, the sinusoidal profile can create roughness in the direction of the grooves and open head capillary tubes can amplify the wettability, which is undesirable (see Figure 39).

3.19.4.2.2 3D surfaces

The profile analysis shows the critical roughness parameters when contact lines are parallel to the grooves. The 3D surfaces of more general practical cases accompanied by different types of roughness are presented here.

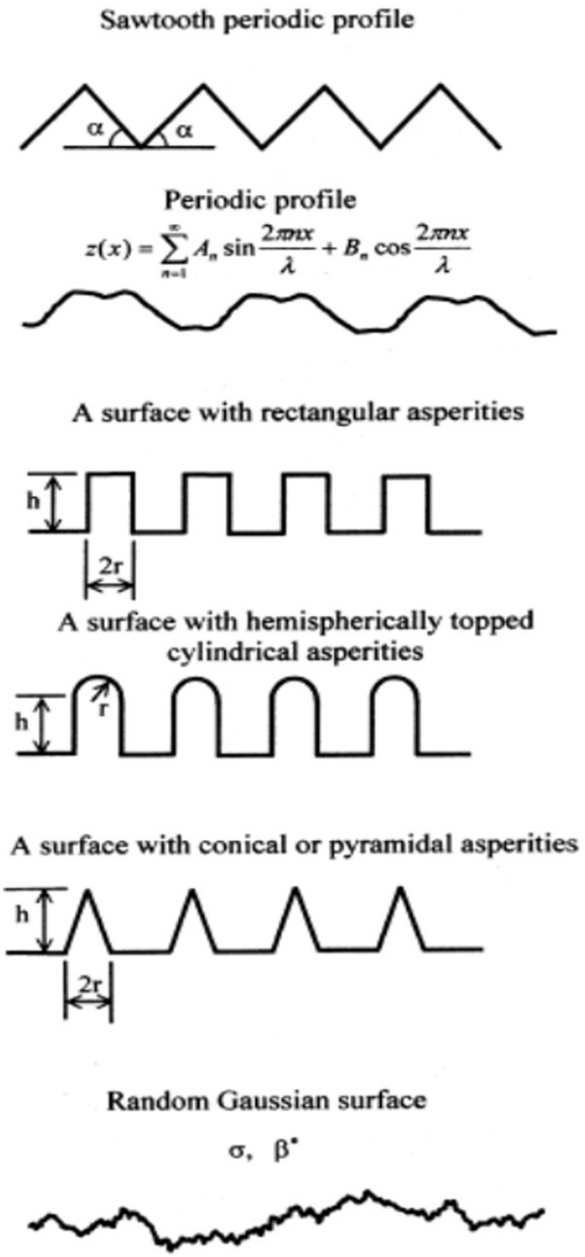

Figure 39 Schematic of the different rough surfaces.[97]

3.19.4.2.2.1 An array of inequalities with the same shapes and sizes

In this section we describe surface profiles that contain inequalities with the same shapes and sizes as rectangular inequalities, formulize the mathematical functions for them, and subsequently calculate the contact angle and roughness factor. It is necessary to introduce parameter η, which is the density of inequalities in the unit of area, and also parameter ρ, which is the parameter of classification and identifies the classification of the inequalities.

To identify the critical values of the roughness parameters of the interface, whether the local slope can achieve a value higher than the critical value of α_0 and whether the interface has a tendency to stabilize should be analyzed. Performing

these analyses is difficult due to the complexity of the problem. It can be approximately determined that by increasing the mean value of the diagram's slope, both parameters of the local slope increase and instability of the intersection decreases because the surface would be less flat. Therefore, we assume that, in a case similar to 2D profile, the absolute value of the line's slope is responsible for the transition to the composite interface of air–liquid–solid; for rectangular, hemispheric head, pyramidal, and conical inequalities, the mean value of the final slope, m, is equal to multiple density inequalities and the flat surface is reflected in the absolute value of the mean slope (which is equal to two values of the slope direction ratio).

$$m = \eta\pi r2(h/r) = \eta\pi hr \qquad [39]$$

The critical value can be obtained using the same trend for eqn [18].

$$m_0 = \eta\pi hr = \tan(180 - \theta_0) = \tan(-\theta_0) \qquad [40]$$

According to the applied equations in this section, for the value of $\theta_0 = 120^\circ$ for rectangular, hemispheric head, pyramidal, and conical profiles, the contact angle tends toward 180° before the critical value of roughness gets to the value of h/r which is shown in **Figure 40**.

The equations in this study are used for calculating the contact angle of the lotus leaf and results are compared to the measured data. The lotus leaf almost has a head of hemispheric inequality and is covered with wax, as shown in **Figure 35**.[94,95] The static contact angle for the droplet of water on the surface of the wax has been a reported to be 104° by Craig[102] and 103° by Kamusewitz.[103] According to the information provided by Wagner,[95] the amount of inequalities in a lotus leaf is approximately 3400 mm^{-2} ($\eta = 0.0034$ μm). The mean diameter of the head of hemispheric inequalities is 10 μm and the ratio of the slope is approximately 1. According to the equations, these

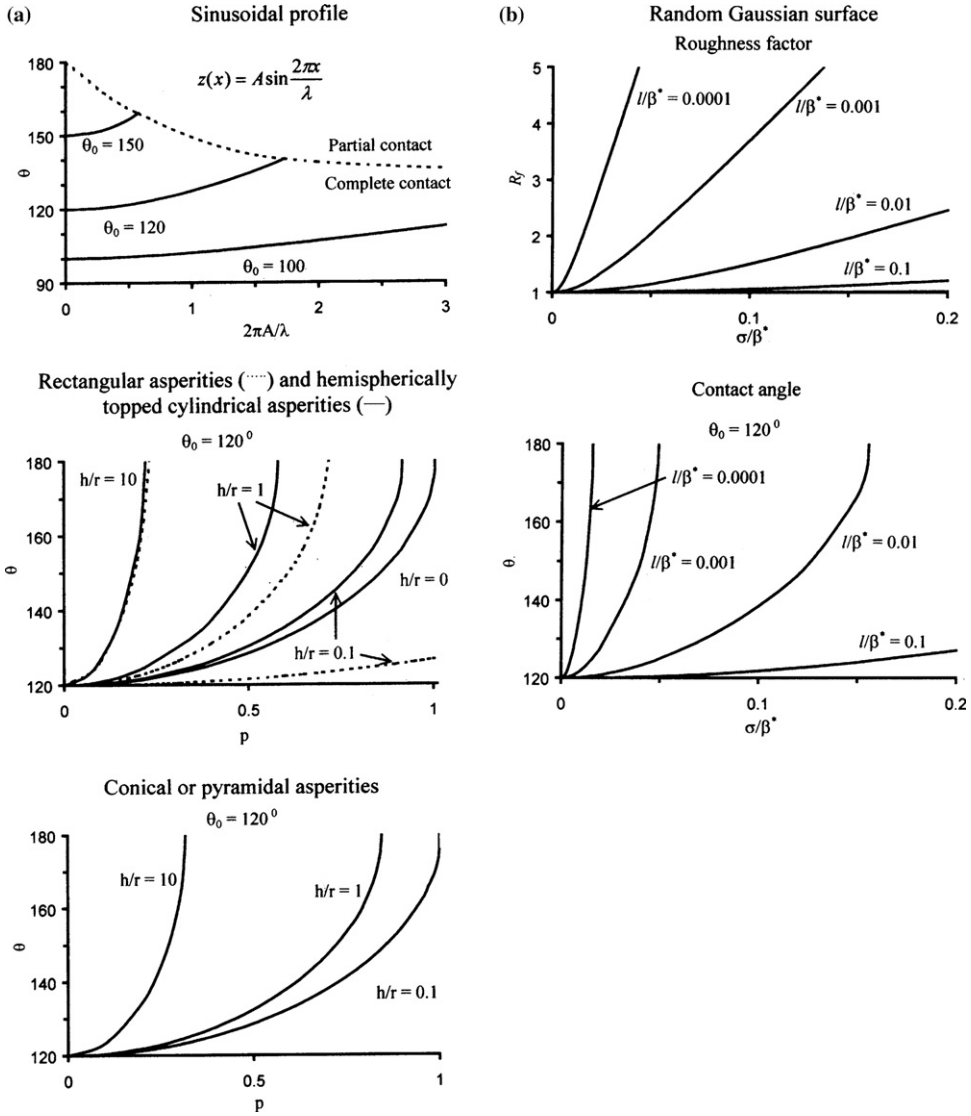

Figure 40 (a) The contact angle of a rough surface (θ) as a function of surface parameters for the surfaces with sinusoidal, rectangular, cylindrical, hemispheric head, pyramidal, and conical profiles. (b) Dependence of roughness factor and the contact angle of a coarse surface on the roughness parameters for a Gaussian surface.[97]

values yield a roughness factor of 4 and a contact angle of 160° (using $\theta_0 = 104°$ for the wax). The contact angle for the droplet of water on the lotus leaf has been reported as 162°.[94]

3.19.4.2.2.2 Random rough surface

A simple, random rough surface can be assumed as the interface of a flat surface, and a 2D random process can be identified using height distribution and correlation function. Many rough natural and engineering surfaces can be identified using a Gaussian height distribution and exponential correlation function.[38,39] In this case, a rough surface can be introduced by standard deviations and two other parameters including: height of inequalities σ and the length of correlation β^*. The length of correlation is a space parameter and can be used as a criterion for the measurement of roughness. This parameter is responsible for horizontal scaling, and σ is used for vertical scaling. The measured roughness is dependent on the limits of measurement of long and short wavelengths.[38,39]

Also, the absolute value of the slope of the Gaussian surface has a Gaussian distribution with a mean value as represented here:

$$m = \frac{\sigma}{I}\sqrt{\frac{1 - \left[\exp\left(-\frac{\beta^*}{L}\right)\right]^2}{\pi}} \qquad [41]$$

where L is the range of samples or the range of short wavelength, which is the distance between the data points during measurement.[104] For a surface, the measurement ranges are given with a limit of wavelength lower than Gaussian roughness and is compared with the atomic scale.

To determine the critical values of the roughness parameters, we assumed that the absolute mean value of the slope is enough for the transition of the air–liquid–solid interface. The critical value of the Gaussian is equal to:

$$m_0 = \left(\frac{\sigma}{L}\sqrt{\frac{1 - \left[\exp\left(-\frac{\beta^*}{L}\right)\right]^2}{\pi}}\right) = \tan(-\theta_0) \qquad [42]$$

Figure 40(b) shows the dependence of the roughness factor on the σ/β^*. It is clear that the roughness factor and the contact angle increase with the increase of σ/β^*. According to eqn [42], it can be shown that for the value of $\theta_0 = 120°$, the contact angle arrives at 180° before the critical parameters of roughness, which has been demonstrated for the values of σ/β^* and L/β^*. It is notable that for most engineered and natural Gaussian surfaces the ratio of $\sigma/\beta^* \ll 0.1$, and the mean value of the slope is very small ($m \ll 1$). So, the more that roughness is lower than the critical value, the more difficult it is achieve the high contact angle with a random Gaussian area with a real value of σ/β^*.

3.19.4.3 Modification of Surfaces to Achieve the Highest Contact Angle

3.19.4.3.1 Modification on the basis of monoscale roughness profiles

Among all the surface types, the highest contact angle can be achieved through the saw-toothed profile, rectangular, spherical head, pyramidal, and conical inequalities. As we predicted, this saw-toothed profile is undesirable due to the sharp edges that might trap the triple line and the grooves that might increase the wettability. Therefore, preventing hysteresis of the contact angle is necessary to prevent the age inequalities with the sharp edges, because they might trap the triple line. The best inequalities are the spherical ones.

Two-tiered roughness that involves two wavelengths has been assumed by some researchers as the agent for reduction of wettability.[105] Nonetheless, this is similar to involving the sharp edges, which is undesirable, and results in instability of the combined intersection of air–liquid–solid.

According to the equations and the results in **Figure 40**, the maximum of the contact angle can be achieved by increasing the ratio of h/r and the scaling parameters of ρ. The maximum value of the slope direction ratio can be achieved by increasing the height of inequality. The maximum of scaling parameters can be achieved by hardening the scaling of inequalities.

The square of scaling parameter, ρ, is equal to the ratio of the ground area of the inequalities to the overall surface area. So, the higher the ρ, the higher the density of the scaling. For circular inequalities, the square of inequalities distribution results in ½ r scaling of the rows in the unit of area with ½ r of inequalities in the unit of length of each row. More density of the scaling of inequalities can be achieved using a hexagonal distribution of inequalities (see **Figure 41**). This distribution pattern can result in the scaling of $1/\sqrt{3}\ r$ of the inequality rows in the unit of length with the ½ r inequality or $\eta = \frac{1}{2\sqrt{3}r}$, resulting in:

$$\rho = r\sqrt{\pi\eta} = \sqrt{\frac{\pi}{2\sqrt{3}}} = 0.952 \qquad [43]$$

Therefore, it can be advised that for the modification of surfaces, spherical head inequalities with a hexagonal scale and a high slope direction ratio should be used. It has been mentioned that some plants have a tendency for inequality distribution similar to hexagonal distribution.

Another shape that creates scaling density is pyramidal inequality with a squared base. To prevent the sharp edges, the

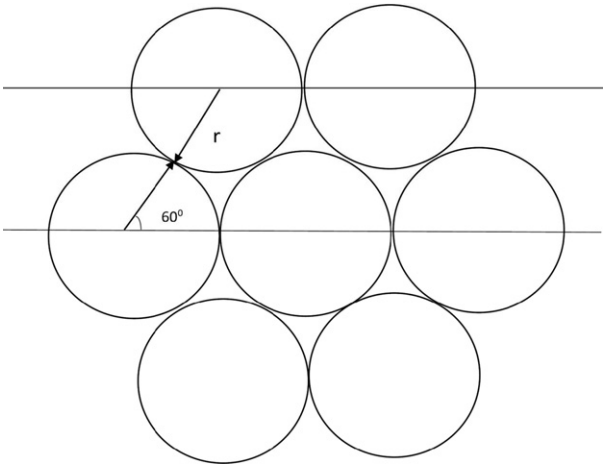

Figure 41 Hexagonal pattern of circular inequality scaling for the highest density of scaling.

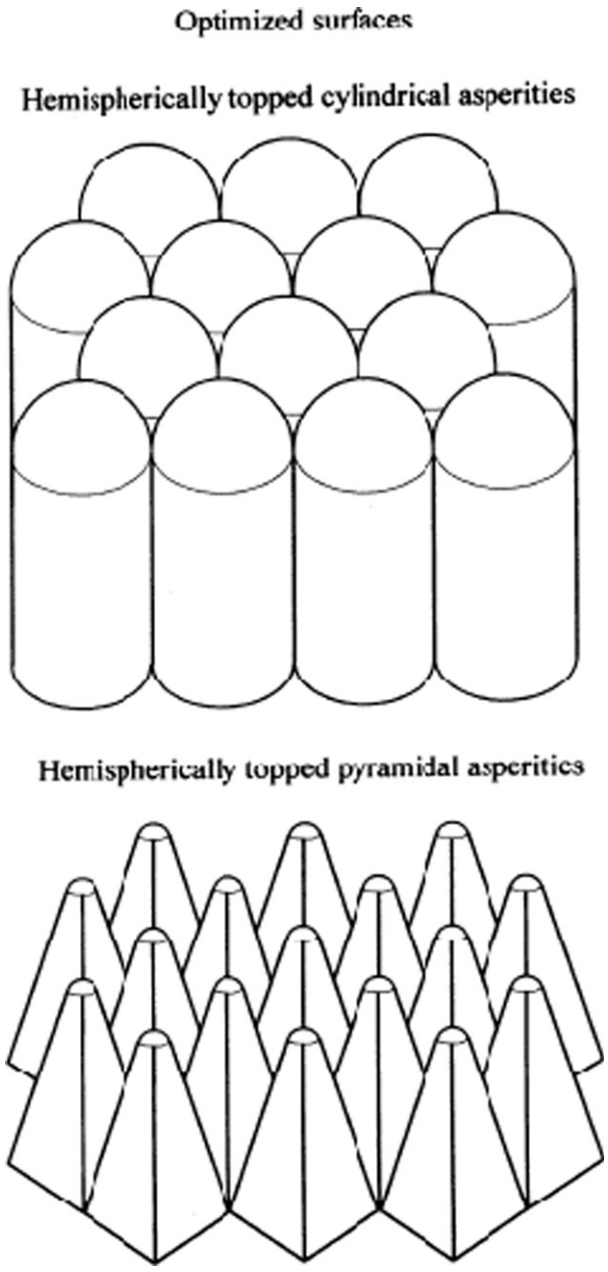

Figure 42 The modified distribution of cylindrical hemispherical head inequalities and pyramidal inequalities with the squared base and rounded heads. The squared bases provide higher scaling density but involve unwanted sharp edges.[96]

head of inequalities should be rounded to the hemispherical shape (see **Figure 42**). The rectangular inequalities do not provide any space for the diffusion of liquids. So, for the inequalities with the square base, the pyramidal shape should be used. It should be mentioned that valleys with round edges have the same effect as inequalities on the contact angle.

The diameter of the specific inequalities, r for a circular base or $2r$ for a square base, should be small in comparison with normal droplets. The high limit of the droplet size can be estimated according to this necessity because the effect of gravity is small in comparison with the surface tension (a bigger droplet tends to be divided into many small droplets). The gravimetric energy of the droplet is given by the density, ρ, which is multiplied by volume, the constant of gravity, and diameter.

$$W_g = \left(\frac{4}{3}\right)\pi r^3 \rho g r \qquad [44]$$

The energy related to the surface tension can be calculated by multiplying the area of the surface in the surface tension:

$$W_S = 4\pi r^2 \gamma_{LA} \qquad [45]$$

Because $W_g \ll W_s$, the maximum diameter of the droplet can be calculated as:

$$r_{max} \ll \sqrt{\frac{3\gamma_{LA}}{\rho g}} \qquad [46]$$

The usual quantities of water, $\rho = 1000\ \mathrm{kg\ m^{-3}}$ and $\gamma_{LA} = 72\ \mathrm{mJ\ m^{-2}}$, result in $r_{max} \ll 4.7$ mm. Although these little droplets tend to unite and create bigger droplets, the minimum diameter of the droplet only limits the molecular scale; therefore, it is desirable for r to be as small as possible.

Briefly, it can be said that the highest contact angle and the lowest hysteresis of the contact angle can be obtained by hemispherical head inequalities with the scaling pattern of hexagonal or pyramidal inequalities with rounded heads. These suggestions can be used for manufacturing superhydrophobic surfaces.

For wetting, the roughness of the liquid can reduce the contact angle according to eqn [31]. So, for manufacturing superhydrophobic surfaces by using the roughness effect, a hydrophobic layer (film) is needed. The hydrophobic coating is a known method of increasing the hydrophobia of materials.[106]

3.19.4.3.2 Modification on the basis of multiscaled roughness profiles

The effects of multiscaled roughness (hierarchical) on the modification of superhydrophobic structures of solid surfaces have been studied theatrically. Three kinds of alternative surface topography have been demonstrated regarding the effects of additional roughness scales on the transition contact angle of wet surfaces. This can be performed by calculation of the Gibbs energy of a droplet, which is dependent on the position of the liquid–air interface inside the grooves and the geometry of the contact angle (the contact angle has been considered a variable for Gibbs energy). In this study the wetting system is considered a 2D system that contains a cylindrical droplet on a 2D rough surface that is chemically homogeneous. The selection of this system is due to the ease of calculations. The qualitative results of 2D calculations have been compared to the 3D reality.[107,108]

Three roughness topography includes sinusoidal bumps with three roughness scales, flat head rods with three roughness scales, and self-similarity and triadic Koch with four roughness scales. The geometrical details have been shown in **Figure 43**. These topographies have been selected because they

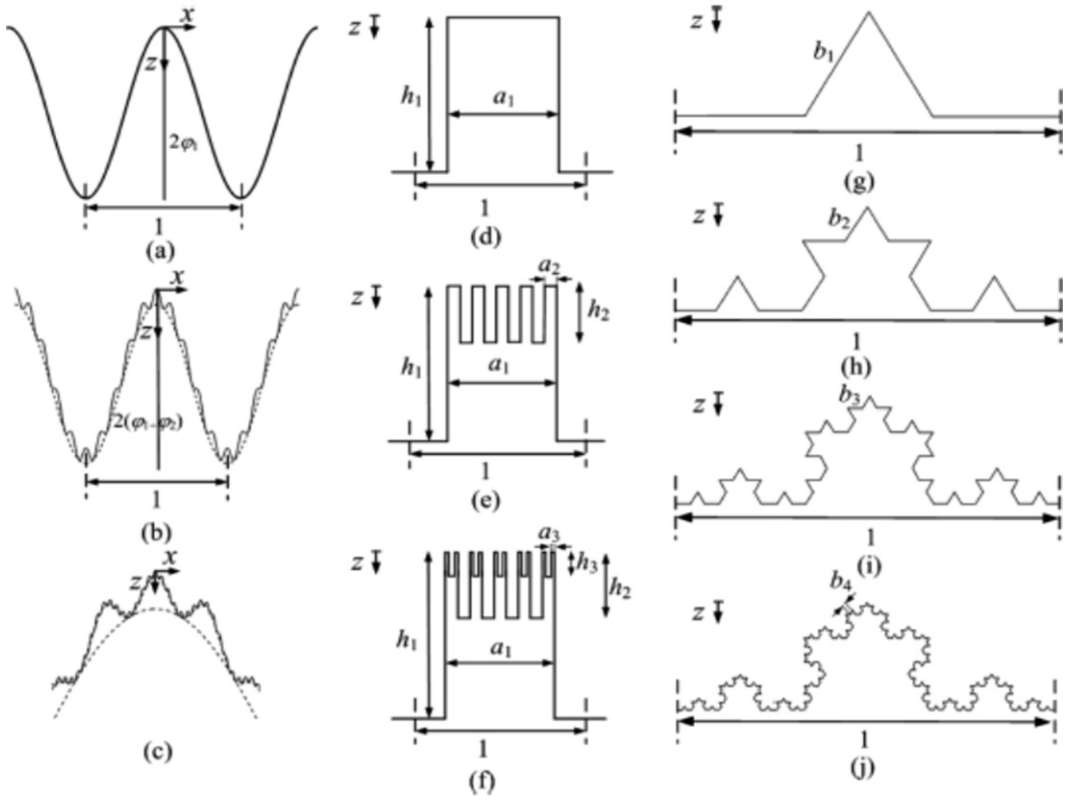

Figure 43 The unique topography cells of 2D solid surfaces. Three scales of sinusoidal surface topography are shown (a–c). (c) Picture has been magnified in comparison with the two other pictures. Three scales of flat head rods are shown (d–f). Four scales of roughness of the artificial surface of triadic Koch are shown (g–j).[117]

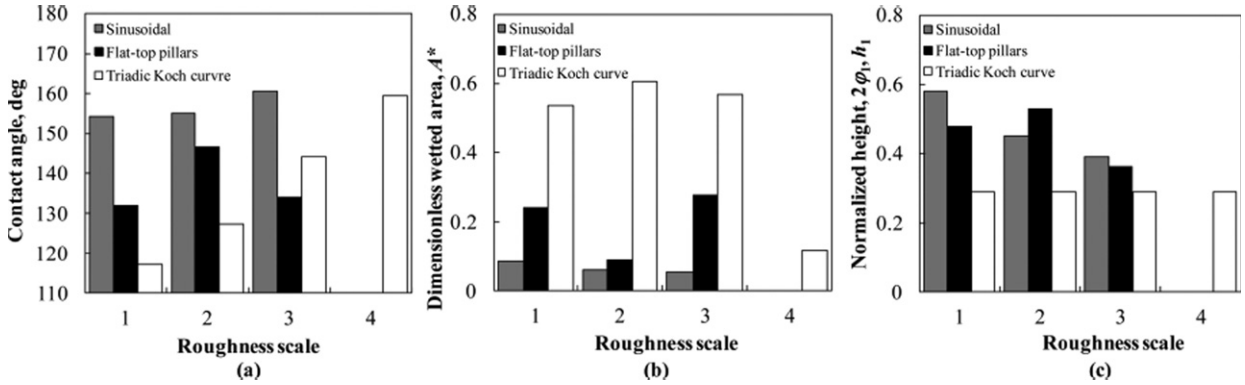

Figure 44 Comparison between three topographies in the transition point and between the Wenzel and Cassie–Baxter states, but not for the triadic Koch diagram because the transition point is not clearly identified. (a) The most stable contact angles. (b) Scale of less wetted areas. (c) Height of roughness composition.[117]

exist in nature as well as in artificial sensitized surfaces. The sinusoidal topography is similar to lotus leaf inequalities and is produced using microscaled techniques with different scales of roughness. The topography of flat head rods is widely used for modification to achieve a high contact angle and low contact angle hysteresis.[109–114] The triadic Koch diagram is a fractal example that has been analyzed to investigate whether the fractal nature can result in unique properties.[115,116]

An important practical criterion for nonwettability is the wetted area (the contact angle of liquid–air), which identifies the ability of sliding on the surface. This wetted surface is usually smaller (or much smaller) in the Cassie–Baxter state wettability equation in comparison to the Wenzel state, even when the contact angles are equal. These wetted surfaces might be difficult to measure in laboratory conditions (usually the sliding angle is reported), but with design calculations they can be explained.

The second important criterion for nonwettability is the thermodynamical stability of the Cassie–Baxter state in comparison with the Wenzel state. The transition point between

these states, according to stability, occurs when the contact angles are equal. This transition angle is the main criterion because the contact angle of the design surface must be equal to or higher than the transition angle. This might be difficult in some cases, including the triadic Koch diagram because of the impossibility of detecting the exact transition point because the variables might not be continuous (see **Figure 44**).

The mechanical stability of rough surfaces is dependent on the height of the roughness among all other parameters. Therefore, height is an important parameter that should be considered.

The modification of the design for a hydrophobic surface is a complicated process that contains many other parameters. Also, the modification process should begin with identifying the lowest wetted surface and the lowest values of properties in the transition contact angle.

By increasing the quantity of roughness scales, the following differences occur in 2D systems: (1) for sinusoidal surfaces, the transition contact angle slowly increases and the wetted surface slowly decreases, but the composition of the roughness significantly increases; (2) for flat head rods, the variations are not uniform; the minimum of the wetted surface is achieved at the maximum of the contact angle, but in the maximum of the height the composition of the roughness can be attained; and (3) for roughness of the triadic Koch diagram, according to the definition, the high property is constant and the Cassie–Baxter state is only stable when four scales of roughness exist.

3.19.5 Conclusion

By comparing three 2D topographies, it can be concluded that multiscaled roughness is better, but this strongly depends on the geometrical basis of the roughness. Therefore, there is no guarantee for the benefit of multiscale roughness. Among all the studied examples, sinusoidal topography is the most applicable because it has the lowest contact surface and the highest contact angle, and has height similar to that of other topographies. This conclusion is similar to the previous conclusion regarding single-scale roughness. This is in agreement with the superhydrophobic surfaces in the nature, including the bumps of the lotus leaf. Generally, it seems that the round headed properties are more beneficial in comparison with sharp edges for superhydrophobicity.

3.20.1 Introduction

A good adhesion property, which is defined through the processing, test, and service condition, is one of the most fundamental necessities of each substrate coating system. A large number of factors define a good adhesion property and many of them are too difficult without assuring gradual process. The process has been developed in an empirical manner, and has been thereby aided by some of the basic intended factors like giving a good adhesion property or other properties, which are vital for a good adhesion. From this point of view, it seems that one can make an acceptable decision in terms of doing some influential works in obtaining, good a adhesion, or which method is correct to test the adhesion property. ASTM has defined the adhesion in the form of a condition which two surfaces absorb each other either through valence forces, or by interlocking with mechanical forces, by becoming coalescence.[1] In **Figure 1** the diverse reasons of the adhesion coating to the substrate can be observed.

In engineering applications, adhesion is the physical resistance of the interface between regions of a material system. These interfaces have been found in the grain boundaries, abrasion and failure surfaces, and also, in substrate-film systems. Failure adhesion is defined as the separation in/or near the interface in a large space, which usually occurs under tension. The ultimate result of failure or changing the shape of materials is adhesion disruption, and it may depend on the properties of substrate material in the nearness of the interface, materials within phase, or material coating. Adhesion resistance is an irreversible macroscopic property of the system that can be tested. A good adhesion takes place, when the intersection region is not disrupted under circumstances of service, or unacceptable low tensions. To have a good adhesion, mechanical properties of intersectional materials, are very important points. These intersectional materials presumably have different properties, composition, and microstructures other than the rest mass of the materials. An intersection can be sharp or penetrating, rough or smooth. Formation and presence of the intersection region can possibly affect the composition, tension, or microstructures. Tensions that might wipe out the adhesion are involving mechanically (tension, pressure, communal, shock, etc.), chemically (corrosion, solubility), and temperature/time (penetrating reactions). The residual film stresses, may cause disruption. The major methods for acquiring the adhesion comprising are: reducing the surface energy, high failure energy for the intersection region, or using bonding agents in order to obtain new surface. Deposition process and variables of the procedure may have an important effect on the results of adhesion through the changing of nucleation growth and deposition properties. Deposition operations may be used to increase the adhesion. These operations containing: heating, ion mixing, and penetration of the free active particles in the intersection. Heating the couple substrate film causes the tension releasing in many of the systems. We can make changes in adhesion under confined situations anytime, and this procedure may be

 doi:10.1016/B978-0-12-803581-8.09201-8

occurred by tension releasing and particle penetrating in intersection.[2]

3.20.2 Preparation of the Sample's Surface

3.20.2.1 Grinding

Grinding is applied to smooth the samples and remove the sharp edges and deep grooves created by cutting tools. During the grinding, the sample should be kept cool with water or other cooling liquids, to prevent from microscopic structure changes of the samples that may occur.

3.20.2.2 Sanding

After disappearing of the lines and unevenness caused by the cutting tool during grinding, sanding operations are respectively applied on the sanders 60, 100, 200, 400, 600, 800, 1000, and 2000. The sander number 60 is the roughest and 2000 is the softest.

The most considerable points during sanding: the direction of sanding has altered from a sander to another one, and each time it is rotated with the amount of 90° in the case of fading the former lines and creates vertical lines over the previous. By the softer sander, we can do the sanding smoother with the lower pressure but spending more time. Sanding should be done on the sanders that water flows over them to not contaminate the former coarser particles next to the sander surface. After finishing sanding operations, the samples should be washed, dried, and then transferred to the next phase.

3.20.2.3 Polishing and Burnishing of the Samples

Polishing is carried out to completely wiping out the remained lines through the samples during the sanding.

3.20.2.3.1 Mechanical polishing

Mechanical polishing is done on a rotating disk covered with a felt, and is sprayed with a very fine abrasive materials (e.g., aluminum oxide or magnesium oxide). Because of, not creating grooves on the samples, brush or the felt that is employed here, should be thick and have no hard particles especially dust. At the entire period of polishing, it is necessary to smear the felt with suspended aluminum dust in water frequently. Grading of the aluminum oxide particles is different and we usually polish hard materials such as steel and cast iron with coarser aluminum powder rather than the soft metals like aluminum and lead. The alumina is in two forms: allotropic alpha (hexagonal) and gamma (cubic). The polishing properties of these two forms are different, so that alpha alumina acts faster in abrasion of metals and is more suitable for rough polishing, while gamma alumina prepares a polished surface with the high quality, so it is apt for the final polishing. Sometimes, it is utilized magnesium oxide for polishing aluminum and its alloys. This substance absorbs the carbonic gas of the air and produces carbonate. Therefore, aluminum oxide is usually used in the metallurgy laboratory. A disk with a velvet coating and diamond powder is being used to obtain a mostly polished surface and devoid of any grooves. Often, it is better to use an appropriate lubricant such as alcohol for diamond paste, to

remaining free or rising up the power of cutting powder of diamond particles, and also to increase the life of velvet coating.

3.20.2.3.2 Electro polishing and burnishing

An electronic or electrolytic polishing is defined as dissolution of a metal surface in an electrolytic solution. This kind of polishing is used in metallographic parts, stainless steels, copper alloys, magnesium, zirconium, aluminum alloys, and other metals that their polishing is typically formed by the mechanical methods. Here, the studied sample case is in the role of anode, a sheet of stainless steel in case of cathode, and electrolyte is in the role of the solvent. By the above mechanism, the unevenness of segment surface is solved, and the surface changing of layers created during the sanding, is entirely removed.[2]

3.20.2.4 Etching

Etching is defined as a metal surface corrosion by the corrosive liquid; that is usually kind of an acid. Some metals show their microscopic structure without etching (after polishing) such as emerging layer and spherical graphite in gray and ductile cast iron. In a microscopic investigation of polished samples, only properties such as porosity, type and distribution of inclusions, and corrosion cracks can be observed. During the etching the areas of surface with high energy-like grain boundaries are corroded, and the grading of segments would be appearing. Also, grains and different phases of the material have different corrosion rate, and this is another point to recognizing them from each other. In the case of metals that are consisting of different phases, different constituent components with varied intensities are corroded, and this happens because of the lack of equality of solution between various phases of a metal in the etch solution. High energy locations such as impurities, displacements, and grain boundaries are intensely corroded in touch with the etch solution, and are seen as darker areas under the microscope. Etching process is doing in both electrolytic and chemical methods.

3.20.2.4.1 Chemical etching

Chemical etching is the most common process that is used for disclosure of the microstructure of a substance. The goal of chemical etching is to clarify the different comprising phases of the sample. To be appeared the structure of iron and non-iron alloys, there are different types of etching solutions. The most famous etching solutions for microetching of carbon and alloy steels are Nital 2% and Picral 4%. Since both solutions have the same etching properties, usually they are used instead of each other. But, under some conditions, selecting an etching solution may cause remarkable differences. For example, in a low carbon steel with the substructure of perlite and ferrite, the 2% nital solution etches grain boundaries of ferrite and therefore causing to ultra-etching of perlite. On the other hand, the 4% picral solution etches the pearlite phase, but has no effects on ferrite grain boundaries. The sample is put under microscopic studies, after suspending into the etch solution and then drying. The most sufficient way to dry the samples is using drying devices. With the advent of any problem and damage surface of samples such as ultra-etching, it is necessary to polish and etch the samples again.

3.20.2.4.2 Electro etching

Electro etching is an imposing corrosion in the presence of an electrolyte and electrical current. This method is hardly used in carbon and alloy steels, but is applied for the alloys that are impenetrable, or their reaction with the chemical materials is slow. Stainless steels, heat resistant alloys, nickel based alloys, cobalt and chrome alloys are materials that the electrolytic etching is used to them. In this mechanism, the polished sample (anode) is suspended into the electrolyte, and a positive voltage is applied to it. The consumption, current and voltage used in electrolyte etching, is usually less than the voltage and current needed to electro polishing. Electro polishing is not only a method to finalizing and suitable surface payment in many laboratorial works but also a very adequate way to prepare the surface for coating deposition. The most important industrial parameters for determining the quality and durability of the coatings, is the quality of the adhesion. The effect of electro polishing in adhesion amount of the hard chrome coating has been investigated, and grooving test in additional to gloss meter searches, and optical and electron microscopes, have been used to determine the adhesion amount. The results of various experiments demonstrate that the electro polishing process causes a distinct increase in adhesion of the hard coating chrome, but amount of adhesion is dependent on the type of consumption solution, time, and the current density. Results showed that increasing of time of electro polishing samples in current densities above 225 A dm^{-1}, may causes in decrease of surface roughness, arising of glossiness, and also increasing of the adhesion. The relation between adhesion and surface roughness which is obtained by the use of electro polishing, indicating this matter that the bonding strength has a little mechanical locking and, in turn, mostly depends on penetrating theories and chemical bonding.[3]

As an instance, researchers have investigated the zirconium oxide as a preparation or pretreatment before applying due to the aluminum alloy, and having used the coating without chrome. In this way, by the sol–gel mechanism, the thin ZrO_2 coating has been deposited over the Al2024 with the use of spraying technology; and for doing the adhesion test, the zirconium oxide surface is covered with organic polymer. Adhesion and the electrochemical behavior of the coating have been investigated. The applied coating has increased resistance to the corrosion and adhesion.[4]

Galvanized steel is used for various technology applications, and this process is traced back to its high corrosion resistance. The protection capabilities of zinc are rising by applying a thicker coating, or painting the substance metal with the suitable polish. The main problem in painting the zinc is reaching to the good adhesion of color to the galvanized steel. If preparation or pretreatment be done with appropriate acid formulation, it could obtain an excellent adhesion, and then the study taken coatings with scanning electron microscope (SEM), X-ray diffraction, and energy dispersive analysis of X-rays analysis.[5] **Table 1** is a classification of these type articles.

3.20.2.5 Posttreatment, Additional Operations and Different Methods of Surface Analyses

In this section some posttreatment, additional operations and different methods of surface analyses were studied. For example,

Table 1 Investigation of pretreatment type, substance, coating contents, and acquired results of them

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
ZrO_2 coatings and hybrid organic–inorganic coatings	AA2024 aluminum alloy	ZrO_2	Cerium nitrate introduced in hybrid organic–inorganic films evidences an inhibition effect on corrosion processes, which can be attributed to cerium compounds	Promote adhesion	4
Pretreatment procedures	Galvanized steel	Alkyd resin + 3% HsP (water-borne resin, water-borne acrylic-styrene copolymer + phosphoric acid) + 3% $HsPO_4$ (vinyl resin + 3% $HsPO_4$)	It is possible to develop effective acid pretreatments for galvanized steel by a correct formulation and an adequate application	The adhesion of binders strongly depended on the nature of the conversion layer	5
Pretreatment of magnesium-based components	High-pressure die-cast AM30 magnesium alloy	Siloxane-based lubricant	Good corrosion performance homogeneity over the entire component optimized concerning defects, pores, and impurities	Good topcoat adhesion	6
Epoxy nanocomposite	St-37 type steel	Nano-sized ZnO particles	Excellent corrosion resistance, good paint adhesion, and low cost	Good paint adhesion	7
Pretreatment processes in powder coating	Hot rolled steel (HRS)	After pretreatment and dry-off process, all test panels were painted in an electrostatic powder coating booth. White industrial triglycidyl isocyanurate-free polyester powder coating was used	Zinc phosphate conversion coating gave the best performance, and zirconium-based nanostructured conversion coating was superior to that of iron phosphate conversion coatings on HRS	Best adhesion	8
Pretreatments epoxy resin was applied on the pretreated steel substrates	Cold-rolled carbon steel panels	γ-glycidoxypropyltrimethoxysilane	Reduced the disruption of interfacial bonds at the binder/substrate interface. Addition of 2 wt.% cerium nitrate into the silane formulation led to the maximum efficiency of resultant coating	Improvement of cathodic disbondment and also dry and wet adhesion of epoxy coating	9
Cerium-based conversion coatings as pretreatments	AA606	R_2 and constant phase element CPE2	Improved the quality of coatings	Excellent polyester coating adhesion was found independently on aluminum surface pretreatment	10
Altered migration and adhesion potential	Human bone marrow stromal	–	The basal migration of m-NSC was significantly reduced compared with MSC (6 versus 27 out of 10 000 cells migrated within 6 h).	Adhesion of m-NSC to the filter membrane was delayed and not affected by IGF1 or PDGFbb: 90% of MSC, but only 20% of m-NSC, adhered within 1 h, with 90% of m-NSC adhering within 3 h	11

(*Continued*)

Table 1 Continued

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
Fiber metal laminates	Aluminum 2024	ARALL (aramid-reinforced aluminum laminate) based on aramid fibers, GLARE (glass-reinforced aluminum laminate) based on high strength glass fibers and CARALL (carbon-reinforced aluminum laminate) based on carbon fibers	Offer several advantages such as better damage tolerance to fatigue crack growth and impact damage especially for aircraft applications	Adhesively bonded fiber metal laminates have been shown to be far more fatigue resistant than equivalent mechanically bonded structures	12
Epoxy-bonded	AA6060 aluminum	Hydrated aluminum oxide deposited Ti (and Zr) oxide only covered a small fraction of the total surface area, mainly located at the cathodic – Al(Fe,Mn)Si particles	The conversion coating formed in pH 4.0 solution was relatively thick over a considerable area fraction of the AA6060 surface. Under similar coating conditions, the thickness of deposited Ti–Zr oxide layer surrounding the particles was observed to be of the order 50–100 nm	Promoted adhesion	13
Powder coated aluminum alloy	Aluminum (1050) sheet	Aluminum hydroxide	Relatively good performance of the powder coating is due to a high ohmic resistance of the coating prior to and after saturation with water, low water solubility of the coating itself and good adhesion of the coating to the substrate	Improved the dry adhesion performance	14
Cleaner technologies	–	–	Most of the factors identified in the empirical literature could be drivers and barriers to innovation depending on the circumstances, time, and contexts in which they are considered	If a firm perceives that consumers have little willingness to pay for more expensive products, this might deter it from investing in cleaner technologies. The signals from the market must be the right ones	15
Cryoblasting involves bombarding a substrate with carbon dioxide particles	Aluminum and its alloys, 5251 alloy	Degreased-only aluminum 5251 alloy coupon	This method will be elective for other metals. To solvent degreasing or as the first stage, to replace organic solvents, in a multi-stage pretreatment	Would be expected to benefit adhesion	16

Table 1 Continued

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
PEG-based coatings other protein-resistant surfaces PEG and other coatings release- and contact-based antimicrobial coatings	Most metallic surfaces	Protease-based anti-fouling films photoactivated self-cleaning films release-based approach	Resistance to adhesion of biocontaminants or degradation of the biocontaminants	Preventing the adhesion of proteins or microbes involves the functionalization of surfaces with PEG or oligo (ethylene glycol) groups	17
Auto-catalytic plating based on a wet blast system	Ferrous iron	$Zn_3(PO_4)_2 + 2Fe_3(PO_4)_2$	Improvement in physical properties of the coatings and the reduction of effluent problems	Excellent adhesion of very fine grained crystals, which exhibit good corrosion and lubrication characteristics	18
Laser technology	Commercially available 2024-T3 and 7075-T6 aluminum; 4130 steel; GM3006 fiberglass/epoxy, IM7/977-3 graphite/epoxy, and AMS3902 Kevlar composite materials; and metallic honeycomb core	Replace chemical stripping and dry media blasting in coatings removal applications	Any of the lasers tested due to the potential to exceed recommended IR and UV levels	Paint adhesion tests also yielded that the process is suitable for use on all material	19

the methods of Simmons and Beard have been applied to hydroxylated iron surfaces to determine the values of pK I and pK II using anion and cation exchange. Results showed that a value of IEPS ~10 was obtained, which is good agreement with published data. The values of surface coverage obtained in these experiments are lower than the predicted results from those obtained in model experiments.[20] In other research SHIMIZU studied the route toward the enhanced understanding the corrosion and filming behavior of aluminum and its alloys. Results showed that the combined use of the ultramicrotomy approach and atomic force microscopy is expected to play a great role in enhancing the understanding of the corrosion and filming behavior of aluminum and aluminum alloys, as well as for other metals.[22] **Table 2** shows some examples of this type of articles.

3.20.3 Conversion Coatings

The terms, conversion coating, is referred to the coatings that are created by the reaction of the atomic layers of the metal surface with anions that are produced at the center of the metals. Therefore, the process of creating conversion coating is a controlled process that has been formed artificially, and finally creates a layer on the metal surface. This layer has a strong connection with the base metal, and practically is insoluble in water and intervening environment, and also, is a good electrical insulator.

Many investigators have introduced and applied different conversion coatings such as the coating based on elements: lanthanum, zirconium, potassium, cerium, zinc chromate coatings, phosphate chromate, non-chromate, etc., on various substrate like aluminum, copper, steel or magnesium, and as it is expected, these coatings, after enactment, observing and assessing their specific morphology of the coatings have achieved an excellent adhesion and corrosion resistance. Although, the magnesium alloys have low densities and high mechanical properties, but their applications have been restricted because of their weak corrosion resistance. The investigators have studied different conversion coatings to solve the problem. As an, example we can see below the conversion coatings based on cerium, zirconium, and niobium on the AM50 alloy, that they have obtained desired results with the contribution of electrochemical calculations, leading to polarization curves and electrochemical impedance spectroscopy, and also, the difficult procedure of inspecting the corrosion resistance such humidity and salt spray. Adhesion has been improved in addition to corrosion resistance improvement.[25] For example, to applying a cerium-based conversion coating, the aluminum 7075 samples are suspended into sodium nitrate solution, and adequate coverage is achieved at room temperature and specified time. This coating can be used by spraying or other methods.[10]

Another sample is lanthanum-based conversion coating on the Mg–8Li alloy. For exerting this coating, the substrate metal is prepared first. Then it is put in the bath containing considered elements (in this example lanthanum, and bath comprising lanthanum nitrate), and after each phase, samples are washed with distilled water. Finally, the applied coating has been dried with air and is to analyze.[26] Nevertheless,

Table 2 Posttreatment types, substrate, coating contents, and obtained results

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
2.5 wt.% $(NH_4)_3PO_4$ posttreatment after silica treatment	A6092/SiC/17.5p aluminum metal	Si–P composite coatings	Provide a maximum localized corrosion protection to AMMC. The surface morphology of Si–P composite coatings and the ability to protect AMMC substrate from localized corrosion in Cl-media were examined as a function of phosphate treatment time	Excellent adhesion	14
Inorganic surfaces	Pure iron	Hydroxylated iron	The values of surface coverage obtained in these experiments are lower than that predicted from the or those obtained in model experiments	–	20
Hygrothermal ageing and thermal shock	C151 Cu alloy black Cu oxide	Cu oxide	Prevention of corrosion and oxidation of Cu leadframes and substrates	Improving the interfacial adhesion with organic adhesives	21
Corrosion and filming behavior	Pure aluminum specimens	The Al_2Fe particles are oxidized during anodizing in sulfuric acid solution\forming a porous type oxide containing iron and having a texture similar to \but slightly higher than\that grown over the surrounding matrix surface	Improve mechanical strength\corrosion resistance	Improve the adhesion strength	22
Hydrofluoric (HF) treatment	Mg-2.5 wt.%, Zn-0.5 wt.%, Zr alloy	MgF_2 protective coating	HF treatment improves the corrosion resistance of Mg–Zn–Zr alloy and slows down the release rate of Mg^{2+} into the anticoagulated blood	–	23
Plasma treatment	AA 2024-T3	Hexafluoroethane layer deposited on the trimethylsilane plasma polymer substrate	Specific chemical changes take place in the first several days after film formation. These changes can be summarized according to elemental species and specific components	Improve adhesion of primer coatings	24

magnesium alloys has low density despite their good mechanical properties, but their utilizations have been somewhat limited from their weak corrosion resistance point of view. For solving this issue, investigators have reviewed diverse conversion coatings based on cerium, zirconium, and niobium over the AZ91 alloy in the following; that with the help of electrochemical impedance spectroscopy, and as well as, any dissimilar methods have been investigated. In the end, they have acquired favorable outcomes relating to corrosion resistance, including humidity and salt spraying. Corrosion resistance and adhesion have also been meliorated.[25] As it is seen in the **Figure 2**, with the increasing of the immersion time, current density and potential have reduced. Therefore, the corrosion resistance has been raised, also.

Figure 3 is the results of the magnesium alloys X-ray photoelectron spectroscopy experiments with the cited conversion coating at the room temperature. As it is shown, the obtained coating includes zirconium oxides, cerium oxide, niobium

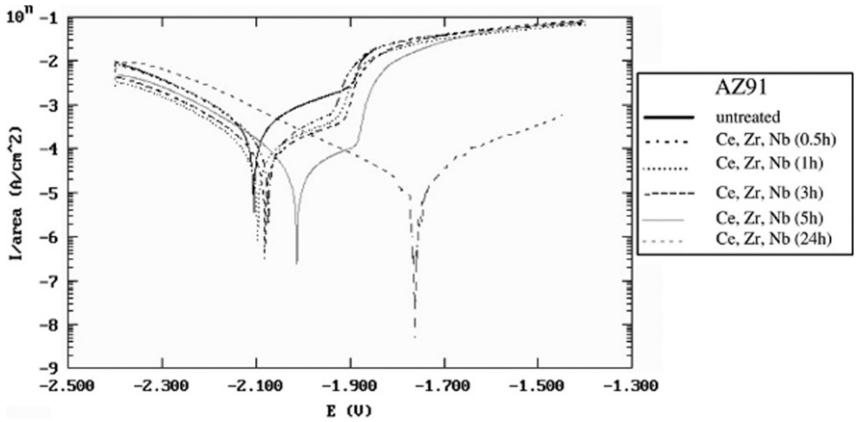

Figure 2 The polarization curve of AZ91 alloy according to the maintenance time in the bath Ce–Zr–Nb into the sodium sulfate solution.[25]

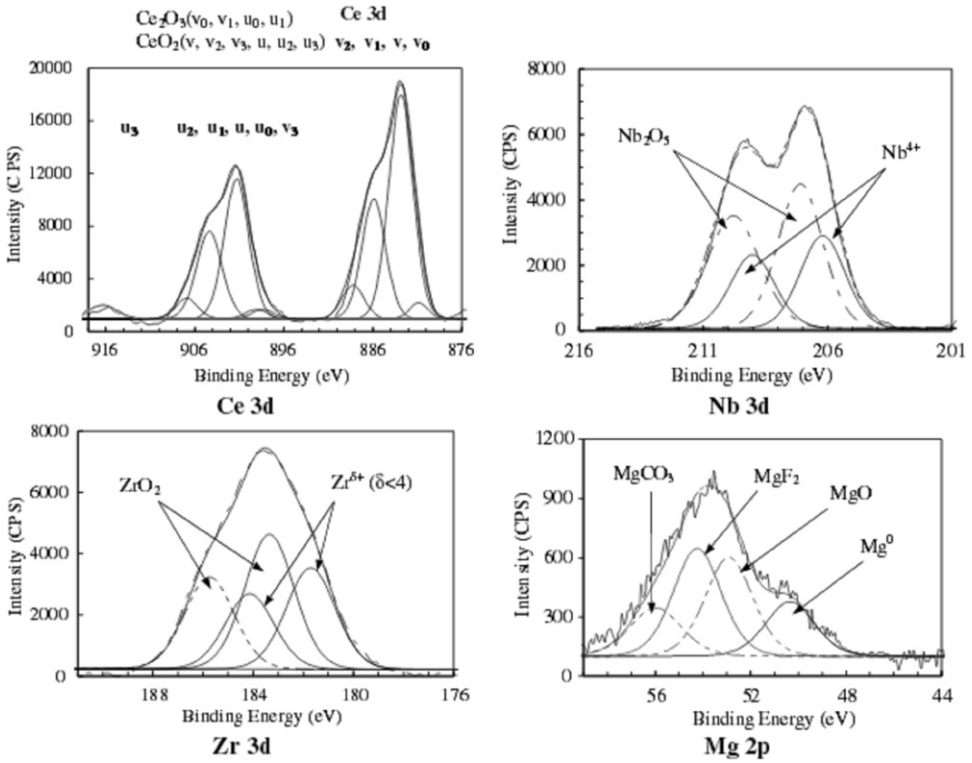

Figure 3 Chemical spectra X-ray photoelectron spectroscopy of the AZ91 alloy containing components Ce–Nr–Nb after 5 h keeping in the bath at the room temperature.[25]

oxide, and magnesium oxide. Table 3 demonstrates the various examples regarding this field.

3.20.3.1 Chromate

Chromate method is one of the processes of the conversion coatings that has progressed and developed widespread during the last two decades. The term of 'chromate' called to chemical and electrochemical operations of metals and the metal coating solutions which there are chromate acid, chrome, or dichromate in them. The consequence of such treatments is to create a protective conversion coating including components trivalent and hexavalent chromium on the metal surface. It has been known well the preventing properties from corroding of materials through the chromate. By adding small amounts of the substance to the water circulating system, the surface of metal is being coated and so, being prevented of corrosion. Chromate coatings are applied widely in products of industries like: machine manufacturing, electric, electronic, telecommunications, and auto engines industries. They also play a major role by replacing some certain metals instead of metals having less half-life. As an example, chromated zinc, which is replaced

Table 3 Classification of conversion coating type, substrate, coating contents, and obtained analysis

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
Cerium-based conversion coatings	AA606	R_2 and constant phase element CPE2	Improved the quality of coatings	Excellent polyester coating adhesion was found independently on aluminum surface pretreatment	10
Ce, Zr, and Nb-based conversion coating	AZ91 and AM50 magnesium alloys	Coating includes $CeO_2 \cdot Ce_2O_3$, ZrO_2, Nb_2O_5, MgO, and MgF_2	Increased corrosion potential, decreased corrosion and anodic dissolution current densities, and increased polarization and charge transfer resistances	Excellent paint adhesion	25
Lanthanum-based conversion coating	Mg–8Li alloy	$La(OH)_3$	The electrochemical results revealed that the lanthanum-based conversion coating possessed better corrosion resistance than the Mg–8Li substrate	Good adhesion to substrate	26
The relative proportion of coherent crystalline regions increases with time	The amorphous alumina evolves toward a partially crystalline form during the drying of the coating and with ageing	Crystallized mixed oxide such as Fe $(Cr,A1)_2O_4$. Moreover, $A1_2O_3$ phases which prevented the thermal oxidation of the stainless steel	Fe–17% Cr ferritic stainless steel	Conversion alumina coatings	27
Conversion coating produced by the permanganate-based system	Strip of galvanized steel	The manganese oxide-aluminum oxide	Extra thickness is due to the slow formation of the coating, which provides a more corrosion-resistant surface	Excellent paint adhesion due to the large number of attachment points available to the applied coating	28
The manganese oxide, zinc oxide conversion coating produced by the permanganate-based system	Zinc and zinc alloys	Chromium: 17%; zinc: 12%; carbon 10%; oxygen: 54%; aluminum 6%; and trace: copper and fluorine (less than 2%)	Will more easily accept applied coatings and/or resist corrosion. They are rather thin (not more than 6000 nm on zinc), quickly and easily formed, easily scratched	If used to improve upon paint adhesion – they are coated shortly after being formed to prevent degradation of the conversion coating	29
Lithium-based conversion coating. All coatings were painted with the 10P4-2-primer epoxy resin	AA2024-T3 aluminum alloy	Non-chromate (LBCC-DIP, LBCC-POL-5 and LBCCM. POL-45) and chromate conversion-coated surfaces (ALOD)	Non-chromate conversion-coated surfaces are very porous, while the chromate conversion-coated surfaces are more uniform non-chromate films they protect the AA2024-T3 aluminum alloy against corrosion since the corrosion rate of surfaces covered with these film were lower than the one of surfaces covered with the chromate films	The adhesion between primer epoxy and the conversion coating films is better for the chromate film than for the non-chromate films proposed in this work	30

Table 3 Continued

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
Conversion Coating	Cold-rolled steel	Nano-structured metal oxide, titanic, and/or zirconic composite	Provide phosphate-free and environmentally friendly pretreatment, which has corrosion protection	Paint adhesion properties at least equal to iron phosphate	31
Conversion coatings	Fe–17% Cr ferritic stainless steel	Conversion coating (sulfuric acid)/ alumina, N: conversion coating (nitric acid)/ alumina, P: conversion coating (phosphoric acid)/ alumina	The conversion coating obtained in phosphoric or nitric acid baths present low concentration of sulfur at the surface and the same morphology of standard conversion coating obtained in sulfuric acid	Conversion coating obtained in nitric acid modified by alumina deposit, have the best effect on the thermal oxidation resistance of the stainless steel, equivalent to standard coatings	32
Conversion alumina coating	Stainless steel Fe–17% Cr stainless steel	Duplex conversion – alumina coating	An efficient thermal barrier character thiosulfate and nitric acid concentrations have an important influence on the formation of conversion coating	Strong interfacial adhesion and must be very porous	33
Conversion coating growth in sulfuric acid medium	Carbon steel	Electrochemical alumina deposit	High roughness and high real surface area	Strong interfacial adhesion	34
Barium phosphate chemical conversion coating	Mg alloys	An under layer of mixed amorphous phosphates and a top layer of crystalline $BaHPO_4$	Improved corrosion resistance of the AZ31 magnesium alloy with the barium phosphate coating, with the two-layer coating being more corrosion resistant than a single under layer coating	The top layer exhibits a lower adhesion than the under layer	35
Zirconium-based conversion coating (ZrCC)	Mild steel	Oxide–hydroxide of zirconium and adsorbed fluoride ion on the mild steel surface	A drastic improvement of adhesion bonding between organic coating and steel substrate. Zirconium-based conversion layer could increase the chemical and/or physical interaction between epoxy organic coating and the steel substrate leading to enhancement of adhesion strength of the base substrate	ZrCC increased adhesion strength of mild steel to the organic coating and the zirconium treated mild steel adhesion performance is better than that of the three cationic phosphate layer	36
Chemical conversion coatings	Plain carbon steel (0.5–0.8% carbon by weight)	Bonderite 245 treated 15 N 20 plain carbon steel surface	The initial glycidoxypropyl-trimethoxysilane treated single lap shear (SLS) joints demonstrated mainly cohesive failure of the adhesive when observed optically. Following exposure for up to 8 weeks the	Good adhesion	37

(*Continued*)

Table 3 Continued

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
			failure was always mainly cohesive with limited apparent interfacial failure observed after as little as 2 weeks		
Fluoacid-based conversion coatings	Aluminum alloy (6063-T52)	Stoichiometry suggests that the ZrF_6^{2-} complex is broken upon integration into the substrate oxide	Provide chrome-equivalent corrosion protection and facilitate the adhesion of paint. Polymer choice is critical in assuring good performance	Enhance paint or lacquer adhesion	38
ZrCC	Cold-rolled steel	$ZrO_2 \cdot 2H_2O \cdot H_2ZrF_6$	According to zirconium energy dispersive spectrometer (EDS) map, uniform distribution of Zr along the surface of treated sample was observed. ZrCC can increase corrosion performance of fully painted systems	Adhesion tests exhibited considerable high values	39
Chemical conversion coating	Aluminum	Alumina	To restore corrosion protection and ensure paint adhesion after plastic media blasting	Excellent adhesion	40
Zinc phosphate coatings	AA6061 alloy	$AlPO_4$	Give strong adhesive bonding and improve corrosion resistance	Strong adhesive bonding	41
Conversion coating	Copper	Cupric oxide	Black oxide was originally developed for multilayered printed circuit boards (PCBs). To enhance the adhesion between organic prepreg layers and copper foils. The main benefits of copper oxide coating in the PCB applications are the increased available surface area for bonding through the rough, porous copper oxide crystals and the passivation of the copper surface to prevent its contamination during the manufacturing processes at elevated temperature	Applied onto the copper substrate to improve its interfacial adhesion with polymeric adhesive	42
Hydrotalcite conversion coatings	Aluminum aerospace alloys AA2024 (Al–4Cu–1.5Mg) panels were coated with a nitrate-based hydrotalcite coating (NO_3HT)	NO_3HT	Adsorption of the anionic SLS would decrease the negative surface charge of the hydrotalcite (HT) surface and decrease the electrostatic attraction of the	Increased adhesion is believed to be due to the increased wettability of the HT	43

(*Continued*)

Table 3 Continued

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
			chloride anion. The adsorption of the cationic Adogen should increase the adsorption of the chloride ion		
HT-based conversion coatings	Aluminum alloy panels for adhesion testing. The alloy used was AA2024-T3 (Al/4Cu/1.5Mg	CO_3HT, NO_3HT, and S_2O_8 HT conversion coating powders	Increased epoxy adhesion can be achieved by modification of the wettability or electrostatic characteristics of the HT coatings	Increase the adhesion	44
Conversion coating	Clad 2024-T3 aluminum alloy	Oxide layer sol–gel-treated epoxy aluminum joint	Macrorough structures drive the crack to within a thin epoxy layer close to the polymer–metal interface, which enhances the initial strength of the sol–gel-reinforced interface	Enhanced adhesion	45
Phosphating	Steel	$Fe(H_2PO_4)_2$	Improved corrosion resistance, wear resistance	Highly adherent to the underlying metal	46
Chromate/phosphate conversion coating	1050 Al alloy	Aluminum hydroxide and polymer-oxide bonds and different mixture compounds	Good corrosion performance highest surface free energies	Best adhesion strength	47
Zinc phosphate coating	AZ91D magnesium alloy	$Zn_3(PO_4)_2$ H_2O, Zn, $AlPO_4$, and $MgZn_2(PO_4)_2$	Good corrosion resistance	The adhesion of paint on the zinc phosphate coating was better than that of paint on chromate conversion coating due to the microporous structure of the phosphate coating	48
Oxide films	Pure aluminum	Alumina	Improved performance in corrosion resistance of these metals is the improvement of the hydration resistance of the oxide film or the oxidocoating interface	Improved performance in adhesion	49
Conversion coatings	High purity aluminum	Chlorinated rubber primer	Anti-corrosion primer performance	Conversion coatings were mainly employed to improve metal-polymer bonds. The adhesion performances of polymer–metal interfaces were attributed to mechanical interlocking	50
Deleterious effects of water	Metal/epoxy interface by the presence of water	Metal/epoxy interface	Chemical conversion-coated samples were found to be much more stable in wet	Maximum bond strength	51

(*Continued*)

Table 3 Continued

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
			conditions compared to samples without conversion coating		
New oxide layers	AA2024-T3 aluminum alloy sheets	Oxide layers and cerium-based conversion coatings cerium oxyhydroxide layers	Improvements in the mechanical performance after adhesive bonding	Increased adhesion	52
Hydrotalcite conversion coating on	Mg alloy	Double hydroxide (Mg–Al LDH) film	The results suggest that the LDH film has the potential to become an environmentally friendly replacement for increasingly regulated chromate conversion coatings	The cross cutting showed that the adhesion between the film and the substrate was very strong, which enhances its potential for practical application	53
Conversion coating is composed of pyrophosphate with a flower-like microstructure	Carbon steel	Conversion coating contains P, Fe, and O elements $FeH_{10}(PO_4)_4$	This conversion coating presents much better anti-wax performance than carbon steel and heat-treated carbon steel in water-contained crude oil	Has a special wettability, which is super-oleophobic with low oil-adhesion in water and hydrophilic in oil	54
Conversion coatings	Aluminum alloy 6061-T6	Hydrated Ce(III)/Ce (IV) oxide	Increase in corrosion resistance	Improved adhesion	55
Coating degradation and delamination process.	Phosphated steel	Additional paint, wax, or sealer coatings	Long-term degradation processes leading to the failure of high performance coatings can differ in mechanism from those important for coatings that fail quickly	–	56
Zinc–aluminum–chromium conversion coating	Metal surface	Zinc and aluminum existed mostly as zero-valent zinc and zero-valent aluminum, but chromium existed mostly as trivalent chromium oxide	At the same time, the chromic acid in the treatment chemical reacted with the metal surface of the substrate forming a chemical bond providing strong adhesion	Good adhesion	57
Conversion coatings	AZ31 magnesium alloy	Cerium hydroxides/oxides	The coating was at two-layer structure. The adhesive weakness between the surface layer and the inside layer was a crucial factor that limited the coating protection ability	Poor adhesion	58
Chemical conversion and organic coatings	AZ91D Mg alloy by precision die-casting	Corrosion product, consisting of MgO, $Mg(OH)_2$, and $Mg_2(OH)_3Cl$ filled up the blisters	Scanning electron microscope/EDS and Fourier transform infrared analysis showed the blistering initiated because of *in situ* loss of adhesion at the organic coating/substrate interface,	If the conversion coating is contaminated in any way adhesion will be poor and mostly result in blister formation on contaminated spots	59

phosphates that utilized one or more metal cations in addition to zinc		hopeite and rhombic scholzite crystals [$Zn_2Ca(PO_4)_2$ _92 H_2O]; the percentage of metals incorporated into the conversion coating mixture of vivianite and magnetite		to create the rubber-to-metal bond	

by the metals coated with cadmium can be mentioned. The objectives of using chromated metals including:

a. Increasing the corrosion resistance of the metal or protective metal coatings, in the recent case, it is likely led to prolonging the first coming out of corrosion on the base metal and coating metal.
b. Decreasing the surface damages generated from finger traces (surface scratches).
c. Raising adhesion of the paint and other organic coatings.
d. Staining or better acceptance of decorative coatings.

The high consumption of these coatings in the industry is because of creating properties such as corrosion resistance, and improving the color traits or coating of the surface. For instance, conversion coating of chrome with the use of the permanganate system over the galvanized steel can be investigated.[28] As a well understood case, researchers in the multi-components coating for magnesium have used a chemical conversion process without acid washing, and the sample has been put in the bath comprising elements of P, Al, Mg, K, Ca, Mn, Zn, and O. Obtained coating includes multi-component oxides of mentioned elements, and caused to improve the corrosion resistance of the cited alloy.[66] In another essay, the AZ91D magnesium alloy has been etched with sodium chloride, then has been suspended in Nanomyte DT-60 for 10 min at the room temperature. During this process, alloy sheets that were initially gray, have been covered with a bright yellow micrometer 2–3 layers. This yellow layer, that is the considered coating, has been increased durability and stability of the alloy in various environments.[67] **Table 4** denotes the samples of chromate conversion coating properties, and obtained results of applying them.

3.20.3.2 The Hexavalent Non-Chromic Coatings

Nowadays, most of converting and surface coatings of steel parts, especially parts that are utilized in vehicles containing hexavalent chrome. The excellent capability of surface protection and corrosion resistance are the reasons of this general exploitation. But environmental and health problems and hazards relating to hexavalent chrome, have made the industrialized countries that are the greatest costumes of these coatings, to regulate some programs to remove and replace these materials. The July first 2007 was the deadline for the elimination the certain form of chrome metal and replacing chrome-free coatings in the coatings of auto parts of the European Union. The table below represents the comparison between adhesion and the type of the failure in the coating. As it is observed, in the case of chromate, failure was taken place in the primer, and in the case of the coating-free sample; it has occurred in the substrate, and chromate coating has led to increasing of the adhesion.[80] **Figure 4** is the weight reduction curve and the coating type of the AZ92A magnesium alloy samples. The weight reduction of the MLTC + MLT coatings, chromate and the coating-free sample has respectively risen. The corrosion rate of the chromated sample is five times less than the coating-free sample.[80]

Table 5 demonstrates samples with conversion chromate coating, properties, and the results of applying them.

3.20.3.3 Replacement Schedule

On September 18, 2000 the parliament of Europe put on the agenda the elimination of harmful substances to the environment in manufacturing auto parts. The plan of the Committee consisted of determining a deadline that the members being ensured that in auto parts, elements such as lead, mercury, cadmium, and hexavalent chrome will not be used. These parts including connectors, press parts, casting parts, machining parts, and accessorial parts which are employed from zinc coatings, dichromate coatings, and chrome coatings for corrosion protection of them. In the case of hexavalent chromes, in the beginning, it was declared the program of limiting authorized total amount to maximum 2 g amount in each automobile until 2003. But, since this procedure does not give a standard method concerning analyzing the use of chrome, and there is not any other solution for replacing all hexavalent chrome coatings, belonging to the Europe Agreement with the EU Auto industry[85] an agreeable gradual program was approved with the name of eliminating hexavalent chrome. The steps of the plan were the followings:

1. Stopping shiny and blue chromatic systems until July 2002.
2. Stopping yellow chromatic systems until 2003.
3. Elimination of hexavalent chrome in zinc systems until the January 1, 2005.
4. Elimination of hexavalent chrome in the surfaces of black and olive chromatic coatings until the July 2007.

Table 4 Different chromate conversion coating, substrate, coating contents, and obtained results of them

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
Chromate conversion coatings (CCCs)	Metal such as cold-rolled steel, galvanized steel, and copper and aluminum alloys	Silane films	A superior application method because of more uniform and compactness of prepared films and thereby the best barrier properties compared with other application methods. The properties of the silane, as a corrosion-resistant pre-treatment coating, may significantly improve by the incorporation of rare earth salts and nanoparticles	Excellent adhesion and good barrier properties	9
Conversion coating produced by the permanganate-based system	Strip of galvanized steel	The manganese oxide-aluminum oxide	Extra thickness is due to the slow formation of the coating, which provides a more corrosion-resistant surface	Excellent paint adhesion due to the large number of attachment points available to the applied coating	28
Chromium VI as alternative oxidizing species, sodium molybdate, tungstate and vanadate, and ammonium molybdate, $(NH_4)6Mo_7O_{24} \cdot 4H_2O$	Zinc galvanized steel	$Cr(OH)_3$, $CrO(OH)$ and $ZnCr_2O_4$	Both improve the corrosion resistance and enhance the chemical adhesion of organic coatings	Enhance the chemical adhesion of organic coatings	68
CCCs cerium and rare earth oxide-based coatings cerium oxides	2024-Al varying amounts of Ni^{2+} and Mn^{2+}	Al–Cu–Mg(ZPO coating crystals at the edge of the particle but not over most of its central area). CeO_2, $Ce(OH)_4$, and $Ce(OH)_3$	More easily accept applied primer and/or paint and offers corrosion resistance in the event that the covering layer is damaged	Adhesive coating	69
CCC	Aluminum, Grade 1050	Insulating oxide film on aluminum	Chromating will provide enhanced corrosion resistance	Increase the adhesion of paints or other subsequently applied coatings	70
Alternative treatment to CCC	AA 6082 aluminum alloy	Deposition of films of $CeO_2 \cdot 2H_2O$ (or $Ce(OH)_4$ on aluminum alloys in a few minutes at room temperature with or without a catalyst	Coatings obtained without a catalyst had some interesting properties though EIS revealed that their performances still did not equal those of CCC	The catalyst also improved the adhesion of the $CeO_2 \cdot 2H_2O$ layer but has dramatic effects on the anti-corrosion properties	71
CCCs	Al 2024-T3	Cr^{3+} hydroxide	Inhibition of Al corrosion is derived from both inhibition of oxygen reduction and inhibition of metal dissolution reactions mainly due to a delay in the onset of pitting	Excellent adhesion	72
CCCs sol–gel chemistry-based coating	Aluminum	Cr(VI), alodine film oxide materials	Improve corrosion resistance and paint adhesion	Improve paint adhesion	73

(*Continued*)

Table 4 Continued

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
		hybrid organic/ inorganic			
CCCs	Commercial purity rolled aluminum	Chromate film	Good paint and lacquer adhesion	Improve the adhesion strength	74
Conversion coatings	99.99% pure aluminum	Hydrated chromium oxide/hydroxide and chromium phosphate	Improve corrosion resistance and paint adhesion	Enhancing adhesion	75
CCCs	5083 aluminum alloy	Epoxy paints were applied to the chromate and non-chromate treatment surfaces	Corrosion propagation from the scratched area in the painted samples with chromate treatment was lower than for the non-chromate coated surfaces coating system including chromate treatment presented lower corrosion current densities, higher polarization resistance, and less negative corrosion potential than the corresponding values obtained for the non-chromate conversion-coated surfaces	Adhesion of coating systems (including chromate treatment) was better than the adhesion of non-CCCs	76
Failure of chromate-treated aluminum bonded in lap shear configuration using a structural epoxy paste	2219 Al alloy was treated with Alodine 1200	Chromium is present in the conversion coating as both Cr(III) and Cr(VI) species, and that other components are present at the conversion coating surface, some in a reduced form	High strength and good toughness durable in high and low temperatures, thermal cycling, radiation, atomic oxygen exposure	Excellent adhesion	77
0.5 g $Fe(NH_4)(SO_4)_2 \cdot 12H_2O$ to 20 ml of 0.05 M $K_4Fe \cdot (CN)_6 \cdot 3H_2O$ solution [Fe(II):Fe (III)51:1]	Aluminum alloys, such as AA 2024-T3 aircraft alloy	CCCs have	Corrosion-resistant coating strongly coating	Adhesive coating	78
CCCs	A sandwiched type of electro-galvanized (EG) steel sheet	Bonded with poly (vinyl butyral) (PVB)	Enhanced both initial tensile shearing strength (TSS) and the joint durability in the corrosive environment. Improvement on the shearing properties of the EG steel sandwiches	Good adhesion of TSS equal to 17.8 MPa	79

3.20.3.4 The Comparison of the Hexavalent and Trivalent Chromes

The danger of skin cancer increases in utterly subjecting to the hexavalent chrome coatings. The hexavalent chrome is the only form of chrome that penetrates into the cell membrane of human beings, and subsequently destroys cells. This action creates environmental pollutions during the destruction or recovery of the vehicles. Nonetheless, hexavalent chrome gives the best corrosion resistance of the conversion and surface coatings. Trivalent chrome is safe for the environment and health problems, but its corrosion protection properties are not as similar as hexavalent chrome. So, it is necessary to use a topcoat in most cases, and this issue increases the cost of the coating. Practically, controlling the coating bath corresponded to trivalent chrome and sustainable maintenance of it

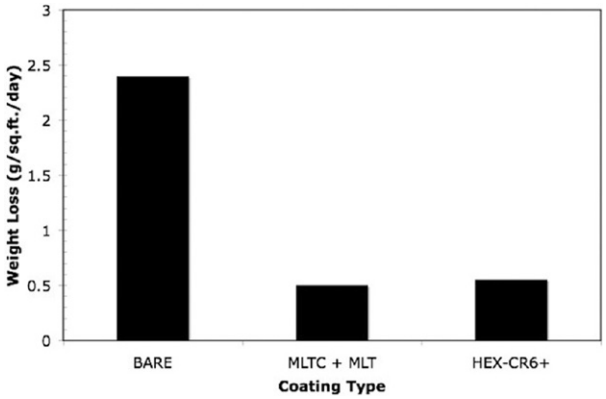

Figure 4 Weight reduction curve and the coating type of the sample, with AZ92A magnesium alloy.[80]

is thoroughly problematic. On the other hand, appearance and quality facet also is not feasible to stay stable. The coating adhesion to the metal is less, as well. The trivalent chrome coatings are cheaper than hexavalent ones. For example, this value for trivalent shiny blue chrome is approximately 10–20%. But, as discussed above, with regard to having less corrosion protection properties of trivalent chrome, and computation in the use of a topcoat, the cost of the coating increases. On the other side, coatings comprising trivalent chrome prominently involve the exploitation of oxidizing agents, which converts them into the hexavalent chrome in the coated surfaces. Nevertheless, the use of hexavalent chrome coatings creates not only a better corrosion resistance but also an easier operation and higher stability.[85]

3.20.3.5 Phosphating

Phosphate–zinc coating (plating) is one of the first conducted plating in the industry.

This plating is done both in the forms of immersion and spray. The purpose of phosphating is improving the color adhesion, increasing the corrosion resistance, aiding to alteration of cold deforms, and raising the surface abrasion resistance. Consisting materials of the zinc–phosophating bath are zinc oxide, phosphoric acid, nitrites, or nitrates (as a catalyst) and distilled water. Phosphate coating as a conversion coating is the result of reaction between iron parts and phosphate solution. This reaction takes place only in the surface of parts. This process along with decreasing and sometimes pickling, have been recognized as preparation of the components. This coating is in the form of dark rainbow in the iron group phosphates, and dark gray to black crystals in either zinc or magnesium group phosphates. By using activators and accelerators, the appearance changes in unevenness and the size of phosphate crystals could be made up. Phosphate coatings are applied to three general purposes following:

1. Increasing color adhesion: phosphate crystals increase the color adhesion by creating roughness on the surface of the parts.
2. Raising corrosion resistance: phosphate crystals are suitable sites for maintaining anti-corrosion oils longer, by creating roughness over the surface of the components. It also prevents rusting of the screws and nuts, while welding of the parts to each that is carried out. This application is called anti-galling.
3. Wire tension of sheets, pipes, or rods: phosphate crystals are an appropriate carriage for preserving tension oils or powders by creating roughness, which makes better lubricating through crushing the crystals in the tension process or pressing, in addition to increasing the quality of the parts and avoid the lines and scratches.

Electrical properties of the phosphate coating are given below:

Zinc oxide: this substance is used as a basic ion of zinc; this material has been exerted between similar components because of many aspects such as being more economical and cheaper, easier transportation and usage, and also, produced in diverse grades.

Phosphoric acid: this substance is used as a base for phosphate ion. It is also a supplier of some required acids in terms of acid washing process and dissolution of iron ion from the part's surface.

Nitric acid: generally, this material is applied for: (1) regulating the free acid and total acid, and as a result regulating the deposition grain size. (2) pH regulating, and (3) supplier of the nitrate ion. If its value heightens, because of increasing free acid, coating with finer grains is obtained.

Nickel ion: nickel salts are used in this process as facilitators, meanwhile Nickel itself gets deposited on the surface and causes the darkness of sediment.

The coating process: the coating process is commenced over the metal surface firstly, with processes of oxidation and releasing the iron ion in suspension. At this stage, initially, the metal surface is oxidized through the various oxidations existing in suspension, and two positively charged iron ions are released into the bath. At this phase, the amount of acid bath and type of oxidizing play decisive role in the speed and type of reaction in the acid washing. For two common oxidizers, nitrate and chlorate, following reactions can be considered:

$$4Fe + NaNO_3 + 10H^+ \rightarrow 4Fe^{2+} + NH_4{}^+ + Na^+ + 3H_2O$$

$$3Fe + NaClO_3 + 6H^+ \rightarrow 3Fe^{2+} + NaCl + 3H_2O$$

In these kinds of reactions in addition to surface acid washing, released hydrogen ion from the surface part also combined with the oxidizing material and as a result, impedes of releasing hydrogen gas from the surface of the material. It is so called that releasing of the hydrogen gas from these surfaces leads to increasing the thickness of the iron-saturated layer and hence, it takes more time to become supersaturated; so, the overall speed of the process is decreased; because the layer that is stationary on the part's surface must initially be saturated by metal ions in the favor of getting ability of depositing crystals on the part's surface by the cited layer. After saturating of the solution, zinc phosphate crystals are formed over the surface and deposited on the piece. The mechanism of deposition includes nucleation and growth steps. The type of oxidizer, solution composition, temperature, and pH are also the agents that affected this mechanism.

Table 5 Classification of the types of non-chromic coatings, substrate, coating contents, and obtained results

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
The manganese oxide, zinc oxide conversion coating produced by the permanganate-based system	Zinc and zinc alloys	Chromium: 17%; zinc: 12%; carbon 10%; oxygen: 54%; aluminum: 6%; and trace: copper and fluorine (less than 2%)	Will more easily accept applied coatings and/or resist corrosion. They are rather thin (not more than 6000 nm on zinc), quickly and easily formed, easily scratched	If used to improve upon paint adhesion – they are coated shortly after being formed to prevent degradation of the conversion coating	29
Multi-elements complex coating	AZ91D magnesium alloy	$Ca_{0.965}Mg_2Al_{16}O_{27}$, $Mn_5 \cdot 64P_3$, $ZnAl_2O_4$, and $(Mg_{0.66}A_{l0.34})(Al_{0.83}Mg_{0.17})_2O_4$	Good corrosion resistance	Can provide better protection to the substrates of magnesium alloy	66
Chromate-free conversion coating	Magnesium alloys Mg AZ91D	NANOMYTE PT-60	Anti-corrosion performance exhibits less corrosion than other chromate and non-chromate industry standards	Excellent adhesion	67
Replacement to the conventional hexavalent chromium-based chemfilm technologies for magnesium alloys	Cast AZ92A-T6 magnesium alloy	Conversion coating, hexavalent chromated, and trivalent chromium treated	The new non-chromated conversion coating technology could be a drop-in replacement to the conventional hexavalent chromium-based conversion coatings	Coated samples had relatively higher pull-off adhesion value of 3140 psi compared to the hexavalent chromated samples (2542 psi)	80
Chrome-free conversion coating	Magnesium, aluminum and zinc, and their respective alloys	Oxidation of magnesium, aluminum, and zinc	Electrical conductivity, filiform, and neutral salt-spray corrosion resistance	With the same level of adhesion and secondary corrosion resistance as that found in chrome containing conversion coating systems	81
Conversion coating	AZ91D magnesium alloy	$K_2HPO_4 \cdot KMnO_4$	Corrosion resistance of the conversion coating by phosphate-permanganate solution is matched to that of the conversion coating by traditional chromate solution, but for the corrosion resistance after painting, the former is better than the later	Good adhesion to matrix	82
Chrome-free nanocomposite sol–gel coatings	AA5083	Tetraethylorthosilicate and 3-glycidoxypropyl-trimethoxysilane	Minimum corrosion current density	Strong adhesion	83
Created by Cr(III), Cr (VI), Cr(III)-Co(II), and Cr(III)-Ni(II) conversion coatings. Epoxy nanocomposites	Hot-dip galvanized steel (HDG) samples	Epoxy nanocomposite on the HDG steel samples, treated by different kind of conversion coatings	Improve the corrosion n resistance of the epoxy coating on HDG. Decrease of contact angle (φ) and increase of surface roughness (*Ra*) of the pretreated HDG samples were obtained	Increase of the adhesion strength	84

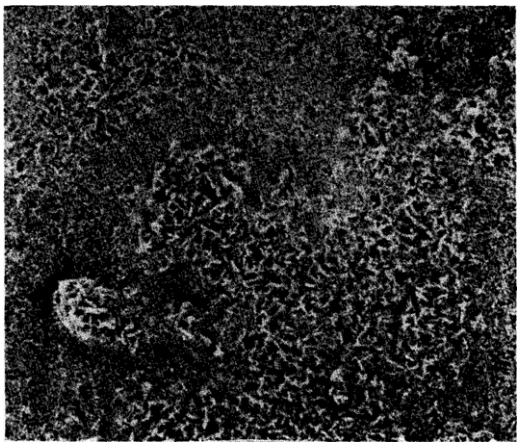

Figure 5 The scanning electron microscope image of the zinc phosphate coating applied over the galvanized steel.[28]

The conventional reaction of forming coating is followed by:

$$3Zn^{2+} + 6H_2PO^{2+} \rightarrow 4Zn_3(PO_4)^{2-} + 4H^{4+} + H_2PO_4^-$$

However, relying on the composition of a solution, other reactions can take place as follows:

$$2Zn^{2+} + 4H_2PO^{2+} + 4Fe \rightarrow Zn_2Fe(PO_4)^{2+} + 2H^+ + H_2 + 2H_2PO_4^-$$

$$2Zn^{2+} + 6H_2PO_4^- + Ca \rightarrow CaZn_2(PO_4)^{2+} + 4H^{4+} + H_2PO_4^-$$

Each phase that is made in these reactions, has different properties.

For instance, in the third reaction of this category $CaZn_2(PO_4)_2$, it is observed that by applying that on the coating, the roughness of the coating is decreased.[86] **Figure 5** shows the SEM image of the zinc phosphate coating over the galvanized steel. The thin crystalline structure of this coating is a the result of high forming speed of coating and because of the presence of active regions, gives the best color adhesion.[28]

Figure 6 is the SEM image of the galvanized steel with the cited chromate coating. Over passing of immersion time and being thickened of the coating, the corrosion resistance properties have been modified. Also, the created roughness on the surface, provides the conditions of good adhesion for subsequent layer.[28] The potentiodynamics of the sample without coating and the sample containing zinc phosphate coating, that has been applied over the 6061 aluminum alloy shows that the phosphated sample has more negative potential and, relative to other sample is more active.[41] The test results of adhesion and corrosion resistance show that both cases improve with applying this coating.[41] The **Table 6** shows several samples of the applied phosphate coatings on different substances in which adhesion and other coating properties have been investigated.

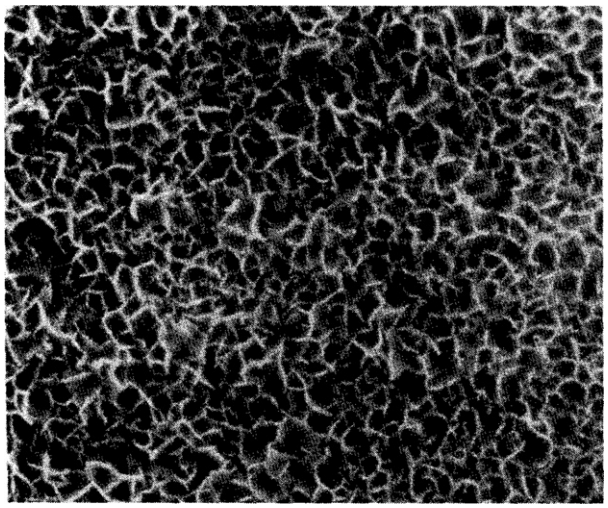

Figure 6 Scanning electron microscope image of the thick zinc phosphate coating over the galvanized steel.[28]

3.20.4 Polyurethane Coating

Outdoor usages and using a polyurethane coating in front of the UV ray increase durability of the coating system, and ultimately the structure itself is affected. Applying this coating is recommended over the available and compatible anti-corrosive liners and intermediates in sites and environments with different atmospheric conditions. Using in the acute acidic situations is not recommended. The coating has good adhesion to most metals. Marine and steel structural coatings, bridges, exterior surfaces of tanks, refiners, petrochemical plants, the final coating for protection of metal structures in acute and corrosive environments that the color and loss stability are required, metallic structures in chemical and petrochemical industries, power stations, waste water treatment plants, decks and the ship's hull are some of its applications either.[95]

This coating, as the last layer, undertakes the protecting of the surface and underlying layers of the coating system against the climatic situations. The high resistance against the ultraviolet radiations is distinguished characteristic of this color. Flexibility and high hardness have caused to the extraordinary efficiency in the difficult mechanical conditions.

- High adhesion and hardness on the metallic surfaces.
- Excellent case against ultra-radiation.
- Supplying supreme endurance in marine and industrial ambient.
- Resistant to water, impact and abrasion.
- Very good stability against climatic changes and extreme weather environments.[95]

Preparing and spraying steps: the needed surface should be clean and devoid of any pollution, fat, oil, and humidity. The cleaning operation is done by proper detergents. If the paint is directly applied on the surface, the surface should thoroughly be prepared. After preparation of the surface, the color components are mixed through the certain mixing ratio (according to the guidelines), and stirred with an appropriate stirrer until obtaining a uniform and homogenous mixture.

Table 6 Scrutinizing variety of phosphate coatings, substrate, coating contents and the handled results of them

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
Zinc phosphate coatings	AA6061 alloy	$AlPO_4$	Give strong adhesive bonding and improve corrosion resistance	Strong adhesive bonding	41
Phosphating	Steel	$Fe(H_2PO_4)_2$	Improved corrosion resistance, wear resistance	Highly adherent to the underlying metal	46
Zinc phosphate coating	AZ91D magnesium alloy	$Zn_3(PO_4)_2$ H_2O, Zn, $AlPO_4$, and $MgZn_2(PO_4)_2$	Good corrosion resistance	The adhesion of paint on the zinc phosphate coating was better than that of paint on CCC due to the microporous structure of the phosphate coating	48
Phosphated substrates were coated with epoxy coatings	Galvanized steel specimens	Manganese modified phosphate conversion coating and primer, calcium modified phosphate conversion coating and primer	Enhance paint or lacquer adhesion and promote corrosion resistance	Improves the adhesion of organic coatings due to removal of strong organic contaminations and alteration of oxide layer	50
Conversion coatings	High-strength cold-rolled sheet steel supplied by the Bethelehem Steel Corporation	$Zn_3(PO_4)_2 \cdot 2H_2O$	The suppression and controllability of the crystal growth of Zn–Ph conversion coatings precipitated on high-strength cold-rolled steels depends primarily on the internal diffusion and segmental chemisorption of polyelectrolytes having functional carboxylic acid and sulfonic acid pendant groups on the embryonic crystal faces	Promoting adhesive strength	87
Copper on zinc phosphate conversion coatings	Al 2024-T3 alloy	Cu 2p spectra from the sample coated by solution containing 1 ppm Cu^{2+}	Cu in phosphating solutions that aim to meet the overall challenge of forming coatings that can improve the passivation of different Al alloy surfaces	Increased adhesion	88
Phosphatizing coating	Bare 2024-T3 Al panel	ISPC painted on chromated	Superior paint performance improved durability of paint	Improved adhesion	89
Conversion coatings	Steel	Polyacrylic acid (PAA) modified zinc phosphate crystal	Improve both resistance to corrosion and topcoat adherence. It has been reported that the addition of PAA reduces the size of crystallites, which leads to greater film ductility	Improved adhesion properties	90

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
Thermoplastic polyurethane elastomer is co-molded with galvanized steel	Galvanized steel	Aminopropyl trimethoxysilane amino silane	The model, compared to experimental results, also revealed that it is important to account for internal stresses, mostly for treatments leading to low intrinsic interfacial shear strength values	The best silane treatments led to mixed cohesive–interfacial failure, while other treatments showed a purely interfacial failure	97

In order to dilute and adjusting the viscosity of color tinnier gradually add to the color, and stirred to the getting desired uniform composition. This coloring is applicable by airless spray, air spray, immersion methods, electrostatic spray, brush, and a roller. And, the unpainted and damaged parts on a small-scale can be repaired by brush.[96]

Researchers have investigated thermoplastic Polyurethane Elastomer adhesion to galvanized steel over the following article. When the thermoplastic polyurethane elastomer is applied to the galvanized steel, adhesion, and durability of that have a great dependence on chemical bonding thermoplastic polyurethane elastomer-metal. Aminopropyl trimethoxysilane gamma amino silane deposits under various parameters such as solvent type and pH. The preparation processes include sanding, pickling, air flow, and a zinc phosphate conversion coating. Polyurethane adhesion to the substrate was assessed by tensile tests and showed the desired results.[97] In **Table 7**, an example of presented papers has been studied.

3.20.5 Sol–Gel

This method is usually used for producing materials, as an example metal oxide starting from a colloidal solution (sol) that is as a precursor substance for an interconnected network (gel) of discrete particles or network polymers. Precursor substances typically include alkoxide and metal salts (such as chlorides, nitrates, and acetates) that are put under different hydrolysis and polymerization reactions. Generally, sol is

introduced as a stable suspension containing solid colloidal or polymeric particles in a liquid. These particles can be amorphous or crystalline. Solid colloidal particles that are nanosized dimensions are formed through two reactions. Simply said, sol is a mixture of solids with various sizes between 1 and 100 nm in water that are not deposited. It is comprised of:

1. Hydrolysis: through the effect of salt dissolved in water, the metal cathode ions establish complex with water. In this state, the pair electron transfer from water molecules to empty orbitals of transited metal cathode ion is possible. Hydrogen's particle charge is increased and water molecule catches acidic properties. According to the acidity of the water, types of hydrolysis reactions can be obtained. In general, raising the density of the metal ions cause to increasing the bridges of metal ions by AKSU and HYDROKSU ligands, and increasing the number of hydrogen existed in ligands and so an easier hydrolyzes.
2. Condensation: this reaction is done through two different friendly nuclear mechanisms and depends on the neighboring numbers of metals. When the needed neighboring number is provided, condition is done by a substituted friendly nuclear reaction, and when the needed neighboring number of metal is not provided, there is friendly coral additive.[98]

The condition reaction is actually a kind of polymerization itself, and is divided in two sections:

1. Alishan: a condition process that makes hydroxide bridges between two metals.
2. Axylishen: a condition reaction in which oxygen bridges between two metals occurred.

Sol formation is generally divided into two categories:

1. Formation of real solution from the considered precursors (alkoxide precursors or metal salt precursors) into the solvent that can contain water, alcohol, or acid.
2. Formation of the colloidal solution (sol) through the converting the metallic atoms to the metallic complexes by hydrolysis and condition reactions, that are actually the creator reactions of colloidal particles; by conducting these reactions, particles are getting larger and reaching the colloidal particle dimensions from 1 nm to approximately 100 nm. At this level of experiment, nanoparticles that are usually amorphous have been formed.
3. Stabilizing the colloidal particles and deterring them from depositing by a stabilizing agent. This agent can be controlled either by curbing the environmental factors such as pH controlling, sol temperature, the amount of sol is stirring, or by adding chemical materials.

Gel is a continuous three dimensional porous network that has inserted a liquid phase into itself. In most of sol–gel systems, the formation of the gel is followed by creation covalent bonds, and gel is not reversible; this means that, it has not the capability of reversing to sol state. If the acquired gel assets, bonds aside from other covalent bonds, it could be reversible. The types of gel based on formation mechanism:

Colloidal gels: in colloidal gel, the network is created by agglomeration (sticking) of the colloidal particles.

Polymeric gels: in polymeric gel, the network has a polymeric microstructure; in other words, it consists of polymeric units which are making up the gel.

The processes of the gel formation: after three steps that were mentioned in the formation of sol, the formation processes of gel that actually are in the sequence of sol formation steps depending on the types of gel (colloidal or polymeric) are followed as:

1. If gel is colloidal, it is obtained through sticking the colloidal particles to each other by weak van der Waal's forces as a result of evaporation of the solvent surrounding the colloidal particles.
2. If gel is polymeric, that means the surround of colloidal particles would compose of molecules which are susceptible to forming a polymeric matrix. In this case colloidal particles are stabilized like raisins in a raisin cake. Therefore, it can be led to stabilizing this polymeric network by changing the surrounding agents such as pH, temperature and time regulation, or adding chemical materials. Then, it can be gotten rid of the polymeric network around the gel by contriving it into an oven, and we will then just have nanoparticles at this level of function. Eventually, by putting the obtained product in the oven being aware of the minimum calcination temperature, the amorphous nanoparticles can be transformed into crystalline nanoparticles. Aluminum and its alloys are used expansively in

Figure 7 The scheme of the coating system (a) conversion, (b) new sol–gel coating, and (c) the technology of non-chromium super primer.

the industries of marine, aerospace, and Auto industries. This metal has good mechanical and physical properties, but it has not acceptable corrosion and abrasion resistance because of its porosity. Typically, chromate coating is used for preparation of the surface; although, it is forbidden the usage of chrome compositions due to causing cancer diseases.[98]

The hybrid sol–gel coating based on silica is an appropriate alternative to chromate compositions because of forming the

Table 8 Sol–gel coating type, substrate, coating contents, and acquired results

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
Conversion coating	Clad 2024-T3 aluminum alloy	Oxide layer sol–gel-treated epoxy aluminum joint	Macrorough structures drive the crack to within a thin epoxy layer close to the polymer–metal interface, which enhances the initial strength of the sol–gel-reinforced interface	Enhanced adhesion	45
Nanocomposite sol–gel coatings	AA5083	Tetraethylorthosilicate and 3-glycidoxypropyl-trimethoxysilane	The evaluation of the result obtained from abrasion shows cohesive and interfacial wear with abrasive and adhesive mechanisms, respectively. Liquid impact results show cohesive failure of the coatings without any sign of delamination	Good mechanical properties of optimum nano-composite coatings, such as excellent adhesion to the substrate (4.74 MPa)	98
Sol–gel-based hybrid coatings	316 l stainless steel	Titanium-isopropoxide and 3-glycidoxypropyl-trimethoxysilane	A three dimensional network of –Si–O–Si– linkages environment-friendly technology with number of advantages like room temperature synthesis, chemical inertness, high oxidation and abrasion resistance, excellent thermal stability, very low health hazard	Excellent adhesion to metal as well as to the subsequent coat via strong covalent bond	99
Hybrid nanocomposite sol–gel coatings	Aluminum 5083 alloy	Fourier transform infrared spectra of the hybrid films for different samples	Exhibit excellent mechanical properties as well as adhesive to the substrate	Maximum adhesion of coating to the substrate	100
Hybrid sol–gel	Aluminum alloy AA2024	Two different types of coating were applied: a non-inhibited film consisting of two layers (non-inhibited system) and a similar film doped with cerium nitrate in an intermediate	Improve corrosion behavior of aluminum alloys	Improved adhesion	101
Sol–gel	Mg	MgF_2 coating on Mg and the HA coating on MgF	Improved the corrosion resistance and the bioactivity of Mg. The coating layers were uniform, dense and strongly adhered to the Mg substrate without any posttreatment. The double coating layer effectively reduced the Mg corrosion rate and prevented the formation of any by-products in the SBF solution	Strong adhesion to the Mg substrate, with a bonding strength of 34 MPa the bonding strength of HA coating on the MgF_2 (25 MPa) was slightly higher than the HA coating on the bare Mg (22 MPa)	102

SiloxaneDance network. Hybrids have been noteworthy to researchers because of having both polymeric and ceramic material's properties.[98] In other case, the SEM image of low carbon stainless steel 316 with and without sol–gel coating after polarization test showed that the sample without coating has been locally and uniformly eroded and there were cavities on it; while there were fine cracks on the coated sample.[99] To resolve this problem, multi-layer and sophisticated systems below have been proposed, and the best results have been obtained with the help of super primer as shown in **Figure 7**.[98]

As it is observed, coating of tetraethylorthosilicate and glycidoxypropyltrimethoxysilane over the aluminum alloy resulted in increasing corrosion resistance of this alloy. In addition, uniformity and homogeneity of this coating to improve the adhesion.[100] **Table 8** consists of the hybrid and nanocomposite sol–gel coatings have been applied to diverse substances and led to increasing the adhesion properties and improving mechanical properties, abrasion resistance and corrosion resistance.

3.20.6 Electro Deposition

Electro deposition is a strong method for coating the surface. The main electrodeposits' properties are abrasion resistance, hardness, formability, porosity, inner tensions, coating adhesion, and corrosion resistance. All of these properties and characteristics can be changed by selecting a few numbers of variations such as temperature, component's concentrations, pH of electrolyte, current density, condition of electrolytic current, and using the electrolytic additives. Creating a surface coating by the way of electro deposition may comprise a variety numbers of important processes, including the preparation of the substrate, coating formation, and final checkout. The thickness of applied deposit is controlled through operations in a constant time and a constant current density. As it is derived from the Faraday law for electrolysis, for an intended metal (M) which is deposited from the location of its ions (M^{z+}), the following relationship is established:

$$M^{z+} + Z^{e-} \rightarrow M$$

Under constant circumstances with constant current density (I), thickness rate of the coating (X) develops related to time which is described through the following equation:

$$dx/dt = (MI\varphi/\rho AzF)$$

As M is the molar weight of materials, φ current efficiency, ρ density of the sheeted layer, A deposited space, z the number of transferred electrons, and F is Faraday constant. Hence, with the assumption that current efficiency is 100%, with a given current density and knowing the electrode ambiance, the coating thickness can be stabilized for each metal by time, so that this phenomenon for the selection of materials that use 1 A dm^{-1} current density; deposited thickness can be altered from several single layers up to hundreds micrometers.[103] There are two hypothesis:

1. 100% current efficiency, which cannot be real, although reaching to 100% efficiency may be possible in some systems.
2. Deposit density is in equilibrium to the density of pure metal, which also this case is not essential against high porosity of some deposits. The current efficiency and density of the coatings that are in the formation of electrolytic deposits are decreased by raising the current density. Generally, in order to decoration of electrolytic deposits, they have to be smooth and flawless and also mirror-polished. While engineering does not need special decorative coatings, deposits should be compressed and homogenized. They also have to coat all substrates. Some intermediate depositions lead to electrolytic deposit over the unacceptable surface coatings. This case, also, comes to pass by using high current densities which resulting in irregular settlements. The more applicable method to developing and changing the structure and appearing electrolytic depositions is integrating the additives in the electrical plating bath.[104] In addition to pure metals, alloys (double, triple, and complex), oxide layers, conductive polymers, and composition layers can be produced by using electrolytic methods. A wide range of engineering applications could be manufactured by electrolytic deposition that involving conductive coatings for electronic

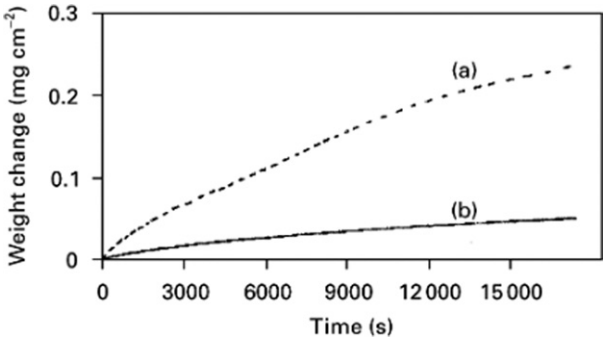

Figure 8 The graph of weight changing (a) steel without coating and (b) steel with electrolytic coating relied on time with temperature 1000 °C.[106]

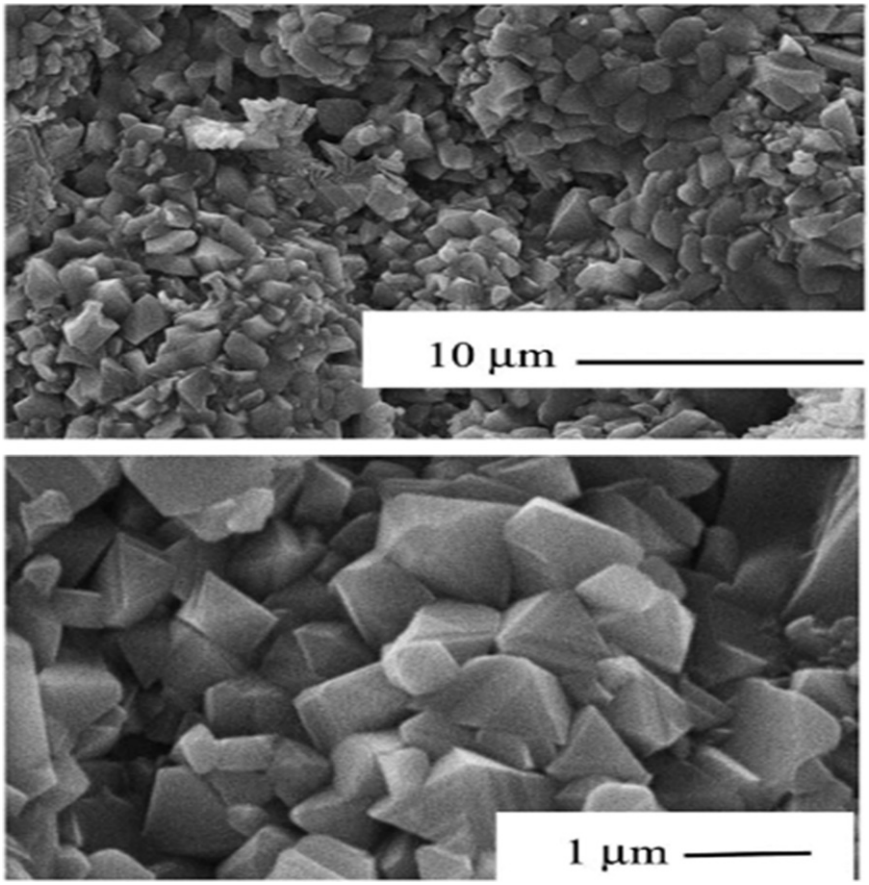

Figure 10 The scanning electron microscope image of formed alumina coating in air 1000° after oxidizing for 8 h.[106]

industry, tribological layers for mechanic engineering and nano structures for specific magnetic semi-conductors and optical applications. Coatings are categorized in metallic, composite and anodized groups. This classification is based on the relation between process conditions and deposit features. Electrolytic deposition can be categorized into two separate methods:

1. Electrolytic deposition: soluble ionic components that are mainly metal ions, decrease at the cathode and obtain from depositing an electrolytic deposition layer of the electrolytic solution. Anode can be either soluble or insoluble.
2. Electrophoretic deposition: deposited material exists in the form of fine powder in the electrolyte. Selective absorption, which has been done on the particles, separating ions of the particles, encountering bipolar molecules or electron transferring in solution, all create charges over the particles. When a surface charge is applied, the electrical potential between anode and cathode initially causes surface separation which had been coated. Electrolytic coatings can be applied in different classifications. Their range is wide from simple homogenous layers to complex multi-depositions. Electrolytic depositions can be getting proper to special applications.[105] Morphology and properties of electrode-deposited metal coatings vary according to many factors containing electrolyte bath composition, coating method, deposition thickness, and electrolyte temperature. As it is said, the electrolyte or immersion method is a way to apply coating that is done generally on stainless steel, aluminum, and magnesium. Such properties that these kinds of coatings create are excellent adhesion and appropriate roughness along with corrosion resistance.[105] **Figure 8** shows the corrosion resistance or weight loss with time for the samples with and without coating. It is obvious that, the alumina coating applied on an authentic stainless steel has improved the corrosion resistance of the alloy.[106]

The **Figure 9** shows the profile distribution of different elements in the applied Alumina coatings over the austenitic stainless steel with the passing of the bombarding time. It is clear that by passing of the bombarding time, the percent of alumina has been reduced, in contrast to increasing of Fe.[106]

The **Figure 10** is the SEM image of applied alumina coating on austenitic stainless steel. As it can be seen, the alumina structure with complicatedly mixed crystals contributes to the creation of a penetrable boundary layer and increase the corrosion resistance and on the other hand, appropriate surface roughness makes it ready for the subsequent coating application.

Table 9 Different electrolytic coatings, substrate, coatings contents, and obtained results

Treatment type	*Base metal*	*Coating type*	*Results*	*Adhesion*	*References*
X-ray photoelectron spectroscopy	Pure aluminum	Alumina	Improved performance in corrosion resistance of these metals is the improvement of the hydration resistance of the oxide film or the oxidocoating interface	Improved performance in adhesion	49
Electrolytic alumina deposit	Austenitic stainless steel	Alumina	Improving the resistance to thermal oxidation	Strong interfacial adhesion with the substrate	106
Alumina coatings	Fe–Cr–Al alloy	Crystallized alumina coating	Conductive and porus enough to permit during the electrolysis for the aluminum salt modifies the oxidation kinetics of the alloy very high temperature resistance	Strong adhesion	107
Aluminum hydroxide deposited from an aqueous solution of an aluminum salt	Fe–17% Cr ferritic stainless steel	Precipitation of aluminum oxyhydroxide	Fabrication of thermal barrier on a metal conversion coating substrate	Excellent adhesion	108
Electrodeposited ZnN	Steel sheet	4-nitrothiophenold and 4-nitrobenzenediazonium	Improve the corrosion properties as well as the durability of the hybrid coating. Functionalities depending on the rest of the molecule structure such as lubrication and adhesion	Excellent adhesion	109
Electrodeposited	AZ91 Mg alloy	$Mg(OH)_2$	Superior corrosion resistance for the coated AZ91 Mg alloy as the corrosion current density decreased, for coated specimen and the corrosion potential increased at the same condition	Maximum bond strength	110
Deposits of alumina added or not with yttrium	Fe–17% Cr stainless steel	Alumina	Yttrium improved the protecting character of alumina coating; reduces the rate of oxidation and increase the adhesion of deposits	Enhances its adhesion	111
Plasma electrolytic oxidation	Aluminum (Al), magnesium (Mg), titanium (Ti), and their alloys	Substrate metal oxides (such as Al_2O_3, TiO_2, and MgO on Al, Ti, Mg and their alloys, respectively) complex oxides and compounds which involve the components presented in the electrolytes	Poor tribological properties, such as low wear resistance, high friction coefficient and difficulty to lubricate, have seriously restricted their extensive applications	Superior wear resistance, large thickness, high microhardness and good adhesion to substrates	112

In the following essays in Table 9, it has been reviewed electrolytic coatings that have been applied on the various substrates and caused to improve the mechanical properties, hardness, and adhesion and corrosion resistance.

3.20.7 Conclusions

Adhesion is the physical resistance of an interface between regions of the material system. Such interfaces have been

found in the grain boundaries, surface abrasion and failures, as well as, in the substrate-film systems. To evaluate the adhesion quality and amount of it in the substrate-film systems, different coatings containing preparations, supplementary operations, conversion coatings, chromate, phosphate, polyurethane and sol–gel coatings, and electrolytic depositions have been scrutinized in the forms of tables. As it was obviously inferred, the type of preparation process and supplementary operation play a vital role in the adhesion quality of surfaces. Then phosphate and chromate conversion coatings were analyzed, which the results demonstrated an increase and improvement of diverse properties especially adhesion. Polyurethane coatings modify the morphology of the surface and sol–gel coatings increase adhesion properties, reformed of mechanical properties, abrasion resistance, and corrosion resistance. In the end, electrolytic deposition coatings lead to improving mechanical properties, hardness, adhesion, and corrosion resistance.

3.21.1 Introduction

NiTi is a near equiatomic alloy of nickel and titanium. NiTi exhibits unique properties such as shape memory effect (SME), superelasticity, and biocompatibility. Shape memory alloys (SMA) are materials that have the ability to return to a predetermined shape when heated. The unique shape memory and superelastic properties of Nitinol are due to a phase transformation called SME.[1–2]

The melting and production of NiTi is challenging in that it is sensitive to both changes in chemistry and processing. The NiTi transformation temperatures are extremely sensitive to any small variations in the concentration of nickel or titanium.[3–5] Generally SMA are produced by casting, the two most common methods of producing NiTi are vacuum arc remelting (VAR) or vacuum induction melting (VIM) followed by cold or hot working.[3–12] However cast metals have some issues associated with them such as the inability to control chemical composition, segregation, and excessive grain growth which results in poor fatigue properties.[12–14]

An alternate route to casting that became popular in the last 20 years was powder metallurgy. Powder metallurgy became a popular method due to its ability to avoid the problems associated with casting and it allows for better control over the composition of NiTi alloy and can therefore control the transformation temperature.[12,14] Some powder metallurgy processes that are used for NiTi production include conventional sintering (CS),[15–19] hot isostatic pressing (HIP),[12,20–25] metal injection molding (MIM),[26–29] self-propagating high temperature synthesis (SHS),[30–34] and spark plasma sintering (SPS).[14,35–41]

In recent times the SPS technique has emerged as the most efficient powder metallurgical method of melting NiTi. In the SPS process powder particles are uniformly heated to a high density at relatively low temperatures and have a shorter sintering time than CS.[14,42]

In this chapter we review the methods generally used for NiTi fabrication, casting, and powder metallurgy. We concentrate specifically on SPS of binary and ternary NiTi. We also present some of our own work on SPS of binary and ternary NiTi.

3.21.2 NiTi SMA

NiTi is an alloy that contains equiatomic amounts of Nickel and Titanium. It is commonly referred to as Nitinol. The name Nitinol was derived from its place of discovery. In 1962 two researchers William Buehler and Frederick Wang discovered the properties of equiatomic nickel–titanium alloys while doing research at Naval Ordnance Laboratory. This is how the name NiTiNOL was derived, Nickel Titanium Naval Ordnance Laboratory. Nitinol is a SMA.[1]

NiTi exhibits some unique properties such as shape memory and superelasticity. This special property of Nitinol is called SME. SME allows the material to return to its original shape upon heating or cooling.[2] In SME it undergoes a change of crystal structure at a certain temperature called the transformation temperature. Above this transformation temperature NiTi has a crystal structure called austenite and below this transformation temperature the crystal structure is called martensite. This is a reversible transformation so the alloy can transform from one crystal structure to the other and is prompted by a change in temperature or by adding a load to the material.[2]

Figure 1(a) is a stress–strain curve for a SMA that is undergoing SME. In this diagram it can be seen that at high temperature NiTi is in the austenite phase and as previously discussed when a stress is added the NiTi undergoes a phase change from austenite to martensite. But the difference here is that when the stress is removed the NiTi will stay in the martensite phase unless it is heated at which point it will

 doi:10.1016/B978-0-12-803581-8.09202-X

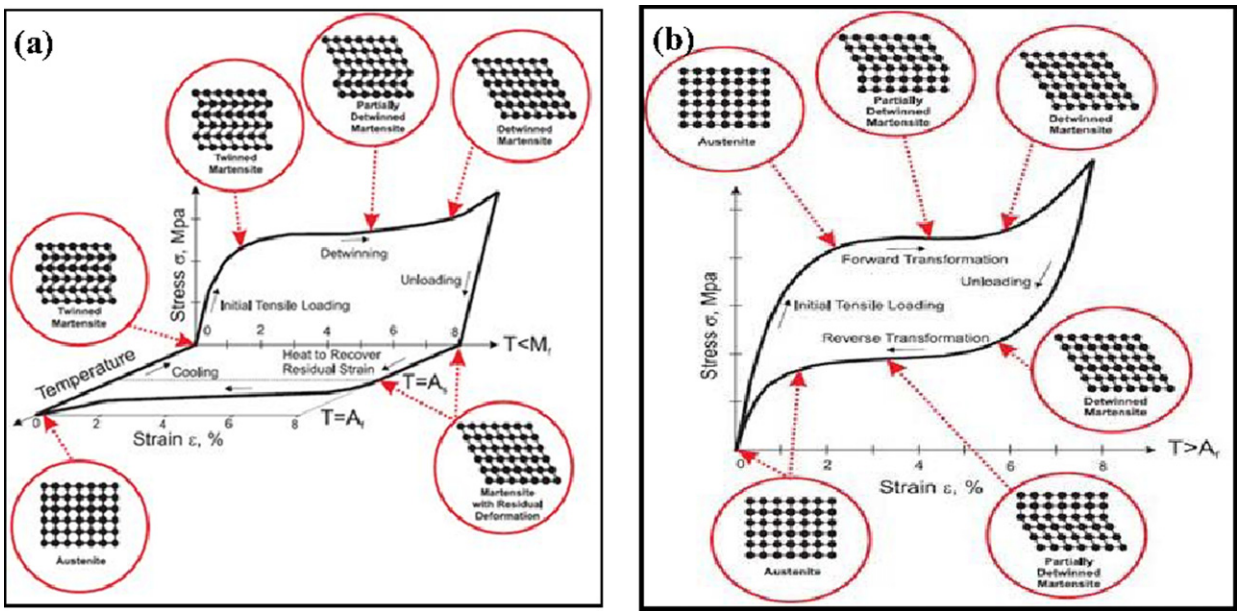

Figure 1 (a) Stress–strain curve for NiTi alloy undergoing shape memory effect and (b) superelastic effect.[43]

return to its original shape.[1,44,45] **Figure 1(b)** is a stress–strain curve for NiTi undergoing superelastic effect. It shows NiTi in the austenite phase but when a stress is added, either cooling or a load is added, it causes the austenite to form detwinned martensite and when the stress is removed the detwinned martensite will return to its austenite state.[1,44,45]

As we know a NiTi alloy is made up of elemental nickel and titanium. What is interesting about this particular alloy apart from its shape memory and superelasticity properties is that it naturally oxidizes to form an oxide layer on the surface. This natural oxide layer is quite thin, 5–10 nm.[46] This layer is mainly composed of titanium dioxide (TiO_2).[47] This TiO_2 layer is what provides the NiTi alloy with its biocompatibility and allows for its use in many biomedical applications. This oxide layer prevents the release of nickel from the alloy into the body. This oxide layer forms from oxygen in the atmosphere that reacts with titanium on the surface of the alloy.[48] It is because of these unique properties that NiTi became widely used in the dental and medical industries in applications such as braces, wire guides, and stents, NiTi is also used in the manufacture of clinical instruments.

3.21.3 Methods of Processing NiTi

The melting and fabrication of NiTi is challenging as it is sensitive to both changes in chemistry and processing. The NiTi transformation temperatures are extremely sensitive to any small variations in the concentration of nickel or titanium. This sensitivity will increase with the nickel content in the alloy. If an alloy has a weight of 55.0% nickel, and if there is even a 1% weight deviation in the concentration of either Ni or Ti, then the transformation temperature will shift by approximately 100 °C. Impurities such as carbon, nitrogen, and oxygen should also be avoided as they can influence the transformation temperature, strength, and ductility of the material. This extreme sensitivity puts a very strict requirement on the alloy melting method that can be used. The alloy melting method needs to be able to control the nickel and titanium ratio so as to not change the transformation temperatures as the alloys SME and superelasticity are dependent on this.[3–5]

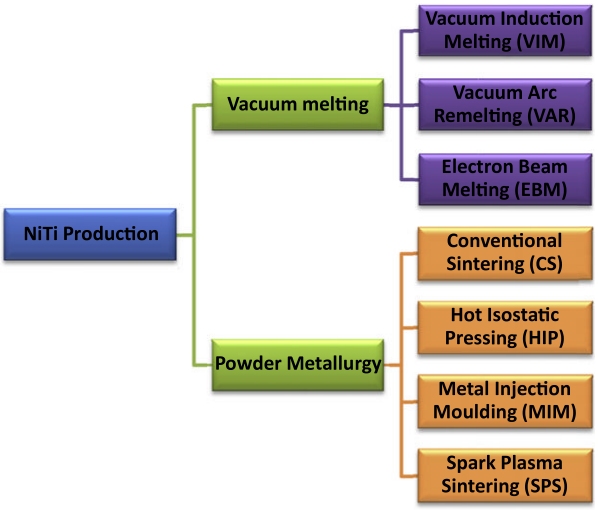

Figure 2 Schematic showing the different ways of producing NiTi.

Figure 2 shows there are two main methods of producing NiTi either by casting or powder metallurgy. Many casting methods include VAR, VIM and electron beam melting (EBM), some of which will be discussed in the next section.[3–5] These methods are the most widely used casting methods for the production of NiTi. Powder metallurgy is another method used to manufacture NiTi. Some of the most commonly used powder metallurgy processes include CS, HIP, MIM, and SPS.[5]

3.21.3.1 Vacuum Melting

3.21.3.1.1 VAR

VAR is a consumable electrode remelting process which is carried out in vacuum and generally used for the production of NiTi. It is not a commonly used method for melting and producing of metals as it is both expensive and time consuming, this method is for specialized materials that oxidize easily. In this method no crucible is used, instead the nickel and titanium are weighted out in the correct ratio and are then packed into a compact. This compact is then used as a consumable electrode. The consumable electrode is melted using an electric arc into a water cooled copper crucible, a frozen skull is formed preventing contamination from the crucible and because of this VAR melting achieves the highest possible purity of the resultant alloy. As the molten metal is formed, the electrode is slowly withdrawn as the metal solidifies at the bottom of the melt pool. Only a small amount of the ingot is molten at any time, so complete mixing throughout the entire ingot does not occur and the ingot must be remelted to achieve a homogeneous mixture.[3–5]

Foroozmehr *et al.*[8] investigated the microstructure during homogenization of NiTi by VAR. As VAR does not rely on electromagnetic forces during melting several remelts of the ingot is necessary to achieve a homogeneous material. A Ti-50%-Ni alloy was prepared via VAR in a water cooled copper crucible. The material was remelted four times to achieve a homogenous mixture at 1000 °C. The microstructure of the material during homogenization was studied using an optical microscope and a scanning electron microscope (SEM). The chemistry and crystal structure of the material was investigated using energy dispersive X-ray spectroscopy (EDS) and X-ray diffraction (XRD). The SEM results showed that the microstructure of the as-cast material was segregated. EDS and XRD results showed that the alloy consisted of monoclinic, Ni_3Ti, and Ti_2Ni phases. It was also found that if the holding time is increased during the homogenization process the amount of the austenite phase increased while other phases decreased. A holding time of 4 h was found to achieve an austenite phase as well as decreasing the hardness of the material.[8]

3.21.3.1.2 VIM

VIM is a process that uses an electrical current to melt metal components in a vacuum environment. For VIM of NiTi, the raw materials are weighed out in the correct ratio and placed in an electrically conductive crucible, usually graphite. An induction coil produces an alternating magnetic field which is the source of the eddy currents that are used to heat the crucible and melt its components. Once molten the induction field and electrodynamic forces stir and mix the melt. This method results in homogenous mixture. There are many advantages to this melting method as the chemistry and transformation temperature of the NiTi can be easily controlled. One disadvantage of this method is that there is some carbon contamination from the graphite crucible, between 200–500 ppm, however this does not affect any of the materials shape memory properties.[3–5] Frenzel *et al.*[9] developed a method to reduce carbon contamination during VIM of NiTi alloy. Graphite crucibles are mainly used in VIM as they have many advantages such as they are cheap, resistant to thermal cracking as well as good electrical properties. Even though the graphite crucibles possess these properties there is still the issue of carbon contamination. Carbon contamination needs to be kept at a minimum in order for NiTi to maintain its unique properties. It was found that if NiTi is melted in a fresh graphite crucible and the nickel is in direct contact with the crucible then the carbon contamination is high. However, it was found that the carbon contamination is lower when the crucible is used a second time. It was shown that the formation of a titanium carbide layer acts as a diffusion barrier. Frenzel *et al.*[9] found that avoiding direct contact between nickel and the graphite crucible reduces the carbon contamination. This is achieved by titanium disk cladding. This is for nickel rich NiTi alloys.[9]

Nayan *et al.*[10] investigated a new novel method of charging for reducing carbon contamination during VIM of NiTi alloys. A certain material arrangement scheme is used for melting the NiTi alloy and reducing the carbon contamination. The main objective of the study is to reduce the contact between the molten titanium and the graphite crucible. This was done by dissolving the titanium in molten nickel. It was found that a titanium carbide layer formed on the crucible after the first melt with a significant titanium loss and high carbon contamination. However it was found that the composition of the desired material was achieved with minimal titanium loss and a significant reduction in carbon contamination. High temperature SMA have a transformation temperature above 100 °C this can be achieved by adding a third element, such as platinum (Pt), palladium (Pd), gold (Au), zirconium (Zr), or hafnium (Hf) to the alloy.[10] Zhang *et al.*[11] investigated melting ternary NiTi alloys by VIM. Various elements such as copper (Cu), iron (Fe), hafnium (Hf), and zirconium (Zr) were added to NiTi as a ternary element to produce a high temperature SMA. A previous technique that was developed was used to keep the carbon contamination to a minimum in this experiment. SEM, EDS and differential scanning calorimetry (DSC) were utilized to investigate the microstructure, chemistry, and transformation temperatures of the ternary alloys. The results showed that ternary NiTiX where X is Cu, Fe, Hf, and Zr can be produced by VIM with low concentration of carbon and oxygen. It was found that microstructural hetrogeneities were present in the samples mainly because of the solidification process. It was found that these could be partly removed by homogenization treatments.[11]

3.21.3.2 Powder Metallurgy

The powder metallurgy route has certain advantages as it can avoid problems such as segregation and excessive grain growth that are often associated with casting. It also offers the ability to control the chemical composition of the alloy. As mentioned earlier in this section some of the most commonly used powder metallurgy processes include CS, HIP, MIM, SHS and SPS. Some examples of the use of NiTi and porous NiTi in CS and HIP will be described later in this section. SPS will be discussed in more detail in the next section.[5,12]

3.21.3.2.1 CS

Sintering is the bonding of particles by diffusion of atoms to reduce surface area. CS is typically performed by pressing

powders into a compact and heating the compact to a point, below the melting temperature, where the atoms can diffuse. Diffusion is a thermally activated process, requiring a minimum energy to begin. As atoms diffuse, some will move into positions that reduce the total surface area and thus reduce the surface energy. The driving force for atoms to move to positions that reduce the surface energy is associated with the stress at the particle surface.[49] The sintering temperature is usually set between two thirds to three quarters of the absolute melting temperature of the metal.[50]

Li *et al.*[15] investigated the properties of porous NiTi prepared by CS of elemental Ni and Ti. Elemental Ni and Ti powders were used in the sintering process, titanium hydride (TiH_2) was added to the mixture as a pore forming agent. The aim of this study was to investigate the effects varying parameters such as sintering temperature, sintering time, and TiH_2 concentration on the porosity, pore size, distribution, and phase composition. The results found that sintering at a lower temperature resulted in the formation of Ni_3Ti phase with pure Ni and Ti also present. Sintering at higher temperature for a longer time resulted in NiTi being the main phase, the pore size and distribution were also found to be homogeneous at higher sintering temperatures.[15] Zhang *et al.*[17] fabricated porous NiTi with gradient porosity and large pore size by CS using ammonium bicarbonate (NH_4HCO_3) as a space holder. Ni and Ti powders were blended with various concentrations of NH_4HCO_3, the porosity, pore size, phase, transformation temperature, and mechanical properties were then investigated. It was found that the porosity and pore size increased linearly with increasing concentration of NH_4HCO_3. The use of NH_4HCO_3 did not have any adverse effect on the phase transformation behavior or microstructure of the alloy. Sample with both high and low porosity were found to have high recoverable strain as well as superelasticity and strength.[17] Li *et al.*[19] produced porous NiTi with controllable pore characteristics by CS and using urea ($CO(NH_2)_2$) particles as space holders. The porosity, pore size, distribution, phase composition, phase transformation, and mechanical properties of the porous NiTi were then analyzed. The results showed that the use of $CO(NH_2)_2$ particles as space holders had no effect on the microstructure of the NiTi Alloy. It was found the when compared with NH_4HCO_3 that the $CO(NH_2)_2$ particles offered higher porosity, strength, and better superelasticity.[18]

3.21.3.2.2 HIP

HIP is a pressure enhanced sintering technique. This technique is used to manufacture dense products.[5,12] For isostatic compaction the powders must be encapsulated in an evacuated gastight welded can. The can transfers the pressure to the powders. This can or mold can be mild steel, stainless, a metal, or a glass capsule. The HIP process subjects powders to simultaneous elevated temperatures of over 1000 °C and pressures of over 98 MPa to eliminate internal micro-shrinkage.[51]

Bram *et al.*[12] investigated the use of HIP to fabricate NiTi shape memory parts. Elemental powders of nickel and titanium were used as the starting material. The powders were homogenized for 24 h in a Turbula mixer. Stainless steel capsules were used for the HIP of NiTi powders. In order to avoid damaging the capsules the powders were pre-compacted. HIP was carried out at a constant pressure of 195 MPa and at various temperatures 850, 950, and 1050 °C for 5 h. After the HIP process the stainless steel capsule was removed by machining. In order to achieve a homogeneous mixture the samples were solution treated at 850 °C for 1 h and water quenched. The water quenched samples were then annealed at 500 °C for 1 h. The microstructure, composition, phase transformation, and mechanical properties of the samples were then analyzed. It was found that HIP carried out at 195 MPa and 1050 °C for 5 h resulted in a dense NiTi sample with good homogeneity. The solution and annealing treatments resulted in the formation of Ni_4Ti_3 precipitates which influences the phase transformation and temperature. Tensile testing showed shape recovery at a low level.[12] Yuan *et al.*[20] manufactured porous NiTi by HIP and investigated the microstructure and transformation behavior of the resulting alloy. Elemental Ni and Ti powders were used for this experiment and were mixed for 4 h. The powders were then pressed to cylindrical green samples at a pressure of 100 MPa using a hydraulic press. HIP was carried out on the samples at pressure of 150 MPa, temperature of 1050 °C for 7 h. The microstructure, transformation temperature, and mechanical properties were then investigated. The results showed that the transformation behavior and superelasticity of porous NiTi is similar to that of dense NiTi.[20]

Yuan *et al.*[21] prepared porous NiTi using capsule free-HIP (CF-HIP). The aim of this experiment was to control the porosity and superelasticity of porous NiTi by monitoring the microstructure, transformation temperature, and mechanical properties. The results showed that porous NiTi with near spherical pores and a homogenous microstructure was fabricated using CF-HIP. After the appropriate thermo-mechanical treatment the porous NiTi alloys exhibit excellent superelastic properties. It was also found that the alloys superelasticity is controlled by the pore size, shape and distribution.[21]

3.21.4 SPS

3.21.4.1 Introduction

SPS was first developed in the 1960s by Inoue *et al.*[52,53] It was a newly developed process for powder sintering and it was expected that sintering assisted by plasma would help develop advanced materials.[54] The SPS or plasma activated sintering (PAS) process is based on the electrical spark discharge phenomenon, where a high energy low voltage pulsed current, momentarily generates spark plasma at high localized temperatures, between powder particles, and causes the surface of the powder particles to vaporize and melt.[14,55] SPS enables compressed powder to be sintered under consistent heating to high density at relatively lower temperatures and in a much shorter time period compared to CS.[14,42] This shorter sintering time is thought to prevent exaggerated grain growth.[56]

The SPS process is a pressure assisted pulsed current sintering method that uses ON-OFF DC pulse energy. This method generates (1) spark plasma, (2) spark impact pressure, (3) Joule heating, and (4) an electrical field diffusion effect. In the SPS process the generation of spark plasma produces a high temperature sputtering event that eliminates adsorbed gas and impurities that exist on the powder particles. The spark impact pressure causes high speed diffusion of the ions and

material transfer. The joule heat generation helps with high speed diffusion of the ions and material transfer and also promotes efficient heating and plastic deformation. The electrical field diffusion effect also promotes high speed diffusion of the ions and material transfer. When the spark discharge appears between the powder particles a high temperature state is generated momentarily, which causes the evaporation and melting of the surface of the powder particles, necks are formed around the area of contact between the particles.[57]

3.21.4.2 SPS of Binary NiTi

Over 20 years ago the interest in using powder metallurgy specifically sintering as a way of processing NiTi began. It was found that this process can avoid problems that are associated with casting methods, VIM and VAR, such as segregation and extensive grain growth.[12] The advantage of using powder metallurgy is the precise control of chemical composition which is important when trying to maintain the unique properties of NiTi. However there are certain difficulties with the powder metallurgy route such as oxidation, porosity, and the tendency to form other NiTi phases.[12,14]

Ye *et al.*[35] studied the properties of amorphous NiTi powders fused via SPS. Mechanically alloyed NiTi powders were used for this experiment. These powders were then consolidated by SPS at a pressure of 50 MPa for 10 min and at different temperatures of 900 and 1100 °C. Various different characterization techniques were used to investigate the crystal structure, transformation temperature, morphology, and chemistry of the consolidated material. The results showed a densified sample was produced with 3 phases (Ni_3Ti, NiTi and $NiTi_2$) present. The formation of 3 phases was due to the inhomogeneous mixture of the powders. It was found that sintering at 900 °C provided a compact sample with a better structure and grain size.[35] Zhao *et al.*[36] investigated the compression behavior of the porous NiTi to use a high energy absorbing material. NiTi was processed with via SPS. Two samples with varying porosities were produced and compared to a dense sample. The dense sample was produced at a pressure of 50 MPa at 850 °C for 5 min. The first porous sample had 13% porosity and was produced at a pressure of 25 MPa at 800 °C for 5 min. The second porous sample had 25% porosity and was produced at a pressure of 5 MPa at 750 °C for 5 min. Compressive tests were carried out at 22 and 15–25 °C to obtain the stress–strain curve of the porous and dense samples. These experimental results were then compared to a model of the stress–strain curve of the porous and dense samples. Experimental results showed that the 13% porosity sample had high ductility and a good microstructure when compared to the 25% porosity sample. The model and experimental results for the 13% porosity NiTi sample were in reasonably good agreement.[36]

Shearwood *et al.*[14] investigated the properties of TiNi nano-powders prepared by SPS. The sintering experiments were carried out at a constant pressure of 30 MPa and at varying temperatures of 700, 800, 900, and 1100 °C. Various different characterization techniques were then carried out on the TiNi nano-powder and sintered samples to analyze their microstructure, chemical composition, crystal structure, and transformation temperatures with the aim to find the ideal sintering temperature. The results showed that the samples sintered at 700 °C had high porosity but had SME. However it was found that the samples sintered above 900 °C suffered from oxidation and loss of SME. The samples sintered at 800 °C produced dense samples with good SME.[14] Fu *et al.*[37] studied the biocompatibility of TiNi nano-powders prepared via SPS. The sintering experiments were carried out at a constant pressure and temperature of 30 MPa and 800 °C for 5 min. The samples were then chemically treated in hydrogen peroxide (H_2O_2) solution at 60 °C for varying times to produce a titania layer on the surface. These samples were then heat treated at 400 °C for 1 h to enhance to bioactivity of the surface. The samples were then characterized to analyze their morphology, chemistry, crystal structure, and transformation temperature. *In vitro* studies were also carried out to determine the biocompatibility of the samples. The results showed that SPS at 800 °C produced a TiNi material with martensitic transformation behavior. A TiO_2 coating was found to have formed on the surface after chemical treatment. This chemical treatment also improved the bioactivity of the TiNi sample. Cell culture results showed the sample to be biocompatible.[37]

Butler *et al.*[39] investigated the production of NiTi wire from elemental nickel and titanium powders fabricated by SPS. Commercially pure powders were used in this experiment. These powders were ball milled for 20 min to obtain a homogeneous equiatomic NiTi powder. These powders were then sintered at a pressure of 50 MPa at 850 °C for 1 and 10 min and at 900 °C for 10 min. Further testing showed that the sample sintered at 900 °C for 10 min was best for extrusion testing. The results showed that SPS reduced the impurities and phases present in as sintered NiTi samples. The resulting wire showed shape memory and superelastic effects as well as low porosity and homogeneity.[39] Zhang *et al.*[41] studied the superelastic effect of porous NiTi prepared by SPS. The Ti and Ni powders were ball milled for 10 h to obtain a homogeneous NiTi powder. After ball milling ammonium hydrogen carbonate (NH_4HCO_3) particles were sieved into the mixture. This was done as a space holder to adjust the porosities of the material. A one step SPS method was carried out at varying temperatures between 800–1050 °C. The samples were then analyzed to determine the pore size, microstructure, crystal structure, compressive strength, and elastic modulus of the material. The results showed NiTi porosity between 10–61%, with an average pore size between 21–415 μm. It was found that the material consisted mainly of NiTi with some Ni_3Ti and Ti_2Ni phases present. It was found that with increasing porosity and pore size the elasticity of NiTi decreased.[41]

3.21.4.2.1 Fabrication of binary NiTi using SPS

A near equiatomic (55.74%Ni, 44.26%Ti) NiTi powder was sintered in a graphite-die (10.4 mm inside diameter). SPS was carried out using Dr. Sinter, SPS-515S model from 700 to 900 °C in vacuum with a holding time of 5 min and a uniaxial pressure ranging from 20 to 50 MPa. The bulk density of the sintered pellets with 10 mm diameter and 1 mm thickness was measured based on the Archimedes' principle. SEM was one of the characterization techniques used to analyze the NiTi samples. The SEM images were able to verify the percentage

porosity/density results. DSC was used to measure the transformation temperatures of each NiTi sample. Equations [1] and [2] were used to calculate the density and porosity of the sintered samples.

$$\text{Density} = \frac{\text{Mass}}{\text{Volume}} = \frac{\text{Weight}}{\pi r^2 h} \quad [1]$$

$$\text{Porosity} = \frac{\text{Theoretical Density} - \text{Actual Density}}{\text{Theoretical Density}} \times \frac{100}{1} \quad [2]$$

Figure 3 below shows a graph of how the calculated percentage density of the NiTi samples varies with pressure and temperature. From the graph it can be seen that density of the NiTi sample increases as both the temperature and pressure increase.

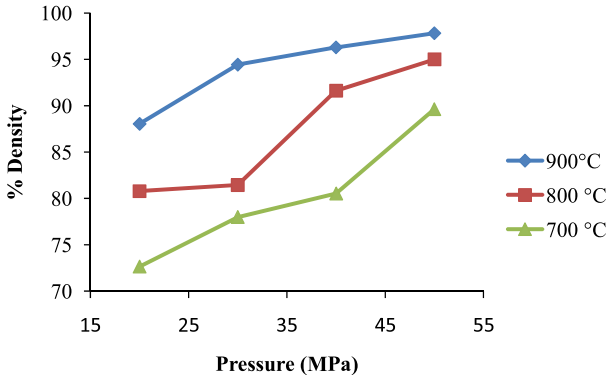

Figure 3 Change of relative density of NiTi as a function of applied pressure during SPS.

SPS at high temperatures and high pressures causes the surface of the NiTi particles to vaporize and melt. The material from both particles then begins to diffuse into neighboring particles. Joule heating is then responsible for the activation of diffusion processes leading to sample compaction and densification. During this process the pores begin to reduce in size and results in the densification of the NiTi sample.

Figures 4(a)–4(c) shows SEM micrographs of the NiTi samples sintered at (a) 900 °C, (b) 800 °C, and (c) 700 °C at a pressure of 50 MPa taken a magnification × 200. From **Figure 4(a)** it can be seen that the particles consolidated well and not many pores are apparent. **Figures 4(b)** and **4(c)** it can be seen that the NiTi powders have not consolidated to form a homogeneous sample.

At a higher temperature diffusion of the melted NiTi powder particles into neighboring particles is faster the pressure being applied to the sample is high so the sample is therefore more compact. In a compacted sample the NiTi powder particles are more tightly packed together, so diffusion into neighboring particles would not take as long and a more compact sample is expected.

DSC was carried out on the samples after sintering. The DSC was used to measure the transformation temperatures of the NiTi samples that were sintered at various temperatures and pressures. From **Figure 5** it can be seen that the results for the NiTi samples sintered at 700 °C/50 MPa, 800 °C/50 MPa, and 900 °C/50 MPa have all been combined into one graph. From the graphs it can be seen that as the temperature decreases the martensite peak moves to the left. As the temperature increases the austenite peak moves from the right to the left. Also from the combined graph it can be seen that the austenite peak decreases in size as the temperature decreases.

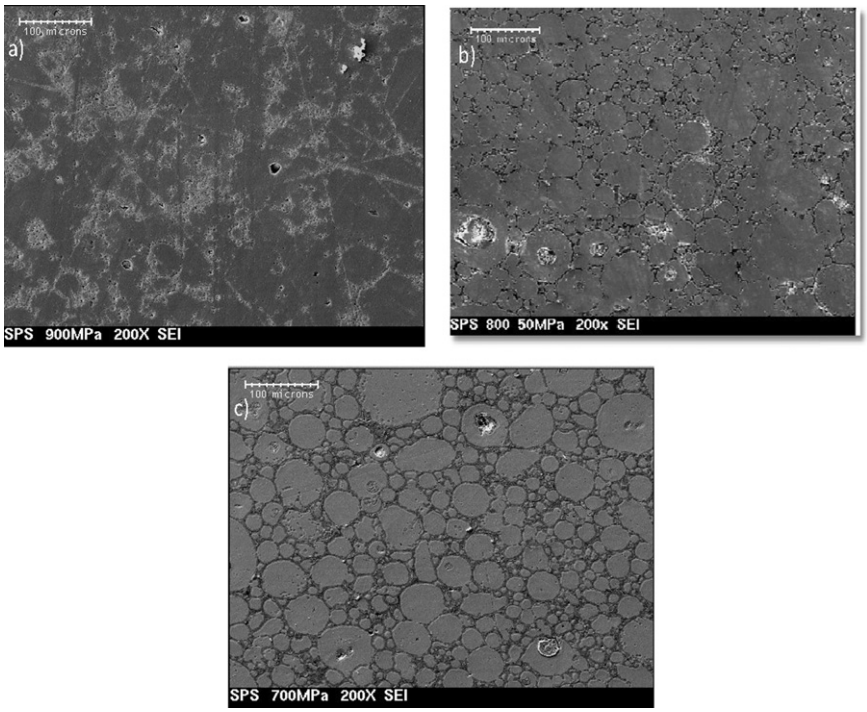

Figure 4 SEM images of SPS sintered NiTi (a) 900 °C (b) 800 °C, and (c) 700 °C 50 MPa.

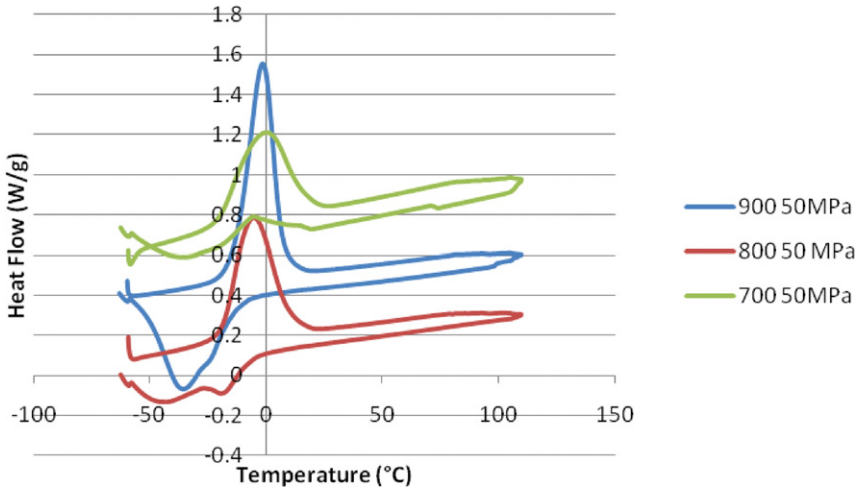

Figure 5 DSC graphs of NiTi sintered at 50 MPa at various temperatures.

This is also seen to be true for the martensite peak. Figure 3(b) shows the DSC curves for the un-sintered NiTi powder. The A_S temperature was found to be -7, A_F temperature was found to be 45, M_S temperature was found to be 12.5, and M_F temperature was found to be -58. If this is compared to the sintered samples it can be seen that the M_F temperature is relatively the same for all the samples only a slight difference is seen. The A_F temperature was found to be 45, these decreases when the NiTi samples are sintered. It was found that as the sintering temperature decreases the A_F temperature increases. The lower the sintering temperature the higher the austenite transformation temperature will be. The M_S temperature of the un-sintered NiTi sample was found to be 12.5 this decreases to negative figures when the NiTi samples are sintered. If this is compared to the sintered NiTi samples it can be seen that as the sintering temperature decreases the M_S temperature of the sintered NiTi samples increases. The A_S temperature for the un-sintered NiTi sample was found to be -7 this decreases as the NiTi samples are sintered. Sintering causes a change in the transformation temperatures of the NiTi samples. It appears that sintering decreases the transformation temperatures of the NiTi alloy.

3.21.4.3 SPS of Ternary NiTi

The primary objectives of adding a ternary element to binary NiTi are to

1. Decrease or increase the hysteresis by adding Cu or Nb, respectively,
2. Lower the Austenite transformation temperatures (Fe, Cr, Co, Al),
3. Increase the Martensite transformation temperatures (Hf, Zr, Pd, Pt, Au),
4. Strengthen the matrix (Mo, W, O, C),
5. Increase radiopacity (Pt, Pd, Ta, W, and rare earths).

Despite the achievements in developing these ternary alloys, over 90% of NiTi used today is still binary NiTi with a nickel content between 49 and 51 at%. The advantages gained by adding these ternary elements are offset by losses in other properties or by huge increases in cost. Of the 10% of NiTi that is alloyed with a ternary element, the approximate order of total estimated volume produced for these alloys can be listed as follows: NiTiFe, NiTiNb, NiTiCr, NiTiCu, NiTiCo, NiTiV, NiTiPt, and NiTiHf.[58] Table 1 below lists the common elements added to NiTi and the effects they will have on the alloys properties.

Although studies have been carried out on VIM of ternary NiTi and SPS of binary NiTi, there are not many reports on SPS of ternary NiTi. Tofail *et al.*[59] investigated the X-ray visibility and metallurgical features of NiTi–Er processed by SPS. Binary NiTi, ErFe, and Er–Ni powders were ball milled for 20 min to obtain a homogeneous mixture. These powders were then sintered using Dr. Sinterlab SPS 515S, with sintering temperature of 760 °C. Hot and Cold working was then carried out on the resulting sample. Various characterization techniques such as SEM, DSC and tensile testing were then carried out on the NiTi–Er sample to investigate the morphology, transformation temperature, and ductility of the sample. The results found that the radiopacity of NiTi improved with the addition of erbium however the austenitic transformation temperature will need to be lowered if the alloy is to be used for superelasticity in biomedical applications.[59] Cristea *et al.*[60] investigated the microstructural and mechanical properties of NiTi and NiTi–Cu fabricated via SPS. Mechanical homogenization and mechanical alloying were used to prepare the homogeneous mixtures. SPS was carried out using HP D25 instrument, sintering was carried out at pressure of 30 MPa and a sintering temperature of 850 °C for 5 min. Various characterization techniques were then used to analyze the samples morphology, chemistry, crystal structure, hardness, and elasticity. The results showed that participates were present in all samples and the mechanically alloyed samples were more homogeneous than the samples that were not mechanically alloyed. The samples that were mechanically alloyed had a higher Vickers hardness when compared to the samples that were not mechanically alloyed. The results from the Young's modulus test showed that the samples were in the austenite phase.[60]

Table 1 List of elements added to NiTi and the effect of ternary additions on workability, radiopacity, transformation temperatures, and hysteresis

Element	*Effects*
Nb	Increases stress hysteresis; improves corrosion resistance and machinability; reasonable ductility; enhances radiopacity [Duerig *et al.*[58]].
Pt	Reduces workability and ductility; usually forms NiTi–PtTi; decreases the TTs up to 10 at% and further additions increase the TTs almost linearly; enhances radiopacity
Ta	Decreases TTs. Results in a radiopacity improvement.
V	Reduces workability and ductility; decreases TTs, can be substituted in small quantities for Ni without seriously impairing the shape memory effect.
Cr	Reduces workability and ductility; decreases TTs, can be substituted in small quantities for Ni without seriously impairing the shape memory effect.
Mn	Reduces workability and ductility; decreases TTs, can be substituted in small quantities for Ni without seriously impairing the shape memory effect.
Al	Reduces workability and ductility; decreases TTs, can be substituted in small quantities for Ni without seriously impairing the shape memory effect.
Co	Workability increases or unaffected; decreases TTs, can be substituted in small quantities for Ni without seriously impairing the shape memory effect.
Fe	Workability increases or unaffected; decreases TTs, can be substituted in small quantities for Ni without seriously impairing the shape memory effect.
Pd	Reduces workability and ductility; Usually forms NiTi–PdTi, decreases the TTs up to 10 at% and further additions increase the TTs almost linearly; enhances radiopacity. Results in a radiopacity improvement. B addition as a quaternary element increases workability.
Au	If substituted for Ni can have a neutral effect or it can increase the TTs. Results in a radiopacity improvement.
Cu	Usually forms as NiTi–CuTi. If substituted for Ni will reduce stress hysteresis; can be substituted for nickel in substantial amounts without affecting the martensitic phase transformation, while fully retaining shape memory and superelasticity; results in a sharp reduction in the hysteresis at approximately 7–8 at%.
Hf	Not as workable or ductile as binary NiTi, NiTiCo, or NiTiFe. If substituted for Ti (Ni $<$ 51%) will increase TTs. More than 30 at% can be added without severely impacting the shape memory effect. Results in a radiopacity improvement.
Ag	Only small amounts added to date. Results in a radiopacity improvement.
Zr	Reduces workability and ductility; If substituted for Ti (Ni $<$ 51%) will increase TTs. More than 30 at% can be added without severely impacting the shape memory effect. Results in a radiopacity improvement.
W	Drastically reduces ductility; results in a radiopacity improvement.

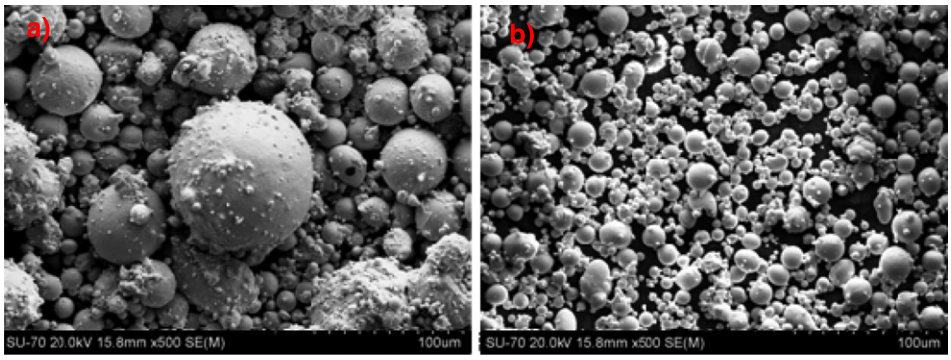

Figure 6 SEM of pre-alloyed gas atomized powders of (a) titanium rich NiTi and (b) nickel rich NiTi starting powders.

3.21.4.3.1 Fabrication of ternary NiTi using SPS

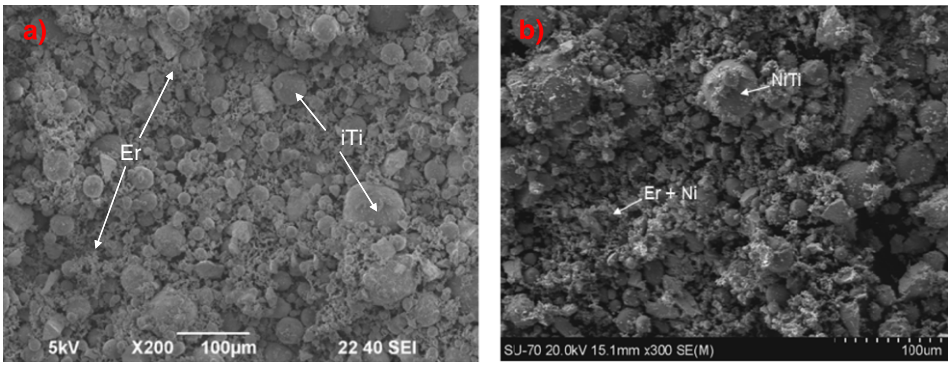
In this experiment ternary NiTiEr was fabricated by SPS. Small nickel rich NiTi powders and Hydrogenated–DeHydrogenated (HDH) erbium powders were ball milled for 20 min. These powders were then sintered at temperature of 800 °C and a pressure 70 MPa using the Dr. Sinterlab SPS 515S.

Figures 6(a) and 6(b) below are SEM images showing pre-alloyed gas atomized NiTi powders. Figure 6(a) shows the morphology and size of these NiTi powders. These powders are titanium rich. Figure 6(b) shows the morphology and size of NiTi powders that are nickel rich.

It can be seen from the SEM images that the gas atomized titanium rich powders have a higher average particle size when compared to gas atomized nickel rich NiTi powders.

Figures 7(a) and 7(b) below show SEM images of NiTi powders ball milled with erbium powders. Figure 7(a) shows SEM images of NiTi powders ball milled with HDH erbium powders. Figure 7(b) shows SEM images of NiTi powders ball milled with nickel erbium powders.

These images highlight the huge variation in powder sizes and indicate that the smaller powders will surround the larger powders during mixing, and ultimately during and after



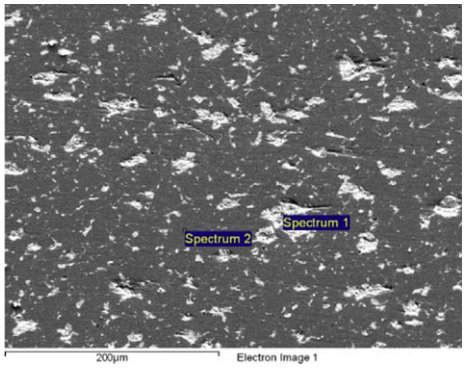


Figure 7 SEM the ball milled (a) NiTi + HDH Er and (b) NiTi + (Er + Ni) starting powders.

Area	Ni	Ti	Er
Spectrum 1	2.61	3.88	93.51
Spectrum 2	50.32	49.57	0.11

Figure 8 SEM/EDS of nickel rich NiTi and HDH Er, sintered at 800 °C and 70 MPa.

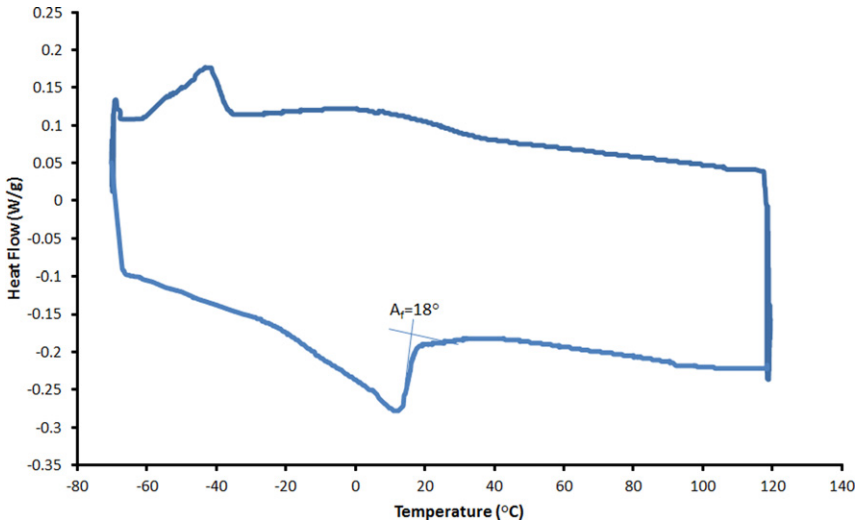

Figure 9 DSC of nickel rich NiTi and HDH Er powder, sintered at 800 °C and 70 MPa.

sintering. While this will not be a problem with the binary alloys, it will cause issues in the ternary NiTiEr alloys if the rare earth powders are finer than the NiTi powders.

SPS was carried out at using both ball milled NiTi and HDH Er powders and NiTi erbium/nickel powders at various temperatures and pressures to find the ideal sintering parameters for the production of ternary NiTiEr. The aim of these experiments was to keep the transformation temperature of the ternary NiTiEr below body temperature and prevent the erbium and nickel from alloying together. It was found that by dropping the sintering to 800 °C and increasing the pressure to 70 MPa, to keep the density >95%, the transformation temperature was more easily controlled.

Figure 8 below shows the microstructure of nickel rich NiTi and HDH erbium powder, using a sintering temperature of 800 °C, temperature ramp rate of 25 °C per minute, and a pressure of 70 MPa.

The hardness was found to be 333 HV in the sintered state. The SEM/EDS analysis showed that the 'HDH Er' was not alloying with the nickel in the nickel rich NiTi powder particles.

Figure 9 shows the DSC graph of nickel rich NiTi and HDH Er powder, sintered at 800 °C and 70 MPa.

This clearly shows that the extra nickel in the nickel rich powder, in combination with the lower sintering temperature, has reduced the A_f transformation temperature to an acceptable level well below body temperature.

3.21.5 Conclusions

This chapter has outlined the main methods of producing NiTi, either by casting or powder metallurgy. Casting, either VIM or VAR, are generally the main methods used to commercially produce NiTi. An alternate route used to casting is powder metallurgy. The main powder metallurgy methods used to produce NiTi such as CS, HIP and specifically SPS were also highlighted in this chapter.

This chapter mainly focused on SPS of NiTi. Some original work on SPS of binary and ternary NiTi was also presented in this chapter. For the binary NiTi work it was concluded that the sample sintered at the higher temperature and pressure has the best qualities that would be required for using this NiTi alloy in products such as stents. From the ternary NiTi work it was found that sintering at lower temperatures and higher pressures resulted in a workable alloy with good transformation temperatures.

3.22.1 Sintering

Sintering as a technique has been known for a few millennia and has been used in pottery, tile, and sanitary ware production and fine ceramics. The process itself bases on compression and solidifying powder materials through heat and/or pressure. Sintering is also used extensively in powder metal compactions, a field known as powder metallurgy. Sintering of polycrystalline ceramics has been extensively reported by chemists, physicists, and materials scientists. In recent years, there has been a considerable interest in new sintering methods and their outcome. In materials finish applications, ceramic and metal coatings have been used for longevity, artistic, and decoration purposes. Functional ceramic coatings on metals known as 'cermets' combined hardness and corrosion resistance of ceramics to the toughness and shock resistance of metals and used in cutting tool industry for many decades.

In order to start sintering process, free energy of the system has to be decreased, and pressure becomes the main driving force. Mass transportation kinetics can enhance the process in terms of time efficiency. As a result, diffusion plays an important role in the process, as it is responsible for the transport of the atoms in crystalline solids. Control of the diffusion process is beneficial to the outcome of sintering process, and there are two parameters that have direct effect on diffusion: temperature and concentration of defects in the sample. Defects concentration on its own depends on temperature, gaseous atmosphere, and concentration of dopants and impurities.[1] Furthermore, microstructure is dependent on pre-firing processing variables, however, the effect of controlling variables in firing stage is also critical.

Sintering methods can be divided into two main groups: (1) conventional (free or pressure less) sintering, which is more economical because there is no external pressure and (2) pressure sintering, which employ external pressure during sintering. Pressure sintering can produce material with higher density and finer-grained microstructure.[1]

In conventional methods, there are two important parameters: sintering process steps (duration and temperature) and process environment (vacuum, oxygen, etc.). To heat up the samples two methods can be used: conventional sintering and microwave-assisted sintering. In conventional method, samples are placed in the electrical furnace and heat is being transferred from heating elements, whereas in microwave heating, samples are heated internally due to absorption of microwaves (**Figure 1**).

3.22.1.1 Sintering Procedure

Sintering can include steps such as the burnout of solvents used for binding the powder into a compact form and phase transformation can occur during such processes. Because of this complexity, controlled and multiple-stage processes may be required as presented in **Figure 2**.

The first stage of the process is the burnout of the binder by slow heat up, where duration of the process and the temperature depend on the amount of binder and sample size. The second stage is the low temperature soak during which modification of microstructure is achieved. Chemical homogenization like solid-state reaction or liquid phase formation may occur at this stage. The next step is heating-up to the sintering temperature. Critical parameter during this stage is the heating rate, as the higher the heating rate value, the more the densification occurs. As grains are exposed to high temperature

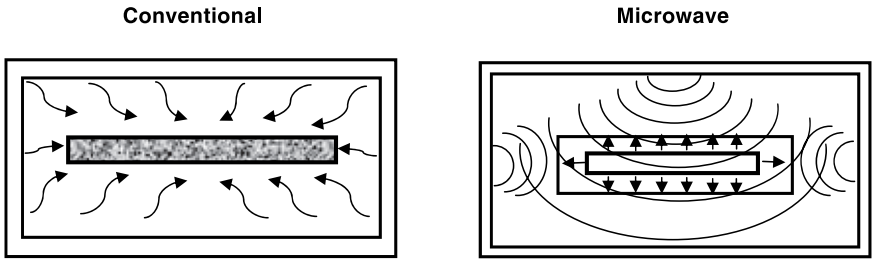

Figure 1 Conventional sintering versus microwave sintering process.[1]

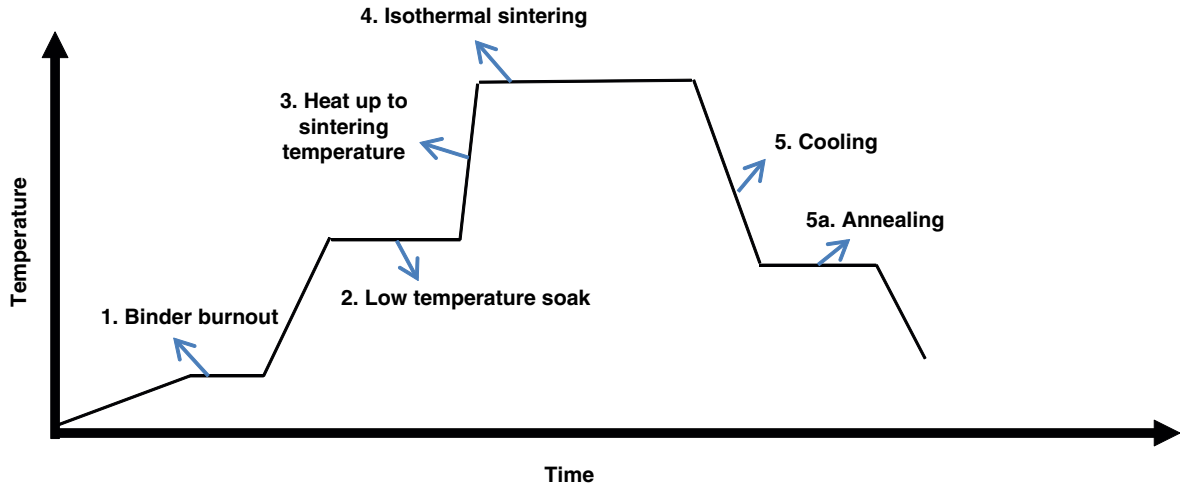

Figure 2 A typical sintering schedule.[1]

for shorter time they do not grow rapidly, and their sizes are finer. The fourth stage is the actual isothermal sintering which leads to final densification. Duration and sintering temperature affect grains coarsening and can cause subsequently abnormal grain growth. For a proper chemical homogenization, sintering time should be extended. The fifth stage is the cool down to the room temperature or in some cases, during cool down an additional annealing step is required to decrease thermal stresses within the sample. Cooling rates can vary depending on the size of the sample, for small samples it can be faster, on the other hand larger samples require slower cooling rate to prevent temperature gradients within the sample that can cause cracking. In order to achieve good structural modification, cooling rate has to be controlled.[1] In practice, some of the above stages may not be needed. For example, green compaction without a binder may not need any binder burnout.

3.22.1.2 Spark Plasma Sintering

Spark plasma sintering (SPS) or pulsed electric current sintering (PECS) are hybrid electrical–mechanical methods used for rapid sintering of metallic and ceramic powders. Pulsed direct electrical current pushed through the sample together with high uniaxial pressure at low atmospheric pressure leads to rapid densification of powders. This process is applicable to sintering of conductive and nonconductive powders. In SPS direct heating of the samples occur by passing electrical current through the sample. High heating rates can be easily achieved, leading to high densification of the powders in a very short time. The high heating rate prevents from undesired grain growth in the sample. Electrical current passes through the sample, and electrical discharge occurs at the contact points of the grains, leading to homogenous heating of the sample. As the result there is a low grain growth and high densification at a very short time, enabling significantly improved or even completely novel materials. The SPS machine consists of following parts: electrodes, two graphite punches (upper and lower), one graphite die, uniaxial pressurizing clamp, vacuum chamber and integrated water cooling system, and controlling system (Figure 3).

Similar to conventional techniques like hot pressing (HP) and hot isostatic pressing (HIP), SPS utilizes simultaneous delivery of heat and pressure. However, there are significant differences between them. In HP and HIP methods, heating rate is much lower than in SPS, as the heating is applied by conventional heating elements in a box furnace. The heat is conveyed to the sample by means of radiation, but it is a very inefficient and slow process. In general high reproducibility, controllability, and speed are the most prominent advantages of SPS over other conventional sintering techniques.

3.22.1.2.1 History of SPS

Sintering assisted by an external electric field was proposed as early as in the 1930s.[3,4] It was based on the combinational use

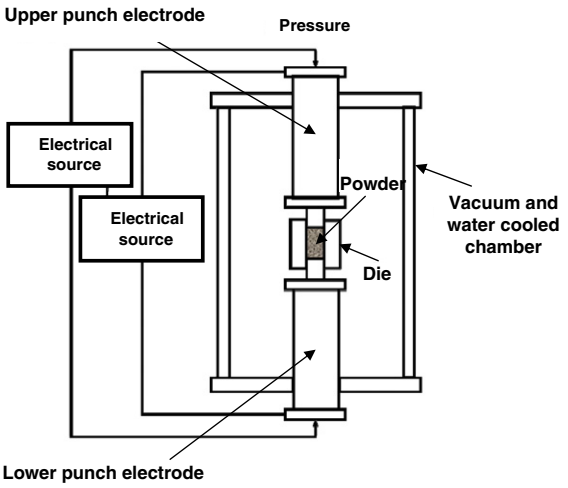

Figure 3 SPS machine schematic.[2]

of electrical heating and pressurized sintering under vacuum or hydrogen gas atmosphere. Electrical discharge sintering was proposed by Inoue in 1960s[5,6] for conductive metallic powders with some of nonconductive materials. In these techniques grains are brought in contact with each other by pressure. By applying electrical current to the sample, ionization and local heating occurs at grain interfaces due to electrical discharge generated at these regions. SPS and plasma activated sintering (PAS) machine was commercially available since 1999.[7] PAS process consists of short pulses of direct current followed by long period of constant direct current. As a result the heating mechanism in the first stage is based on electrical discharge between grains interfaces, while in the second stage resistance heating is the dominant heating mechanism.[7]

3.22.1.2.2 Sintering principles and mechanism

Regarding the differences in the heating mechanisms between SPS and conventional sintering, the densification mechanisms are also different from the diffusion process, which occurs during conventional sintering processes. The process is divided into four steps as shown in **Figure 4**. These steps are: (1) vaporization and solidification, (2) volume diffusion, (3) surface diffusion, and (4) grain boundary diffusion. With the appearance of spark discharge, high temperatures are generated causing vaporization and melting of particles surface, followed by formation of a neck in the contacting area due to volume diffusion. Expansion of necks and plastic deformation of grains occurs leading to densification of the sample.[8] The electrical discharge of SPS process facilitates the removal of oxidized surface of the particles hence, improving the neck formation.[8] Steps 1 and 2 are controlled by voltage breakdown of SPS process. The two last steps depend on Joule effect and applied pressure, which enhances the neck growth and also speed up plastic deformation and finally densification.[8]

Considering the effective parameters in SPS process, compressive pressure is necessary to achieve higher densifications during SPS.[9] As the yield strength of most of the ceramic and metallic materials such as MgO and Al_2O_3 decreases at higher temperatures, once the applied stress reaches the particle yield

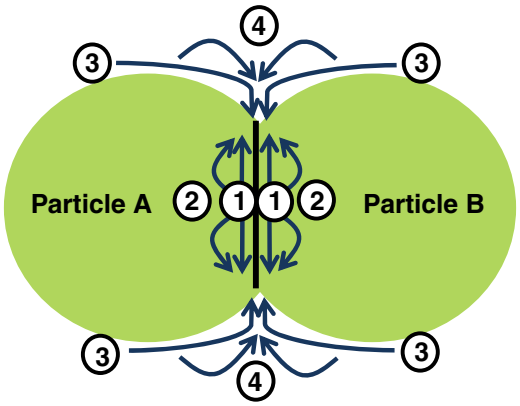

Figure 4 Diffusion process in spark plasma sintering.[7]

stress at a certain temperature, the densification starts the plastic deformation. This mechanism is the main reason of choosing lower sintering temperatures in SPS for materials with low yield strength compared to conventional sintering. However, in high yield strength materials such as YAG (yttrium aluminum garnet, $Y_3Al_5O_{12}$) which keep their high yield strength even at high temperatures, this mechanism is not predominantly active. In these cases, grain rotation and sliding are the main densification mechanisms. Changes of mechanical and electrical properties of the material by temperature determine the main densification mechanism.[9]

3.22.1.2.3 Advantages of SPS over conventional sintering

Direct heating of the sample during the SPS process by electrical discharges facilitates high heating rate. The high heating rate reduces undesired grain growth during the sintering, which is a common drawback in conventional sintering. Furthermore, the simultaneous application of pressure enables setting lower temperatures of sintering compared to conventional sintering. Also, as high temperatures can be reached in short times, sintering takes less time, so SPS can be seen as economically more efficient process.

The research interest in SPS started from two decades ago and has kept its increasing rate until now. It can be obviously seen in the number of papers published on SPS during recent years (**Figure 5**).

3.22.1.2.4 Application of SPS

Because of the advantages of the SPS, there has been a growing interest in using this technology to sinter variety of materials. For instance, it was used to sinter ultra-high temperature materials like WC–Si_3N_4,[10] TiC–ZrC composite,[11] and B_4C.[12] Furthermore, ferroelectric and piezoelectric materials such as $Ba(Zr_{0.2}Ti_{0.8})O_3$,[13] $BaTiO_3$,[14] lead-free materials like $(Na_{0.5}K_{0.5})NbO_3$-$LiTaO_3$[15] have been sintered using SPS. Also, extensive studies were conducted on sintering biomaterials like hydroxyapatite (HAp) by SPS.[16–18]

Considering the broad spectrum of application of SPS in biomaterials and ferroelectric ceramics, following sections of the chapter are focused on sintering these two groups of materials.

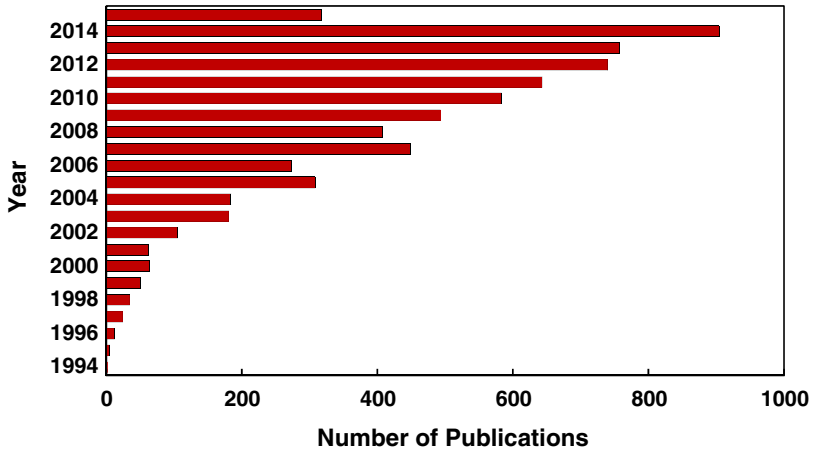

Figure 5 Number of papers published on 'spark plasma sintering' during recent years.

3.22.1.2.4.1 SPS in biomaterials (HAp)

HAp $Ca_{10}(PO_4)_6(OH)_2$ has been used for several years in orthopedic and dental implants, and also in scaffolds enhancing bone growth after hip or knee surgery.[19] The conventional sintering temperature of HAp usually ranges between 1000 and 1500 °C. While porosity of HAp is advantageous for bone growth it is destructive to its mechanical strength and limiting its application. HAps fatigue resistance, tensile and compressive strength depend on total porosity volume after sintering. Furthermore, the dehydroxylation behavior of HAp is another problem, as HAp can be decomposed from its hydrated phase to anhydrous phases such as tricalcium phosphate (TCP) phase at 1200–1450 °C leading to the collapse of HAp structure.[20] The optimum conventional sintering temperature of HAp is reported to be within the range of 1250–1300 °C.[20,21] High sintering temperatures cause grain coarsening, which negatively affects mechanical properties.

High speed, low sintering temperature techniques seem to be beneficial in decreasing the sintering temperature and time, and consequently, prevention of the dehydroxylation and undesired grain growth. Conventional pressure less sintering processes were used to sinter HAp, but methods like HIP, HP, microwave sintering, and SPS have shown promising results in reducing negative effects of conventional sintering. Among all these techniques, SPS has attracted a huge interest due to its high heating rate and application of pressure during sintering.[22] Sintering parameters like: temperature, time, cooling and heating rate, pressure, and atmosphere have been extensively studied by several authors to improve mechanical and biological properties of HAp,[20] produce transparent HAp specimens,[16,18] and also to sinter HAp composite ceramics.[23,24]

3.22.1.2.4.1.1 Microstructural and mechanical properties of spark plasma sintered HAp

Gu *et al.*[2] Sintered HAp at 50 MPa uniaxial pressure with 50 °C min^{-1} heating rate at temperature values varying between 850 and 1100 °C, where holding time was 5 min. The results showed that the optimum densification and best mechanical properties were found in samples sintered at 950 °C, so 300 °C less than in conventional sintering.[2] This drop in sintering temperature is benefits in reducing undesired grain growth and decrease HAp decomposition to TCP. It was reported that the grain growth is negligible until 950 °C.[2] As shown on **Figure 6** the highest relative density (99.6%) was obtained for samples sintered at 950 °C.

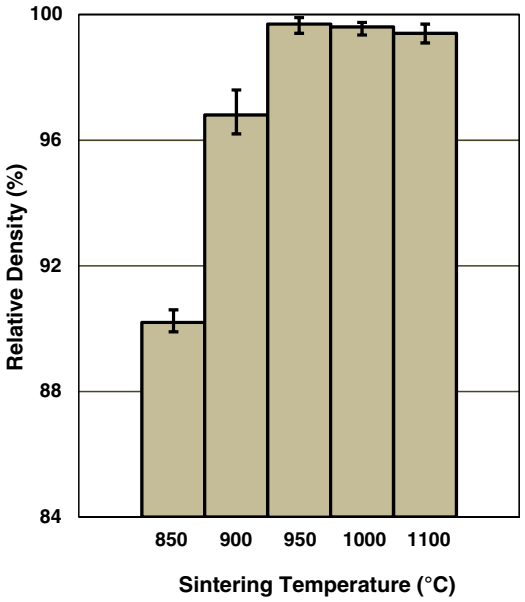

Figure 6 Relative density of HAp sintered by SPS.[2]

Furthermore, samples sintered at 950 °C possessed the highest Young's modulus and Knop hardness. However, above this temperature the grain growth increases rapidly and relative density decreases due to the dehydration of HAp to TCP. The densification process is a two phase process: first one occurs below 900 °C and is linked to the grain boundary diffusion, while a more energetic bulk diffusion process takes place at higher temperatures.

The effect of the initial structural properties such as particle sizes and phase composition on the sintered HAp samples was studied by Cucu *et al.*[25] It was shown that powders with initial smaller particle sizes lead to higher density of sintered samples at lower temperatures. Furthermore, it was reported that the phase decomposition of HAp to TCP during sintering process

hinders the densification of the samples. Consequently, thermal stability of powders can be an important factor in densification process. In addition, particle size and phase composition of the initial powder can affect the final grain size and optical transparency of the samples. Bigger grains and higher TCP phase content in the samples, decreases the transparency.

A comprehensive study on microstructural and mechanical behavior of SPS sintered HAp samples at different sintering temperatures and pressure has been carried out by Li *et al.*[26] They observed that no decomposition of HAp took place up to 1000 °C in vacuum. They also studied the effect of the temperature and pressure on the relative density of the samples. It was shown that sample density increases with higher temperature and pressure a rapid increase of density (from 92 to 98.9%) was observed after increasing the temperature from 800 to 1000 °C at 22.3 MPa.[26] Also, after increasing the pressure from 22.3 to 66.9 MPa at 800° C the density of the samples increased from 92 to 98.9%.

However, it was found that above 900 °C no major variations in density was observed, indicating limitation of temperature impact on the densification of HAp samples. The highest relative density of 99.7% was achieved at 1000 °C and 66.9 MPa. This density is achieved at the sintering temperature, which is about 200–400 °C lower than the conventional sintering temperature. Although higher densities were observed at higher temperatures and pressures, but at the cost of larger grains which resulted in poor mechanical properties of the samples. Hence, the balance between density of the samples and grain size has to be considered with respect to samples mechanical properties. The mechanism that relates the impact of applied pressure and temperature on densification mechanism can be understood into three steps. At temperatures below 850 °C particles are in contact with each other and 'necks' between particles are being formed. In the second stage, within temperature range of 850–900 °C volume and grain boundary diffusion occurs. In this step the density increases and grains grow. During final step, at temperatures higher than 900 °C, continuous pores disappear and closed pores are being formed. These pores are moveable compared to closed pores, and lead to rapid increase in density.[26] Although the densification pressure and temperature depend on the physical and microstructural properties of the powders, the common range of sintering temperature of HAp samples has been reported to be between 900 and 1000 °C depending on various initial powder properties.

The calculated grain growth activation energy based on Arrhenius equation, depicts lower activation energies at higher temperatures and pressures. In this case, the activation energy at 850–900 °C is 55 kcal mol^{-1} and 51 kcal mol^{-1} at 22 and 44.6 MPa, respectively. Lower activation energy was observed at temperatures higher than 950 °C (42 kcal mol^{-1}). This is the main reason of the proliferated grain growth rate at temperature higher than 950 °C. The flexural strength achieved at 44.6 MPa and 950 °C is 131.5 MPa, which is extremely higher than the one achieved by conventional sintering at higher temperatures.[26] Lower flexural strength was observed at higher sintering temperatures than 950 °C, which can be attributed to the higher grain size. It is stated that HAp decomposition, residual stress and grain growth are the main factors in mechanical strength loss of HAp samples.[26] Gradual increase of the optical transparency was observed by increasing sintering temperature and pressure. The highest density and optical transparency was achieved in samples sintered at 1000 °C and 66.9 MPa. The effect of SPS parameters on optical properties of HAp samples will be discussed thoroughly in the next section.

3.22.1.2.4.1.2 Optical properties of SPS HAp

The optical transparency of the HAp in addition to its high chemical stability and biocompatibility,[19] can facilitate its application in new untouched fields. For example, it can be used for applications such as use of confocal microscopy for observation of human cells activities, and transparent window for implantable bio-devices for direct observation of biological activities.[16,18] Spark plasma sintered transparent HAp at temperatures between 800 and 1300 °C under pressure of 30–50 MPa and 5–10 min total sintering time. Local discontinuities such as grain boundaries, microstructural defects, grain size, crystallographic anisotropy, and heterogeneous composition play an important role in the optical properties of HAp ceramics.[16,18] The effect of SPS on crystallographic orientation and finally optical properties of HAp is investigated in our group.[18] The differences in optical transmittance versus sintering temperature are illustrated in **Figure 7**. Samples sintered between 700 and 790 °C with 100 °C min^{-1} heating rate under 50 MPa pressure for 20 min were opaque, while the highest transparency was observed at 900 °C. Samples sintered at higher temperatures were translucent with 40–50% transmittance.[18]

A rapid increase in density was reported in the range between 700 and 900 °C. This trend is almost stopped above 900 °C (**Figure 8**). A comparison between increase of density and transmittance with temperature up to 900 °C showed that the elimination of optical diffraction sources such as pores, grain boundaries, and grain growth are effective in enhancement of both density and transmittance, simultaneously. However, the grain growth above 900 °C resulted in a reduction of the transparency.

The density of the sample sintered at 900 °C is close to the theoretical density and there are not many pores in the structures, which show that the light transmittance is mostly dependent on the samples' microstructure. It was shown that in samples sintered between 700 and 900 °C, *c*-axis is aligned perpendicularly with respect to the uniaxial pressure direction. Eventually, *c*-axis of the most of the grains is perpendicular to the incident light. At temperatures higher than 900 °C there is enough energy available to rotate grains and grow in other directions even under uniaxial pressure. This rotation creates some out of plane grain orientations. This is another reason that can negatively affect the light transmittance after saturation of the density.[18] Consequently, it can be stated that the crystal orientation is one of the most influential factors on optical properties of HAp samples sintered by SPS. HAp crystal orientation plays a considerably important role in protein adsorption. The protein adsorption on *a*-plain of HAp was observed to be extremely higher than that of *c*-plain.[27] These HAps were electrically polarized to show unprecedented piezo, pyro, and ferroelectricity.

In another study, Watanabe *et al.*[27] reported a transparent HAp samples by sintering at 1200 °C with heating rate of

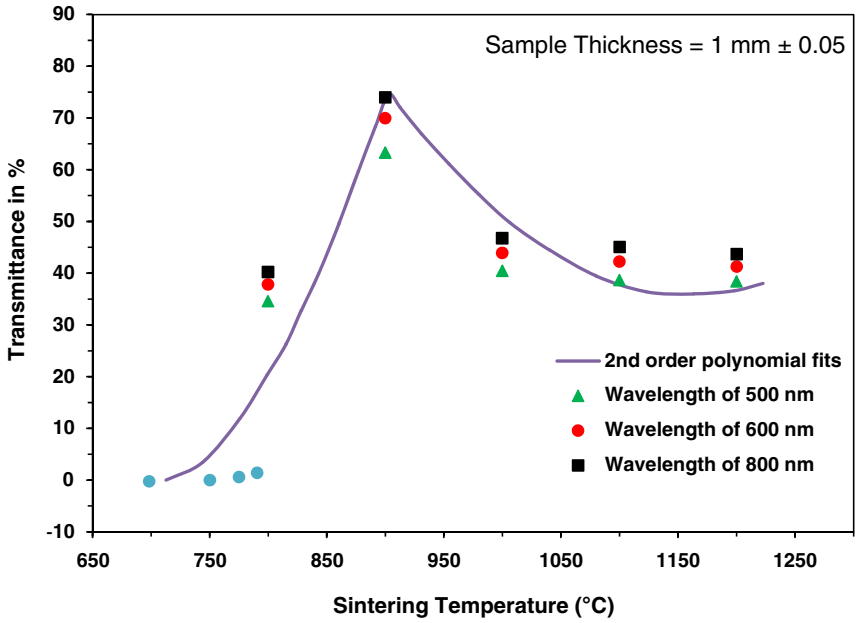

Figure 7 Optical transmittance of the samples sintered at different temperatures.[18]

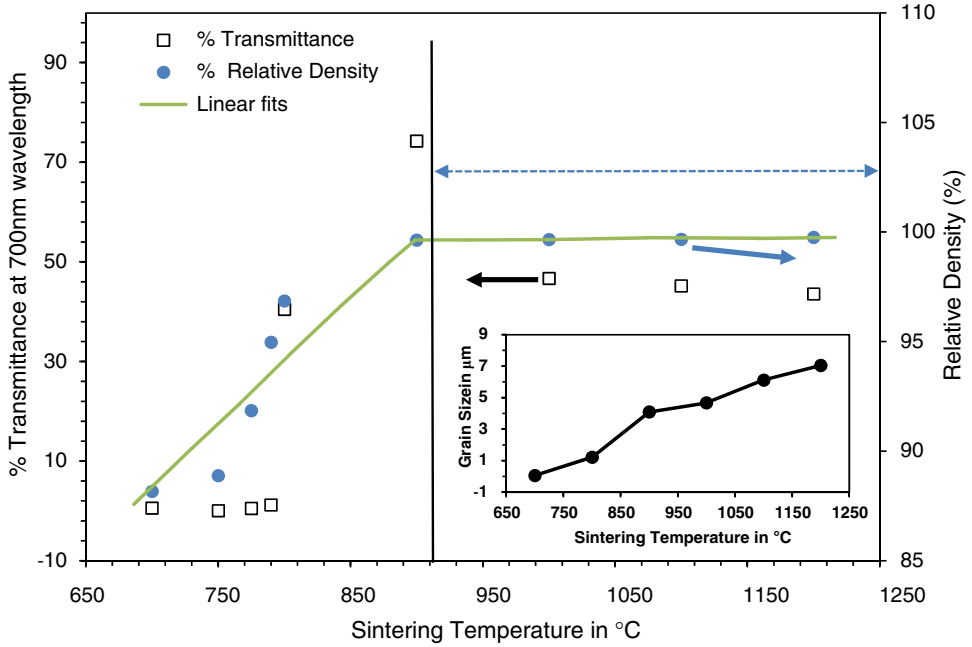

Figure 8 The effect of sintering temperature on relative density, optical transmittance, and grain size of the HAp samples.[18]

50 °C min^{-1} under 50 MPa of applied pressure and 10 min of sintering time.[27] The relative density of 99.7 and 70% transmittance over 700 nm was observed in these samples. This was observed at higher temperature and pressure ranges compared to what Gandhi *et al.*[18] reported. Regardless of the possible different properties of initial powders this can be related to the lower sintering rate that has been exploited in their sintering process. X-ray diffraction pattern of sintered samples in two directions: parallel and perpendicular to the pressure direction shows the effect of sintering pressure on the grains preferential orientation. As it is shown in **Figure 9**, (002) and (004) plains possess the highest intensity in the parallel section. The (100), (200), and (300) plains show the highest intensity in perpendicular direction. It can be deducted that the *c*-plains are formed mainly in perpendicular direction of the sintering pressure.

3.22.1.2.4.2 SPS in lead-free ferroelectric ceramics

Ferroelectricity was discovered in 1921.[28] The ferroelectricity in ceramic materials was found in the 1940s for the first time in barium titanate ($BaTiO_3$).[29] There are other materials within the

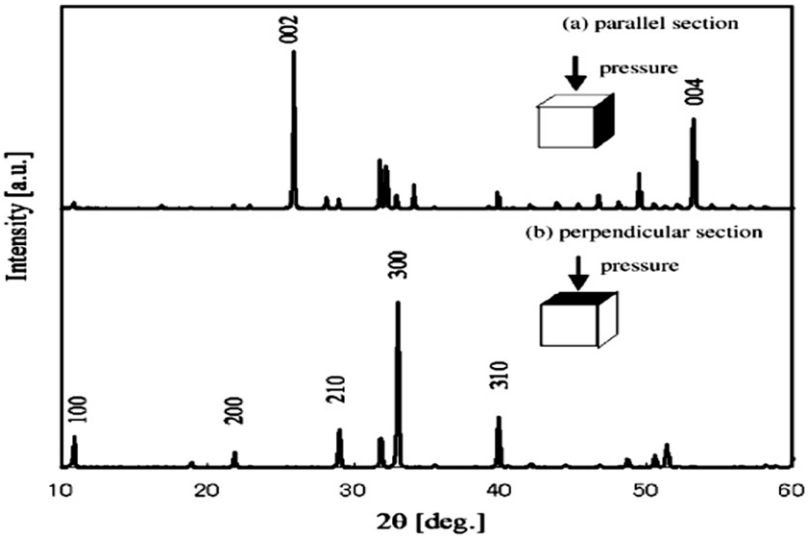

Figure 9 The X-ray diffraction pattern of HAp samples cut in (a) parallel orientation to the pressure and (b) perpendicular orientation to the pressure.[27]

same group of Perovskite structure, which exhibit ferroelectricity such as $PbZr_{1-x}Ti_xO_3$ (PZT), PZT:La (PLZT), $PbTiO_3$ (PT), $Pb(Mg_{1/3}Nb_{2/3})O_3$ (PMN), and $(K_{0.5}Na_{0.5})NbO_3$ (KNN).

One of the most widely exploited ferroelectrics was $PbTiO_3$–$PbZrO_3$ also known as PZT. Because of the new legislations, significantly reducing application of lead in ferroelectric materials,[30] it has drawn attention of academia and industry into new field – lead-free ferroelectric ceramics. Sintering of the lead-free ferroelectric ceramics has been a scope of interest of many researchers during recent years.[31–34] Following lead-free ferroelectrics have been investigated: tungsten bronze type materials, bi-layer structured materials, and Pervoskite type materials.[6] Ferroelectric ceramics such as barium titanate (BT), sodium bismuth titanate (NBT), alkali niobates ($ANbO_3$), for example, potassium niobate, potassium sodium niobate (KNN), and potassium tantalate niobate (KTN) have been investigated as the most promising lead-free ferroelectrics.[35]

Conventional sintering techniques and even high pressure sintering techniques such as cold isostatic press or HIP are not suitable for sintering such materials.[36] The main drawback of conventional sintering of ferroelectrics are the large particle size, high impurity contents as a result of repetitive calcination and grinding processes, and also lower chemical activity.[37] Furthermore, high energy requirements and time consumption are other disadvantages of conventional sintering methods.[35] SPS and microwave sintering are two of the sintering techniques, which most likely suitable for ferroelectric ceramics sintering. However, the simultaneous use of pressure, high heating rate, and direct heating in SPS makes it even more advantageous over microwave sintering.[38]

Accordingly, in this section the SPS sintering of lead-free ferroelectric ceramics and the effect of SPS sintering on their properties is reviewed. In this regard, the SPS process of different lead-free ferroelectrics is discussed.

3.22.1.2.4.2.1 BT

BT as a ferroelectric ceramic is extensively used in various applications such as piezoelectric devices like underwater transducers, sensors, heaters with positive temperature coefficient, and multilayer capacitors.[39,40] These applications require specific properties: high dielectric constants and good resistivity properties in small volumes. BT is an example of material possessing perovskite crystalline structure. It has a cubic structure above its Curie temperature (130 °C) and below that it can have tetragonal, orthorhombic, and rhombohedral structures.[41] BT is mostly synthesized in powder form and because of undesired grain growth during long conventional sintering processes, SPS could prove much better method for sintering such crystalline structure.[42] The whole process leading to sintering of BT usually consists of four steps: BT powder synthesis, powder preparation (grinding/ball milling), sintering, and annealing at lower temperature for a longer time (5–12 h).[43,44]

In one of the first studies on SPS sintering of BT samples, the effect of grain size on ferroelectric properties of BT was investigated.[45] It was shown that the samples with average grain size about 1 μm show the highest values of piezoelectric coefficient d_{33}, planar electromechanical coupling factor k_p, and relative permittivity $\varepsilon'(\varepsilon'=6079$, $d_{33}=519$ pC N^{-1}, and $k_p=39.5\%)$. These values varied with changing grain sizes.[45,46] Consequently, controllable grain growth has a great impact on ferroelectric and piezoelectric properties of BT.[47]

SPS due to its highly controllable process parameters shows a very promising method for BT sintering. As grain size seems to play important role in materials performance, there has been a considerable interest to investigate BT properties with respect to the average grain size. Significant number of papers reported SPS sintering of nano grain size BT samples.[42,43,48] Takeuchi *et al.*[31] used SPS sintering of BT samples in order to achieve submicron grain sizes with acceptable ferroelectric properties. It was shown that SPS sintered samples had smaller grain size (<1 μm) and higher density (>95% relative density) compared to conventionally sintered samples (2–10 μm and 80–90% relative density). Also higher electrical permittivity was observed in samples sintered using SPS method compared to samples prepared by conventional sintering. Samples sintered at lower temperatures showed higher permittivity values. This property was linked to the lower

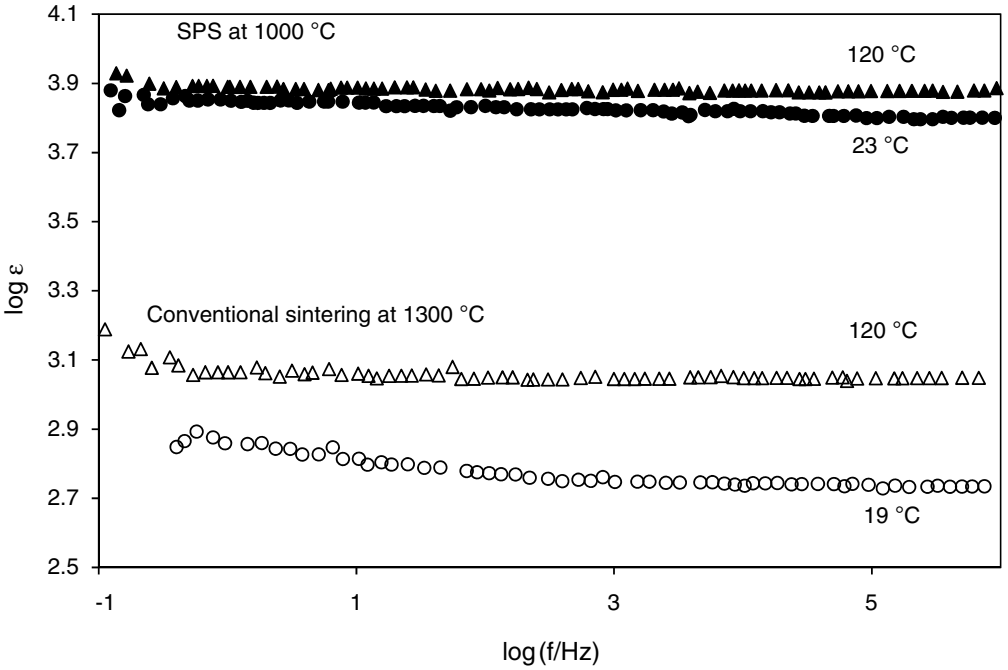

Figure 10 Frequency dependence on permittivity of SPS samples (SPS BT01) and conventionally sintered samples (CH BT01) at two different temperatures.[31]

grain size in samples sintered at lower temperatures. Furthermore, frequency dependence of permittivity in the range of 10^{-1}–10^{6} Hz was lower in SPS sintered samples (**Figure 10**). This was attributed to the removal of air gaps in SPS sintered samples.[31]

Though, it has been stated in many studies that the optimal ferroelectricity can be achieved in samples with average grain size lower than 1 μm.[43,45] The effect of lower grain sizes on the ferroelectricity has not been understood well yet. Felgner *et al.* suggested that the presence of an interconnected low permittivity non ferroelectric grain boundary at low grain size and high grain boundary conditions can decrease the permittivity of the BT samples.[49] In another study, the presence of a dead layer between the grains in samples with grain size of less than 0.5 μm is linked to the reduction of dielectric constant.[43] Other phenomena such as depolarization at small grain sizes,[50] significant decrease in ferroelectric phase transition driving force,[51] the defects of hydroxyl ions residing on the oxygen sites and compensation of the cation vacancies have also been listed as possible reasons of ferroelectricity decrease in grain sizes smaller than 0.5 μm. Deng *et al.* showed piezoelectric properties, phase transition properties, and ferroelectricity[43] in SPS sintered samples with 20 nm grain size. In the studies performed in the temperature from 83 to 437 K shown that all phase transition happens as usual in coarse grain BT samples. Furthermore, post sintering procedures such as thermal annealing have a significant effect on releasing residual stresses, removing excess oxygen vacancies and also, elimination of incorporated hydroxyl groups during SPS process. No significant grain growth has been reported during annealing process.[43] Maiwa *et al.*[44] have observed that as SPS sintered samples of $Ba(Zr_{0.2}Ti_{0.8})O_3$ were dark and deoxidized but after annealing samples would be oxidized and retain a brighter color.

In some other studies barium strontium titanate (BST) has been sintered by SPS in order to achieve transparent ferroelectrics.[32] Transparent ferroelectrics are widely used in electro-optical devices including digital light modulators, optical shutters and switchers, and image memory devices. SPS has shown it applicability in sintering optically transparent samples. This is because its capability in sintering of high density and low grain size samples in short time. To summarize, SPS allows sintering of high density, low grain sized BT samples. The sintered BT samples with grain size lower than 1 μm and higher than 0.5 μm show high dielectric constant, high permittivity, and low frequency dependence of dielectric constant.

3.22.1.2.4.2.2 *$ANbO_3$*

$ANbO_3$ with the common formula of $ANbO_3$ were proposed as a family of lead-free ferroelectric ceramics with perovskite structures in 1950s and 1960s.[52] Ferroelectric materials such as $KNbO_3$ and its solid-state solution with antiferroelectric $NaNbO_3$ given (K, Na)NbO_3 (KNN), (K, Ta)NbO_3 (KTN), (Li, Na)NbO_3 (LNN)[6,53] are among the most prominent alkali niobate structures. The appropriate choice of stable precursors of alkali metals and densification process are the key challenges in the production of lead-free ferroelectric ceramics. For instance, in KNN structure, the volatilization of potassium at high temperatures is the most important problem.

In terms of possible low temperature densification of alkali niobate ferroelectrics several possible solutions have been proposed:

1. electric field or pressure assisted (SPS) sintering,
2. reduction of initial particle size in order to increase the sintering driving force,

3. addition of glass phase,
4. addition of sintering aid agents such as oxide impurities,
5. introduction of lattice defects.[6]

SPS sintering as an electrical field and pressure assisted sintering technique have been used in sintering of low grain size, high density alkali niobate structures. In the following part the SPS sintering of KNN will be discussed further.

3.22.1.2.4.2.3 KNN

The first dense KNN structure was sintered by Jaeger and Egerton in 1962 by HIP techniques,[54] and its high piezoelectricity and Curie temperature were reported. The highest d_{33} reported for KNN was about 416 pC N^{-1}.[55] However, in order to achieve this value in industrial scale there are many points to be considered. SPS with the aforementioned advantages can be a breakthrough in sintering of KNN. Li *et al.* sintered a KNN sample with SPS at 950 °C, for 5 min with heating rate of 100 °C min^{-1}. The sintered sample achieved 99% relative density and grain size range of 200–500 nm.[56] The polarization-electrical field (P-E) hysteresis loop for as-sintered samples, and thermally annealed samples at 900 °C for 1 and 4 h revealed the crucial effects of annealing. The round shape of P-E hysteresis loop of 1 h annealed sample illustrate the insufficiency of annealing time for KNN. On the other hand, the slim polarization hysteresis loop of 4 h annealed samples showed the better elimination of oxygen vacancies. Also, a perfect polarization hysteresis loop was observed when higher bias fields were applied to the samples (**Figure 11**).[56]

Also, according to the initial powder grain size it has been suggested that ultra-fine starting powder can enhance sintering of KNN samples. High energy ball milling processes can be helpful in achieving submicron grain size distribution for initial powders. In this regard it was revealed that the samples with lower grain size distribution can attain higher densities compared to samples with larger grain size distribution. Furthermore, the addition of various oxides for creating low melting point phases and consequently low temperature sintering has been investigated.[6] Although this method can decrease melting point and results in higher density samples, the electrical properties of samples will be also affected by the presence of these new phases.

Some investigations have been done on KNN doped with Li, Sb, and Ta.[57] It was shown that SPS can be very helpful in sintering of dense small grain size samples of $(Na_{0.52}K_{0.44}Li_{0.04})(Nb_{0.86}Ta_{0.06}Sb_{0.08})O_3$ (LTS-KNN). The initial powder with grain size of 11–34 nm was sintered at 750 °C and 120 MPa for 10 min. The final samples had 99.4% relative density and its grain size distribution was in the range of 200–400 nm.[57] In term of ferroelectricity the sample showed a slim polarization curve showing the difficulty in domain walls flip of fine grain ceramic samples. In **Figure 5** $d33$, Kp, ε_{33} T/ε_0 at 1 kHz and tanδ of the annealed ceramic are shown, and they were 296 pC N^{-1}, 49.7%, 920 and 0.025, respectively (**Figure 12**).

3.22.1.2.4.2.4 $(Bi_{0.5}Na_{0.5})TiO_3$

$(Bi_{0.5}Na_{0.5})TiO_3$-$BaTiO_3$ (BNT-BT) has been proposed as a potential replacement for PZT ferroelectrics. Pure BNT with perovskite structure has rhombohedral crystal structure at room temperature. It undergoes a phase transition at 320 °C to tetragonal structure.[58] BNT possesses good ferroelectric properties with high values of remnant polarization $P_r = 38$ μC cm^{-2} with coercive field $E_c = 73$ kV cm^{-1}. BNT has been doped with $BaTiO_3$ in order to improve ferroelectric properties.[59] BNT-BT has been proposed a good candidate to replace PZT ceramics.

SPS has shown a great promise in rapid sintering of BNT-BT ceramics as well. This is because of short sintering time, low sintering temperature and as a result less loss of Bi and Na during sintering process.[59] Since SPS hinders undesired grain growth in BNT-BT samples and thus results in an enhancement of its mechanical strength. It was shown that BNT powder with grain size of around 30 nm, sintered at 900 °C for 5 min under pressure of 65 MPa has the highest relative density (99.62%). The average grain size in the sintered samples was around 50 nm.[5]

According to the ferroelectric properties of sintered samples it was shown that samples sintered at higher temperatures (900 °C) with higher density and grain size have higher

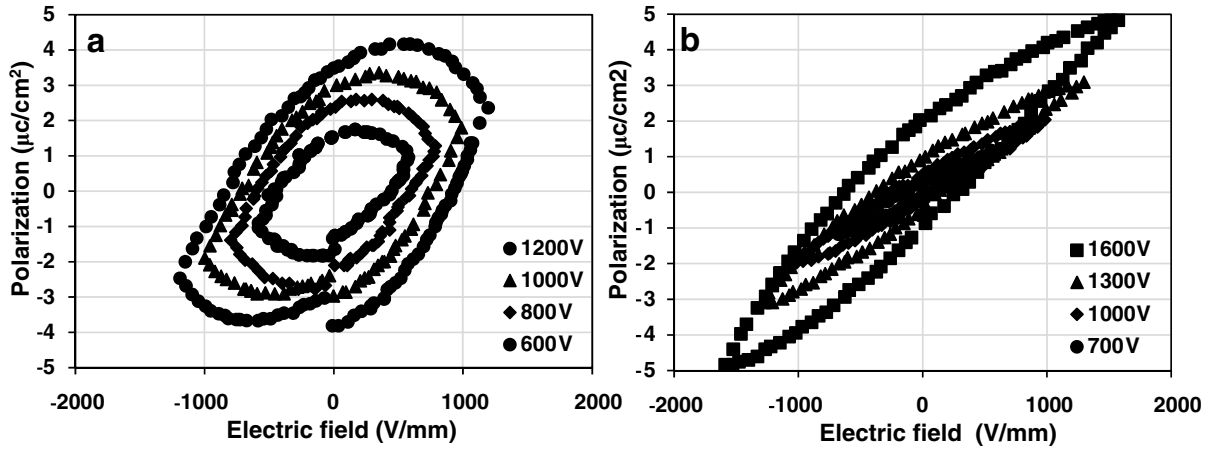

Figure 11 Polarization hystersis curves of $Na_{0.5}K_{0.5}NbO_3$ ceramic spark plasma sintered at 920 °C for 5 min and then annealed for different times in air (a) 1 h and (b) 4 h.[56]

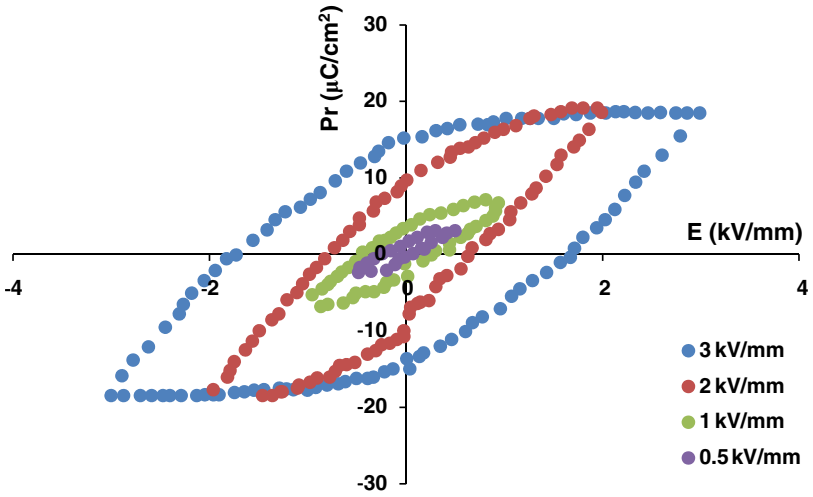

Figure 12 Ferroelectric properties of the annealed LTS-KNN ceramic.[57]

permittivity $\varepsilon_r = 2213$ and loss factor tan $\delta = 5.5$ %. The frequency dependence in all BNT-BT samples shows a decrease in permittivity at higher frequencies.[59]

3.22.2 Conclusion

SPS has shown a huge promise in sintering of biomaterials and lead-free ferroelectric ceramics. In this article, the potential use of SPS in sintering of HAp as a biomaterial with piezoelectric properties and also, in sintering of lead-free ferroelectric ceramics was reviewed. Its main advantages compared to conventional sintering methods are: lower sintering temperature, high heating rate, fast sintering, higher density, and lower grain size distribution in final product. As it was shown, these properties can lead to production of transparent HAp and ferroelectric samples because of high relative density and low grain size of the sample. Furthermore, in case of $ANbO_3$ ferroelectrics the lower sintering time of SPS hinders the technological problem of alkali metals volatilization, which happens during conventional sintering of these materials. To summarize, it can be concluded that SPS is a highly controllable sintering method leading to high density low grain size materials with improved mechanical and electrical properties. Although the current chapter discussed the processing of bulk ceramics but the information gathered here can be used in developing thick films and composite ceramic coatings of such materials.

3.23.1 Introduction

Electrochemistry deals with the interconversion of chemical energy and electrical energy and finds applications in those daily life products which involve chemical reactions to generate electricity such as batteries, calculators, automobiles, personal gadgets, etc.[1] Electrochemical processes and their derived and hybrid processes are used to meet various processing requirements of the electrically conducting materials. Some worth-mentioning are (1) coating of different materials by electrochemical deposition or electroplating (EP) to improve their surface properties such as corrosion and wear resistance, surface finish, surface integrity, aesthetics, etc.; (2) precision machining of components with a complex shape and difficult to machine materials by electrochemical machining (ECM) process; (3) finishing of intricate components by electrochemical finishing (ECF) process; (4) damage-free grinding of various components by electrochemical grinding (ECG) process; (5) high quality of finishing of gears, cylinders, bushes, sleeves, bearings, etc., by electrochemical honing (ECH) process; (6) removal of different types of burrs with almost no damage to the workpiece by electrochemical deburring (ECDe) process; (7) generating nanoparticles by electrochemical winning (ECW) process; and (8) purification and recycling by electrochemical refining (ECR) process. These processes can easily fabricate difficult-to-fabricate materials namely high strength temperature resistant (HSTR) materials such as superalloys, titanium alloys, stainless steel, copper–beryllium alloys; refractory materials such as tungsten, tantalum, molybdenum, niobium and their alloys; and wear-resistant materials such as nickel, cobalt, chromium and vanadium and their alloys; shape memory alloys, etc. Processing of these materials by conventional processes such as drilling, grinding, boring, turning, lapping, shaping etc. are not able to produce the components with the required quality especially in terms of surface quality and geometric tolerances. The irregularities at the surface and subsurface of components may lead to various undesirable effects such as reduced service life, premature failure, poor load carrying capacity, reduced working efficiency, generation of noise and vibration, etc. These limitations, constantly increasing use of miniature components and ever increasing requirement of high-quality complex shaped components in engineering products have made electrochemical processes as first choice of industries due to its noncontact nature, flexibility, and ease of operation. Therefore, electrochemical processes find many applications in various industries such as aviation, automobile, space, biomedical, consumer products, manufacturing, nuclear, semiconductors, micro- and nano- electromechanical systems (MEMS/NEMS), optics, nano-manufacturing, fashion, etc.

Electrochemical processes involve Faraday's laws governed electrolysis phenomenon in a container called as electrochemical cell which consists of two electrodes (i.e., anode connected to positive terminal of direct current (DC) supply and cathode connected to negative terminal of DC supply) separated by each other by an appropriate interelectrode gap (IEG) and submerged in a suitable electrolyte solution enabling the electrochemical reactions to occur. Some cells have a diaphragm or membrane between the anode and cathode which separates reaction products at anode and cathode. Figure 1 shows a simple electrolysis process for anodic dissolution of iron in brine water. The metallic atoms leave the anode and become ions and the ions move toward the body and become atoms. This process continues and attains

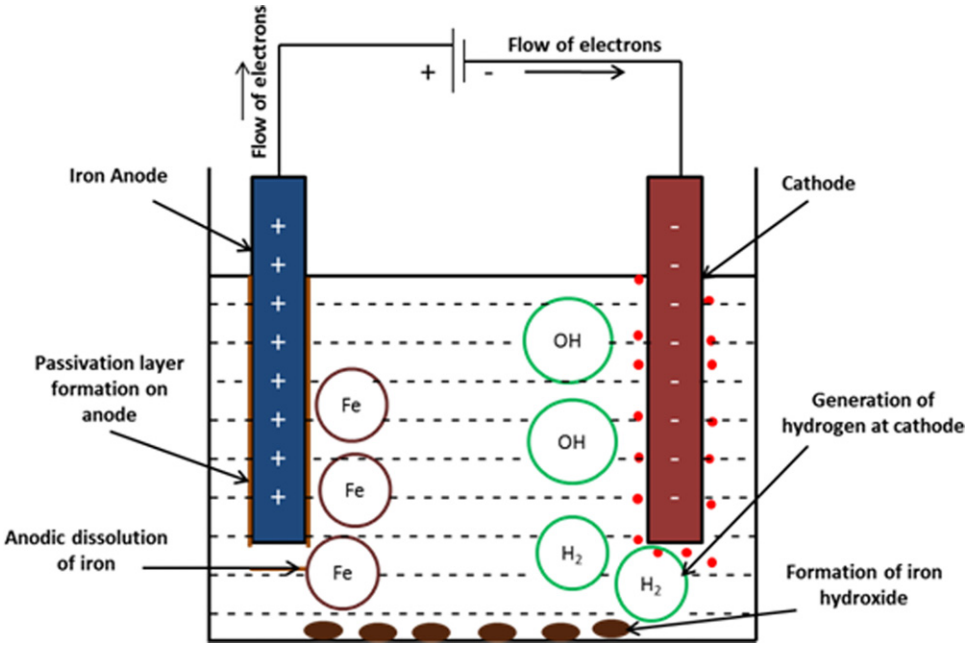

Figure 1 Schematic of a simple electrolysis process.

equilibrium. A potential difference, known as electrode potential exists between a point on the surface of an electrode and an adjacent point in the electrolyte. The electrode potential depends on the combination of electrode and electrolyte. If two different electrodes are submerged in an electrolyte then a potential difference between these electrodes exists which is known as cell 'electromotive force' (cell emf).

The following electrochemical reactions occur when a voltage is applied across the electrodes.

$Fe \rightarrow Fe^{2+} + 2e^{-}$ (at anode; the anodic material dissolves leaving two electrons).

$2H_2O + 2e^{-} \rightarrow H_2\uparrow + 2(OH)^{-}$ (at cathode; water gets the two electrons from the cathode and produces hydrogen gas at cathode and hydroxyl ions).

The positive metal ions move toward the negatively charged cathode. The negatively charged (OH) ions moves toward the positively charged anode and combines with positively charged metal ions to form an insoluble precipitate, i.e., metal hydroxide.

$Fe^{2+} + 2(OH)^{-} \rightarrow Fe(OH)_2$ (Insoluble precipitate)

Faraday's first law of electrolysis states that "the chemical change produced (or amount of any material deposited or dissolved) by flow of electric current through an electrolyte is directly proportional to the quantity of electricity passed through it" and according to Faraday's second law of electrolysis "the amounts of different substances dissolved or deposited by the same quantity of the electricity are proportional to their chemical equivalent weights."

Mathematically, Faraday's laws can be expressed as;

$$m \propto EIt \rightarrow m = \frac{EIt}{F} \rightarrow m = \frac{MIt}{ZF} \quad [1]$$

where,

m = mass of anode material dissolved (grams)

I = amount of current passed (A)

t = time for which current is passed (seconds)

E = chemical equivalent weight of the anode material (grams) $= \frac{M}{Z}$

M = atomic weight of the anode material (grams)

Z = valency of dissolution of the anode material

F = Faraday's constant (F = 96 500 C or A s)

3.23.2 Types of Electrochemical Processes

There are some basic electrochemical processes such as ECM, ECF, ECW, ECR, and various derived and hybrid processes have also been developed to meet the specific requirements for electrochemical processing of the materials and/or product. Table 1 lists these processes.

Table 1 Various types of electrochemical processes and their derived and hybrid versions

Basic electrochemical processes	*Derived and hybrid processes*
• Electrochemical machining (ECM) • Electrochemical finishing (ECF) • Electroplating (EP) • Electrochemical winning (ECW) • Electrochemical refining (ECR) • Electrochemical micro machining (ECMM)	• Electrochemical drilling (ECD) • Electro stream or jet drilling (ESD or EJD) • Shaped tube electro drilling (STED) • Capillary drilling (CD) • Electrochemical turning (ECT) • Electrochemical milling (ECMI) • Electrochemical sawing (ECS) • Electrochemical trepanning (ECTr) • Electrochemical boring (ECB) • Electrochemical broaching (ECBr) • Electrochemical ballizing (ECBz) • Electrochemical deburring (ECDe) • Electrochemical buffing (ECB) • Electrochemical super finishing (ECSF) • Electrochemical grinding (ECG) • Electrochemical honing (ECH) • Electrochemical discharge machining (ECDM) • Electrochemical wire cutting (ECWC)

3.23.3 EP

EP or electrochemical deposition is the application of a metallic coating to an electrically conductive surface by electrolysis phenomenon. It involves passing an electric current through an electrolyte to reduce cations of the coating material and coat that material as a thin film on an electrically conductive workpiece surface. It is an economical technology to protect and enhance the functionality and surface properties of the workpiece. It imparts special or improved properties to the significant surfaces of a part or assembly and/or protecting or enhancing their function in their operating environment. Essentially any electrically conductive surface can be electroplated. The metals and alloy substrates electroplated on a commercial scale are cadmium, chromium, cobalt, copper, gold, indium, iron, lead, nickel, platinum, silver, tin, zinc, brass, bronze, lead–tin, nickel–iron, nickel–cobalt, nickel–phosphorus, tin–nickel, tin–zinc, zinc–nickel, zinc–cobalt, and zinc–iron, etc.[2] Special techniques such as coating with metallic-loaded paints or silver-reduced spray can be used to make nonconductive surfaces such as plastics electrically conductive for EP.[2,3]

3.23.3.1 Principle of EP

Figure 2 depicts schematic of a typical EP cell used for depositing copper using copper sulfate solution. It consists of four major components:

- DC or pulsed DC supply unit: for providing DC power supply between cathode and anode. Usually a rectifier or motor generator is used as DC source to supply the current in the EP cell. The means of regulating the voltage and current maintain their values at the chosen levels.
- Cathode and its positioning means: the substrate material (i.e., workpiece) on which plating is to be done is made as cathode. Its positioning means ensuring its position

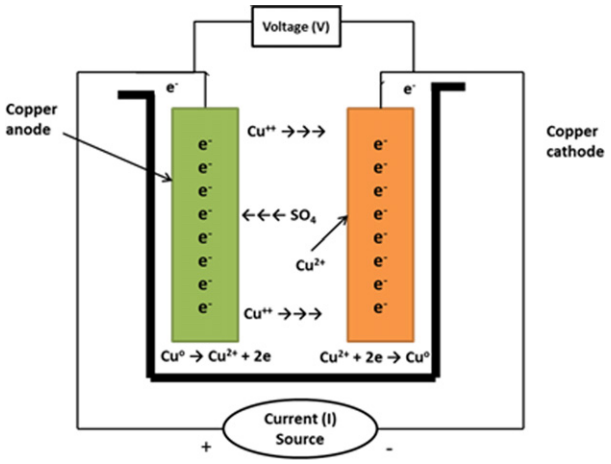

Figure 2 Schematic of a typical electroplating cell.

remains fixed in the in the plating solution and contact with the DC power supply is maintained.

- Anode: the coating material which is to be plated or deposited is made as anode.
- Platers: electrolyte solution is referred as platers. Generally, salt solutions are used as platers.

In an EP process, the deposition reactions at cathode are referred as reduction reactions since electrons are consumed reducing the valence states of the ions involved. The reactions occurring at anode are oxidation reactions in which electrons are liberated and atoms are ionized increasing their valence states. Electrochemical reactions are reversible reactions and independent of each other. They are governed by the condition of material balance, i.e., electrons liberated at the anode must be equal to the number of electrons consumed at the cathode.

For depositing copper using copper sulfate solution, the aqueous solution of electrolyte contains positively charged copper ions and negatively charged sulfate ions. When DC power is supplied, copper from the anode dissolves into the solution leaving two electrons and forming positively charged copper ions (i.e., $Cu \rightleftharpoons Cu^{2+} + 2e^-$) which migrate toward the cathode where they are deionized and are deposited as copper atoms on the anode. The sulfate ions remain unchanged in quantity during the electrolysis.

$$Cu^{2+} + 2e^- \rightleftharpoons Cu(atom)$$

The overall reaction at the anode is the oxidation of water.

$$2H_2O \rightleftharpoons 4H^+ + O_2 + 4e^-$$

If anode material other than copper is used then concentration of Cu^{2+} ions will decrease and that of H^+ ions will increase with time. To avoid and overcome this state, extra copper sulfate must be added to the solution at particular interval of time and the hydrogen ions must be removed by neutralization with an alkali or by using a buffer solution. In practice, the chemical reaction that occurs near the electrode area are more complicated than that shown in Figure 2. Under the influence of an applied potential, rearrangement of ions near the electrode surface results in an electrical double layer called the 'Helmholtz double layer,' followed by the formation of a diffusion layer as shown in Figure 3. These two layers combined are known as 'Gauy–Chapman layer.' Their process sequence is as follows[4]:

- Migration: the hydrated metal ions in the solution migrate toward the cathode under the influence of the applied current as well as by diffusion and convection.
- Electron transfer: at the cathode surface, a hydrated metal ion enters the diffused double layer where the water molecules of the hydrated ion are aligned. Then the metal ion enters the Helmholtz double layer where it is deprived of its hydrate envelope.
- The dehydrated ion is neutralized and adsorbed on the cathode surface.
- The adsorbed atom then migrates or diffuses to the growth point on the cathode surface.

3.23.3.2 Factors Affecting Quality of Deposition

In EP process, the measures of deposition quality namely thickness, composition, density, porosity, surface finish, microstructure, micro-hardness, etc., depend on electrolyte related parameters, current characteristics, EP process, and various types of properties of the workpiece (i.e., cathode) material. Figure 4 lists all these parameters. Out of these parameters those affecting the surface finish and density of the deposition are briefly discussed in following paragraphs.

3.23.3.2.1 Effects of current characteristics

Different types of current and their sources are used for EP. Selection of current source depends on the specific requirements and desired surface quality of the end product. Earlier, alternating current (AC) superimposed on DC (Figure 5(a)) was used as the current source for EP applications; but obtained quality of deposition was not as per requirements and standards because it produces uneven depositions with high values of roughness due to nonuniform current distribution which adversely affects the deposition density and surface finish and may also lead to high porosity in the deposition. Consequently, constant DC is the most commonly used current source in EP applications because it helps in producing a smooth and uniform deposition with high deposition rate and very low or almost negligible porosity. Use of constant DC source makes the process faster. Usually rectifiers or motor generators convert AC to DC. Silicon rectifiers are most commonly used for this purpose. Current characteristics depend on type of its waveform. Most commonly used waveforms are sinusoidal, half-wave and full-wave (Figure 5(b)), periodic reverse (PR) and interrupted (Figure 5(c)), unipolar and bipolar (Figure 5(d)), and pulsed and pulse-reverse (Figure 5(e)). Further developments in DC sources are inclusion of short pulse current (PC) and pulsed reverse current (PRC) in which modulated current waveforms are used to provide a better leveling of the deposition, maximize the surface finish and to minimize the porosity, contamination, etc. Complex current waveforms can be generated by using pulse rectifier: unipolar and bipolar pulses. PR under the proper conditions, produces dense fine-grain, striated, leveled, and bright deposition.[5] A typical PR cycle is 15 s plating and

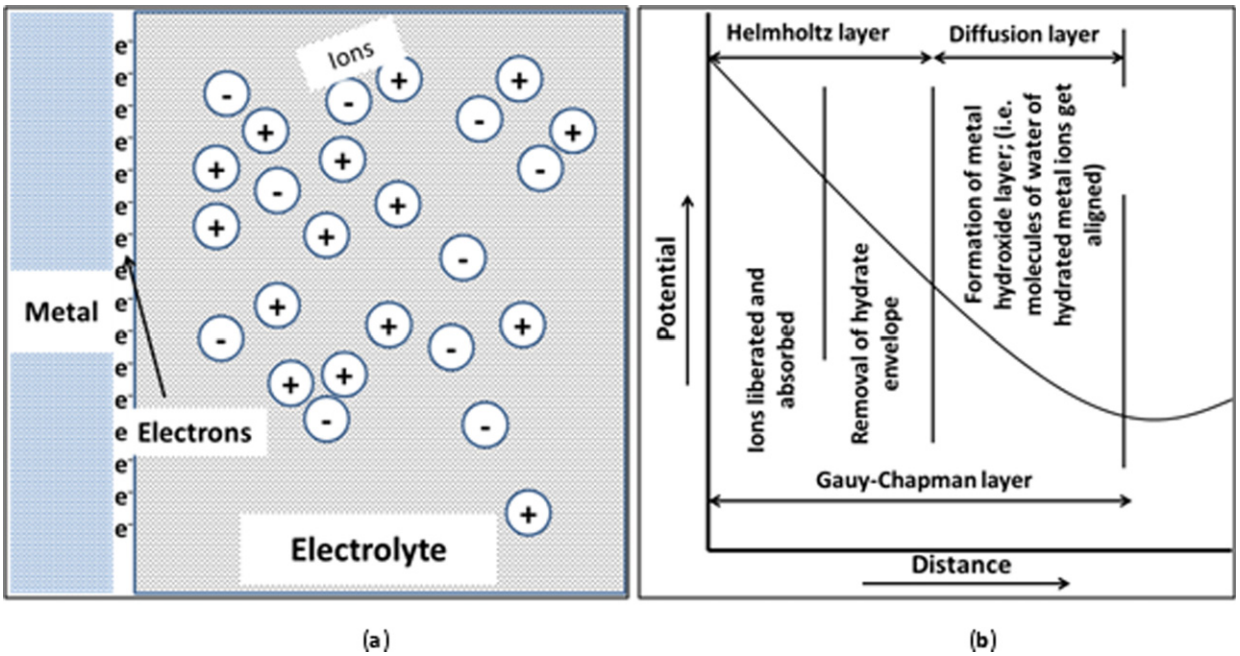

Figure 3 (a) Schematic of ion migrations and (b) graphical representation of Gauy–Chapman layer.

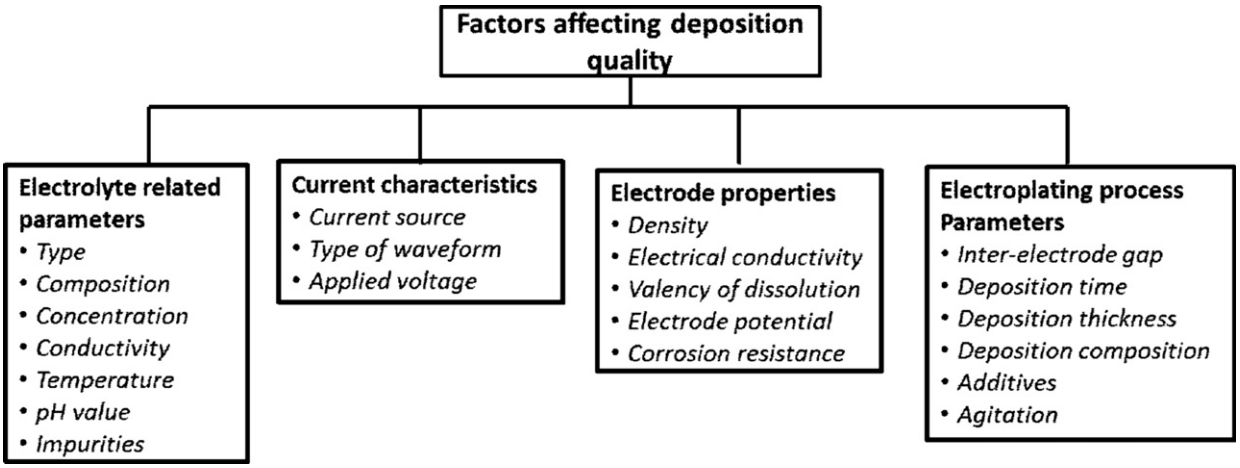

Figure 4 Various parameters affecting deposition quality in the electroplating process.

3 s deplating. Longer the deplating (reversal) cycle, smoother is the deposition.

From the study of effect of pulse power use in EP on current distributions and throwing, it was observed that pulse EP does not affect the primary current distribution, provides less-uniform secondary current distribution, whereas tertiary distribution can be improved by using short-duration high current density pulses as compared to constant DC EP.[5] Deposition quality of some metal and alloy depositions was found to be superior while using pulsed DC than that using constant DC. Some of the advantages of pulse EP are:

- faster deposition rate due to increased permissible current densities,
- denser deposition (i.e., lesser porosity),
- higher purity of deposition and less tendency for impurities to be included in the deposition,
- smoother and finer-grained deposition,
- reduced need or elimination of addition agents,
- less hydrogen evolution thus providing better surface finish and very less hydrogen embrittlement,
- decreased stress in deposition,
- increased Ni or Co contents in alloy-hardened gold deposition with less polymer formation.

3.23.3.2.2 Effects of electrolyte parameters

Electrolyte parameters such as its type, composition, concentration, conductivity, temperature, flow rate, pH value, and impurities greatly affect deposition quality in the EP process.

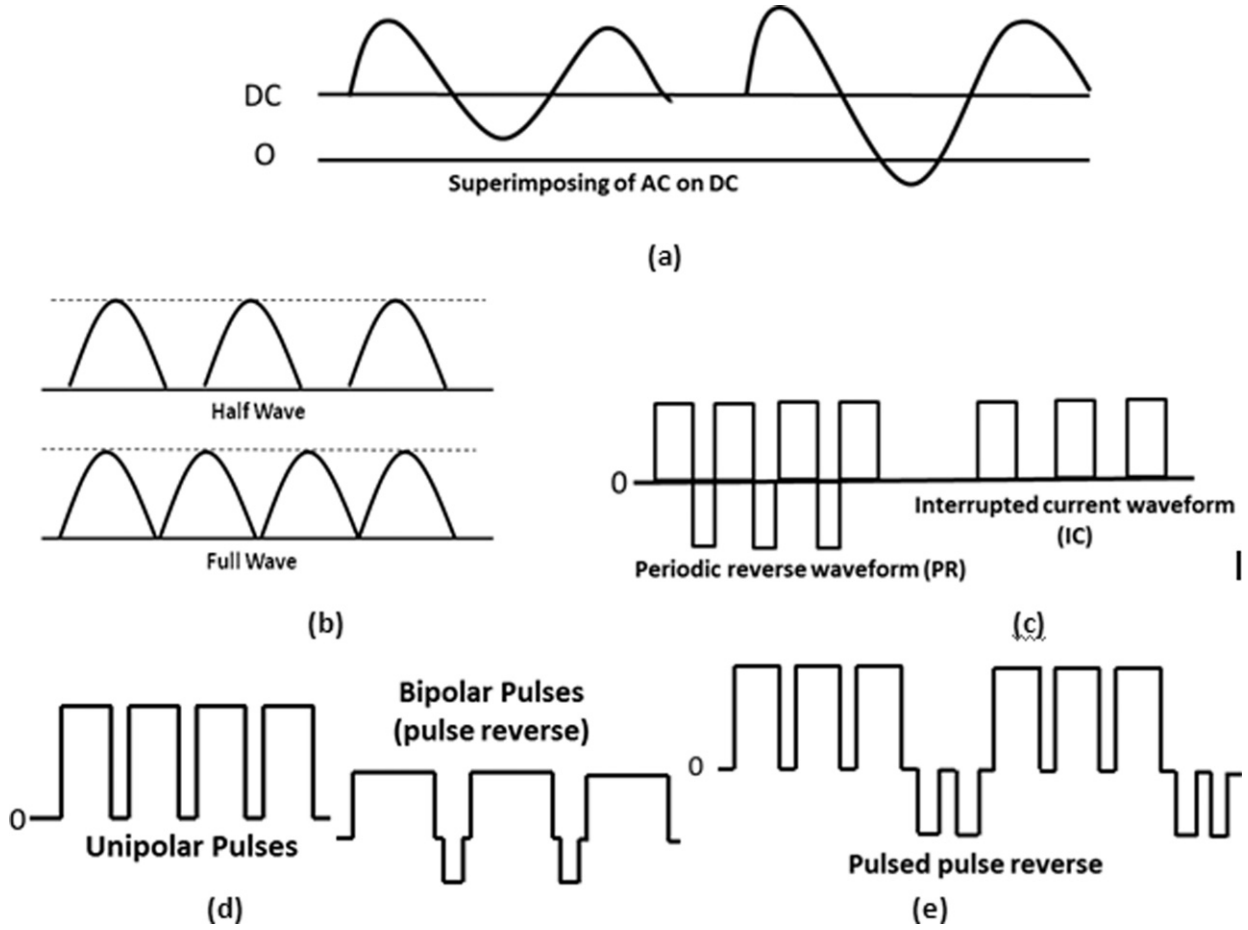

Figure 5 Schematic of different types of electrical waveforms.

Most of these parameters are interdependent and they exert an influence on the structure and functional properties of the deposition. Their accurate prediction is generally very complicated and their optimum ranges can be determined empirically. Type of electrolyte (i.e., salt-based, acidic or alkaline, and passivating or non-passivating) is selected on the basis of physical, mechanical, and electrochemical properties of the electrode material. Role of the electrolyte composition in EP is to facilitate generation and movement of the ions which are to be deposited on the cathodic workpiece and to provide supporting ions. Its other functions are to (1) stabilize the electrolyte, (2) improve electrolyte solution conductivity, (3) to prevent excessive polarization and passivation of the anode, and (4) to provide compatibility with the desired plating conditions. Supporting ions reduces the current shared by the metallic ions or complexes thus making convection (agitation) a more significant factor. EP is mainly dominated by two factors namely, (1) dissolution of the freshly deposited metal atoms on the substrate and (2) formation and absorption of metals hydroxides on the electrode surface.[6] A lower pH value favors the dissolution of freshly deposited material and depresses formation and absorption of the metallic hydroxides. Whereas, higher pH value favors the formation and absorption of metal hydroxides and depresses the dissolution of the freshly deposited metal atoms.

3.23.3.2.3 Effects of EP process parameters

Surface properties of the deposition (i.e., texture, finish, and brightening) by EP are highly affected by the impurities of the electrolytic solution and it is practically impossible to maintain a plating solution free of impurities. This may be due to the fact that the particles deferred in the solution may be attached to the cathodic workpiece surface and resulting in rough and nodular deposition or forming pits if they fall off. Either of these produces adverse effects on surface finish, surface integrity, and corrosion resistance of the deposition.[7] Most common sources of the electrolyte impurities are: impurities in anode, decomposition of additives, dissolution of other deposition chamber parts during EP process, corrosion of auxiliary components of the deposition chamber, improperly cleaned anode and filters, chemicals used for make-up and maintenance, hardness of water, etc. Impurities may lead to poor deposition due to: presence of pitting, poor deposition coverage, poor adhesion, lower cathode efficiency, harder more brittle stressed and darker deposition, cracks in deposition, off-color deposition, etc.[7–11]

Additives are often added to the EP solution to achieve the desired deposition characteristics. They may be organic or colloidal in nature although few of them are soluble inorganic compounds. Their presence might be desired or may be accidental. They are intentionally used to improve the brightening,

leveling, grain-refining, stress-relieving, anti-pitting, etc. of the deposition. Use of additives is found as an important parameter in the EP due to their positive influence on the deposition potential, growth, and structure. Generally, additives promote formation of smooth and shiny coatings and they are added to electrolytic solution in a very small amount. Specific activity of an additive is generally understood in terms of its absorption onto the cathode surface during EP. Additive molecules adsorbed on the cathode surface can affect the activation energy and the rate of charge transfer in the electrochemical reaction and may also influence the mechanism of electrocrystallization.[11,12] They affect the physical and mechanical properties of the deposition. For example, efficiency of the EP process and the characteristics of the Zn–Fe deposition can be improved by employing additives such as glycerin in the plating bath.[13] Recently, various complexing agents such as citrates, tartrates, fluoborates, sulfamates, gluconates, and glycinates have been used. These agents are nontoxic, easily available and their effluent treatment is easier upon degradation.[13,14]

3.23.3.3 Selection of Deposition Material

Selection of suitable coating or deposition material requires understanding and knowledge of the different deposition materials and their properties. Deposition material is chosen primarily on the basis of function and application requirements of the end product. Other factors namely shape, size, product life, cost, wear and corrosion resistance, and operating environment are also to be considered. **Tables 2** and **3** present summary of different metals and alloys along with their applications according to different characteristics of deposition by the EP process. **Table 4** presents comparison of different deposition characteristics for most commonly used depositions by the EP process.

3.23.3.4 Advantages

- Improved corrosion resistance.
- Improved wear resistance.
- Excellent finish and shining.
- Hazardless process.
- Pollution-free process.
- No hydrogen embrittlement.
- No effect on fatigue life.

3.23.3.5 Limitations

- High capital cost.
- Coating on internal diameters cannot be done.
- More time consuming process.
- Plating may not be uniform.

3.23.3.6 Applications

EP is used in many diverse industries including home appliances, jewelry, automotive, aircraft, aerospace, and electronics for both decorative and engineering applications. Purpose of decorative plating is to provide an excellent durability (i.e., surface integrity, and corrosion and wear resistance) and high quality of surface finish and aesthetic properties to the surface of manufactured products by adding a protective layer of different materials. Although, decorative applications have diminished somewhat primarily due to added expenses and problems associated with plant effluent (pollution) control and waste treatment, but its applications in engineering, electroforming, and electronics have increased.[14–17]

- Decoration: coating a more expensive metal onto a base metal surface in order to improve the appearance. Applications are jewelry, furniture fittings, hardware, and tableware.
- Protection: corrosion-resistant coatings such as chromium plating of automobile parts and domestic appliances, zinc and cadmium plating of nuts, screws, and electrical components.
- Wear-resistant coatings such as nickel or chromium plating of bearing surfaces and worn shafts and journals.

Table 2 Summary of different metals and their applications according to characteristics of deposition by the electroplating process

Deposition characteristics	*Metal*	*Applications*
Corrosion resistance	Zn, Cd	Sacrificial coatings, fasteners, and hardware fittings
	Sn	Food containers
	Ni, Cr	Food processing equipment requiring wear resistance
Wear resistance	Ni, Cr, E–Ni,	Aerospace, space, and hydraulics
	Rh, Au	Electronic contacts
High temperature oxidation resistance	Cr, Rh, Pd, Pt	Avionics
Diffusion barrier	Au, Ni	Electronic devices
Decorative	Cu/Ni/Cr	Household appliances and automotive trim
	Ag, Au, Rh	Jewelry
Reflectors	Ag, Rh, Cr	Visible light reflectors
	Au	Infrared reflectors
Soldering and bonding	Pb, Sn, Pb, Cu, Ag, Au	Containers, printed circuits, and other electronic
	Sn, Cd, Ni	Assemblies and chassis
Electroforms	Ni, Cu, Fe, Cr, Co	Radar plumbing, screens, bellows, containers, and molds
Dielectrics	Al,Ti, Ta	Condensers and capacitors coatings

Table 3 Summary of different alloys and their applications according to characteristics of deposition by the electroplating process

Deposition characteristics	*Alloy*	*Applications*
Corrosion and wear resistance	Ni–P, Sn–Ni, Sn–Pb	Avionics, computer hard disks, printed circuits boards, electronic assemblies, assemblies and chassis, bearings, corrosion-resistant coatings, and solderable coatings
Decorative and wear resistance	Au–Co, Au–Ni	Jewelry hardened gold alloy deposition for electronic contacts and components with high wear rate
Electroforms and decorative	Co–Ni	Molds for plastics, screens, bellows, and containers
Decorative	Ni–Fe, Cu–Zn, Cu–Sn	Rubber bonding, antique, household appliances, and automobile accessories

Source: Schwartz, M. Deposition from Aqueous Solutions: An Overview. In *Deposition Techniques for Films and Coatings*, 2nd ed.; Bunshah, R. F., Ed.; Noyes Publications: Park Ridge, NJ, 1994; pp. 480–590.

Table 4 Comparison of different deposition characteristics for most commonly used deposition materials by the electroplating process

Deposition characteristics	*Copper deposition*	*Nickel deposition*	*Chromium deposition*	*Nickel and chromium deposition*	*Remarks*
Thickness range (μm)	12.5–500	12.5–500	12.5–500	12.5–500	Grinding required over 200 μm thickness
Hardness (HV)	60–150	200–300	850–950	850–950	Indicates abrasive wear resistance
Corrosion resistance	Very poor	Very good	Poor	Very good	Minimum 50 μm thickness of Ni is required
Low friction anti-stick	Poor	Poor	Excellent	Excellent	Indicates adhesive wear resistance
Resistance to impact	Medium	Very good	Medium	Very good	Thin coats and soft substrates prone to damage
Maximum working temp. (°C)	50	650	650	650	–
Covering complex shapes	Medium	Medium	Very poor	Medium	–
Nontoxicity	Excellent	Very good	Very good	Very good	–
Cost for given thickness	Low	Medium	High	Very high	Depends on shape and size
Typical applications	Lubricant in forming, Heat sink, and selective case hardening	Below or in place of Cr in corrosive condition and printing surfaces	Molds, tools, valves, rams, pistons, shafts, gauges, dies, and saw blades	Marine cranes, hydraulic rams, mine roof supports, and print rolls	–

- Electroforming: manufacture of sieves, screens, dry shaver heads, record stampers, molds, and dies.
- Enhancement: coatings with improved electrical and thermal conductivity, solderability, reflectivity, etc.
- Other applications of EP include salvage of mismachined or worn-out parts and other types of reworking as well as material savings.

3.23.4 ECM

Material removal processes are the most versatile manufacturing process and play a vital role in giving shape to different engineering components. Increased use of high strength and tough materials such as titanium alloy, superalloys, copper, beryllium, etc. in a variety of industries ranging from aerospace to biomedical engineering, found conventional material removal processes to be inefficient in machining these materials and their use may lead to subsurface damage to the workpiece and tool. Conventional machining processes are also found be ineffective in manufacturing the complex and miniature components due to the limited tool size and geometrical limitations. Another limitation with the tools used in the conventional machining processes, is that they may leave rough surfaces or burrs on the machined surface. These roughness and burrs on the machined surfaces are undesirable in most of the engineering applications. For example, in the auto vehicles and other motion machine elements, the roughness in components may cause high noise and vibration and even the parts may lead to premature failures. In biomedical instruments presence of even very small burrs will damage living tissues where these machined parts are used as

implants. In the electronic devices, where a number of components are in close contact, the burrs may lead to short circuits.[18] Limitations of conventional machining processes necessitates the need of an alternative and advanced machining process which is capable of machining the material of any hardness without giving any undesirable effects on the workpiece surface. ECM is emerged as a strong alternative for all the conventional machining process.

3.23.4.1 Working Principle of ECM and Pulsed-ECM

ECM is controlled dissolution of anodic workpiece through electrolysis process governed by Faraday's law of electrolysis. It can be considered as reverse of EP process with certain modifications. In this process, approximately complementary image of cathodic tool is reproduced on the anodic workpiece dissolving it electrolytically but without any deposition in the cathode. It can be used for machining of any electrically conductive material irrespective of its hardness. Figure 6 depicts schematic of a simple ECM setup. It generally uses low value of DC voltage in the range of 8–30 V applied between the anode and a pre-shaped cathode separated by a very small (usually in the range of 0.1–1.0 mm) IEG thus producing a high current density in the range of 10–100 A cm^{-2}. Generally, salt-based electrolytes such as NaCl, $NaClO_3$, $NaNO_3$, or their combination is supplied through the IEG to dissolve the anodic material under the influence of high current density. Products of electrochemical reaction (usually gases and sludge in the form of metal oxides) are flushed away from the IEG by making electrolyte to flow at a rate in the range of 10–50 liter per minute (lpm). The anodic dissolution rate referred as material removal rate (MRR) is governed by Faraday's laws of electrolysis and it depends on the electrochemical properties of the workpiece material, electrolyte properties, and electric current/voltage supplied. Schematic of mechanism of material removal in ECM is presented in Figure 7. There are several process configurations that can be selected based on the requirements and the capabilities of the machine. The various configurations are[18–20]:

- Both the tool and the workpiece are stationary.
- The tool is given linear and rotary motion while the workpiece is stationary.
- Both the tool and the workpiece move.

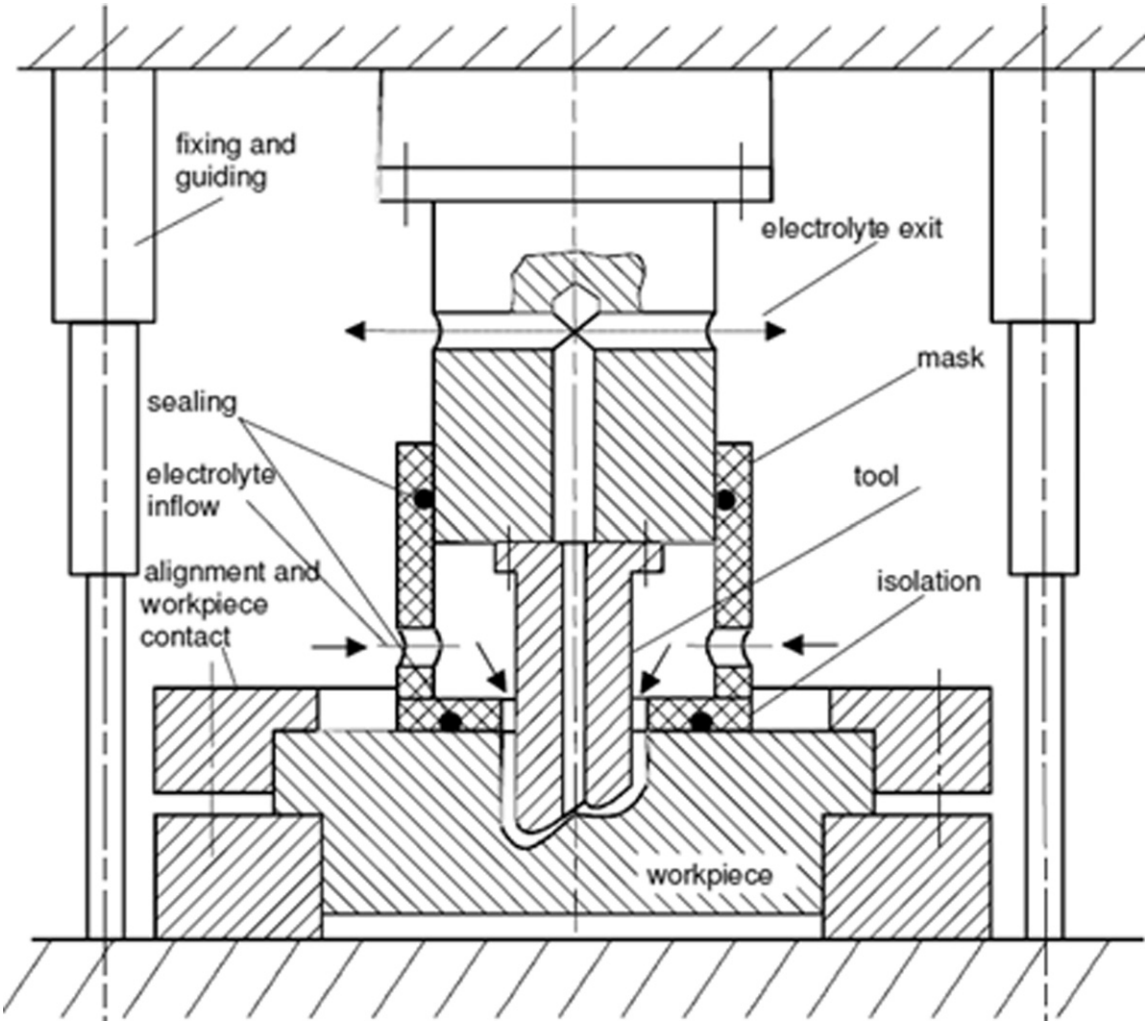

Figure 6 Schematic of a simple electrochemical machining setup.

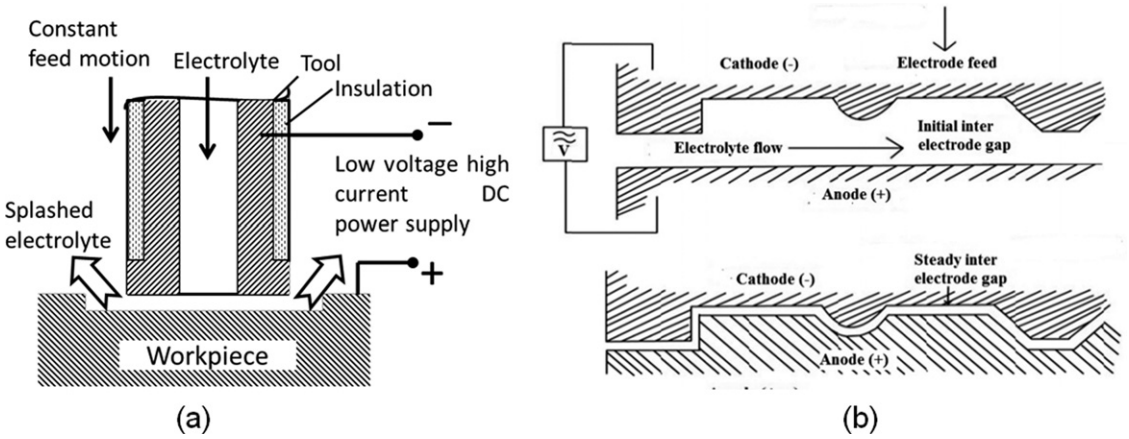

Figure 7 Schematic diagram of (a) working principle and (b) generation of shape on anodic workpiece, in the electrochemical machining process.

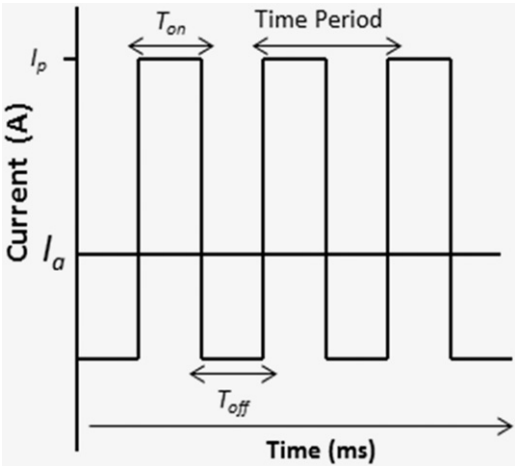

Figure 8 Waveform of the pulsed current.

Further research and development on ECM process and on its derived and hybrid processes are continuing to meet various end product requirements. Pulse electrochemical machining (PECM) is a derived version of ECM in which current is supplied using a pulse generator in the form of short current pulses across the two electrodes. In constant-power ECM, only two parameters related to DC power supply namely current (I) or current density (J) and voltage (V) are the controllable variables. But in PECM, two more additional parameters out of three parameters related to pulsed DC power supply (i.e., pulse-on time '$T_{on,}$' pulse-off time '$T_{off,}$' and duty cycle 'ξ') are also controllable variables. Duty cycle is defined as the ratio of pulse-on time to the total pulse time (eqn. [2]) and is found to have huge impact on the surface quality of the workpiece. A simple waveform of pulsed current is shown in Figure 8. In PECM process, products of electrochemical reaction are flushed away from the IEG during the pulse-off time (T_{off}) which helps in maintaining the clean environment in IEG thus helping electrochemical dissolution to continue resulting in more effective and efficient material removal.

$$\text{Duty cycle}(\xi) = \frac{T_{on}}{T_{on} + T_{off}} 100\% \qquad [2]$$

Introduction of pulse-on and pulse-off times in the ECM leads to higher machining accuracy, better process stability, and suitability for control. These advantages are due to the improved electrolyte flow conditions in the IEG, enhanced localization of anodic dissolution, and small and stable IEG. Although, use of pulsed current slows down the overall process as compared to constant DC supply-based ECM process, but the process becomes more effective as better surface finish and better geometric accuracy can be achieved by PECM.[21]

3.23.4.2 Material Removal in ECM Process

Theoretical expressions for machining time, gravimetric, volumetric, and linear MRR, and current density 'J' in the IEG can be evaluated by using the following equations derived from the Faraday's laws of electrolysis and based on the following assumptions[18–20,22,23]:

- Electrical conductivity of the electrolyte in the IEG remains constant.
- Electrical conductivities of the tool (cathode) and workpiece (anode) are very large ($10^5\ \Omega^{-1}\ \text{cm}^{-1}$) as compared to that of electrolyte ($0.1–1.0\ \Omega^{-1}\text{cm}^{-1}$). Therefore, surfaces of electrodes can be considered as equipotential surface.
- Effective voltage working across the electrodes is $(V - \Delta V)$. Where, ΔV is the total overvoltage at anode and cathode and it is assumed to remain constant.
- Anode dissolves at one fixed valency of dissolution.

$$\text{Machining time} = T_m = \frac{m}{I}\left(\frac{ZF}{M}\right)(\text{seconds}) \qquad [3]$$

$$\text{Gravimetric material removal rate} = Q_g = \eta\left(\frac{M}{ZF}\right)I(\text{g s}^{-1}) \qquad [4]$$

$$\text{Volumetric material removal rate} = Q_v = \eta\left(\frac{M}{ZF\rho_a}\right)I(\text{mm}^3\ \text{s}^{-1}) \qquad [5]$$

Where, η is the current efficiency; ρ_a is the density of the anode material (g mm^{-3}). Ohmic resistance of the electrolyte in the

IEG 'R' is given by

$$R = \frac{\sigma_e Y}{A_p} = \frac{Y}{K_e A_p}\,(\text{Ohm}) \quad [6]$$

Here, σ_e is electrical resistivity (Ω mm) of the electrolyte; K_e is electrical conductivity of the electrolyte ($\Omega^{-1}\,\text{mm}^{-1}$); Y is IEG (mm); A_p is the projected area of the tool face (mm^2), i.e., common area through which current is flowing. Current density in IEG is given by:

$$\text{Current density} = J = \frac{I}{A_p} = \frac{1}{A_p}\,\frac{(V-\Delta V)}{R} = \frac{K_e(V-\Delta V)}{Y} \quad [7]$$

$$\text{Linear material removal rate or penetration rate} = Q_l = \eta\left(\frac{M}{Z\rho_a \text{F}}\right)J \;\; (\text{mm s}^{-1}) \quad [8]$$

Actual rate of change of IEG $\frac{dY}{dt}$ is equal to difference in linear MRR and tool feed rate, i.e.,

$$\frac{dY}{dt} = Q_l - f = \eta\left[\left(\frac{M}{Z\rho_a F}\right)K_e(V-\Delta V)\right]\frac{1}{Y} - f \;\; (\text{mm s}^{-1}) \quad [9]$$

Under the equilibrium condition in the ECM process, the penetration rate 'Q_l' equals to tool feed rate 'f,' i.e., IEG does not change with time. This can be used to obtain expression for equilibrium IEG 'Y_e' from eqn [9] yielding,

$$Y_e = \eta\left[\left(\frac{M}{Z\rho_a \text{F}}\right)K_e(V-\Delta V)\right]\frac{1}{f} \quad [10]$$

3.23.4.3 Factors Affecting the ECM Process Performance

MRR, surface finish, and geometric accuracy of the components machined by ECM depends on parameters related to electrolyte (i.e., type, composition, concentration, temperature, flow rate, pressure, and pH value), properties of the workpiece material (electrochemical equivalent, valency of dissolution, electrode potential, electrical conductivity, and density), ECM process parameters (i.e., IEG, type of power supply, current density, and voltage), and tool design. Following paragraphs discuss them briefly.

3.23.4.3.1 Electrolyte related parameters

Electrolyte is the most important element of ECM system. Generally, an aqueous solution of an appropriate electrolyte is supplied through the IEG at the required flow rate. Main functions of the electrolyte flow are (1) to provide ideal conditions for the electrochemical dissolution of the workpiece material without depositing it on the cathodic tool; (2) flush away the products of ECM formed due to electrochemical reactions (i.e., metal hydroxides and reaction gases); (3) to take away the heat generated due to passage of current and may be due to electrochemical reactions thus maintaining a constant temperature in the IEG; (4) not allowing concentration of ions on the electrodes; and (5) not to allow oxygen evolved at anode to passivate it by forming metal oxides. **Table 5** presents summary of different role/functions of an electrolyte and the required electrolyte property to fulfill each function.

Table 5 Functions and required property of an electrolyte in electrochemical machining process.[18,19,22]

Role or function of electrolyte	*Required electrolyte property*
To complete the electrical circuit and allow large currents to pass	Large electrical conductivity
To sustain required electrochemical reactions	Electrolyte should be such that anode material is continuously dissolved but it is not deposited on the cathode
To carry away the heat generated in the machining zone	Higher specific heat and lower viscosity
To carry away the waste or the materials removed	Good chemical stability
Economics and safety of machining process	Low density, noncorrosive, nontoxic (safe), and inexpensive

Electrolytes used in ECM can be classified as (1) sludging electrolytes, or (2) non-sludging electrolytes. Sludging electrolytes are those which form precipitates as product of electrochemical reactions which remove material from the anodic workpiece, while non-sludging electrolytes dissolve the products of electrochemical reactions. Generally, salt-based electrolytes (i.e., NaCl, $NaNO_3$, $NaClO_3$, KCl, KNO_3, etc.) are sludging electrolytes whereas acidic electrolytes (i.e., HF, HCl, HNO_3, H_2SO_4, etc.), and alkaline electrolytes (i.e., NaOH, KOH, NH_4OH, etc.) are non-sludging electrolytes. Consequently, sludging electrolytes can be reused by filtering them properly and then recirculating them whereas non-sludging electrolytes cannot be reused. Electrolyte can also be classified as passivating and non-passivating electrolytes. Passivating electrolytes contain oxidizing anions such as sodium nitrate ($NaNO_3$) whereas non-passivating electrolytes contain aggressive anions such as sodium chloride. Passivating electrolytes are known to provide better machining quality due to formation of protective oxide layer and oxygen evolution in stray current region.[24,25] Additives such as sodium tartrate, glycerin, and glycol are used to get better results.

In the ECM-based processes, movement of the ions from the cathode toward anode depends on the properties of the electrolyte. Electrolyte conductivity in the IEG is affected by various parameters namely; (1) initial value of IEG, (2) electrolyte concentration, (3) local hydroxide concentration in the electrolyte, (4) bulk and local temperature, and (5) electrolyte pressure and flow rate.[24,26] Selection of an appropriate electrolyte for a particular application depends on the following considerations[27,28]:

- nature of the workpiece material,
- surface finish and dimensional tolerance requirements, and
- required productivity.

Table 6 presents the most commonly used type of electrolytes for different types of alloys. Aqueous solution of $NaNO_3$, NaCl or $NaClO_3$, or their combinations are the most commonly used electrolytes due to the following facts:

- Sodium chloride (NaCl) is more corrosive but its conductivity is very stable over a wide range of pH values.

Table 6 Commonly used type of electrolytes for different alloys[18,19]

Type of alloy	*Preferable electrolytes*
Iron-based alloys	$NaNO_3$, $NaClO_3$, or NaCl
Co–Cr–W-based alloys	NaCl
Ni-based alloys	HCl or mixture of brine and H_2SO_4
Ti-based alloys	10% HF + 10% HCl + 10% HNO_3
WC-based alloys	Strong alkaline solutions

- Sodium nitrate ($NaNO_3$) is less corrosive but it creates a strong passivation layer on the workpiece, due to which less MRR is found in comparison with NaCl. Due to less dissolution of anodic workpiece material better smoothness can be achieved. Also, the electrolytic reactions require higher voltage when using strong passivating electrolyte.

MRR increases with increase in the electrolyte concentration because more ions will be available in the electrolyte solution which increases electrolyte conductivity in IEG enhancing anodic dissolution of the workpiece material. Therefore, concentration of electrolyte should be high but higher concentration may increase passivation effect. Electrolyte conductivity is very sensitive toward electrolyte temperature and increases with it. Electrolyte temperature rises across the IEG due to the use of high current density in IEG. It affects the surface finish and geometric accuracy of the workpiece adversely and may also stop the further machining action in an abrupt manner. Also, higher electrolyte temperature may increase the passivation effect. Electrolyte flow rate is another important parameter to control and optimize the electrolyte conductivity in the IEG. It is a difficult task to maintain the flow of electrolyte in the extremely small IEG without affecting the tool stability.[18–20]

3.23.4.3.2 IEG

Face width of tool electrode and its position with respect to the workpiece determines the IEG between them which is in range of fraction of millimeter. Higher value of IEG necessitates use of higher applied voltage to maintain the required current density in the IEG for the controlled anodic dissolution of workpiece material; but use of higher voltage may give poor surface finish and geometric accuracy. Use of small IEG causes anodic dissolution of workpiece to occur at lower voltage which results in very good surface finish and geometric accuracy; but maintaining small IEG is very difficult and also flow of electrolyte through it because chances of short-circuiting and clogging are very high in a small IEG. Therefore, value of IEG needs to be maintained accurately because any abnormal change in IEG may give poor surface quality of the machined component.[29]

3.23.4.3.3 Current density and voltage

Either constant DC power supply (in ECM) or pulsed DC power supply (in PECM) can be used in ECM-based processes. Constant DC power supply provides continuous current or voltage whereas pulsed power DC supply is used to supply current or voltage in the form of short pulse with specific pulse-on time and pulse-off time. MRR is proportional to the applied voltage. From eqn [5] it can be seen that on increasing the value of voltage the current density will increase which leads to provide a higher MRR. Use of PC has the following advantages [26,30]:

- The sludge products generated from anodic dissolution of workpiece material can be removed during the pulse-off time because formation of the sludge in the narrow IEG might lead to clogging and deposition on the tool which will have an adverse effect on the ECM process.
- It prevents the electrolyte from reaching high temperatures. The use of sufficient pulse-off time allows it to cool down.
- Gap checking and tool repositioning can also be conducted during these pulse pauses to establish the required IEG value before next pulse is on. This leads to significant reduction in the indeterminacy of the IEG and shaping accuracy in the ECM process.

3.23.4.3.4 Mass transport phenomenon in ECM

Mass transport phenomenon plays very important role in controlling the anodic dissolution of workpiece material and in achieving desired level of surface quality because it affects the current density distribution at macroscopic and microscopic levels. Controlled dissolution by mass transport smoothens the surface because IEG at peaks of a surface is smaller than the IEG at the valleys giving more current density and more material removal from the peaks than the valleys (this is referred as 'leveling effect').[24] The anodic leveling can be achieved by three types of nonuniform current distribution, i.e., primary current distribution (Ohmic), secondary current distribution (kinetic), and tertiary current distribution due to nonuniform local mass transport.[25] In ECM, effect of secondary current distribution is negligible if sufficient IEG and electrolyte flow velocity are maintained. Therefore, primary and tertiary current distributions mainly contribute toward smoothening of the workpiece surface. Moreover, influence of the charge transfer kinetics is negligible and differences due to grain orientation, grain boundaries, dislocations, or small inclusions do not play any significant role because of controlled limiting current by mass transport. As a result, material removal at molecular level results in a very smooth surface topography (brightening effect).[24–26]

3.23.4.4 Capabilities of ECM and Its Effects on Workpiece Material

The capabilities of ECM can be judged by knowing its finishing, drilling and cutting capabilities, and its environmental and economic prospects. Table 7 presents the capabilities of ECM process and it can be observed that high geometric accuracy and finishing can be achieved by ECM.

Following are the effects of ECM on the workpiece material:

- Material removal in ECM is smooth and gentle as compared to conventional machining process.
- No effect of ECM on ductility, yield strength, ultimate strength, and micro-hardness of electrochemically machined components.

Table 7 Capabilities of electrochemical machining process

Type	*Capability/characteristics*		*Common value/range (attainable)*
Finishing capabilities	Surface roughness [R_a in μm]		0.4–6.3 (0.05)
	Dimensional tolerance or accuracy [±μm]		50–125 (10)
	Minimum corner radii (mm)		0.2 mm
	Minimum overcut (mm)		0.12 mm
	Minimum surface damage (μm)	Chemical damage	No
		Mechanical damage	No
		Thermal damage	No
Drilling capabilities	Hole diameter (mm)		6.3–75 (3.17)
	Aspect ratio		8
	Hole depth (mm)		127 mm (305)
	Minimum taper (μm/mm)		25
	Maximum number of holes that can be drilled simultaneously		100
	Minimum angle of inclination hole axis with surface		90°
Cutting capabilities	Width of cut (mm)		3.17
	Thickness of cut (mm)		Up to 127 mm
	Range of cutting rate (mm/min)		2.5–12.5
Economic aspects	Initial investment or capital cost		Very high
	Tooling and fixtures cost		Medium
	Power consumption cost		High
	Tool consumption cost		No tool wear
Environmental aspects	Safety		Normal problem
	Toxicity		Normal problem
	Contamination of machining medium		Critical problem

- Depth of work hardened surface in ECM is negligible (approximately 0.001 mm) as compared to turning (0.5 mm) and milling (1.5 mm).
- Hardly any evidence is available about hydrogen embrittlement of electrochemically machined components.
- ECM produces almost stress-free surface.
- Surface finish produced by ECM exhibit better wear resistance, friction resistance, and corrosion resistance than those produced by other processes.
- Compressive residual stresses, that are responsible for higher fatigue strength are very low in ECM process as compared to conventional machining process (approximately 50 kg mm^{-2}). This results in 10–25% lower fatigue strength in the electrochemically machined components.
- Removal of compressive stress layer is primarily responsible for reduction in fatigue strength of electrochemically machined components. Secondary reasons include intergranular attack (IGA) and exposition of micro-cracks and pits at the surface.
- Required fatigue strength can be achieved by some appropriate post-ECM treatment such as mechanical polishing, glass bead blasting, vapor blasting, etc.

3.23.4.5 Advantages

- Performance of ECM is independent of mechanical properties of the workpiece material. Therefore, strength, hardness, toughness, etc., do not affect the measures of ECM; performance such as MRR and surface finish;
- produces burr-free and stress-free surfaces;
- no tool wear due to noncontact nature of the process;
- complex three-dimensional products can be fabricated easily due to its copying nature;
- excellent surface finish can be achieved;
- higher MRR as compared to other unconventional machining processes; and
- no subsurface damage.

3.23.4.6 Limitations

- Very high specific energy consumption (approximately 20 times more as compared to conventional machining processes);
- only electrically conducting material can be machined;
- corrosion of the components of ECM machine, workpiece, and tool due to use of electrolytes;
- design and manufacturing of the ECM tool specially for the complex workpiece is very challenging;
- extreme sharp corners that cannot be machined;
- can cause IGA;
- limited aspect ratio;
- very high initial investment cost;
- high maintenance and tooling cost;
- extremely hazardous while using strong acidic electrolytes; and
- disposal of the used electrolyte is challenging.

3.23.4.7 Applications

- ECM finds various applications in different industries for machining of automobile dies, axial flow turbine blades,

axi-symmetric turbine blades, jet engine parts, chain sprockets, biomedical components, components with micro- and nano- holes, etc.
- Machining and finishing of very complex shaped components.
- Manufacturing of components and machine tools with precise geometry and excellent surface finish (up to 25 μin) can be achieved.
- Machining of heat resistant and hard materials.
- For making deep blind holes of micro-size and pockets.

3.23.5 ECG

ECG is a hybrid finishing process combining advantages of ECM and mechanical grinding processes to produce burr-free, stress-free, and super finished components. Figure 9 depicts the schematic of a simple ECG setup in which the abrasive grinding wheel is made as cathode and while the workpiece is made anode using appropriate DC power supply. ECG grinding wheel is similar to a conventional grinding wheel except that its bonding material is electrically conductive. Commonly used bonding materials are copper, brass, nickel, or copper impregnated resin. Abrasive particles protruding outside from the bonding material of the wheel maintain a constant IEG between the grinding wheel and workpiece. Alumina is the most commonly used abrasive with mesh size in the range of 60–80 μm. Grinding is performed as usual but instead of coolant, a spray of electrolyte is supplied by a nozzle. Both mechanical grinding and ECM take place simultaneously and the grinding wheel is sharpened easily and quickly. The electrolyte takes away the heat and the electrochemical reaction products from the machining zone. Mainly sodium chloride and sodium nitrate is used as electrolyte in ECG.

Majority of the material removal (almost 90–95%) is removed by the electrolytic dissolution of the workpiece material. The role of grinding wheel is only to remove the passivation layer of metal oxide formed on the workpiece surface during the electrochemical dissolution process thus contributing 5–10% of the material removal. Due to very less pressure applied on the grinding wheel in ECG process, life of grinding wheel is more than 10 times than the conventional grinding wheel.[18,19] The ECG process can be used in different forms for different purposes namely electrochemical cylindrical grinding, peripheral or surface grinding, face grinding, form wheel or square grinding, cone wheel grinding, and internal grinding. Main parameters that affect performance, efficiency and effectiveness of ECG process are[31,32]:

- applied voltage and current density,
- type, concentration, and delivery method of electrolyte,
- type, speed, pressure, and running accuracy of the grinding wheel, and
- feed rate of workpiece.

Selection of optimum values of these parameters help to optimize surface finish and MRR.

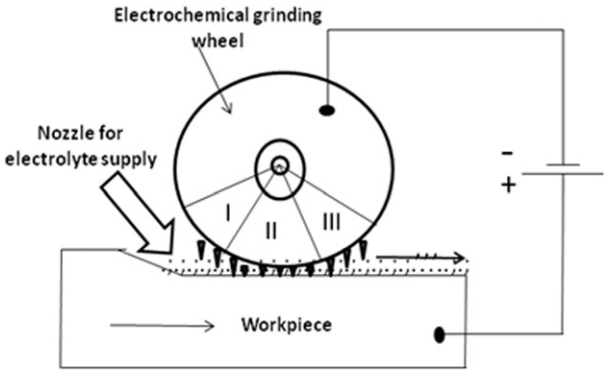

Figure 9 Schematic of electrochemical grinding process.

3.23.5.1 Advantages

- MRR achieved during ECG may be high as 10 times as compared to conventional grinding on hard materials having hardness up to 65 HRC.
- Excellent surface finish under controlled process parameters. Surface finish obtained by ECG ranges from 0.12 to 0.8 μm. Surface finish produced on nonhomogeneous materials during ECG is better than that produced during conventional grinding.
- Minimum inside corner radius of 0.25 mm and outside corner radius of 0.025 mm can be produced by this process.
- No thermal and mechanical damage to workpiece.
- Absence of work hardening.
- No grinding burrs or grind lines over workpiece surface.
- Absence of distortion in thin/fragile/thermo sensitive parts.
- Narrow tolerances can be achieved.
- Longer life of the grinding wheel.
- Relatively small environmental impact because of the reuse of the electrolyte economically viable machining of high grade aerospace components made possible.

3.23.5.2 Limitations

- Process is limited to only electrically conductive materials,
- not suitable for soft materials,
- requires dressing tool preparation for the grinding wheel,
- higher power consumption,
- higher initial investment cost due to specially design and manufacture the grinding wheel, and
- corrosion problem due to use of electrolyte.

3.23.5.3 Applications

- Production of tungsten carbide cutting tools and other tools made of difficult-to-machine materials,
- burr-free sharpening of hypodermic needles,
- grinding of turbine blades made of superalloys,
- form grinding of fragile honeycomb materials used for aerospace applications,
- reprofiling worn locomotive traction motor gear, and
- removal of fatigue cracks from steel structures that have been used for underwater applications.

3.23.6 ECH

ECH is a hybrid superfinishing process which combines capabilities and advantages of ECM with mechanical honing and simultaneously overcoming their individual limitations. Main capabilities of ECM process include: capability to machine/finish material of any hardness, production of stress-free and crack-free surface, higher MRR, and no tool wear. While main capabilities of honing are: ability to correct the geometric errors and controlled generation of functional surfaces. Main limitation of ECM process is passivation of anodic workpiece surface by the metal oxides formed due to evolution of oxygen gas at anode during its electrolytic dissolution. This anode passivation prohibits further electrolytic dissolution of the workpiece. While, major limitations of honing process includes limited life of honing tool, low productivity, incapability of finishing a hardened workpiece, and possibility of mechanical damage (i.e., micro-cracks, hardness alternation, and plastic deformation) to the workpiece material.[33] ECH can be used to correct errors/deviations in geometry/shape such as out-of-roundness or circularity, taper, bell-mouthhole, barrel-shaped hole, axial distortion, boring tool marks, etc., for cylindrical surfaces and ability to correct form errors (i.e., deviations in lead and profile) and location errors (i.e., pitch deviations and runout) for cylindrical and conical gears. Use of pulsed current in the ECH process also helps in enhancing the process performance without requiring higher electrolyte flow rate thus minimizing the size and cost of the equipment for the pulsed-ECH (PECH) processes.[34]

3.23.6.1 Process Principle of ECH

Material removal in ECH is based on a controlled anodic dissolution of workpiece material using a cathodic tool in an electrolytic cell. Generally, a low DC voltage in the range of 8–30 V is applied between anode and cathode separated by a very small value of IEG (usually in the range of 0.1–1.0 mm) which is maintained by the specially designed cathode tool. Current density of the order of 10–100 A cm^{-2} and volumetric MRR in the range of 0.1–1,000 $mm^3\,min^{-1}$ are achieved. Electrolyte should be such that the material removed from the workpiece must not deposit on cathode tool. Products of electrochemical reaction are flushed away from the IEG using an aqueous solution of the salt-based electrolyte such as NaCl, $NaClO_3$, $NaNO_3$, or their combination supplied through the IEG at a flow rate in the range of 10–40 lpm. This helps in maintaining the clean environment in IEG thus helping electrochemical dissolution to continue. The electrolyte flow also takes away the heat generated due to passage of current and possibly due to electrochemical reactions. A passivating layer of metal oxide is generated on the workpiece due to evolution of oxygen at anode which prohibits its further dissolution. Thickness of this protective layer is more at valleys as compared to that on the peaks. The honing tool selectively removes this passivating layer by remaining in continuous contact with the workpiece enabling electrolytic dissolution and mechanical honing to take place simultaneously.[33] Main parameters that affect the performance, efficiency, and effectiveness of ECH process are majorly categorized into three parts, i.e., (1) parameters related to ECM; (2) parameters related to mechanical honing; and (3) parameters related to work material and tooling system. The details these parameters are presented in Table 8.

3.23.6.2 ECH equipment

ECH equipment consists of five subsystems namely (1) DC power supply system; (2) electrolyte supply and cleaning system; (3) specially designed cathode and honing tool; (4) system for providing the required relative motion between the workpiece, cathode, and honing tool; and (5) finishing chamber for housing and holding workpiece, cathode, and honing tool. Out of these subsystems details of DC power supply system and electrolyte supply and cleaning system are similar to those used in the ECM process and described in Section 3.23.4.3. Remaining three subsystems depend on the geometry of the workpiece. These subsystems are described for finishing the internal cylinder and gears in following paragraphs.

3.23.6.2.1 Finishing of internal cylinders by ECH

The tool used for finishing of internal cylinders by ECH is shown in Figure 10. It combines cathode and honing tool in a single unit. It consists of a teflon shaft over which a hollow stainless steel sleeve is fitted. It has even number of equally spaced and radially outward protruding honing sticks on its

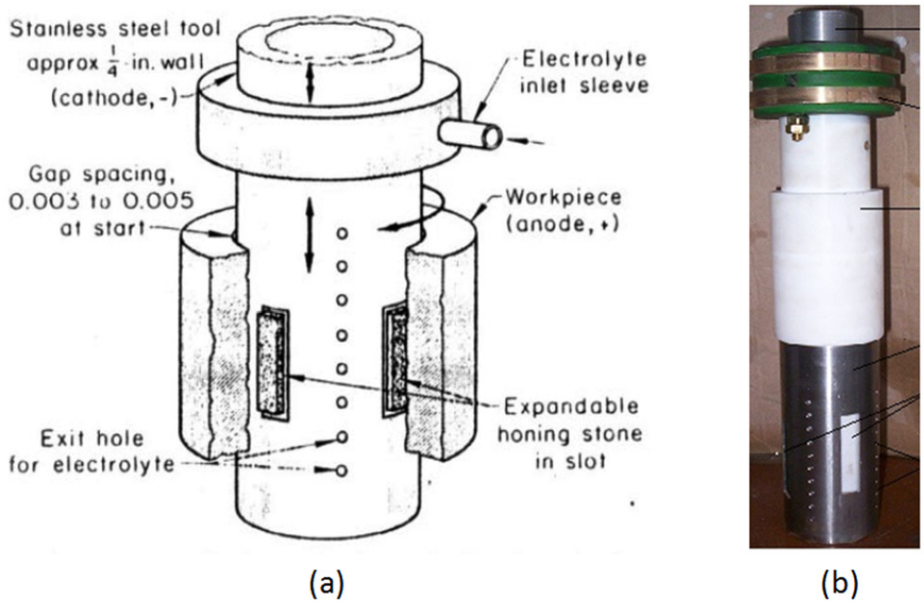

Figure 10 (a) Schematic and (b) photograph of a typical tool for finishing internal cylinders by ECH.[33]

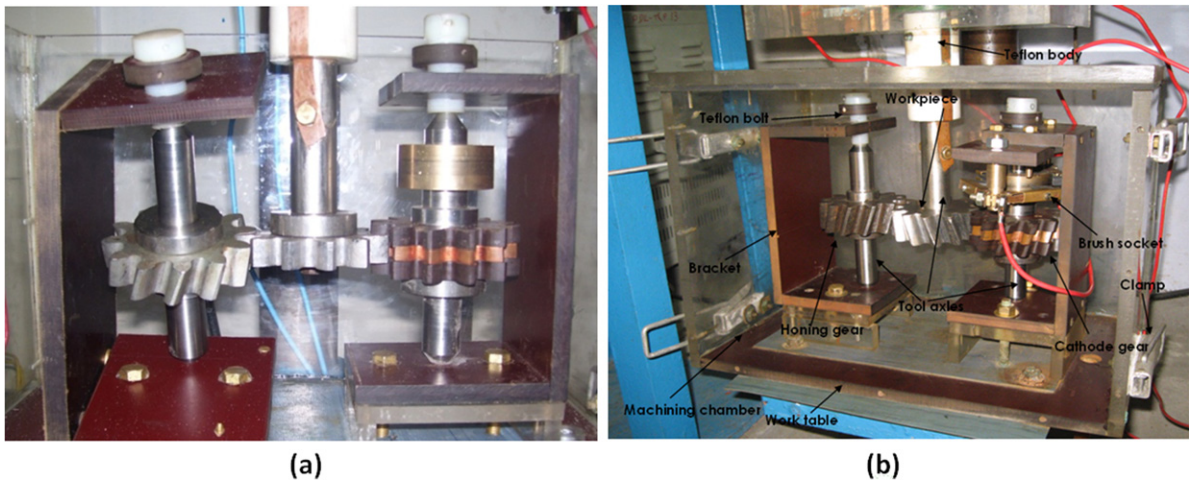

Figure 11 Photographs of machining chamber for high quality finishing of (a) spur gear [35] and (b) helical gear,[36] by the ECH process.

periphery. These sticks are spring controlled which help in adjusting the required honing pressure. These honing sticks act as insulator and amount by which they protrude radially outward determines the IEG between the cylindrical workpiece and the cathode tool. Honing sticks preferentially remove the nonconductive passive layer of metal oxide from the high spots to correct errors or deviations in geometry of the cylindrical workpiece. The electrolyte enters the tool body via a sliding inlet sleeve from which it exits into the IEG through several rows of small holes in the tool body. The electrolyte exits from the top and bottom of the bore. Current is supplied to the tool through a slip-ring copper brush assembly. The tool is provided a precisely controlled combination of rotation and reciprocation simultaneously. Rotary motion is provided by a speed controlled DC servomotor, while reciprocating motion by a microprocessor programmed stepper motor.[33]

3.23.6.2.2 Finishing of gears by ECH

Finishing of gears by ECH requires cathode tool and honing tool to be separate. The workpiece gear meshes with the cathode gear and honing gear simultaneously. Cathode gear is to be specially designed and fabricated in such a way that its electrically conducting portion never touches the anodic workpiece gear thus avoiding short-circuiting and at the same time it maintains the required IEG between the anode and cathode gear. For the cylindrical gears (spur and helical gears) this is ensured by sandwiching a conducting layer between two nonconducting layers and undercutting the conducting layer by an amount equal to the required IEG as compared to the nonconducting layers. The axes of shafts of the workpiece and cathode gears are parallel to each other for finishing the spur and helical gears (Figures 11(a) and 11(b)). The workpiece gear is provided by controllable rotary motion by means of DC

motor while cathode and honing gear rotate by virtue of their tight engagement with the workpiece gear. Since, entire face width of the cathode gear is not electrically conducting therefore a reciprocating motion is also given to workpiece gear by means of a programmable stepper or servomotor to ensure finishing of the entire face width of the cylindrical gear.[35–36] Majority of finishing or material removal is done by the ECM action which occurs between the anodic workpiece gear and the cathode gear while role of the honing action, which takes place between the workpiece and the honing gear, is just to remove selectively the passivation layer of metal oxide formed on the workpiece gear. All the three gears should have same involute profile and same module.

For 'spur gear finishing' by ECH (Figure 11(a)), a helical gear is made as honing gear, it can either be an abrasive impregnated gear or a gear having hardness more than the workpiece gear. It is mounted on a floating stock to ensure dual flank contact between the honing and workpiece gear. The honing gear is mounted in such a way having cross-axis arrangement with the workpiece gear so as to reduce the tooth surface contact and the pressure required for finishing.[35] 'Helical gear finishing' by ECH (Figure 11(b)) does not require the cross-axis arrangement because honing and cathode gears have opposite helix angle to that of the workpiece gear, i.e., if workpiece gear is right-handed helical gear then cathode and honing gears will be left-handed and vice versa.[36]

Finishing of bevel gears by ECH is much more difficult than finishing of cylindrical gears due to their complex geometry which inhibits reciprocation of the workpiece gear required for finishing its entire face width. This problem was solved by Shaikh *et al.*[37] envisaging a novel concept of twin complementary cathode gears as shown in Figure 12(a). In this concept, one of the cathode gears has an electrically conducting layer of copper sandwiched between two nonconducting layers of metalon while, other complimentary cathode gear has a nonconducting layer of metalon sandwiched between two conducting layers of copper. The conducting layers in both the complementary cathode gears are undercut by the required amount of IEG as compared to the insulating layers so as to avoid short-circuiting when these gears mesh with the workpiece gear during the finishing operation. This also ensures that IEG required for electrolytic action is maintained between the workpiece and cathode gears. During the process of anodic dissolution of the workpiece gear material, the electrolyte forms a passivating metal oxide layer on the workpiece gear tooth surface which restricts further finishing by electrolysis action. These passivating layer of metallic oxides generated over the workpiece surface is removed by the honing gear which simultaneously comes in mesh with the workpiece and cathode gears to continue the further finishing by electrolysis action. As the process carries on, the geometric accuracy of the workpiece gear is rapidly improved. Figure 12(b) depicts the photograph of finishing chamber developed by implementing the concept of the twin complementary cathode gears. The tool is provided by a precisely controlled rotation by a speed controlled DC servomotor, while reciprocating motion to the workpiece gear holding shaft for its proper engagement and disengagement with the ECH tools is provided by a microprocessor programmed stepper motor.[38]

3.23.6.3 Advantages

- Material of any hardness (but electrically conducting) can be finished by ECH.
- ECH can achieve surface roughness up to 50 nm and tolerances up to ± 0.002 mm.
- It produces surfaces with distinct cross-hatch lay pattern which is very useful for lubricating oil retention, surfaces with compressive residual stresses required for the components subjected to cyclic loading, and completely stress-free surfaces.
- ECH not only produces high quality surface finish and surface integrity but also has ability to correct errors/deviations in geometry/shape such as out-of-roundness or circularity, taper, bell-mouthhole, barrel-shaped hole, axial distortion, boring tool marks, etc., for cylindrical surfaces and ability to correct form errors (i.e., deviations in lead and profile) and location errors (i.e., pitch deviations and runout) for cylindrical and conical gears.

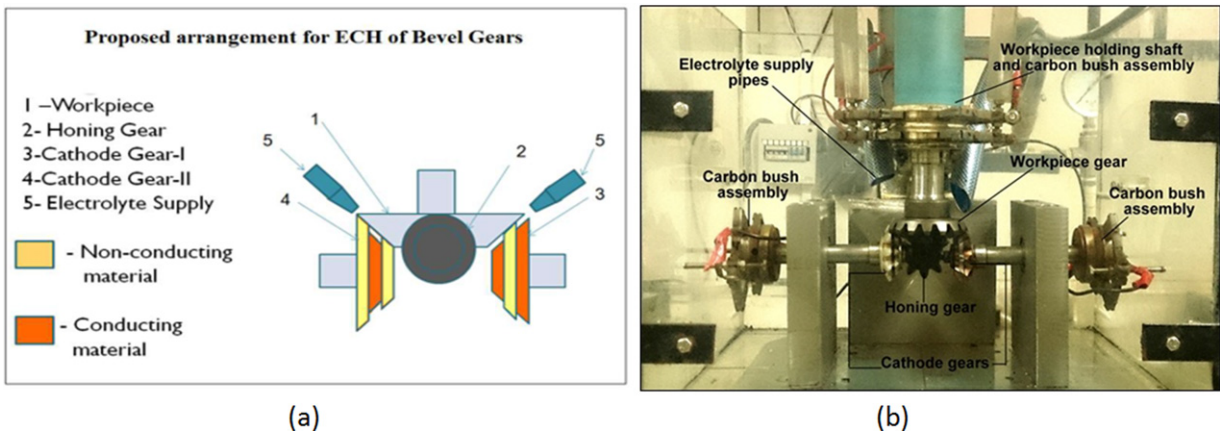

Figure 12 (a) Concept of twin complementary cathode gears for high quality finishing of straight bevel gears by ECH [37] and (b) photograph of the finishing chamber based on this concept.

- It takes less finishing time as compared to ECM and mechanical honing. ECH can finish materials up to 5–10 times faster than mechanical honing and four times faster than internal grinding. Gain is more pronounced for higher material hardness.
- Very less amount of heat is produced thus making it suitable for the processing of parts those are susceptible to heat distortions.
- ECH automatically deburrs the work surface.
- Increased life of abrasive sticks/tool due to very limited role of mechanical honing.
- There is less distortion while finishing thin-walled tubes due to less pressure required between work surface and the honing tool.
- As a by-product, sharp or burred edges of a cross-holes or other intersections which break into the bore are automatically deburred as the main hole is being finished by ECH.

3.23.6.4 Limitations

- It can be used for finishing electrically conductive materials only.
- It is more costly than the mechanical honing due to its electrical, fluid handling elements, need for corrosion protection, costly tooling, and longer setup time. This makes ECH more economical for longer production runs than for tool room and job-shop conditions.
- Difficult to finish the blind holes.
- ECH cannot correct location of hole or perpendicularity.

3.23.6.5 Applications

- ECH can be used to finish the various hard to finish materials such as cast tool steels, high-alloy steels, carbide, titanium alloys, Incoloy, stainless steel, Inconel, and gun steels.
- ECH is an ideal choice for superfinishing, improving the surface integrity, and increasing the service life of the critical components such as internal cylinders, transmission gears, carbide bushings and sleeves, rollers, petrochemical reactors, molds and dies, gun barrels, pressure vessels, etc., which are made of very hard and/or tough, wear-resistant materials, most of which are susceptible to heat distortions.
- ECH is widely used in automobile, avionics, petrochemical, power generation, and fluid power industries.
- It has been used for bore size ranging from 9.5 to 300 mm and length up to 600 mm.

3.23.7 ECDe

Burrs are sharp edged thin crests generally of triangular shape and developed along the edge of a workpiece during various manufacturing operations such as machining, forging, trimming, casting, etc. Burrs may lead to noise generation, hazardous operation of a machine generates friction and wear in the moving parts and it may also affect the fatigue and service life of the component. There are many types of burrs produced by different manufacturing and finishing processes namely: compressive burr, corner burr, edge burr, entrance burr, exit burr, feather burr, flash burr, hanging burr, parting-off burrs, roll over burr, and tear burr.[23] Different type of deburring processes can be classified as mechanical, thermal, abrasive, and electrochemical. The most frequently used method is mechanical. Mechanical deburring is typically carried out manually by a skilled worker resulting in low productivity and higher cost. In thermal deburring, the process difficulties can be eliminated because the workpiece is subjected to a temperature in excess of 1000 °C for few seconds, causing the burrs to ignite and burn-off. The thermal deburring processes require high capital investment and have some technical problems. Typical abrasive deburring processes use abrasive jet, water jet, abrasive water jet, barrel tumbling, spindle finishing, or sand blasting. Due to the higher initial cost and lack of adequate technical data, the use of abrasive jet deburring is also limited.

3.23.7.1 Mechanism of ECDe

ECDe is based on the principle of the anodic dissolution of workpiece material in an electrolytic cell. Figure 13 show the typical arrangement for ECDe for cylinders in which the section of the workpiece which is to be deburred is made anode while the specially designed tool used to deburr the workpiece is made cathode. Those surfaces of the tool where deburring is not required are insulated. In ECDe the IEG between the burrs and the cathode is minimum which results in higher current density helping in faster anodic dissolution of the burrs. When a suitable DC current (50–500 A) is supplied, the burr dissolves forming a controlled radius. During an electrochemical action, current density at the peak of surface irregularities is higher than that elsewhere. Burrs are therefore removed preferentially and the workpiece becomes smooth.[18,39] The deburring tool should also have a similar contour as that of the workpiece thus maintaining an IEG in the range of 0.1–0.3 mm. Use of a rotating and feeding tool electrode enhances the deburring process by creating turbulent flow in the IEG. The spindle rotation is reversed to increase the electrolyte turbulence. Choice of the electrolyte plays an important role in the ECDe process. Aqueous solution of NaCl and $NaNO_3$ are the most commonly used type of electrolytes.

3.23.7.2 Advantages

- ECDe does not induce any mechanical stress or have thermal effects on a workpiece.

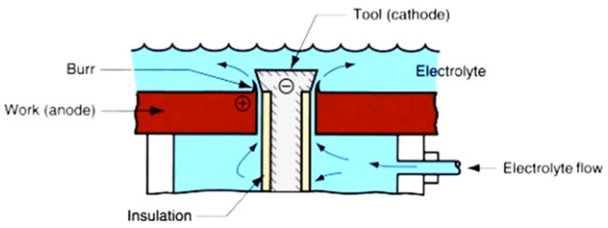

Figure 13 Typical arrangement for electrochemical deburring of a cylinder.

- MRR is independent of the mechanical properties such as hardness and toughness of the machined materials.
- ECDe does not change the physical and chemical properties of a machined surface.
- Elimination of costly hand deburring.
- Very fast deburring process. Normal cycle times for ECDe are between 30 and 45 s.
- Increased product quality and reliability.
- Removal of burrs at the required accuracy, uniformity, proper radius, and clean edge.
- Reduced personnel and labor cost.
- Possibility of automating for higher productivity.

3.23.7.3 Limitations

- It can be used for deburring electrically conductive materials only,
- high power consumption, and
- difficult to remove internal burrs.

3.23.7.4 Applications

- ECDe can be used to deburr gears, spline shafts, milled components, drilled holes, and punched blanks.
- The process is particularly efficient for hydraulic system components such as spools and sleeves of fluid distributors.

3.23.8 Surface Finish in Various Electrochemical Processes

3.23.8.1 Surface Finish in EP

Generally, EP process produces deposition with excellent surface finish in the range of 20–100 nm and shine on the workpiece surface by using controlled EP parameters. Surface finish in EP process depends on the distribution of deposition, leveling, and density of the deposition. Improper and less dense deposition may lead to poor surface finish and high porosity in the deposition. Various additives and levelers in addition to the commonly used EP process parameters (i.e., DC power supply and its related parameters and electrolyte and its related parameters) are used to improve the surface quality of the deposition. Following measures can be used to improve surface finish of the deposition by the EP process:

- stringent control over electrolyte composition and concentration to get good throwing power and use of optimum value of electrolyte temperature and current density,
- minimizing or avoiding the impurities in the electrolyte solution,
- use of pulsed current to achieve clean environment in IEG and uniform deposition,
- use of additive agents such as brighteners, leveling agents, and wetting agents,
- minimizing the convex and concave irregularities in the deposition,
- using optimum value of IEG,
- using conducting or insulating screen and auxiliary anodes, and
- increasing polarization on the cathode.

3.23.8.2 Surface Finish in ECM

Generally ECM process produces very good surface finish but following factors adversely affect surface finish in ECM[40]:

1. selective dissolution,
2. sporadic breakdown of anodic film,
3. flow separation and formation of eddies, and
4. evolution of hydrogen gas.

3.23.8.2.1 Selective dissolution

Each pure material has a particular value of potential at which its electrolytic dissolution occurs. In case of an alloy and metal with impurities, each constituent has its own dissolution potential. In pure metals too, the dissolution potential at grain boundaries is different from those inside the grains. Entire anode surface is equipotential, while electrolyte potential varies across IEG. Consequently, constituents having higher dissolution potential will project away as compared to that of the constituents having lower dissolution potential so as to meet the electrolyte with a lower potential. This results in uneven workpiece surface as depicted in **Figure 14(a)**. Such unevenness can be reduced by increasing the anode potential as shown in **Figure 14(b)**.

3.23.8.2.2 Sporadic breakdown of anodic film

The potential difference between anodic workpiece surface and electrolyte in the region away from the machining area gradually falls and due to this those constituents of the workpiece material that have higher dissolution potentials stops dissolving gradually. This also results in rough workpiece surface. When only few phases remain active and dissolve, a concentration of the electric field results, since active phases occupy a small proportion of the anode surface. Field concentration causes these phases to dissolve very rapidly forming deep pits. Beyond a certain point potential drops to such a low value that no dissolution takes place.

3.23.8.2.3 Flow separation and formation of eddies

Presence of unevenness in the form of peaks and valleys on anode surface causes separation of electrolyte flow and eddy formation. Flow separation may be caused by an improper tool design and improper electrolyte flow path also. Eddy formation leads to higher concentration of metal ions which results in higher concentration over-potential. This causes localized variation in MRRs and consequently unevenness in the machine or finished surface.

3.23.8.2.4 Evolution of hydrogen gas

During the electrochemical dissolution, hydrogen gas is evolved at the cathode. Presence of hydrogen gas reduces electrical conductivity of the electrolyte along its direction of flow. This may result in variable MRR along the flow direction and may deteriorate surface finish of the workpiece.

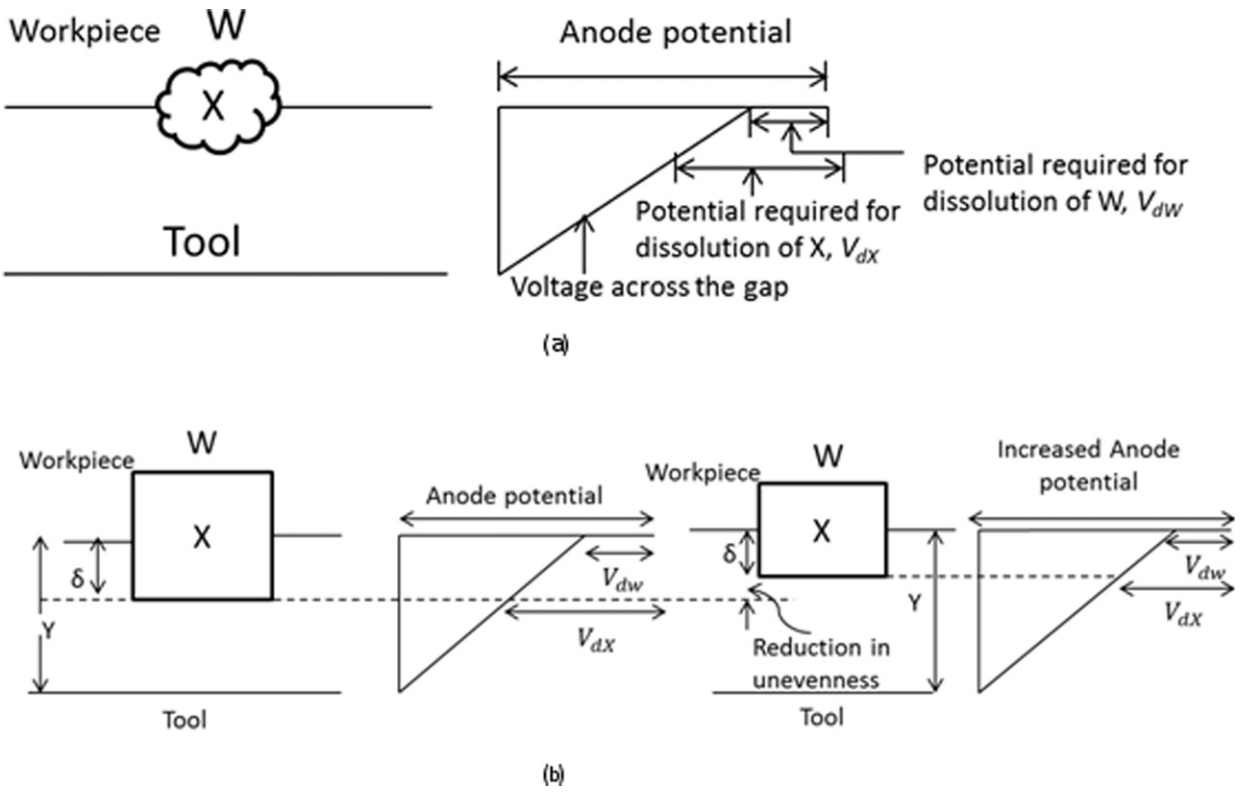

Figure 14 Schematic of (a) unevenness in workpiece surface due to difference in dissolution potential of different phases and (b) reduction in surface unevenness with increase in anode potential.[40]

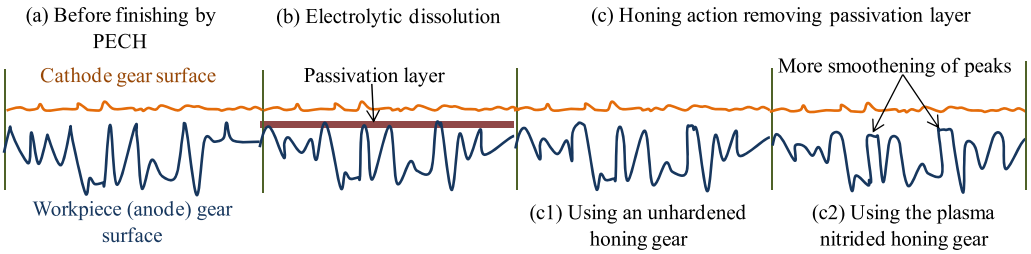

Figure 15 Sequence of finishing the bevel gear by PECH process; (a) before finishing by PECH; (b) after electrolytic dissolution and formation of metallic oxide passivation layer; (c1) after honing action using an unhardened honing gear; and (c2) after honing action using a hardened honing gear.[41]

3.23.8.3 Surface Finish in ECG

ECG process does not produce the typical shiny finish as produced by conventional mechanical grinding process. This is due to the fact that there is no smearing of the material which occurs in the conventional grinding process. Though ECG can achieve surface finish of 0.4 μm or better, it has a matte (dull) rather than a polished look due to the fact that almost 90–95% material removal is due to electrolytic dissolution of the workpiece material and only 5–10% is due to the grinding process. Consequently, above-mentioned causes responsible for poor surface finish in ECM are also applicable to ECG process. Other than ECM related parameters, surface finish in ECG is also affected by speed of grinding wheel and size of abrasive particles used on wheel. Tolerances that can be achieved using ECG depend greatly on the material being cut, the size and depth of cut, and ECG parameters being used. On small cuts, tolerances of 5 μm can be achieved with careful control of the grinding parameters.

3.23.8.4 Surface Finish ECH

ECH can provide the surface finish up to 50 nm using controlled and optimum values of parameters as mentioned in Table 8. In ECH process also, majority of the material removal (90–95%) is due to ECM action only and fraction of material (5–10%) is removed by mechanical honing. Thus factors that adversely affect surface finish in ECM also play major role determining the surface finish obtained ECH process.

Pathak *et al.*[41] have explained the process sequence and mechanism of gear finishing by PECH process as depicted in Figure 15. It can be seen from Figure 15 that during the electrolytic dissolution of the workpiece surface, a metallic oxide passivation layer is formed on its surface prohibiting

Table 9 Comparison of achievable surface finish and tolerance in different conventional and electrochemical processes

Type of process		*Surface finish (μm)*	*Tolerance (mm)*
Conventional machining and finishing processes	Drilling	0.8–12.5	0.03–0.4
	Grinding	0.025–6.3	0.003–0.05
	Boring	0.025–25.0	0.03–0.4
	Broaching	0.4–6.30	0.006–0.3
	Honing	0.025–1.6	0.005–0.04
	Turning	0.025–25.0	0.03–0.5
	Flame cutting	6.3–50.0	0.5–2.0
	Lapping	0.012–0.8	0.005–0.03
	Polishing	0.012–0.8	0.005–0.03
	Shaping	0.4–25.0	0.03–0.5
Electrochemical machining (ECM) and finishing processes	ECM	0.4–6.3	0.05–0.125
	Electroplating	0.05–3.0	–
	Electrochemical grinding	0.013–0.8	0.005–0.05
	Electrochemical polishing	0.1–1.0	0.025–0.025
	Shaped tube electrolytic machining	0.25–6.3	0.005–0.085
	Electrochemical deburring	0.02–1.6	0.005–0.05
	Electrochemical honing	50 nm–2.0	±0.002
	Electrochemical milling frontal	0.01–6.3	0.005–0.5
	Electrochemical milling (side wall)	0.4–15.0	0.025–0.5

its further electrolytic dissolution. Use of an unhardened honing gear (hardness similar to workpiece gear) in the PECH process removes a very small amount of material from some of the highest peaks on the workpiece surface while removing the passivation layer. Whereas, use of a hardened honing gear (30% more harder than workpiece gear) removes material from almost all the peaks on the workpiece surface while scrubbing the passivation layer. This leads to comparatively more reduction in maximum surface roughness which also helps in subsequent electrolytic dissolution to remove some material even from the valley thus giving better and uniform surface finish. They have concluded that honing tool can also participate in material removal process although it must be optimized according to need and system design.

3.23.9 Summary

Surface finish and geometric tolerance of the engineering components plays a vital role in determining their service life, operating performance, and surface integrity. Electrochemical processing of material is found to be superior to the conventional processes due to their ability to machine complex shaped components, machining the harder and tougher materials, excellent surface finish and geometrical accuracy, usefulness in fabrication of miniature components, ease of operation, and higher MRR. **Table 9** presents a comparative analysis of surface finish and tolerance for different conventional processes and electrochemical processes. It can be concluded from this table that electrochemical processes can be used for producing accurate geometry and excellent surface finish.
