EDITOR-IN-CHIEF

Saleem Hashmi is emeritus professor in the School of Mechanical & Manufacturing Engineering at Dublin City University, Ireland. He founded the School in January 1987, in addition to setting up the Materials Processing Research Centre (MPRC), a research centre of excellence in the field of materials processing.

In 1990, Professor Hashmi established Advances in Materials and Processing Technologies (AMPT), a much-needed international conference in materials processing. He continues to be the chairperson of the steering committee for this series of conferences. In 1998 he was appointed as editor-in-chief of Elsevier's *Journal of Materials Processing Technology* and continued in this role until 2008.

In 1995, Professor Hashmi was awarded the higher doctorate degree of DSc, by the University of Manchester, the highest academic degree any university in the UK can award.

Professor Hashmi has supervised or co-supervised 112 PhD and 55 MEng research students to successful completion. Over the years he has also acted as an external examiner and expert assessor for PhD candidates and engineering departments with universities in Ireland, the UK, India, Pakistan, Bangladesh, Hong Kong, Canada, Australia, and Malaysia. He has published in excess of 460 papers and 25 books so far.

Professor Hashmi was the editor-in-chief for Elsevier's 13-volume major reference work *Comprehensive Materials Processing* which was published in 2014.

He has been appointed as the editor-in-chief for Elsevier's *Materials Science and Materials Engineering Reference Module*, a 14-section online resource comprising around 3500 reviewed articles. This launched in December, 2015 and is constantly being updated.

VOLUME EDITORS

Imtiaz Ahmed Choudhury is currently a professor at the Department of Mechanical Engineering, University of Malaya (UM), and has been with UM since 1996. He received his Bachelor degree in Mechanical Engineering from Bangladesh University of Engineering and Technology (BUET), MEng from Asian Institute of Technology (AIT), Thailand, and MSc in Mechanical Engineering from Arizona State University, USA. He obtained his PhD from Dublin City University. He started his career as an assistant engineer in a gas transmission and distribution company, Dhaka, Bangladesh. He worked as a maintenance engineer in a power station for 3 years in Libya. He started his academic career in 1982 as an assistant professor in an engineering college, Bangladesh. Since then, he has been working in academia. Imtiaz's research interests include traditional/nontraditional machining with vegetable oil-based lubricant, tool condition monitoring, machining difficult-to-cut and high strength materials, injection molding and application and use of solar energy. He has been a member of a panel of judges for the SME innovation award 2011–2013, Malaysia, under the category of "Manufacturing Sector." He was a Senate member of the University of Malaya. He has authored and coauthored about 100 papers in referred journals, more than 60 conference papers and some book chapters published in Elsevier works. He has also been a reviewer of various international journals. Imtiaz is a Fellow of Institution of Mechanical Engineers, UK (IMechE), and a life Fellow of Institution of Engineers, Bangladesh (IEB). He is a chartered engineer, UK (CEng).

Professor Shahjahan Mridha was born in Bangladesh and obtained his BSc and MSc in Metallurgical Engineering at the Bangladesh University of Engineering & Technology (BUET), Dhaka, and PhD at the University of Leeds in UK (1980) on Gas Nitriding of Low Alloy Steels. Since 1972 he has worked at the Department of Metallurgical Engineering, BUET for 20 years as a faculty member except for 1986–1987 where he was a Commonwealth Academic Staff member at the University of Birmingham, UK, working on Plasma Nitriding.

Professor Mridha was a senior research fellow at the University of Strathclyde, UK from 1989–1994 and worked on laser processing of aerospace materials in collaboration with UK Ministry of Defence. In late 1994 he moved to Nanyang Technological University (NTU) in Singapore where he was employed as an associate professor until 2001, working on semiconductor materials, composite and intermetallic coatings.

In January 2002 he joined the International Islamic University Malaysia (IIUM) as professor, later assuming the position of Head of the Department of Manufacturing and Materials Engineering. He left IIUM in July 2012 to join the Department of Mechanical and Aerospace Engineering at the University of Strathclyde (UK) as a Leverhulme Trust Professor, and remains there presently as visiting professor.

Professor Mridha has published more than 150 journal and conference papers. His research contributions are primarily on microstructure–properties relationships, semiconductor materials and surface modification of light alloys and steel using high power laser and TIG torch melting technology. He is the pioneer of TIG torch techniques for surface coating applications. Professor Mridha is subject editor of the *Metallic Materials* section in Elsevier's *Reference Module in Materials Science and Materials Engineering* launched in December 2015.

In addition to his academic career, Professor Mridha worked as an international consultant for the United Nations Industrial Development Organization (UNIDO) from 2001 until 2007, delivering expert advice and training to engineers working in manufacturing industries in the Indian and African continents.

Bekir Sami Yilbas is a distinguished professor in the Mechanical Engineering Department, King Fahd University of Petroleum and Minerals, Saudi Arabia. He received his PhD in Mechanical Engineering from Birmingham University, and was awarded a doctorate of Engineering at Birmingham in 2005 due to his significant contribution to his field of study. He has received numerous awards as recognition of his research work. Some of these include President of India's Prize for 1988 by Indian Royal Engineering Society, Technology Prize for 1990 by Science and Technology Foundation in Turkey, Best Research Award for 1997, 2002, 2007 by King Fahd University of Petroleum and Minerals, Silver Jubilee Medal by Silesian University of Technology, Donald Julius Groen Prize for 2007 by Institution of Mechanical Engineers (IMechE), Distinguished University Professor award at King Fahd University of Petroleum and Minerals, 2008 – present by King Fahd University of Petroleum and Minerals, Professor W. Johnson International Gold Medal for 2008 by Advances in Materials and Processing Technologies (AMPT) Steering Committee, Professor Fryderyk Staub Golden Owl Award by World Academy of Metals and Manufacturing, Almarai's Distinguished Scholar Prize by King Abdulaziz City of Science and Technology.

Bekir Sami Yilbas has published 720 journal papers in reputable international journals and presented over 100 papers at international conferences. He has 12 patents issued and is the subject editor of *Arabian Journal of Science and Engineering* and editor of *Journal of Fluids*. He has served as an editorial board member of international journals, including the *International Journal of Machine Tool and Manufacture Design, Research and Application, International Journal of Subsurface Sensing Technologies and Applications, Journal of Materials Processing Technology, Journal of Achievements in Materials and Manufacturing Engineering, International Journal of Nanomanufacturing*, and *Archives of Materials Science and Engineering*, and has received numerous awards as recognition of his research work.

PREFACE

Finish manufacturing processes are final stage processing techniques which are deployed to bring products to a stage where they are ready for marketing and putting in service. Over recent decades, a number of finish manufacturing processes have been developed by researchers and technologists. Some of these new processes have been documented and illustrated both individually and collectively in relation to application in specific areas. The advancement of tools of physics has resulted in considerable changes to these processes, and the precision with which they can be applied. The reporting of these developments are sometimes fragmentary, and this reference work provides a more connected and thorough review of these processes.

Comprehensive Materials Finishing is the primary reference source for researchers at different levels and stages in their career both in academia and industry. This reference work encompasses the knowledge and understanding of many experts into a single, comprehensive work. Containing a combination of review articles, case studies, and research findings resulting from research and development activities in both industrial and academic domains, this reference work focuses on how some of these finish manufacturing processes are advantageous for a broad range of technologies. These include applicability, energy and technological costs, and practicability of implementation. A wide range of materials such as ferrous, nonferrous, and polymeric materials are covered.

This work details the three foremost and distinct types of finishing processes: surface treatment, finish machining processes, and surface coating processes. Surface treatment refers to properties of a material being modified without otherwise changing the physical dimensions of the surface. Finish machining processes involve a small layer of material being removed from the surface by various machining type processes to render improved surface characteristics. Surface coating processes are where the surface properties are improved by adding fine layer(s) of materials with superior surface characteristics to improve the service life of the surface being coated. Each primary surface finishing process is presented in a separate volume, comprising chapters on many of the following relevant specific processes as follows:

Volume 1: Finish Machining and Net-Shape Forming: developments in conventional finish machining processes (honing, lapping, polishing, burnishing, and deburring), fine grinding, free EDM, laser finishing, electrical discharge grinding (EDG), electro-chemical honing (ECH), electrochemical discharge grinding (ECDG), electrochemical grinding (ECG), electrochemical turning (ECT), micro-machining process, and high-speed machining.
Volume 2: Surface and Heat Treatment Processes: This contains aspects of heat treatments, stress relieving, annealing, normalizing, hardening, tempering, austempering, martempering, carburizing (pack, liquid, gas, and post carburizing treatments), nitriding (gas and plasma), salt bath (boriding, chromizing, cyaniding, and carbonitriding), phase transformation of the outer surface (induction, flame, laser, electron beam, and anodizing).
Volume 3: Surface Coating Processes: Plating (electroplating, alloys (bronze/brass and others), chromium, dense chromium, copper and tin, gold, silver and other precious metals, zinc and nickel, electroforming, electroless nickel, hot dip galvanizing, selective/brush plating, surface finish coatings, air spray painting, and chemical vapor deposition (CVD)).

Finishing processes are at the core of successful production of marketable products and address recent progress in materials finishing technologies and science as well as covering recent developments in specific manufacturing processes involved with finishing of products for applications in all areas of engineering, biomedical, environmental, health and safety, and monitoring and control. The in-depth study of these finishing processes as presented in these volumes will assist scientists and engineers in the selection, design, and usage of materials, whether required in small- or large-scale uses across industries.

The initiations for this project began in 2014 and by January, 2015, I had selected the volume editors – Bekir Yilbas, Imtiaz Choudhury, and Shahjahan Mridha and we met with Gemma Tomalin, Joanne Williams, and Graham Nisbet at the Elsevier office in Oxford to finalize the table of contents and plan the project. Throughout 2015, the volume editors and I worked resolutely to select topics to be covered, invite authors, and review their manuscripts, eventually getting all content ready for production by the end of 2015. In 2016, authors returned their proof corrections and final files were produced. To create a work of this scale, the most in-depth reference ever published on materials finishing processes and surface engineering, relies on a collaboration of authors, editors, and the team at Elsevier. I would like to thank the many dedicated authors, whose contributions will be an essential reference for materials scientists and engineers. Each chapter has been reviewed by one of the volume editors, leading experts in their fields, whose knowledge and expertise have proved invaluable. I am indebted to each volume editor and their dedication to making their volume an exhaustive and relevant resource for the scientific community for many years to come. Finally, on behalf of myself and the volume editors, I would like to thank Gemma Tomalin and Joanne Williams at Elsevier for their support, cooperation, and good humor throughout this project – from the first meeting in early 2015, to the publication mid-2016.

INTRODUCTION TO FINISH MACHINING AND NET-SHAPE FORMING

The finish machining process is used to produce precise dimensions and surfaces to improve the aesthetics and sales value of manufactured products. Some common, popular methods of machining are honing, lapping, polishing, burnishing, and deburring.

The honing process is used mainly to obtain precise surface finishing of holes (internal surface) and external cylindrical surfaces or flat surfaces. Compared with grinding, the honing process is a low-speed operation producing cooler chips, with little or no damage/distortion of the material surface. Honing, an abrasive finishing operation, removes material from the internal or external surface of a part. This process is capable of high material removal rates and offers advantages of low-cost equipment. An accuracy of 0.001 mm can be obtained in a wide range of materials.

Lapping is an abrasive finishing operation used on flat or cylindrical surfaces. It utilizes a rough chemical-mechanical-polishing technique for an improved surface finish and accuracy and provides better wear life of a part. It is intended to only remove approximately 0.01 mm of material. The lap, which is usually made of softer material, is attached to an abrasive material or may be used with a slurry to cut harder material.

Burnishing is a cold working process primarily used to polish internal surfaces by utilizing plastic deformation and without actual removal of metal. As the tool passes through a work part, pressure is generated and exceeds the yield point of the work part, this results in the material exhibiting plastic flow. This allows the high spots to be flattened out and the valleys to be filled in. Cold working causes the work part to harden and produces a wear- and corrosion-resistant surface with a mirror-like finish.

Polishing is a process by which a smooth, glossy, and finished surface is produced either by fine-scale abrasive removal or by softening and smearing of surface layers by frictional heating during polishing. Chemical mechanical polishing uses a ceramic slurry in a sodium hydroxide solution when a chemically reactive surface (silicon wafer) is polished.

Thin ridges or small parts sticking to the newly machined surface, known as burrs, generally develop during machining along the edges of the work part. Deburring is the removal of these burrs, and there are various deburring processes available. Deburring is important for functionality, quality, aesthetics, and the smooth operation of work pieces.

Finish machining and net-shape forming of micro-parts are being investigated more because the demand for high-precision components (such as for the aerospace and automotive industry and for medical implants and instruments) has necessitated using micro-machining and net-forming techniques as opposed to conventional methods, which may lead to material wastage. Materials, processing conditions, tools, and machinery are some of the key factors that influence the manufacturing of quality products. These factors have received increased attention because of their roles in creating quality products. Over the years, advancements in micro-machining have been made through the application of light amplification by stimulated emissions of radiation (LASER), which is referred to as laser beam machining (LBM). Similarly, net-shape techniques such as die forming, investment casting, powder injection molding (PIM), and, more recently, additive layer manufacturing (ALM) comprising 3D printing using metal and plastic have been found to be cost-effective for micro-fabrication of intricate and complex micro-parts.

It is now clear that the use of conventional machining has been constrained because of the intricate shape and micro/nano size of the feature's design, as has the emergence of advanced engineering materials. Therefore, stringent micro-fabrication techniques are required. Some commonly used techniques involve boring, such as ultrasonic-assisted lapping, gear honing, polishing, electrical discharge machining (EDM), laser beam machining (LBM), etching, coning, and micro-injection molding (μIM). These techniques are presented in this volume in two chapters covering μIM.

Chapters in This Volume

1.1 Factors Affecting Surface Roughness in Finish Turning
1.2 Effect of Cutting Variables on Boring Process: A Review
1.3 Finish Machining of Hardened Steel
1.4 Review of Gear Finishing Processes
1.5 Robotic Polishing and Deburring
1.6 Precision Grinding, Lapping, Polishing, and Post-Processing of Optical Glass
1.7 Techniques to Improve EDM Capabilities: A Review
1.8 Natural Fiber-Reinforced Composites: Types, Development, Manufacturing Process, and Measurement
1.9 Effect of Electrical Discharge Energy on White Layer Thickness of WEDM Process
1.10 Micro-EDM Drilling of Tungsten Carbide Using Microelectrode with High Aspect Ratio to Improve MRR, EWR, and Hole Quality
1.11 Micromachining

1.12 Laser Machining Processes
1.13 ELID Grinding and EDM for Finish Machining
1.14 Laser Peening of Metallic Materials
1.15 Micro Plastic Part Filling Capabilities through Simulation and Experiment: A Case Study on Micro Gear Shape
1.16 Net-Shape Microfabrication Technique by Micrometal Powder Injection Molding
1.17 Review of Miniature Gear Manufacturing

The volume contains chapters on finish machining, EDM/WEDM, gear manufacturing, micro-machining, laser machining, and net-shape micro-fabrication techniques. The content of each chapter is sufficient to give the reader background information about comprehensive finishing and net-shape forming techniques. Furthermore, the chapters are arranged to provide a progressive understanding of the various techniques as applied in practice. Therefore, it is expected that the reader will find this volume to be a great source for pertinent information on comprehensive finishing and net-shape forming.

Concluding Remarks

The contributions by the authors of this volume are excellent pieces of information relevant to researchers, technologists, students, and industrialists. Current research trends as well as research outlooks in the fields of comprehensive finishing and net-shape forming are presented in this volume.

Acknowledgments

The editor expresses his deep appreciation and gratitude to all the authors and co-authors of the chapters featured in this volume for their commitment, hard work, and comprehensive contributions in various areas related to materials finishing and net-shape forming. In addition, the invitation by Elsevier through Prof. M.S.J. Hashmi to create this project is greatly appreciated. Thank you to the production team, authors, and various institutions, as well as to your employers for this wonderful support.

The editor greatly acknowledges the support provided by the University of Malaya through Research Projects UMRG RP020/2012A and FRGS FP066–2015A.

1.1.1 Introduction

Turning is a common metal removal process in which a single-point cutting tool is moved relative to a rotating cylindrical workpiece on a machine tool. The major application of turning is in the removal of bulk material from the workpiece to achieve the required dimensions. This is known as rough turning, or simply as roughing. However, turning is increasingly used to produce good surface finish in processes known as finish turning. This is done typically to avoid or reduce secondary processes such as grinding or lapping, thus saving production costs. Finish turning usually involves turning using the tip or the curved nose area of the cutting tool insert. The depth of cut is usually less than the nose radius of the cutting tool. The objective of finish turning is to produce products of high-dimensional precision with good surface finish quality.

The surface finish quality of a product is usually assessed in terms of its surface roughness. The roughness of a machined surface is considered as one of the main characteristics of the product as it greatly influences the fatigue life, coefficient of friction, wear resistance, and subsequently the reliable function of the product during service. There are many factors that affect the surface finish quality of a workpiece in turning. These factors can be broadly divided into the following four main categories:

1. Factors due to machining conditions, such as dry turning, wet turning, type of cutting fluid, method of cutting fluid application, chatter vibration, and machine tool rigidity.
2. Factors due to cutting tool parameters, such as tool nose radius, nose angle, tool edge preparation (honed or chamfered), rake angle, side edge cutting angle, cutting tool material, and tool coating.
3. Factors due to machining parameters, such as feed rate, cutting speed, and depth of cut.
4. Factors due to workpiece material properties, such as hardness, microstructure, grain size, composition, and internal defects.

The research work carried out in the past to understand how the various factors affect the surface finish quality of the workpiece in turning is reviewed in this chapter. A greater emphasis is given to the more recent work in this rapidly advancing field which in influenced by the development of modern instrumentation and data analysis techniques. Previous works to optimize the process parameters to obtain the best surface finish and to predict the surface roughness are reviewed. Potential areas for further research that can provide new insights into the effect of the various factors in more detail are suggested at the end of the chapter.

1.1.2 Factors due to Machining Conditions

1.1.2.1 Factors due to Cutting Fluids and Method of Fluid Application

Cutting fluids serve as lubricants as well as heat removal agents during turning. They are used to reduce friction and tool wear, improve surface finish, reduce energy consumption, reduce thermal distortions, facilitate chip removal, reduce tendency of built-up edge (BUE) formation, and protect the newly machined surface from environmental corrosion effects. Cutting fluids are also known as metalworking fluids, coolants, or simply as lubricants. A detailed treatment of the subject on metal cutting fluids is given by Byres.[1]

Extensive research has been carried out in the past three decades to study the effect of the type of cutting fluid and the method of fluid application on the surface finish of various types of workpiece materials during turning. The cutting fluids used in these studies can be classified into four main categories according to their chemical formulation. They are mineral oils, soluble oils (emulsified oils), synthetic (chemical) fluid, and semisynthetic fluids. Cutting oils without further dilution or additives are known as neat oil or straight oil. Besides mineral and chemical-based fluids, vegetable oils, being biodegradable,

have the potential to reduce waste treatment costs and health hazards associated with the petroleum-based oils. Therefore, several researchers have investigated the effect of various bio-based cutting fluids on the surface finish quality in turning. The four common methods of applying the cutting fluid to the cutting zone are by flood filling, jet impingement, mist, and minimum quantity lubricant (MQL). The effects of the fluid application methods on the surface roughness of the finished workpiece have been studied by a number of researchers.

The effect of different cutting fluids on surface finish and tool wear during turning of AISI 304 steel using a carbide tool was investigated by Xavior and Adithan.[2] The authors studied three types of cutting fluids, namely soluble oil (emulsion), neat (mineral) cutting oil, and coconut oil. Coconut oil was chosen as one of the cutting fluids due to its lower onset temperature of thermal degradation compared to sunflower and sesame oils.[3] In their machining experiments the feed rate was varied from 0.1 to 0.35 mm rev^{-1}. Their results showed that at a low feed rate (0.2 mm rev^{-1}) coconut oil and soluble oil produced similar surface finish but neat oil resulted in slightly higher roughness values. At higher feed rates (0.35 mm rev^{-1}) coconut oil produced the best surface finish when compared to the other two fluids. A difference in the average roughness (R_a) of 1.0 μm was obtained at a feed rate of 0.35 mm rev^{-1} when comparing turning carried out using straight oil and coconut oil. This observation was attributed to the much lower tool flank wear when the machining was carried out using coconut oil as the cutting fluid. The authors reported that the lower viscosity of coconut oil allowed easier flow of the cutting fluid thus enabling better removal of the heat at the tool–workpiece interface.

Lawal *et al.*[4] prepared new oil-in-water emulsion cutting fluids by mixing three different types of oils (palm kernel oil, cottonseed oil, and mineral oil) separately with water and additives such as anticorrosion agent, antioxidant, and biocide. The water-to-oil ratio used for each case was 9:1. The turning tests were performed on AISI 4340 alloy steel. Their results showed a general trend of improvement of surface roughness when using palm kernel oil and cottonseed oil-based cutting fluids compared to mineral oil-based cutting fluid. The authors attributed this finding to the reduction in cutting force when using bio-based fluids. This in turn was explained in terms of the formation of a high-strength boundary film that resulted from the high proportion of fatty acids in the bio-based fluids.

MQL refers to the use of a very small quantity of cutting fluid, typically at flow rates of 50–500 ml h^{-1}, which is directed to the cutting zone via nozzles or channels built inside the tool holder. The concept of using MQL (also known as near-dry lubrication or micro-lubrication) in machining was suggested more than a decade ago as a means of overcoming the problems related to the airborne cutting fluid particles that pose health hazards. MQL also leads to significant saving in cutting fluids and reduces workpiece/tool/machine cleaning cycle time. Khan *et al.*[5] studied the effects of MQL using vegetable oil-based cutting fluid on the turning performance of AISI 9310 alloy steel compared to completely dry and wet turning. The MQL was supplied by passing air at high pressure into a mixing chamber that drew a controlled amount of fluid. The mixture was directed at high velocity to the chip–tool interface

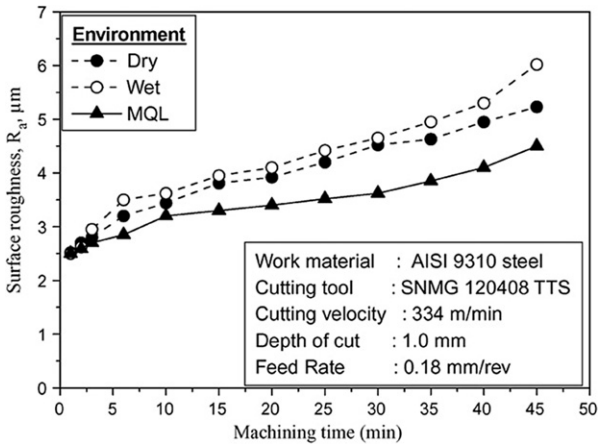

Figure 1 Effect of various cooling conditions on surface roughness.[5]

through a nozzle. Their results (**Figure 1**) show that turning using MQL produced better surface finish compared to dry or wet turning. After 45 min of machining time an improvement of 29% in the average roughness was observed compared to the wet turning. The improvement observed, however, depended on the work-tool materials and was achieved mainly by controlling the deterioration of the auxiliary cutting edge by abrasion, chipping, and formation of BUE. The surface roughness improved effectively due to the reduction of wear and damage to the tool tip due to the application of MQL.

de Angelo Sanchez *et al.*[6] investigated the effect of different methods of cutting fluid application on the turning of difficult-to-cut machine steel (SAE EV-8). The author compared three different methods of fluid application, namely overhead flood filling, MQL, and pulverization. The cutting fluid used for the flood fill was a semisynthetic fluid while that used for MQL was vegetable oil. Pulverization was achieved by using a high-pressure nozzle. Among the methods compared the authors found that the application of cutting fluid jet directed to the chip–tool interface resulted in increased tool life and decreased cutting force, thus improving the surface finish. However, when the reduction in tool wear is the main objective the authors reported that the conventional method of flood filling was more efficient. Shokoohi *et al.*[7] studied the combined effect of MQL and precooling of the workpiece on surface roughness and other effects such as power consumption and chip formation. The machining was carried out on hardened and tempered AISI 1045 steel. The workpiece was precooled using CO_2 as the cryogenic agent. The cutting fluid was made by mixing sunflower oil with water and a small amount of antibacterial agent. The authors reported that the application of the precooling process along with using MQL with the new coolant resulted in the improvement of the surface finish. This was attributed to the colder cutting zone due to the efficient penetration of the oil into the tool–workpiece interface.

Since the conventional cooling methods, such as flood filling and high-pressure jets, are unable to ensure the penetration of the fluid to the chip–tool interface, Sohrabpoor *et al.*[8] used MQL strategy during the turning of AISI 4340 stainless steel. The authors compared four strategies of lubrication namely dry

cutting, air cool, wet with pure liquid lubricant, and MQL. They observed a maximum improvement in surface finish (a decrease in R_a from approximately 27 μm for dry cutting to 6 μm using MQL) at a feed rate of 0.28 mm rev^{-1} and spindle speed of 1000 rev min^{-1}. The improvement observed was explained in terms of the reduced wear at the auxiliary (minor) cutting edge of the tool. Hadad and Sadeghi[9] found that the MQL nozzle position has an important influence on the performance of MQL turning. Oil mist supplied to both the rake and flank faces prevented the adhesion of chip in low temperature and the lubrication effect helped to improve the surface finish.

Amini *et al.*[10] used the term near-dry machining (NDM) to describe MQL and observed a slight decrease in the average roughness compared to dry turning. The authors carried out their experiment by turning AISI 4142 steel. They investigated the effect of several parameters involved in the NDM method, namely flow rate, air pressure, frequency of sending the lubricant, and the nozzle position. Directing the fluid to the machining zone enabled friction to be reduced thus decreasing the machining temperature and preventing formation of BUE and therefore reducing tool wear. However, there were no obvious correlations between the flow rate and the surface roughness or between the frequencies of sending lubricant with the surface roughness.

Extremely high temperatures generated during high-speed turning have detrimental effects on machining. High temperatures not only limit tool life but also deteriorate surface finish by inducing tensile residual stresses, distortions due to thermal gradients and micro-cracks. This problem can to some extent be alleviated using cutting fluids that effectively reduce the cutting temperature. However, since cutting fluid may not remove the extent of the heat efficiently Dilip Jerold and Pradeep Kumar[11] attempted using a cryogenic coolant to reduce the cutting temperatures to lower than those achievable using the conventional coolants. The efficiency of using CO_2 cryogenic coolant was compared to that of dry and wet machining with respect to the surface roughness and other parameters. The workpiece material used was AISI 1045 steel. The authors reported that the use of cryogenic cooling reduced the cutting temperatures by 5–22%. The surface finish improved by 5–25% in the cryogenic cutting condition compared to wet cutting.

Dhar and Kamaruzzaman[12] carried out a similar study by using liquid nitrogen jet as the coolant during the turning of AISI 4037 steel. The results were compared with dry machining and with machining using soluble oil as the coolant. After a machining time of 60 min the average surface roughness (R_a) produced under cryogenic cooling decreased by about 40% and 25% compared to wet and dry cooling, respectively. The authors attributed the reduction in the surface roughness to the reduction in the auxiliary (minor) flank wear due to the retention of tool hardness through the reduction in temperature by the liquid nitrogen jet impinging along the auxiliary edge. Liquid nitrogen, however, is expensive and increases the overall machining cost. Moreover, due to its extremely low temperature (− 196 °C) liquid nitrogen can precool the workpiece significantly thus resulting in thermal micro-cracks.

Dilip Jerold and Pradeep Kumar[13] investigated the effect of carbon dioxide as the cutting fluid in turning AISI 316 stainless steel. Compared to dry machining the CO_2 machining resulted in improvement of surface finish by 57%, while compared to wet machining the improvement was 52%. These observations were made at a cutting speed of 94 m min^{-1} and feed rate of 0.143 mm rev^{-1}. Significant improvement in surface roughness was observed at other feed rates and cutting speeds as well though the difference was more pronounced at higher feeds. The better surface finish obtained when machining using CO_2 as the coolant was explained in terms of the better chip breakability and less accumulation of the chips near the cutting zone. This reduced the frictional contact of the chips with the finished workpiece.

The addition of twisted nematic liquid crystals to mineral oil-based cutting fluids has been found to reduce the coefficient of friction of the friction pairs up to five times.[14] The liquid crystal was selected from a homologous series of fatty acid esters of cholesterol. The liquid crystals were completely melted in the cutting fluid before machining. A reduction in the surface roughness was observed as shown in **Figure 2**. This behavior was explained in terms of the double action of liquid crystalline additive which leads to the reduction of the friction coefficient in the tool–chip–workpiece interface zones.

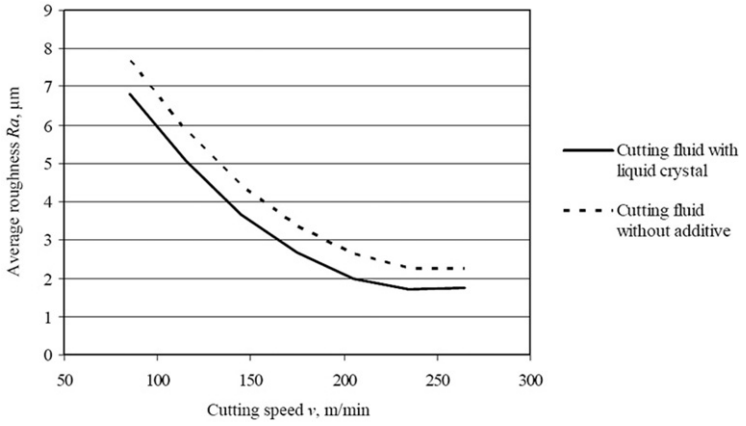

Figure 2 Effect of liquid crystal addition to cutting fluid on average roughness R_a.[14]

The larger molecules of the liquid crystal provided better protection from the direct metal contact.

Ozcelik *et al.*[15] found that the inclusion of 8% of extreme pressure (EP) additive to canola-based cutting fluids resulted in approximately 35% reduction in the average roughness of the workpiece compared to the mineral-based cutting fluid. The EP additive is absorbed into the surface of the workpiece and decreased the shear stress. The authors also reported that a reduction of 24% in average roughness was obtained when compared to semisynthetic cutting fluid. However, a 12% addition of EP increased the average roughness. Although the 8% of EP additive decreased the shear stress on the machine surface, the BUE increased with the increase in the EP additive.

Although many researchers have investigated various types of fluids as lubricants in turning only a few of them have explored the possibility of using solid powders as the lubricants. Srikiran *et al.*[16] used nano-crystalline graphite powder as a lubricant during the turning of AISI 1040 steel using tungsten carbide inserts. The feed rate was varied from 0.05 to 0.125 mm rev^{-1}, the cutting speed was varied from 51 to 192.6 m min^{-1}, while the depth of cut was varied from 0.25 to 1 mm. Four levels of each parameter were considered in their experiments. The authors reported that the decrease in the size of nano-particles caused the cutting forces and tool–chip interface temperature to increase. This effect caused the surface roughness to deteriorate. Vamsi Krishna *et al.*[17] investigated the performance of boric acid and graphite as solid lubricants during the turning of AISI 1040 steel. A considerable reduction in the cutting forces, coefficient of friction between chip and tool interface and average flank wear was observed. These lead to the reduction in the surface roughness of the finished workpiece. Boric acid was found to perform well compared to graphite. The main drawback of using solid powders as lubricants is, however, due to the ease with which the particles get airborne, thus posing health hazards to personnel and possible damage to sensors in the machine tool.

Vamsi Krishna *et al.*[18,19] also used boric acid solid lubricant of 50 nm particle size as suspension in SAE-40 and coconut oil and studied the lubricating properties during the turning of AISI 1040 steel with a carbide tool. The results were compared with pure SAE-40 oil and coconut oil as lubricants. The reduction in surface roughness observed was attributed to the better lubricating action caused by the nano-boric acid suspensions. The suspension caused a reduction in the frictional forces between the tool and the workpiece thereby reducing the temperatures developed, hence decreasing tool wear, and resulting in improved surface finish quality.

The addition of nanoparticles, such as graphite, molybdenum sulfide (MoS_2), copper (Cu), copper oxide (CuO), alumina (Al_2O_3), etc., to cutting fluids has been shown to improve the lubrication properties of the fluid. The nanoparticles not only act like miniature balls in reducing the coefficient of friction but help to conduct away heat more efficiently. Several researchers have explored the addition of nanoparticles to cutting fluids, thereafter known as nanofluids. Amrita *et al.*[20] evaluated the performance of a new nanofluid prepared by adding nanographite powder to soluble oil as the base fluid. The lubricating properties of the conventional cutting fluid (soluble oil) and nanofluid were evaluated by using the four-ball tests. The turning experiments were carried out on AISI 1040 steel. The nanofluid was applied using MQL application at a flow rate of 10 ml min^{-1}. The nozzle was placed 1 cm from the tool–workpiece interface to ensure that the fluid mist enters the interfaces properly. The results of the wear tests showed that inclusion of the graphite nanopowder reduced the coefficient of friction by about 3.5%. The reduction was attributed to the lubricating properties of the lamellar structure which causes the particles to align along the direction of movement and slide over one another. MQL application with nanofluid caused the surface roughness to decrease by 28% compared to MQL without the graphite nanoparticles.

Sayuti *et al.*[21] applied a mist of SiO_2 nano-lubricant by compressed air in the turning of AISI 4140 hardened steel. The optimum SiO_2 nano-lubrication parameter to achieve the lowest tool wear and the best surface finish were investigated. The authors prepared the nano-lubricant by adding SiO_2 nanoparticles with an average size of 5–15 nm to mineral oil. An MQL system equipped with thin-pulsed jet nozzle controlled by using a variable speed control valve was used in their experiments. The best surface finish was obtained using 0.5%wt nanoparticle concentration due to the reduction in the coefficient of friction at the tool–chip interface. The surface roughness was found to increase at higher SiO_2 additions. The authors attributed this behavior to the large number of nanoparticles that transfer additional kinetic energy to the workpiece surface and dissipate more heat.

From the investigations carried out in the past on the effectiveness of various cutting fluids used in turning it is obvious that some types of cutting fluids are better than others as far as surface finish quality is concerned. Vegetables oils have good potential to replace mineral and chemical-based cutting fluids due to their biodegradability and good lubricating and heat removal properties. The effect of the extended use of vegetable oils due to oxidation and bacterial contamination need further study before bio-based oils becomes widely acceptable as cutting fluids. The addition of nanoparticles has also produced an improvement in the surface finish in many turning applications.[22] The improvement, however, depended on several factors such as concentration of nanoparticles, method of fluid application, direction of jet, etc. It is not possible to compare the experimental work published in the literature to determine the best type of nanofluid (nanoparticle and base fluid combination) to obtain the best surface finish quality. This because the surface finish depends on numerous other parameters, such as cutting parameters (particularly, feed rate, and cutting speed), workpiece material, tool geometry, and machine tool rigidity. These parameters were different among different researchers.

1.1.2.2 Factors due to Tool Vibration

Vibrations are unavoidable during turning. Many factors can lead to vibrations, such as the variation of cutting forces, unbalanced masses in the machine tool, and sources outside the machine tool. In modern turning machines the level of vibration caused by the machine tool is kept to a minimum by careful design and by the use of vibration dampers. Thus, the main source of vibration during cutting is tool chatter. Tool chatter results from the violent relative motion between

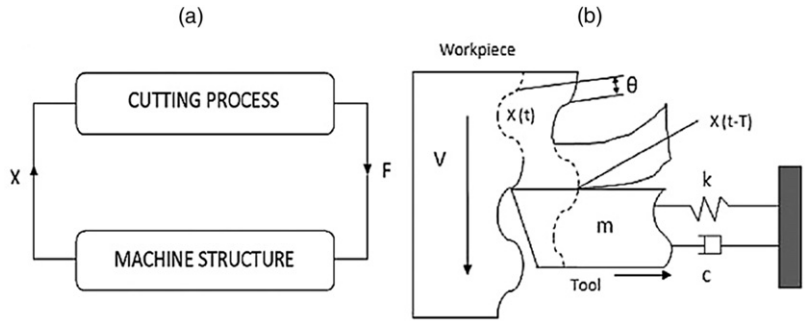

Figure 3 (a) Machine tool and cutting process interaction and (b) mechanism of regeneration.[23]

the cutting tool and the workpiece which is aggravated by tool wear, tool chipping, abnormal chip formation, and surface defects. Chatter vibration is well known to lead to poor surface finish.

Chatter vibration results from the forces generated during the dynamic cutting process and can be divided into primary chatter and secondary chatter. Primary chatter is caused by friction between the tool–workpiece interface and thermo-mechanical effects. Secondary chatter is caused by the regeneration of a wavy surface on the workpiece (see **Figure 3**). Regenerative chatter vibration which occurs at the frequency of the most dominant mode of the machine tool structure has been found to be the most destructive of all other vibrations that occur during turning. The presence of chatter vibration during turning can be recognized by the chatter marks on the machined surface, the appearance of chips produced as well as from the noise generated. Chatter vibration generally leads to reduced productivity of the machine tool.

A review of chatter vibration research in turning is provided by Siddhpura and Paurobally.[23] The authors reviewed 144 papers that deal with chatter stability prediction, chatter detection, and chatter control techniques. Although no papers that correlate chatter vibration with the surface roughness was reviewed, the authors discussed a limited number of papers in which the effects of chatter vibration on tool wear were investigated. In the presence of vibration the cutting speed and chip cross-section has been found to vary, thus affecting tool life.[24] The magnitude of this effect was reported to be large even when the impact of tool loading was excluded. Increased tool wear has also been found to aggravate chatter vibration thus leading to further increase in wear.[25] Kayhan and Budak[26] found experimentally that chatter causes 50–80% reduction in the tool life based on the flank wear limit of 0.2 mm. Siddhpura and Paurobally[23] identified establishing a theoretical relationship between chatter vibration and tool wear as a potential scope for further research. Since tool wear, primarily tool nose wear, has significant effect on the surface roughness the theoretical relationship, once established, can be extended to include the surface roughness parameters.

Very little work has been reported in the literature to correlate the level of chatter vibration directly with surface roughness. Since chatter vibration is a complex phenomenon influenced by a multitude of factors, such as material properties, especially the material microstructure, cutting parameters, cooling methods, tool wear, etc., it is difficult to investigate the effect of vibration on surface roughness in isolation. Lin and Chang[27] studied the effects of vibrations on the surface finish by simulation and experiment. The authors developed a topography simulation model to simulate the surface profile after turning. The effects of the relative motion between the cutting tool and the workpiece together with the effects of tool geometry were incorporated into their model to predict the resultant surface geometry. The authors reported that both the vibration frequency and the vibration amplitude have strong effects on the surface roughness values. They showed that the ratio of the vibration frequency to the spindle rotation speed has a greater effect on the surface roughness than the vibration frequency alone. They noticed that the effects of the radial vibration component on the surface roughness were more significant compared to either the tangential or the axial vibration components. The surface roughness for the surface finish profile generated with the tangential direction vibration was found to increase as the vibration amplitude increased. Although the axial-direction vibration generally degraded the surface finish their results showed that the surface roughness did not always increase as the vibration amplitude increased.

Wang *et al.*[28] investigated the influence of tool-tip vibration on the surface roughness in ultraprecision single-point diamond turning (SPDT). SPDT is used to produce products having very fine surface finish such as optical and medical components. The authors carried out face turning on a polycrystalline copper specimen using a depth of cut of 10 μm under mist coolant. Their results showed that the relative tool-work displacement during turning process is mainly due to the high-frequency tool-tip vibration. This was found to be the dominant factor affecting roughness of the machined surface.

Although vibration has not been correlated directly with surface finish, the effect of vibration on tool wear and tool life has been investigated by several researchers.[29–31] Dimla[29] used vibration features to monitor tool wear in turning. The machining was carried out on EN24 steel using coated inserts and the vibration signals were measured on-line. The authors correlated the measured tool wear forms, namely flank, nose and notch wear, to the features in the vibration signal in the time and frequency domains. They found that the time domain features were more sensitive to the cutting conditions while the frequency domain features correlated well with the tool wear. Their results showed that all three (x, y, and z) components of vibrations were sensitive to the nose and

flank wear forms although the direct correlation between the vibration amplitude and the tool wear was not investigated.

The effect of tool edge wear on the cutting forces and vibrations in 3D high-speed finish turning of nickel-based super alloy Inconel 718 was investigated by Fang *et al.*[30] Since in high-speed finish machining the feed rate is in the same order of magnitude as the tool dimensions, the tool edge wear dominates the wear pattern. The authors analyzed the cutting vibrations that accompany the dynamic tool edge wear using the fast Fourier transform (FFT) and the wavelet transform. They concluded that the FFT method is not best suited to analyze the cutting vibrations caused by the tool edge wear. However, the discrete wavelet transform showed that the vibration amplitude increased as the tool edge wear increased. As mentioned by the authors the scope of their work did not include the study of surface roughness caused by vibrations. Bhuiyan *et al.*[31] used acoustic emission (AE) and vibration signature in turning to investigate the tool wear, chip formation, and surface roughness of the workpiece under different cutting conditions. The effect of vibration on tool wear was found to depend on the chip formation. The tool wear was maximal for the up curled and side curled chip formation. Others have also reported that the severity of chatter decreases the tool life significantly.[32]

In most of these studies the researchers have reported that the tool wear is accompanied by a gradual increase in the chatter vibration whereas sudden tool failure is indicated by an abrupt increase in the vibration amplitude. Since tool wear and tool failure have detrimental effects on the workpiece surface finish an increase in chatter vibration will also have a detrimental effect on the surface finish. Bonifacio and Diniz[33] investigated the correlation between the wear of coated carbide tools and the growth of surface roughness during the turning of AISI 4340 steel by monitoring the vibration of the cutting tool. The authors attached two accelerometers onto the tool holder. The first accelerometer measured the vibration in the cutting direction while the second measured the vibration in the feed direction. Coated cemented carbide tools with three layers of coatings ($TiC + Al_2O_3 + TiN$) were used in their experiments. The parameters used to measure the surface roughness were R_a and R_{max}. The authors concluded that it is not the absolute value of the vibration signal that is important but its change. They recommended that the strategy of automatically establishing the end of tool life is to compare the instantaneous vibration signal with an initial or an intermediate value of the signal. Under all machining condition when the difference between the signals is higher than a predefined value this indicates the time for the tool change.

1.1.3 Factors due to Cutting Tool

1.1.3.1 Tool Geometry

Due to the direct contact of a cutting tool with the machined part the tool itself has the major influence on the roughness of the finished workpiece. There are several factors related to tool that affect the surface roughness of the workpiece. These are: (1) tool geometry (nose radius, rake angle, edge preparation, etc.), (2) tool material (tungsten carbide, ceramic, etc.), (3) tool condition (new or worn), and (4) tool finishing (coating). Dogra *et al.*[34] reviewed 72 published papers that discuss the effect of the tool geometry variation on finish turning in general. The authors pointed out that the cutting edge geometry, which comprises the chamfer angle, chamfer width, and edge hone, has a significant effect on the surface finish and the surface integrity. However, most of the literature reviewed by the authors focused on the effect of the tool geometry on the cutting dynamics, the chip formation, and the machining stability rather than its effect on the surface finish.

Simplified analytical expressions are available for the theoretical average roughness R_a and peak-to-valley roughness R_t as a function of the feed rate and the nose radius assuming that only the rounded nose is involved in the machining. These expressions are given by[35]

$$R_a = \frac{f^2}{32r} \quad [1]$$

and

$$R_t = \frac{f^2}{8r} \quad [2]$$

where f is the feed rate (rev mm^{-1}) and r is the tool nose radius (mm).

Equations [1] and [2] show that for a constant feed the surface roughness is indirectly proportional to the tool nose radius. Therefore, it can be deduced from these equations that in order to reduce the surface roughness the nose radius should be increased. However, there is an upper limit to the nose radius beyond which the cutting forces will increase substantially thus increasing tool wear, particularly groove wear, and introducing vibrations. This in turn will cause the surface finish to deteriorate.

Gokkaya and Nalbant[36] investigated the effects of different insert radii of cutting tools besides other parameters, such depth of cut and different feed rates, on the surface quality of the workpieces. AISI 1030 steel was machined using a CNC turning lathe under dry conditions. Three different insert radii (0.4, 0.8, and 1.2 mm) of cemented carbide cutting tools coated with three layers of coating materials were used in their study. The authors reported that the minimum average roughness was obtained when using a cutting tool of maximum radius (1.2 mm). The surface roughness improved by 293% when the insert radius was increased by 200% (from 0.4 to 1.2 mm). For each depth of cut ranging from 0.5 to 2.5 mm in steps of 0.5 mm and for every feed rate tested the average roughness value was found to decrease when the tool nose radius was increased from 0.4 to 1.2 mm. The greatest decrease in surface roughness was observed at the highest feed rate of 0.35 mm min^{-1}. The difference, however, was not significant at a feed rate of 0.15 mm min^{-1}. The decrease in roughness with increase in nose radius follows an inverse trend as predicted by the theoretical relationship given by eqn [1]. The authors' results show that the effect of vibration at large nose radius does not have a dominant effect on the surface finish for the range of nose radii and cutting parameters tested. Thus, as a rule-of-thumb a larger nose radius should be selected to obtain a better surface finish.

The effect of the tool nose radius on surface finish as well as the tool wear and the cutting forces during tuning of hardened AISI 52100 steel (61 HRC) was investigated by Chou and Song.[37] Ceramic inserts with tool nose radii ranging from 0.8 to 2.4 mm were used in their experiments. The surface finish and tool flank wear were recorded periodically using the stylus profilometer and an optical microscope. The cutting forces during machining were measured using a triaxial force transducer. The author also examined the formation of white layer (phase transformation structures) at the hard turned surface. Their findings show that the tangential force increased only slightly when the nose radius was increased. The increase, however, was more obvious at higher feed rates, whereby an increase in the tangential force of about 20% was noticed. The specific cutting energy, given by the tangential force divided by the uncut chip area, was found to generally increase with the nose radius, particularly at lower feed rates. However, a tool with a larger nose radius was found to produce finer surface finish.

According to the ISO 3685 (1993) standard[38] the manufacturing tolerance allowed on the nose of a cutting tool insert is $0.10r_e$ where r_e is the nominal radius. The 10% deviation allowed in the radius by the standard causes a significant deviation in the shape of the nose profile from that of a perfectly circular profile as reported by Chian and Ratnam.[39] The authors extracted the nose profile of six inserts (total of 18 tool edges) and found that the radius deviated up to 20.3% of the nominal radius. Sung *et al.*[40] showed that the deviation of the true nose profile from that of a geometrically circular profile has a significant effect on the surface roughness of the machined workpiece. Using simulation study alone the authors showed that during ideal 'machining', i.e., in the absence of vibration and tool wear, the deviation in the nose radius causes the maximum peak-to-valley roughness R_t to deviate as much at 32.7% while causing the average roughness R_a to deviate by a maximum of 19.8%. The authors have also shown experimentally that when the turning was carried out under identical conditions using the same batch of inserts, the slight radius variation from one tool to another causes R_t to vary as much as 41.8% while causing R_a to vary by 29.3%. This variation in roughness values was attributed to the random variation in the nose profile due to the radius tolerance allowed in the ISO 3685 standard. Thus, it is important to ensure that the profile tolerance is kept to a minimum especially in tools used for precision turning and finishing operations.

Besides tool nose radius another important factor that has been shown to influence the surface roughness is cutting edge preparation. Cutting edge preparation is particularly important in finish turning because the feed rate used is usually in the same order of magnitude as the cutting edge geometry. Moreover, most of the tool–workpiece interaction takes place along the cutting edge. The effect of cutting edge preparation on surface roughness is best studied in hard turning. Hard turning involves workpiece hardness values typically in the range from 45 to 70 HRC. The tool edge geometry is critical in hard turning because tools with superior edge strength are necessary to withstand the large tool stresses produced during machining. Cutting tools typically have chamfered, honed, or chamfered and honed edges as illustrated in **Figure 4**.

Thiele and Melkote[41] investigated the effect of tool geometry on the surface finish during the hard finish turning of AISI 52100 steel. The authors characterized the edge geometry of each insert to measure the edge features and conducted the turning operations on a rigid machine tool with high spindle accuracy to minimize errors of vibration and run-out. The cutting tools used were made of cubic boron nitride (CBN). These types of tools are commonly used in hard-turning operations. The tool edges used were 'up-sharp' edges, i.e., without strengthening of edges but having finite edge hone, honed, chamfered and chamfers with hones. One up-sharp edge, two-honed edges (intermediate and large), and one chamfer with up-sharp edge were used in their experiments. The radii of the hones were measured using a coordinate measuring machine. The results obtained by the authors when machining a workpiece of 41 HRC hardness showed that tools with smaller hone (22.86 μm) produced better surface finish compared to tools with larger hone (121.92 μm). At a feed rate of 0.15 mm rev^{-1} the R_a value decreased from 1.1 to 0.7 μm, i.e., a drop of 36%. The drop in R_a, however, decreased when the hardness of the workpiece increased to 57 HRC. This observation was explained in terms of the interaction between the chip and the tool along the cutting edge at various feed rates. At low feed rates the ratio of the undeformed chip thickness to the edge geometry is the lowest and the plowing action dominates the cutting process for each type of edge preparation. This effect causes the surface roughness to increase. At higher feed rates the ratio of undeformed chip thickness to edge hone radius increases. The contribution of shearing increases as the contribution of the plowing action decreases thus resulting in better surface finish. For any given feed rate the authors reported that the plowing effect increases with the edge hone radius.

Ozel *et al.*[42] investigated the effects of cutting edge geometry and several other factors on the surface roughness in finish hard turning of AISI H13 steel. Cubic boron nitrite inserts with two distinct edge preparation were used in their study. Since CBN inserts have lower toughness than common

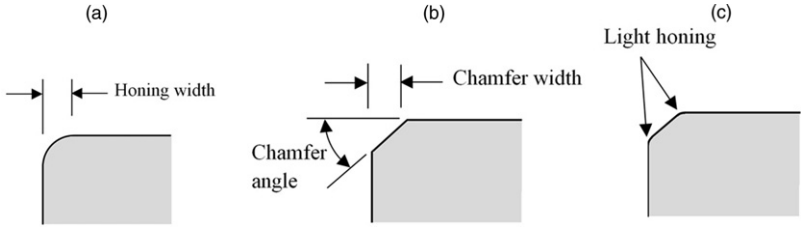

Figure 4 Different type of tool edge preparation: (a) Honed, (b) chamfered, and (c) honed and chamfered.

tool materials and is prone to chipping, proper edge preparation was essential to increase the cutting edge. The authors investigated the CBN inserts with two distinct representative types of edge preparation, i.e., chamfered and honed. The chamfered inserts had 20° chamfer angle and 0.1 ± 0.03 mm chamfer width while the honed inserts had an average radius of 10.5 ± 4.0 μm. At the cutting speed of 100 m min^{-1} the authors found that there was no significant difference in the average roughness (R_a) for feed rates of 0.05 and 0.1 mm rev^{-1}. But, at a higher feed rate (0.2 mm rev^{-1}) machining with honed insert produced significantly lower roughness. The roughness decreased from 1.4 to 0.4 μm. The results were somewhat different at the higher cutting speed of 200 m min^{-1}. The honed insert produced better surface finish at feed rates of 0.05 and 0.1 mm rev^{-1} compared to chamfered edge. But, the roughness at 0.2 mm rev^{-1} from the two insert types was almost similar. These observations were, however, made when cutting a workpiece having hardness value of 54.7 HRC. For a fixed feed rate of 0.2 mm rev^{-1} the authors observed that the surface finish showed improvement for the materials having hardness of 51.3 and 54.7 HRC when machining using the honed inserts. However, this observation was reversed at the lowest feed rated tested (0.05 mm rev^{-1}), i.e., chamfered edge geometry resulted in better surface finish at higher hardness and cutting speed.

Davoudinejad and Noordin[43] investigated the effect of chamfer and honed edge geometry on surface roughness and other factors during turning of hardened DF-3 tool steel (58 HRC) using PVD-TiN-coated mixed ceramic inserts. Good surface finish was obtained using chamfered tool at feeds and speeds ranging from 0.125 to 0.05 mm rev^{-1} and 155 to 210 m min^{-1}, respectively. A larger difference in the average roughness was observed at lower feeds (0.05 to 0.125 mm rev^{-1}). The average improvement obtained was 36%. Thus, the effect of the cutting edge geometry was more significant at smaller feed rates. At higher feed rates tool fracture at the tip of the insert in the chamfered tool caused unstable surface roughness.

The nose edge in the conventional cutting inserts is made up of only one radius. In an attempt to improve the surface finish tool manufactures have introduced inserts having a series of radii that make up the cutting edge. This type of inserts are known as wiper inserts or multiple radii inserts. The wiper edge is made up of a large main radius which is complemented by a number of smaller radii (**Figure 5**). The extended cutting edge at the tool corner is carefully designed to 'wipe' off the miniscule peaks and valleys usually left behind by the conventional insert after the machining. The wiper inserts allow machining at much higher feed rates than the conventional inserts to attain the same level of surface finish. However, due to the larger contact area between the tool and the workpiece, wiper inserts exert a larger force on the workpiece compared to the conventional inserts.

Surfaces produced by wiper inserts and conventional inserts were compared by Elbah *et al.*[44] during hard turning of AISI 4140 steel. Unlike in most previous studies whereby only one roughness parameter is considered, the authors compared the surface in terms of R_a, R_z (average peak-to-valley height), and R_t. All three parameters showed a significant drop (up to 2.5 times) when the machining was carried out using the wiper

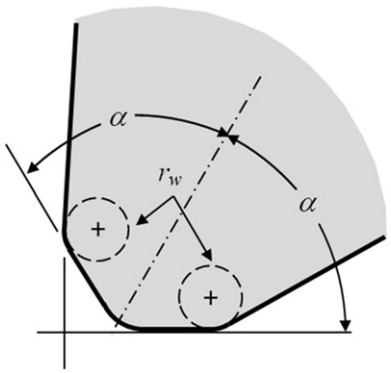

Figure 5 Wiper tool edge design (tool angle = 2α, wiper circle radius = r_w).

inserts. This is due to the smearing effect of the extended cutting edge in the wiper design. The 2-D profile along the feed direction for the conventional insert showed a very repeatable form of peaks and valleys whereas the profile for the wiper insert was random in nature.

Correia and Davim[45] also compared the performance of wiper inserts with conventional inserts during the turning of AISI 1045 steel. The authors evaluated several surface roughness parameters, namely R_a, R_{zD}, R_{3z}, R_a/R_q, R_q/R_t, and R_a/R_t. No significant difference in R_a, R_{zD}, R_{3z}, and R_q was observed at a low feed rate (0.075 mm rev^{-1}). This implied that at very low feed rates finish machining with the wiper inserts produced similar roughness when compared to machining using the conventional inserts. However, at higher feed rates (0.15 and 0.25 mm rev^{-1}) the wiper inserts produced better surface finish. Reduction of about 40 and 60% in the R_a value was reported at the feed rates of 0.15 and 25 mm rev^{-1}, respectively. The other roughness parameter also showed similar drop when the machining was carried out using the wiper inserts.

Ceramic and ceramic composite tools have been found to produce good surface finish due to the high-hot hardness and wear resistance of the ceramic material. Grzesik and Wanat[46] investigated the characteristics of surface roughness produced in turning of hardened low-chromium alloy steel using mixed alumina–titanium ceramic tools equipped with both conventional and wiper edge. The cutting speed was kept constant at 100 m min^{-1} and after each pass the surface finish was measured using a stylus profilograph. A set of 2D roughness parameter were also obtained using a shop-floor roughness tester. The authors analyzed 12 amplitude, spacing, hybrid, and functional parameters. In comparing the average roughness R_a and peak-to-valley roughness R_t the authors reported that at very low feed rates (<0.1 mm rev^{-1}) both the wiper and the conventional inserts produced very similar roughness values. At higher feed rates (>0.2 mm rev^{-1}) the wiper insert produced significantly lower roughness. For instance, at the feed rate of 0.4 mm rev^{-1}, conventional insert produced a R_a value of 5.47 μm while the wiper insert produce R_a of 0.69 μm. A significant drop in the R_t was also observed when using the wiper insert at a feed rate of 0.4 mm rev^{-1}. The authors' results are similar to those reported by Correia and Davim.[45]

The best quality surface finishing in the order of nanometers can be produced by using SPDT. This process is also known as ultraprecision turning. Ultraprecision turning is normally used to produce optical components like lenses and high-precision molds. The cutting edge radius in typically in the range of 50 nm and the positional accuracy and dynamic stability of the machine tool are in the order of 1 to 10 nm. Tauhiduzzaman and Veldhuis[47] studied the effect of tool geometry on surface roughness in SPDT. Single crystal diamond tools were used to perform face turning. Tools with two different nose radii (0.50 and 1.50 mm) were compared. In addition, a specially designed tool with a combined radius of 0.50 and a 0.50 mm flat secondary region was also tested. The authors reported that oblique cutting with a larger nose radius tool produces more chip thinning near the trailing edge of the tool. This in turn reduces the uncut chip thickness and results in better surface finish. This was, however, true only at a feed rate 50 μm rev^{-1}. At lower feed rates the severe chip thinning resulted in more side flow. The more edge serrated chip resulted in poorer surface finish. These observations were, however, depended largely upon the microstructure of the material.

The rake angle in a tool is known to affect chip flow and thus influence surface finish. Positive rake angle causes chips to flow upwards along the rake face while negative rake angles subject chips to compressive stresses. Negative rake angles can lead to micro-cracking and poor surface finish. Ranganath and Vipin[48] studied the effect of rake angle on surface roughness in CNC turning. The tools selected were cemented carbide insert having three combinations of nose radius (0.4, 0.8, and 1.2 mm) and positive rake angles of 16°, 18°, and 20°. At a depth of cut of 0.2 mm and feed rate of 0.05 mm rev^{-1} the authors found that the average roughness decreased from 1.8 to 1.6 μm. The decrease, however, was less at higher feed rates.

Gupta and Kumar[49] investigated the surface roughness during turning of glass fiber-reinforced composite by varying several process parameter independently. Cutting tools having rake angle of $-6°$, 0°, and $+6°$ were used in the machining. Their results showed that the best surface finish ($R_a = 1.793$ μm) was produced when using tool with rake angle of 0°. The rake angle of $-6°$ produced slightly higher roughness compared to the tool rake angle of 6°. Since the maximum variation in R_a was only 0.048 μm the results obtained from machining the glass fiber composite does not lead to a firm conclusion.

1.1.3.2 Tool Wear

Tool wear is the gradual loss of tool material that leads to a change in the shape of the cutting tool from its original shape. Extremely high temperatures and stresses are generated during cutting due to the metal-to-metal rubbing action which aggravates wear. Wear of the cutting tool changes the part of the tool edge geometry that is directly in contact with the machined workpiece. Since the cutting tool leaves an imprint on the workpiece any changes in the tool nose profile due to wear will directly influence the surface finish. However, most researchers' measured flank wear along the major cutting edge and related the flank wear to surface roughness. This is because the major flank wear is the tool life criterion defined in the ISO3685 (1993) standard.[38] According to the standard the maximum width of the flank wear land $VB_{B(\max)} = 0.6$ mm if the flank is not regularly worn. If the flank is regularly worn the criterion for tool life is based on the average width of flank wear $VB_B = 0.3$ mm. Although the major flank of a cutting tool is not directly in contact with the finished surface, increased flank wear increases the cutting force and introduces tool chatter which leads to deterioration in surface finish. Extensive research has been carried out in the past to study wear and surface roughness in turning. However, there are not many papers in which the direct correlation between wear and surface roughness has been investigated. In such situations the relationship between the two variables can only be inferred by comparing the surface roughness and the tool wear plotted separately against other variables such as feed rate or machining time.

The tool wear–surface roughness relationship is not a simple relationship but depends on several compounding factors which include the dynamics of machining and the stability of the machine tool. Pavel *et al.*[50] investigated the effect of tool wear on surface roughness for the case of continuous and intermittent hard turning. For continuous cutting the authors reported that as the tool wear increased the peaks of the roughness profile became higher while the valleys between the peaks flattened. This observation was due to the rapid increase in the notch wear to a steep groove much deeper than other abrasion marks. A different behavior, however, was observed during the intermittent cutting. The average roughness R_a showed only a small increase at the beginning of the cutting and then started to decrease even below the initial value recorded with a new tool. This behavior was explained in terms of the widening of the notch wear and the flattening of the nose radius due the combined action of cutting and interruptions. The shocks caused by the intermittent cutting lead to a very irregular surface profile. Although the surface finish improved with tool wear the authors observed a negative effect at very high levels of wear ($VB_{\max} > 0.15$ mm).

Grzesik[51] compared the effect of wear on three differently shaped ceramic cutting on the surface roughness during turning of hardened steel (HRC 50–60). Conventional and wiper ceramic inserts were used in the study. A set of 2-D roughness parameters as well as amplitude distribution function, bearing curve parameters were analyzed. The notch wear along the minor flank edge (trailing edge) produced substantial modification of the surface irregularities. The average roughness R_a and the peak-to-valley roughness R_z were found to increase gradually with the tool flank wear. The wiper insert, however, produce better surface finish particularly at a lower feed rate (0.1 mm rev^{-1}) compared to the standard insert or wiper insert at twice the feed rate. The smoothing action of the wiper insert also caused the RMS average slope $R_{\Delta q}$ to increase only from 2.4° to 10° during 21 min of machining compared to an increase from 6.6° to 15.2° when using the conventional insert.

Other researchers have also observed that surface roughness generally increased with the tool flank wear. Bhuiyan and Choudhury[52] monitored the vibration frequency signal and found that as the flank wear increased the frequency of vibration along the feed direction decreased until a flank

wear of 0.129 mm. Beyond this the frequency increased continuously until tool failure. The frequency of vibration in the radial direction, however, was found to increase steadily with the increase in nose wear except at the critical point of tool wear when chip breakage occurred. The trend of surface roughness was found to be similar to that of tool wear. When the tool wear rate was steady the trend of surface roughness was also steady. When the tool wear became rapid there was a rapid increase in the surface roughness.

Kilickap *et al.*[53] investigated the effect of tool wear on surface finish during turning of homogenized SiC-p reinforced aluminum metal-matrix composite (MMC). Three different cutting speeds (50, 100, and 150 m min^{-1}), feed rates (0.1, 0.2, and 0.3 mm rev^{-1}), and depths of cuts (0.5, 1.0, and 1.5 mm) were used in their study. Both TiN-coated and uncoated inserts were used in the dry turning. When the machining was carried out using uncoated inserts the authors found that the surface roughness decreased at higher cutting speeds. Coated inserts produced a similar trend only at higher depths of cut. At a low depth of cut and a high feed rate the reverse trend was observed when the machining was done using the coated inserts. But, generally, coated tools produced lower surface roughness. The authors' experimental results also showed that depth of cut had the least influence on the surface roughness.

Tool wear and surface roughness effects during turning are often investigated when studying the machinability of materials. Good machinability is often characterized by good surface finish and high surface integrity of the machined part, minimum tool wear or increase tool life, low cutting forces, and power requirements as well as easy chip control. Sahin *et al.*[54] investigated the machinability of 2024 aluminum alloy reinforced with Al_2O_3 particles using varying size and with the fraction of particles up to 30 wt.% under different cutting conditions. A constant depth of cut of 2 mm and feed rate of 0.1 mm rev^{-1} were used while the cutting speed was varied between 100, 160, and 210 mm rev^{-1}. Two types of cutting tools were used in their experiments, namely TiN-coated tool and TP30 tool. The tool wear was measured using an optical tool microscope to determine the degree of the flank and crater wear. The damage and wear features were also observed using a scanning electron microscope. The average roughness R_a and the maximum peak-to-valley roughness R_{max} were measured using a stylus instrument. The average roughness versus cutting speed data obtained by the authors showed different trends for different particle sizes and different percentage reinforcements. Without the particle addition the average roughness and tool life decreased with increasing cutting speeds. With 30% addition of 16 μm Al_2O_3 particle the reverse trend was observed. The increase in surface roughness of the workpiece at higher speed was attributed to the increased chipping of the tool and the loss of the coated layer.

Sahoo and Sahoo[55] studied the machinability of AISI 4340 steel in terms of the flank wear, surface roughness, chip morphology, and the cutting forces in finish hard turning using uncoated and multilayer coated TiN and ZrCN carbide inserts at a cutting speed of 150 m min^{-1} and feed of 0.15 mm rev^{-1}. The depth of cut was 0.4 mm. The flank wear and the average roughness R_a increased gradually with the machining time while machining using TiN-coated inserts. The uncoated insert, however, showed significant increase in flank wear and a tool life of only 1 min whereas the surface roughness showed significant fluctuation. This behavior was explained in terms of the failure of the uncoated insert by chipping which eventually lead to deterioration of the surface finish quality.

In spite of the advances in tool materials, such as whisker-reinforced ceramics and CBN, for cutting high-strength materials like nickel-based alloys, the coated cemented carbides are still widely used in the industry due to their lower costs. Cantero *et al.*[56] analyzed tool wear mechanism in the finish turning of Inconel 718 in both dry and wet turning using coated-cemented carbide inserts. Inconel 718 is one of the most commonly used Ni alloy in manufacturing aerospace components due to their excellent mechanical properties and corrosion resistance. The authors carried out turning tests on a lathe equipped with a dynamometer for cutting force measurements. Coated carbide inserts having 80° tip angle and 0.4 mm nose radius were used in the machining. The surface quality was assessed using a roughness tester. Five measurements of the average roughness R_a at four different points on the machined surface were recorded. The authors reported that different wear mechanisms occurred during the turning – notching and chipping being the most common. They also observed material adhesion in all their wear tests resulting in BUE formation. The notch formation and chipping were explained in terms of the combination of aggressive conditions involved during the machining of Ni alloys, leading to strain hardening at elevated temperatures. Machining at high speeds was found to accelerate diffusion wear mechanism thus resulting in flank and crater wear. The authors found that the average roughness was maintained in a reasonable range in both dry and wet turning conditions. The roughness values for dry turning was, however, more dispersed compared to wet turning. The dispersion is likely due to chipping of the tool caused by the high temperatures during the dry turning.

Ozel *et al.*[57] investigated surface finish and tool flank wear in the finish turning of AISI D2 steel (60 HRC) using ceramic wiper multi-radii insert. The author found that at very low feed rates, for example, 0.05 mm rev^{-1}, the surface roughness remained almost constant at different machining time although the flank wear increased. At higher feed rates (0.1 and 0.15 mm rev^{-1}) the average roughness increased with the tool flank wear. The authors also developed multiple linear regression models and neural network models for surface roughness and tool flank wear prediction.

Since tool wear is known to influence surface finish the value of surface roughness can be used to establish the moment to change the tool in finish turning. But, studies carried out by several authors show that flank wear or nose wear formation alone is not sufficient to explain the surface roughness variation with cutting time. Shahabi and Ratnam[58] showed that although the tool nose wear increased gradually with machining time the average roughness R_a decreased and then increased. This observation was true at all the feed rates tested by the authors (0.2, 0.25, 0.3, and 0.4 mm rev^{-1}). The authors attributed the decrease in roughness during the initial stage of machining to the gradual growth of nose wear which causes flattening of the roughness profile. As the cutting progresses the growth of the notch wear causes the roughness to increase. Nevertheless, other researchers have shown that the average surface roughness generally increased with increasing flank wear.[49–51,59,60]

In most of the published literature, researchers investigated the effect of tool wear indirectly on a single roughness parameter. The most common parameter considered is the average roughness R_a. The usual justification given by the researchers is that R_a is the most common parameter used in the industry for roughness assessment. But, since R_a is an amplitude parameter that merely provides the average deviation of the surface profile above a mean line the subtle changes in the surface texture due to machining may not be captured by this parameter. R_a is not capable of differentiating between 'spiky' and 'scratched' surfaces. Thus, in some studies the increase in tool wear produced an increase in surface roughness while in the others the trend is reversed. In the continuous hard turning of 1117 hardened steel (62 ± 1 HRC) using PCBN inserts the results reported by Pavel *et al.*[50] showed that R_a increased by a maximum of only about 1.2 μm whereas R_z and R_{pk} (reduced peak height) showed maximum increase of approximately 6.1 and 5.4 μm. Compared to average roughness, R_z and R_{pk} had the most significant deviation from the initial values at the start of machining.

Kumar and Ratnam[61] introduced three new roughness parameters that are unique to turning, namely (1) average slope of profile peaks (Φ_p), (2) average slope of profile valleys (Φ_v), and (3) the relative length of profile (R_{rl}). These parameters are defined as follows:

(a) Average slope of the profile peaks (Φ_p): The mean angle between the tangents drawn on each half of the peak and is measured along the assessment length (**Figure 6(a)**). The parameter is given by:

$$\Phi_{\mathrm{p}} = \frac{1}{N}\sum_{i=1}^{n}\Phi_i \qquad [3]$$

(b) Average slope of profile valleys (Φ_v): The average slope of profile valleys (Φ_v) is defined as the mean angle between the tangents drawn on each half of valley and is measured along the assessment length (**Figure 6(a)**). This parameter is given by:

$$\Phi_{\mathrm{v}} = \frac{1}{N}\sum_{i=1}^{n}\Phi_i \qquad [4]$$

(c) Relative length ratio of the peaks (R_{rl}): The ratio of the length measured below the each peaks at the level selected above the mean line (**Figure 6(b)**). It measures the horizontal characteristics of the peak deviation from its apex. This parameter is determined from the following equation:

$$R_{\mathrm{rl}} = \frac{\frac{1}{N}\sum_{i=1}^{n} L_i}{\frac{1}{N}\sum_{j=1}^{n} L_j} \qquad [5]$$

The authors showed that these three parameters have good correlation with the tool nose wear compared to the other roughness parameters. The average slope of the profile peaks (Φ_p) was found to have a linear and high negative correlation ($R^2 = 0.9762$) with the nose wear. This trend was attributed to the flattening of the roughness profile as the tool gets increasing worn out during turning.

In correlating the tool wear to the surface roughness almost all researchers measured flank wear defined as $VB_{\max}$ (**Figure 7**). But, flank wear does not provide comprehensive information about tool wear during finish turning because most of the cutting takes place at the tool nose corner. Kwon *et al.*[62] proposed tool wear models that gages the tool wear pattern more accurately. Their model considers the wear in the nose area instead of the flank wear. The authors demonstrated using their models as well as experimentally that surface roughness increases with the tool nose wear. A more rapid increase in surface roughness was observed at a higher feed rate.

1.1.3.3 BUE

Another major factor that affects surface roughness and is closely related to tool wear is the BUE formation. BUE is formed under low cutting speeds due to the shearing action of

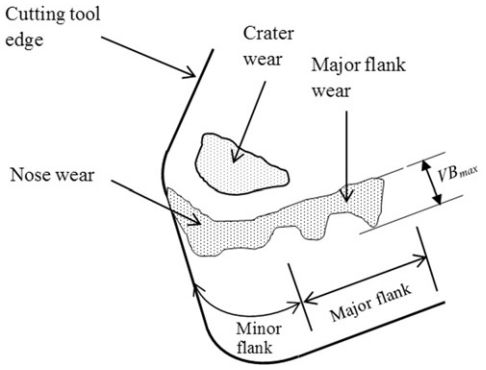

Figure 7 Dominant wear types in cutting tool insert.

Figure 6 Variables used in calculating (a) the profile slope (b) relative length.[61]

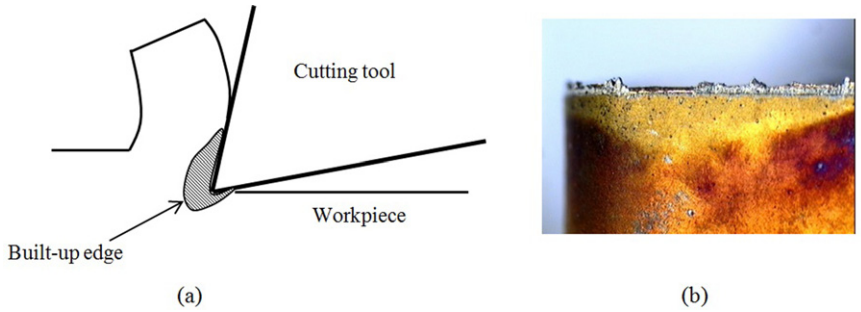

Figure 8 Built-up edge on cutting tool: (a) schematic diagram, (b) photograph to tool. https://www.secotools.com/en/Global/presscentre/Left/Archive-2014/Identifying-and-addressing-eight-common-insert-failure-modes/

the cutting tool. The workpiece material undergoes plastic deformation, melts and adheres close to the tip of the cutting tool at the rake face (see **Figure 8**). Ductile and low hardness materials like aluminum, some high-temperature alloys, and some MMCs have tendency to form BUE on the cutting tool. Low cutting speeds and absence of coolant are among the main factors that contribute to BUE formation. A three-stage cyclic dynamic process is usually involved in the formation of the BUE. These are: (1) the initiation of the BUE at the tool–chip interface, (2) the growth of the BUE to a certain size with various shapes and geometry, and (3) the breakage and disappearance of the BUE. This cyclic process repeats itself throughout the machining operation and has a significant effect on the cutting force, the cutting temperatures, tool wear, tool life, and the surface roughness and dimensional accuracy of the finished product.[63]

Since the BUE can easily tear off during turning some of the torn materials can get attached to the workpiece surface thus affecting the surface finish quality of the workpiece. BUE formation can also lead to changes in the dimensions of the machined product due to the changes in the depth of cut, increased vibration, and the rapid fluctuation in cutting forces. These lead to further deterioration of the surface finish. Fang *et al.*[64] investigated the quantitative relationship between the BUE formation and the cutting vibrations. The authors carried out a set of cutting experiments over a wide range of cutting conditions on 2024-T351 aluminum alloy commonly used in the industry. They analyzed the vibration signals generated from the machining in both the time and the frequency domains. Their results showed that three distinct BUE regions that are characterized by different pattern of cutting vibrations exist. The authors showed that a statistical parameter known as kurtosis can be used to distinguish between the steady and unsteady BUE formation. The authors found that in the steady BUE region the process of formation of the BUE is accompanied by increased vibration magnitude. Although no study on the effect of the BUE formation on surface finish was carried out it is obvious that the increased vibration during turning will lead to increased waviness of the finished surface.

Since BUE formation is a dynamic phenomenon its direct effect on the surface roughness of the workpiece has not been investigated widely. Most researchers select the machining parameters, machining conditions, such as use of proper cutting fluids, to avoid the formation of BUE. Although a new coated tool can avoid BUE formation, wear of the coating during machining can lead to formation of the BUE.[65] Gomez-Parra *et al.*[66] studied the mechanism of built-up layer and BUE formation, their evolution and influence on the dry turned surface quality of aeronautical aluminum alloys. Machining tests were carried out on UNS A92024 (Al–Cu) and UNS A97050 (Al–Zn) alloy cylindrical bars. Uncoated and TiN-coated inserts were used as cutting tools. The cutting speed was varied from 45 to 170 mm min^{-1} while the feed rate was varied from 0.05 to 0.3 mm rev^{-1}. The depth of cut was fixed at 1.0 mm. The results produced by the authors showed that the average roughness (R_a) decreased along the cutting length. The authors explained this observation in terms of the increase in the thickness of the BUE which causes reduction of the tool position angle. An increase in the feed was found to increase the intensity of the adhesion effects. These results, however, seem to disagree with the general understanding of the effect of BUE on surface roughness. The surface finish is known to deteriorate due to the presence of BUE thus increasing the surface roughness. But, the authors' results showed the opposite trend. This could be because the material that had adhered to the tool was still intact and had not torn off during the single pass of the cutting tool.

The BUE effect on tool wear during the turning of medium and high-strength steels at low cutting speeds was investigated by Cassier *et al.*[67] The authors used AISI 1020, AISI 1045, and AISI 4140 steel bars as the workpiece material in their experiments. To ensure BUE formation the authors used dry cutting with low depth of cut (0.4 mm) and low cutting speeds (4–10 m min^{-1}). The authors noted that a total of 13 out of 72 experiments showed BUE formation for the uncoated tools. However, since BUE formation is a dynamic process they caution that this finding does not imply that the other tools did not undergo BUE formation. They also observed that BUE formation was more common on tools used to cut AISI 1045 steel though greater BUE formation occurred on tools used to machine AISI 1020 steel. The greater tendency of BUE formation on the AISI 1020 steel was attributed to the ductility of the material. The formations of BUE lead to increased abrasive wear and poorer surface finish. The coated tools, however, did not show any sign of BUE formation.

1.1.3.4 Tool Coating

The development of coated cutting tools was initiated by the development of new alloys and engineered materials and the

difficulty associated with machining these materials effectively and economically. Coated tools have high wear resistance, are less susceptible to BUE formation and can be used to cut hard materials at high cutting speeds. The commonly used coating materials are titanium nitride (TiN), titanium carbide (TiC), titanium carbonitride (TiCN), and aluminum oxide (Al_2O_3). The coatings are usually applied using the chemical vapor deposition (CVD) and the physical vapor deposition (PVD) techniques. The coating thickness typically varies from 2 to 10 μm.

Gokkaya and Nalbant[68] investigated the effect of cutting tool coatings on the surface roughness of AISI 1015 steel. Four different cemented carbide tools were compared, namely uncoated, coated with AlTiN, coated with TiAlN using PVD, and 3-layer coating with the outermost layer coated with TiN. Five different cutting speeds (50, 73, 102, 145, and 205 m min^{-1}) and two feed rates (0.24 and 0.32 mm rev^{-1}) were used in their study. The authors reported that lower average roughness was obtained by using the three-layer coated insert. Lowering the cutting speed by 33% improved the surface finish by about 69%.

Thakur *et al.*[69] investigated the effect of cutting speed and tool coating deposited by CVD on the machined surface roughness, tool wear characteristics, chip morphology, and chip reduction coefficient during turning of Inconel 825. The turning experiments were carried out using uncoated cemented carbide and CVD multilayer coated (TiN/TiCN/Al2O3/ZrCN) inserts at a constant feed rate of 0.198 mm rev^{-1} and depth of cut of 1 mm. Their results showed that the CVD multilayer coated tool resulted in the deterioration in surface finish as the cutting speed was increased from 50 to 125 m min^{-1}. The average roughness R_a increased from approximately 0.6 to 2.7 μm. The surface roughness obtained using the uncoated insert, however, was almost constant at different cutting speeds. The increase in the surface roughness with the cutting speed was explained by the formation of BUE. This was due to (1) higher surface roughness of the coated inserts and (2) increased edge radius of the CVD coated inserts. The authors concluded that surface roughness could not be improved using the CVD multilayer coated tool under the machining conditions tested.

Yigit *et al.*[70] compared the performance of multilayer coated carbide tool when turning spheroidal graphic cast iron with uncoated tools. TiCN/TiC/Al2O3/TiN multilayered coatings with different thicknesses were fabricated on WC substrate using high-temperature CVD. In all the cutting speed tested (125, 150, 175, and 200 m min^{-1}) the authors found that the best surface finish was produced by the multilayer coated tool having a total coating thickness of 10.5 μm. This was explained in terms of the decreased flank wear and cutting forces for the coated tools compared to the uncoated tool.

Nalbant *et al.*[71] investigated the surface roughness effects of coating method, coating material, cutting speed, and feed rate on the machining of AISI 1030 steel. Uncoated, PVD- and CVD-coated cemented carbide inserts were used in their study. The authors used five different feed rates (0.25, 0.30, 0.35, 0.40, and 0.45 mm rev^{-1}) and three different cutting speeds (100, 200, and 300 m min^{-1}). The depth of cut was kept at 2 mm. At 200 mm min^{-1} cutting speed and 0.25 mm rev^{-1} feed rate the TiN coated with PVD method produced surface roughness of 2.16 μm, TiAlN-coated PVD method produced 2.3 μm while AlTiN coated with PVD provided 2.46 μm. The authors reported that increasing the number of coating layers decreased the friction coefficient and therefore decreased the average roughness of the workpiece. TiN-coated cutting tool produced the lowest roughness whereas the uncoated tool produced the highest roughness. The difference between the average roughness for TiN-coated and uncoated inserts was, however, only 13.5% while that between TiAlN-coated and uncoated insert was only 1.8%. Thus, for the range of cutting parameters tested no significant difference in the average roughness can be observed between the coated and the uncoated tools.

From the published literature it can be noted that machining with coated tools generally improved the surface finish. Uncoated tools have greater tendency to wear by abrasion and adhesion especially at lower cutting speeds. This leads to the formation of BUE thus affecting the surface finish. Coated tools, however, fail mainly by abrasion. The coated tools, in general, experience lesser wear compared to the uncoated tool and this decreases the effects of vibration and tool chatter. However, when the coating is worn the possibility of formation of BUE increases.[66]

1.1.4 Effect of Machining Parameters

The three most common machining parameters that have significant influence on the surface finish and the dimensional accuracy of the machined product and have been studied extensively in the past are the feed rate, cutting speed, and the depth of cut. These three parameters are the most easily controlled parameters compared to other parameters in a turning operation. The manner in which these parameters influence surface finish depends greatly on other factors such as the material property of the workpiece, the type of cutting tool used during machining, the presence or absence of cutting fluid, the method to fluid application, and the stability of the machine tool. Researchers have generally study the effect of the three main machining parameters on the surface roughness in relation to a specific type of workpiece material and often by using a particular type of cutting tool. Many researchers have investigated the effects of the cutting parameters on other factors besides surface roughness, such as tool wear, cutting force, temperatures, BUE formation, and vibration in addition to surface finish. Many of these studies have been carried out with the aim of finding the optimum parameters that produces the best surface finish quality. Previous works on optimization studies are reviewed in greater detail in Section 1.1.6. The focus of this section is to understand the manner in which the various machining parameters, particularly the feed rate, the cutting speed, and the depth of cut, affect the surface roughness of the machined workpiece.

Aouici *et al.*[72] investigated the influence of cutting parameters on the surface roughness and cutting forces in hard turning of X38CrMOV5–1 (50 HRC) using CBN tool. Using analysis of variance (ANOVA) the authors investigated the combined effects of three cutting parameters, namely cutting speed, feed rate, and depth of cut on the surface roughness parameters (R_a, R_t, and R_z) and cutting force components. Each

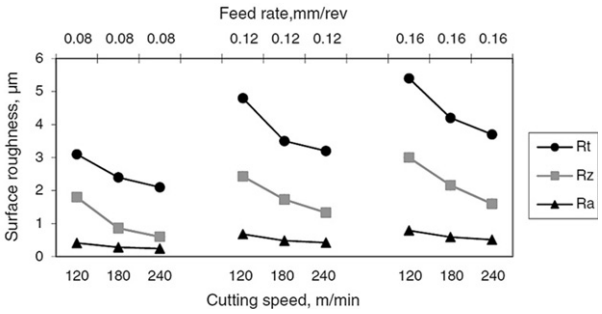

Figure 9 Effect of cutting speed on surface roughness at various feed rates.[72]

cutting parameter was varied in three different levels. The cutting speeds used were 120, 180, and 240 m min^{-1}, feed rates were 0.08, 0.12, and 0.16 mm rev^{-1} while the depths of cut were 0.15, 0.30, and 0.45 mm. Their results (**Figure 9**) showed that the surface roughness increased with increasing feed rate. All three roughness parameters generally decreased with the increasing cutting speed, the percentage decrease being higher at a higher feed rate. The peak-to-valley roughness along the assessment length R_t showed the most significant change compared to R_a and R_z.

Rafai and Islam[73] investigated the effects of the cutting speed, feed rate, and the depth of cut on the dimensional accuracy and the surface finish in dry turning of AISI 4340 (30 HRC) steel. The cutting tool used was cobalt-coated carbide insert with a corner radius of 0.8 mm. The cutting speeds selected were 54, 150, and 211 m min^{-1}, the feed rates were 0.11, 0.22, and 0.33 mm rev^{-1} and the depths of cut were 0.5, 1.0, and 1.5 mm. The surface finish was assessed using the average roughness parameter R_a to enable comparison with the published results. The authors reported that the extent of the influence of feed rate on surface roughness was much higher compared to the influence of the cutting speed and depth of cut. For practical machining operations the authors recommend that the cutting speed and depth of cut can be overlooked provided that the cutting speed is high enough to prevent the formation of BUE.

Many studies to determine the optimal cutting conditions to produce the best surface finish have been carried out by varying the three main machining parameters, namely cutting speed, feed rate, and depth of cut. Gunay and Yucel[74] applied the Taguchi method to determine the optimum surface roughness in the turning of high-alloy white cast iron. Their objective was to minimize the average roughness R_a. The ANOVA was used to determine the statistical significance of the cutting parameters. The workpiece material used was Ni-Hard materials of two different hardness values (50 and 62 HRC). The smaller-the-better performance characteristic for R_a was applied to obtain the optimal cutting parameters based on the signal-to-noise (S/N) ratio. Two type of inserts, namely ceramic and CBN were used in their study. The cutting speeds were 50, 100, and 150 m min^{-1}, feed rates were 0.05, 0.075, and 0.1 mm rev^{-1} while the depths of cut were 0.25, 0.50, and 0.75 mm. The authors reported that the R_a value increased with the increasing depth of cut at 50 m min^{-1} cutting speed for ceramic tool. At a cutting speed of 100 m min^{-1} no significant variation in R_a with the depth of cut was observed. The variation of R_a with the depth of cut, however, was not regular when the cutting was carried out using the CBN tool. At the higher cutting speed of 150 m min^{-1} neither of the cutting tools showed a regular tendency with the depth of cut. The authors attributed the irregular tendency to the randomized distribution of the feed rate due to the design of the experiment. The R_a value was found to increase linearly as the feed increased from 0.05 to 0.1 mm rev^{-1} for machining of the Ni-Hard material with 62 HRC. The authors reported that the smallest R_a obtained was 0.280 µm at 100 m min^{-1} cutting speed and 0.5 mm depth of cut.

Asilturk and Akkus[75] also carried out a study similar to that of Gunay and Yucel[74] using the Taguchi method. Their objective was to optimize turning parameters to minimize surface roughness. Unlike Gunay and Yucel's work the authors measured R_a as well as R_z. The machining was carried out on a hardened AISI 4140 (51 HRC) steel using coated carbide inserts. The cutting speeds tested were 90, 120, and 150 m min^{-1}, the feed rates were 0.18, 0.27, and 0.36 mm rev^{-1} while the depths of cut were 0.2, 0.4, and 0.6 mm. The authors used the Taguchi method and L_9 orthogonal array to reduce the number of experiments. Although the authors did not discuss in detail how each parameter affected the surface finish they reported that the best R_a and R_z values were obtained at the following optimum conditions: 120 m min^{-1} cutting speed, 0.18 mm rev^{-1} feed rate, and 0.4 mm depth of cut.

Kumar *et al.*[76] investigated the effect of cutting speed, feed rate, and depth of cut on the cutting force and surface roughness during dry turning of Al-4.5%Cu/Ti MMC. The Ti content was varied from 5 to 10%. The cutting inserts used were uncoated cemented carbide tools. Turning tests were carried out under three different cutting speeds (40, 80, and 120 m min^{-1}), three feed rates (0.12, 0.24, and 0.36 mm rev^{-1}), and three depths of cut (0.5, 0.75, and 1.0 mm). After each machining run the authors measured the average surface roughness R_a of the workpiece using an optical profiling system with a scan length of 50 µm. The authors reported that the surface roughness of all machined samples with different Ti content were higher at the minimum cutting speed of 40 m min^{-1} and lowest at the higher cutting speed of 120 m min^{-1}. They explained the better surface finish at higher cutting speed in terms of the lesser amount of BUE formed at higher machining speeds thus leading to better surface finish of the samples during the dry turning.

Due to the lack of a comprehensive study on the surface integrity of nimonic C-263 alloy in turning Ezilarasan *et al.*[77] investigated the surface integrity parameters in the turning of this alloy. This material has high content of Nickel (54%) and is used in the manufacture of hot combustion parts such as gas turbines for aerospace applications. The authors used whisker-reinforced ceramic cutting tools. The machining experiments were carried out under dry cutting conditions by varying the cutting parameters. The cutting speeds used were 125, 190, and 250 m min^{-1}, feed rates were 0.102 and 0.143 mm rev^{-1}, and the depth of cut was 0.75 mm. The cutting forces were measured using a three-axis dynamometer while the surface roughness was measured using a surface profilometer. As expected the average surface roughness R_a generally increased

with the feed rate. The authors' results showed that higher cutting speeds produced lower roughness values. The surface roughness also generally increased with the machining time, but the best surface finish (lowest surface roughness) was obtained at 190 m min^{-1}. The higher surface roughness at low speeds was attributed to the tendency to form BUE. The authors concluded that the best cutting condition for the alloy is 0.012 mm rev^{-1} feed rate and 190 m min^{-1} cutting speed.

Kini and Chincholkar[78] studied the effect of varying the machining parameters in turning on the surface roughness and the material removal rate for 30 filament wound glass fiber reinforced polymer in turning using coated tungsten carbide inserts under dry cutting conditions. The authors developed empirical models for the surface roughness and material removal rate using factorial design experiments. In developing the models the authors used two values of cutting speed (59.94 and 133.2 m min^{-1}), two feed rates (0.1 and 0.4 mm rev^{-1}), two depths of cut (0.1 and 0.2 mm), and cutting tools having two different nose radii (0.4 and 1.2 mm). Only one value of surface roughness, namely average roughness R_a was measured. For a constant cutting speed the authors' results showed that the average roughness decreased when the feed rate was increased from 0.1 to 0.4 mm rev^{-1}. This result contradicts those of many other researchers. The surface roughness did not show any trend with the cutting speed. The authors did not explain this behavior as their work was focused on developing the models. Nevertheless, the authors concluded that the feed rate is the main influencing factor on surface roughness followed by depth of cut.

Equations [1] and [2] show that the theoretical surface roughness of the finished workpiece varies as a square of the feed rate. Thus, good surface finish can be obtained by using a small feed rate. But, the machining time will increase leading to increased production cost. The effects of cutting speed and depth of cut on the surface roughness are not so straight forward but depend on many other factors. In machining 7075 Al alloy with 10 wt.% SiC composite Bushan *et al.*[79] found that the surface roughness decreased more or less linearly with cutting speed when using carbide or PCD inserts. The cutting speeds used in their experiment were 180, 200, 220, and 240 m min^{-1}, the feed rates were 0.1, 0.2, 0.3, and 0.4 mm rev^{-1}, while the depths of cut were 0.5, 1.0, 1.5, and 2.0 mm. The decrease in surface roughness (R_a) with the increase in cutting speed was higher when using the PCD insert. Similar observations were made when the machining was carried out on SiC composites. A sharp increase in the surface roughness of both materials was observed when the feed rate was increased. Their results depicted an approximately parabolic relation as predicted by the theoretical relation given by eqns [1] and [2]. The surface roughness also increased with increasing depths of cut due to the increased flank wear.

Unlike the findings of many others, some researchers observed a decrease in surface roughness with increase in cutting speeds. Suresh and Basavarajappa[80] developed a surface response model as a function of cutting parameters in the turning of hardened AISI H13 steel (55 HRC) using PVD coated ceramic tools under different cutting conditions. The cutting speeds used were 42, 80, 140, and 238 m min^{-1}, the feed rates were 0.04, 0.08, 0.14, and 0.20 mm rev^{-1} and the depths of cut were 0.05, 0.15, 0.30, and 0.45 mm. The surface roughness parameter measured was R_a. The authors concluded that cutting speed has the most dominating effect over tool wear followed by feed rate and depth of cut, whereas feed rate is the most significant factor influencing surface roughness followed by depth of cut and cutting speed. Better surface finish at higher cutting speeds was attributed to the lower vibration and lower cutting and thrust forces generated at higher speeds. According to the authors, another factor that contributed to the lower surface roughness at higher speeds is caused by the less heat that was dissipated to the workpiece surface as the heat was swept away by the flowing chips. The minimal surface roughness was obtained with the combination of low feed rate, low depth of cut, and high cutting speed.

Dwivedi *et al.*[81] investigated the effect of turning parameters on surface roughness of A356 alloy with 5% SiC composite produced by electromagnetic stir casting. The cutting speeds used in the study were 100, 145, and 190 m min^{-1}, the feed rates were 0.14, 0.19, and 0.24 mm rev^{-1} while the depths of cut were 0.2, 0.4, and 0.6 mm. The cutting tools used in the machining experiments were tungsten carbide inserts. Their results agreed with those of many other researchers, whereby higher cutting speed results in better surface finish (lower average roughness). They explained this observation in terms of the increased surface temperature of workpiece, which caused softening of the material thus lowering the resistance offered by the material against the tool. The authors noted that as the feed rate increased from the lower to the upper limit the surface roughness increased. The higher material removal rate increased the friction between the tool and the workpiece material. This in turn increased the surface roughness of the workpiece. The authors also noted that the surface roughness increased as the depth of cut increased. This was due to the higher chip thickness. The authors concluded that the best combination of parameters for the lowest surface roughness was cutting speed of 190 m min^{-1}, feed of 0.14 mm rev^{-1}, and depth of cut of 0.20 mm.

Unlike the surface roughness versus cutting speed trend report by many researchers, Qu *et al.*[82] reported the opposite trend. In dry cutting of aluminum bronze alloy using uncoated and coated cemented carbide inserts the authors noticed that the lowest surface roughness was recorded at the lowest cutting speed. As cutting speed increased the surface roughness increased to a maximum value between 16 and 33 m min^{-1}. This increase was attributed to the formation of BUE, which induced sever vibration and scratch effect. From 33 to 126 m min^{-1}, however, the surface roughness decreased due to the weakening forming condition of the BUE. Beyond 126 m min^{-1} the roughness increased again due to sever tool wear resulting in high cutting temperature and forces. With the increase of feed rate, however, the authors noticed that the surface roughness increased monotonically as predicted by theory. However, at higher feed rates the difference between the experimental and theoretical roughness increased. This deviation was explained in terms of the larger cutting force and the increased vibration at higher feed rates thus resulting in more violent vibration of the machine tool structure. The surface roughness versus depth of cut plot had a minimum point at a depth of cut of about 1 mm. The authors explained

the appearance of the minimum point in terms of the 0.4 mm nose radius of the cutting tool. For cutting depths less that 0.4 mm the authors explained that the nose tends not to fully take part in the cutting. The small angle between the workpiece and the cutting tool decreased the amount of heat generated. Furthermore, the heat transfer from the workpiece to the tool decreased thus decreasing the temperature of the workpiece and increasing the temperature of the tool.

Lalwani *et al.*[83] investigated the effect of cutting parameters, namely cutting speed, feed rate, and depth of cut, on the cutting forces and surface roughness in finish hard turning of MDN250 steel using coated carbide insert tool. The MDN250 is a special class of high-strength steel that differs from the conventional steels. MDN250 steel is hardened by metallurgical reaction that does not involve the use of carbon. Three different cutting speeds (55, 74, and 93 m min^{-1}), three different feed rates (0.04, 0.08, and 0.12 mm rev^{-1}), and three depths of cut (0.1, 0.15, and 0.2 mm) were used in their experiments. A single value of roughness parameter (R_a) was measured using an optical surface profilometer. The authors concluded that the feed rate and depth of cut are the most significant factors that influence surface roughness, whereas cutting speed does not have a significant effect on surface roughness.

The influence of the three main turning parameters on the machinability of homogenized Al–Cu/TiB_2 MMC was investigated by Senthil *et al.*[84] The authors used six different cutting speeds (50, 100, 200, 300, 400, and 500 m min^{-1}), six different feed rates (0.05, 0.15, 0.25, 0.45, 0.65, and 0.85 m min^{-1}), and five different depths of cut (0.3, 0.3, 0.9, 1.2, and 1.5 mm). TiB_2-coated inserts were used in the turning experiments. The authors noted a significant drop in the surface roughness from 50 to 100 m min^{-1} cutting speed. Thereafter, the roughness remained more or less constant. The surface roughness value appeared to increase rapidly with increasing feed. The surface roughness was affected only slight by the increase in the depth of cut. The R_a values were within 3–4 μm at different depths of cut.

In most of the studies carried out to investigate the effect of cutting parameters on surface finish the researchers carried out the experiments under dry cutting or a single type of cooling method. Fratila and Caizar[85] investigated the combined effect of the cutting parameters and the cooling method on the surface quality of AISI 1045 steel during finish turning. The authors used dry cutting, minimal quantity lubrication as well as flood cooling. The insert type used was carbide. The cutting speeds used were 62, 90, and 204 m min^{-1}, the feed rates were 0.196, 0.226, and 0.306 mm rev^{-1} and the depths of cut were 0.25, 0.5, and 1.0 mm. Unlike most researcher, the authors measured three roughness parameters, namely R_a, R_z, and R_q (root mean square of the roughness profile). The experimental data were analyzed using ANOVA and F-test to determine the main effects of the process parameters and to establish the optimum process conditions. The analysis showed that the surface quality of the workpiece is strongly influenced by the cutting depth and less influenced by the feed rate. The authors found no significant differences between the roughness parameters and cooling methods.

The friction and lubrication behavior of femoral heads used in bone implants are affected by the surface roughness and the sphericity. Thus, precision finishing of these implants are important. Uddin[86] presented the effect and optimization of the key machining parameters in finish turning of metallic femoral heads. The objective of the investigation was to achieve the best surface roughness and sphericity. The study was carried out using ANOVA. Three different cutting speeds (200, 250, and 300 mm min^{-1}), three different feed rates (0.1, 0.2, and 0.3 mm rev^{-1}), and three different depths of cut (0.2, 0.3, and 0.5 mm) were selected in their L_n orthogonal experimental study. The average surface roughness (R_a) and sphericity (S_p) were measured in each case. The workpiece material was AISI 316L steel. The tools used were diamond-shaped tungsten carbide insert. As in many other machining studies the authors reported that the feed rate is the most significant factor affecting the surface roughness. As the feed rate was increased the surface roughness also increased. Unlike the work of Fratila and Caizar[85] the authors did not notice a marked change in the surface roughness due to changes in the cutting speed and depth of cut.

Chauhan and Dass[87] carried out a study to optimize the machining parameters when machining Grade-5 titanium using PCD (polycrystalline diamond) tools using response surface methodology (RSM). RSM is a set of mathematical and statistical techniques useful for modeling and analysis of problems in which the response of interest is affected by several parameters and the objective is to optimize this response. The machinability performance was evaluated in terms of the average surface roughness (R_a) and the tangential force. The cutting speeds used were 30, 50, and 70 m min^{-1}, feed rates were 0.05, 0.10, and 0.15 mm rev^{-1} while the depths of cut were 0.15, 0.20, and 0.25 mm. The approach angle of the tool was varied from 60° to 90°. Although the authors did not discuss the trends of roughness versus cutting parameters their results showed that the R_a value increased with cutting speed and feed rate and decreased with decrease in the approach angle and depth of cut. The decrease in surface roughness was attributed to the increased friction effect of the chip which lead to increased temperature and stress on the nose of the cutting tool.

Patel and Patel[88] investigated the effect of different cutting parameters (cutting speed, feed rate, and depth of cut) on the surface roughness and the power consumption in the turning of 6036 Al alloy TiC MMC using PCD tools. The cutting speeds used were 63, 103, and 170 m min^{-1}, the feed rates were 0.107, 0.215, and 0.313 mm rev^{-1} and the depths of cut were 0.3, 0.6, and 0.9 mm. The results showed that surface roughness increased almost linearly with feed rate while the depth of cut had minimum effect on surface roughness. The surface roughness, however, decreased with increasing cutting speeds. The decrease was higher at a higher depth of cut.

Khidhir and Mohamed[89] analyzed the effect of cutting parameters on surface roughness and tool wear during the machining of nickel-based hastelloy-276. The RSM method was used to find the combination of factors that gave the optimal response. The cutting speeds used were 150, 200, and 250 m min^{-1}, the feed rates were 0.15, 0.2, and 0.25 mm rev^{-1} while the depths of cut were 0.5, 1.0, and 1.5 mm. The average surface roughness (R_a) was the responding variable. The authors noted that the surface roughness was higher at

lower cutting speed. The surface roughness was lower at higher cutting speeds.

Table 1 provides a summary of the cutting parameters, workpiece material, cutting tools, and the roughness parameters used in many of the literatures related to studies on the effect of machining parameters on surface roughness. It is not surprising to notice that in the order of listing the three common machining parameters the depth of cut is always listed the last. The depth of cut has been found by most researchers to have the least significant effect on the surface roughness while the feed rate has the most significant effect. In most of these studies the authors measured only one roughness parameter, namely R_a. Since R_a represents the average height of the surface profile and the gradual tool wear by abrasion alters the profile height only slightly other parameters that are more sensitive to changes in profile height, particularly the bearing area curve parameters, are expected to exhibit a more accurate trend.

1.1.5 Effect of Workpiece Material

Among the material characteristics that have direct influence on the surface finish are the hardness, grain size, residual surface stresses, subsurface defects, and impurities. The effects of material on the surface finish are usually investigated in terms of the machinability of materials. Machinability is assessed in terms of the surface finish quality, power consumption, chip formation, tool life, and dimensional accuracy of the machined part. Soft and ductile materials like aluminum though very easy to machine tend of form BUE on the cutting tool thus leading to poor surface finish. But, since ductile materials have limited structural applications most metal cutting are done on their alloys.

Among the various material characteristics that affect surface finish the most easily studied characteristic is hardness of the workpiece material. Compared to other characteristics hardness can be easily measured using a hardness tester, such as the Rockwell or Brinell hardness tester. Horváth and Drégelyi-Kiss[90] analyzed the surface roughness of two types of aluminum alloys, namely AS12 eutectic alloy (64 HB) and AS17 hyper-eutectic alloy (114 HB) in fine turning. Two types of inserts, normal (ISO) and wiper, were used in their experiment. The machining parameters were varied as shown in Table 2. The average surface roughness R_a of AS12 alloy was found to vary in the range 0.363–220 μm for wiper insert and 0.284–1.763 μm for the ISO insert. In the case of AS17 the roughness ranges was 0.351–1.040 μm for the wiper and 0.428–1.677 μm for the ISO insert. Their results showed that the average roughness decreased slightly when the hardness of the material increased. The results obtained by Thiele and Melkote[41] during the turning of through-hardened AISI 52100 steel bars also showed slight improvement in the surface finish when machining the harder material (57 HRC) compared to the softer material (41 HRC) under the same machining conditions. The authors used CBN inserts with different cutting edge preparations. The steel bars were heat treated to three desired hardness values (41 HRC, 47 HRC, and 57 HRC). At a feed of 0.05 mm rev^{-1} the thrust force when cutting the harder material (57 HRC) using 93 and 121 μm honed inserts was much higher than when turning the 41 HRC material.

Chinchanikar and Choudhury[91] investigated the effect of workpiece hardness and other factors, namely cutting parameters and type of tool coating, on the different machinability aspects like tool life, surface roughness, cutting force, and chip morphology during the turning of hardened AISI 4340 steel at three different hardness (35, 45, and 55 HRC). Using a hardening and tempering process the authors maintained the maximum variation in hardness of the material to within 1 HRC. The cutting inserts used were cemented carbide inserts coated with a single layer of TiAlN- and CVD-coated multilayer $TiCN/Al_2O_3$. The authors noted a significant improvement in the surface roughness when machining hardened AISI 4340 steel at 45 HRC compared to 35 HRC under all the machining conditions tested. The better surface finish was explained in terms of the chip morphology whereby polished and bright chip back surface showed minimum friction due to the lower cutting forces, thus resulting in better surface finish quality.

Unlike the results observed by Horváth and Drégelyi-Kiss[90] and Chinchanika and Choudhury[91] the results obtained by Ozel *et al.*,[42] however, showed the opposite trend. The authors studied the effect of workpiece hardness among other factors on the surface roughness of AISI H13 steel. They compared the average roughness R_a obtained when turning 51.3 and 54.7 HRC steels. Their results showed that for the same cutting speed and tool edge geometry the harder material produced slightly higher average roughness. Although no explanation was offered it appears that the difference in hardness values between the two materials is too small to produce a significant difference in the surface roughness.

Unlike hardness, material microstructure has a greater influence on the surface finish particularly in very high-precision turning where the depth of cut is in the order of a few micrometers. Tauhiduzzaman and Veldhuis[47] studied the effect of material microstructure including grain boundary density and presence of inclusions, on surface geometry in ultraprecision SPDT. SPDT has the potential of reducing the amount of post process polishing required to fulfill the final product specifications. Controlled studies were performed on samples whose microstructure was refined through mechanical strain hardening processes. The depth of cut used in the face turning operation was 2 μm. The authors reported that 54% strain hardening improved surface roughness by reducing plastic side flow and spring back effect. The strain hardening also introduced dislocations and the high density of dislocations allows the material to fracture easily during machining. However, 82% strain hardening produced voids, fractures, and pitting in the finished surface thus leading to poorer surface finish.

In the work reported by Kumar *et al.*[76] it was found that at a high cutting speed (120 m min^{-1}) the MMC having the lowest Ti content (5%) produced the best surface finish ($R_a = 1.7$ μm) and the MMC having 10% Ti content produce the worst surface finish ($R_a = 2.3$ μm). Although the authors did not explain the exact reason for the higher surface roughness when using 10% Ti content it is believed that the higher percentage of the hard TiC reinforcement caused a larger number of broken particulates and voids to be formed at during the turning operations.

Akasawa *et al.*[92] investigated the effect of microstructure and hardness on the machinability of medium-carbon chrome–molybdenum steel. The authors measured the surface roughness of the workpiece, cutting force, and chip hardness as the measures of machinability. The samples used in the tests were made from the original hot-rolled steel. The processing parameter during the heat treatment and the cold drawing were controlled to produce samples having different microstructures. The 'as hot-rolled' sample had ferrite and pearlite structure with some martensite. The annealed and cold-drawn sample had ferrite matrix with partially spheroidized cementite particles. The normalized (annealed and air

Table 2 Machining parameters[90]

Cutting speed (m min^{-1})	500	667	1250	1833	2000
Feed rate (ISO insert) (mm rev^{-1})	0.05	0.058	0.085	0.112	0.12
Feed rate (wiper insert) (mm rev^{-1})	0.1	0.116	0.17	0.224	0.24
Depth of cut (mm)	0.2	0.267	0.5	0.733	0.8

cooled) sample has ferrite and pearlite structure. The quenched and tempered sample had tempered martensite structure. All the samples, except for the as hot-rolled sample, had almost the same hardness. Unlike most other researchers the authors measured the R_y roughness parameter instead of the usual R_a parameter. R_y is defined as the maximum roughness height within a sampling length. The authors noted that the formation of BUE when machining the low-alloy medium-carbon steel specimens depended on the microstructure of the workpiece material although the hardness was about the same. The annealed and cold-drawn workpiece having ferrite matrix with spheriodized cementite formed BUE only in narrow cutting conditions and produced the best surface finish. The authors also noted that surface finish of the normalized workpiece was the worst among the samples tested in dry machining due to the BUE formation.

1.1.6 Optimization Studies and Development of Surface Roughness Prediction Models

The papers reviewed thus far show that it is possible to achieve the optimum surface finish quality required on a product by carefully controlling the input process parameters and the machining conditions. Since the three main machining parameters, namely the feed rate, cutting speed, and the depth of cut, can be easily controlled by the user during the finish turning many researchers have carried out optimization studies in order to determine the machining parameters that can produce the best surface finish quality in addition to minimizing tool wear. Most of the optimization studies have been combined with the development of surface roughness prediction models. Besides changing the cutting parameters several researchers have attempted to optimize other variables such as tool geometry, workpiece material, and cutting conditions in order to obtain the minimum surface roughness.

Davim[93] studied the influence of cutting conditions on the surface finish based on the techniques of Taguchi. The objective of the study was to establish a correlation between the cutting velocity, feed rate, and the depth of cut with the surface roughness parameters R_a and R_t. The correlation between the process parameters and each roughness variable was obtained by using multiple linear regressions. The workpiece material used in the study was free machining steel (9SMnPb28k) while the tool material was cemented carbide. The cutting speeds used in the study were 71, 141, and 283 mm min^{-1}, the feed rates were 0.1, 0.16, and 0.25 mm rev^{-1} while the depths of cut were 0.5, 0.75, and 1.00 mm. Thus, the three-level Taguchi experimental design consisting of 27 experiments was used in the study. The ANOVA analysis showed that the cutting velocity had greater influence on the roughness followed by the feed rate, while the depth of cut had no significant influence on the surface roughness. The interaction between cutting velocity and feed rate was reported to be the most important compared to the other analyzed parameters. Although the author did not identify the optimum parameters to produce the best surface finish their regression models were able to predict R_a and R_t accurately with errors lesser than those obtained from the geometric theoretical model.

Singh and Venkateswara Rao[94] carried out an experimental investigation to study the effect of the tool geometry, namely the effective rake angle and nose radius, and the cutting conditions (cutting speed and feed rate) on the surface finish during hard turning of AISI 52100 steel. This material is commonly used in the manufacture of ball and roller bearings. The workpiece was heat treated to obtain a hardness of 58 HRC. Mixed ceramic inserts having nose radii of 0.4, 0.8, and 1.2 mm were selected in their study. The effective rake angles were 6°, 16°, and 26°. The cutting speeds used were 100, 150, and 200 m min^{-1} while the feed rates were 0.10, 0.20, and 0.32 mm rev^{-1}. The depth of cut was kept constant at 0.2 mm. Based on the experimental results the authors developed second and third order mathematical models for the average surface roughness using RSM. They optimized the surface roughness models by using genetic algorithm (GA). The GA provided the minimum values of surface roughness and their respective optimal input machining parameters. The lowest surface roughness of 0.4866 μm was achieved using the following parameters: 200 m min^{-1} cutting speed, 0.1 mm feed rate, 6° effective rake angle, and 1.2 mm nose radius.

Unlike many other researchers who optimized the cutting parameters to obtain the best surface finish, Neseli *et al.*[95] optimized the cutting tool geometry parameters for the same effect. The specimen used in their study was AISI 1040 steel. The cutting inserts used were Al_2O_3 coated tools. In all their experiments the depth of cut, cutting speed, feed rate were fixed at 1.5 mm, 150 m min^{-1}, and 0.15 mm rev^{-1}, respectively. The tool geometry parameters varied were the nose radius (0.4, 0.8, and 1.2 mm), the approach angle (60°, 75°, and 90°), and the rake angle (−9°, −6°, and −3°). The authors used RSM to develop a quadratic prediction model for R_a using their experimental data. The L_{27} Taguchi standard orthogonal array was adopted as the experimental design. Using ANOVA the authors showed that the most dominant factor affecting R_a is the tool nose radius, which accounted for 51.45% contribution of the total variation. This was followed by the approach angle (18.24%) and rake angle (17.74%). The optimum combination of the tool geometry parameters to obtain the minimum surface roughness was: 0.4 mm tool nose radius, 60° approach angle, and −3° rake angle. An interesting observation made by the authors is the way in which the nose radius affects the surface roughness of the machined surface. Unlike the predictions of theory and the findings of many other researchers, whereby the increase in tool radius caused the surface roughness to decrease, the authors reported the opposite trend, i.e., as the tool nose radius increased the

surface roughness also increased. The authors explained this behavior in terms of the increased contact length of tool-workpiece during the cutting. The increased contact length caused chatter vibration and therefore increased the surface roughness. However, this explanation was not supported by any experimental data.

Since the surface roughness of the workpiece is strongly correlated with cutting parameters such as insert nose radius, feed rate, and depth of cut, Nalbant *et al.*[96] varied these three parameters to obtain the best surface finish quality. Since surface roughness is not strongly correlated with the cutting speed, therefore the authors did not include this parameter in their study. The workpiece material was AISI 1030 steel while the cutting tools were TiN-coated tools. The authors applied the Taguchi method for the parameter design. The cutting speed was kept fixed at 300 m min^{-1} while the feed rates were varied in three stages, namely 0.15, 0.25, and 0.35 mm rev^{-1}. The radii of the inserts used were 0.4, 0.8, and 1.2 mm, whereas the depths of cut were 0.5, 1.5, and 2.5 mm. The machining performance measure used by the authors was the average roughness R_a. The authors used the L_9 orthogonal array with 26 degrees of freedom. The results reported by the authors are similar to those of many other researchers, i.e., the insert radius and feed rate are the most significant cutting parameters affecting surface roughness. Based on the lower-the-better signal-to-noise ratio and ANOVA the authors concluded that the optimal cutting parameters for surface roughness are: 1.2 mm insert radius, 0.15 mm rev^{-1} feed rate, and 0.5 mm depth of cut.

Many studies on the machining of MMCs have shown that minimizing the surface roughness of such composites is difficult.[97,98] This is due to factors such as the morphology, distribution, and volume fraction of the reinforcement phase as well as the matrix properties. Palanikumar and Karthikeyan[99] studied the various factors affecting surface roughness in the machining of Al/SiC particulate composite using the experimental design concept. The factors considered in their investigation were the % volume fraction of SiC, cutting speed, depth of cut, and the feed rate. All four parameters were varied in two stages. The volume fractions of SiC used were 10% and 25%, the cutting speeds were 50 and 150 m min^{-1}, the depths of cut were 0.5 and 0.15 mm and the feed rates were 0.1 and 0.5 mm rev^{-1}. Assessing the factors and their effect on the surface roughness was carried out using response graphs, normal probability plots, and the ANOVA technique. For the analysis the authors concluded that the optimal conditions to obtain the minimum surface roughness (1.66 μm) were: high cutting speed (150 m min^{-1}), high % volume fraction of SiC (25%), low depth of cut (0.50 mm), and flow feed rate (0.10 mm rev^{-1}).

Hasçalık and Çaydaş[100] carried out an optimization study during the turning of commercial Ti–6Al–4 V alloy using the Taguchi method. In addition to the optimization study, the authors also studied the effect of the machining parameters on the surface roughness and tool life. The cutting speed, feed rate, and depth of cut were varied in three levels. The cutting speeds used were 30, 60, and 90 m min^{-1}, the feed rate were 0.15, 0.25, and 0.35 mm rev^{-1} while the depths of cut were 0.5, 1.0, and 2.0 mm. The smaller-the-better (SB) criterion for the surface ratios was used in their signal-to-noise ratio analysis using ANOVA. An L_9 orthogonal array with four columns and nine rows was used in the experimental design. The optimal machining parameters for the lowest surface roughness was obtained at 90 m min^{-1} cutting speed, 0.15 mm rev^{-1} feed rate, and 0.5 mm depth of cut. The authors also identified the feed rate as the main factor that has the highest significance on the surface roughness. Feed rate was reported as 1.72 more significant compared to depth of cut. They reported that the cutting speed did not have any significant effect on the surface roughness.

Most researchers have used the tool wear in addition to the surface roughness as the performance measures while optimizing the machining parameters. Hagiwara *et al.*,[101] however, considered the chip breakability and surface roughness as the optimization criteria during the contour finish turning of AISI 1045 steel. According to the authors the chip breakability comprises four major factors, namely the chip shape and size, side flow, side curl, and up curl. However, the authors considered only the chip shape and chip size as the chip breakability factor takes care of the side flow, side curl, and up curl factors. The authors conducted full factorial experiments using a range of feed rates (0.04, 0.70, 0.10, 0.13, and 0.16 m rev^{-1}) and a range of depths of cut (0.2, 0.6, 1.2, and 2.0 mm). Unlike in straight turning the effective depth of cut varies along the surface of the workpiece due to the deep slopes in the machined part. The authors reported that although a small constant feed tend to produce good surface finish but the chip breakability was so poor that the surface quality deteriorated. On the contrary, a large feed rate produced good chip breakability but gave poor surface finish. The constant feed of 0.10 mm rev^{-1}, however, produced better surface roughness in most the machined segments of the workpiece.

Muthkrishnan and Davim[102] used two modeling techniques to predict the surface roughness, namely the ANOVA method and artificial neural network (ANN), in the machining of Al–SiC MMC. Both methods provide a systematic and effective approach for the optimization of the cutting parameters. The cutting speed used by the authors ranged from 100 to 600 m min^{-1}, while two feeds rates (0.108 and 0.200 mm rev^{-1}) were selected. The depths of cut used were 0.25, 0.5, and 0.75 mm. The average surface roughness R_a was measured at three different locations of the machined workpiece using a roughness tester. Using ANOVA the authors reported that the feed rate had the highest physical as well as statistical influence on the surface roughness (51%) followed by the depth of cut (30%) and the cutting speed (12%). Based on the signal-to-noise ratio the authors determined the optimum factors to obtain the best surface finish. The data collected from the machining experiments were used to train a three-layer ANN network with a 3–10–1 configuration (3 nodes in the input layer, 10 nodes in the hidden layer, and 1 node in the output layer). The authors reported that the output of the ANN model matched closely with the results of direct measurement of the surface roughness of the workpiece. Since the ANN method consumes less time and produces higher accuracy the authors concluded that optimization using ANN is the most effective approach to obtain the best surface finish compared to ANOVA.

The optimization of cutting parameters and the prediction of surface roughness involve highly constrained nonlinear dynamic optimization problem that can only be solved by

complete enumeration. Raj and Naboothirir[103] developed an improved genetic algorithm (IGA) to optimize the cutting parameters for predicting the surface roughness. The IGA method includes a stochastic crossover technique and an artificial initial population scheme to provide a faster search mechanism. The IGA was equipped with an improved evolutionary direction operator that can efficiently search and actively explore solutions. The authors applied the IGA method to predict the effect of tool geometry, namely nose radius, and cutting parameters (cutting speed, feed rate, and depth of cut) on the surface roughness in the dry turning of SS 420 metal. They compared the proposed IGA method with the conventional GA used in the previous studies. Each of the four parameters used in the study had three levels. To reduce the number of experiments the authors used the Taguchi's robust design and L_{27} orthogonal array method. The feed rates used were 0.059, 0.159, and 0.26 mm rev^{-1}. The cutting speeds were 39.269, 60.475, and 94.247 m min^{-1} while the depths of cut were 0.4, 0.8, and 1.2 mm. The nose radii were 0.4, 0.8, and 1.2 mm. The mathematical models for the average roughness R_a was developed using regression analysis in RSM. The results showed that the IGA optimization method was able to predict the machining parameters that results in much lower surface roughness compared to the conventional GA method.

In the optimization study carried out by Chauhan and Dass[87] (Section 1.1.4) the authors developed a quadratic regression model for the surface roughness using RSM based on their experimental data. The ANOVA analysis was used to test the significance of the regression model, to test the significance of individual model coefficients, and to test for the lack-of-fit. The regression model was then used to predict the surface roughness within the limits of the factors investigated by the authors. They carried out three confirmation experiments for the surface roughness and tangential force. The results of the ANOVA and confirmation tests showed that the quadratic model was able to predict the average roughness accurately within the prediction interval of 95%. However, the authors did not identify the combination of machining parameters and approach angle that produced the best surface finish.

Process optimization is necessary especially in processes where the desired output depends on the complex interaction of numerous parameters. Since surface finish is affected in varying degrees by several factors reviewed in this chapter, it is necessary to determine the combination of factors that produces the best surface finish quality. Homami *et al.*[104] used a full factorial design for the design of experiment to optimize cutting parameters, namely feed rate, cutting speed, nose radius, and approach angle, in order to obtain the desired optimum value of the surface roughness. Full factorial design is a design of experiment in which every level of each factor appears with every level of every other factor. The authors used ANN for modeling the system and GA for the optimization of the cutting parameters. The workpiece material was Inconel 718 (331 HRB) and the cutting tools used were TiAlN-coated tungsten carbide inserts. The nose radii used were 0.8, 1.2, and 1.6 mm while the approach angles were 45° and 75°. The cutting speeds and feed rates used in their investigation were, respectively, 45, 55, and 65 m min^{-1} and 0.2, 0.25, and 0.3 mm rev^{-1}. Using the GA the authors identified that the optimum parameters for the Inconel 718 as 45 m min^{-1} cutting speed, 0.22 mm rev^{-1} feed rate, 1.6 mm tool nose radius, and 60°approach angle. This combination of parameters produced the minimum surface roughness of 0.5498 μm.

Khamel *et al.*[105] investigated the effects of the three common process parameters, namely cutting speed, feed rate, and depth of cut, on the performance characteristics such as tool life, surface roughness, and cutting forces. The workpiece material was AISI 52100 (60 HRC) while the cutting tool was CBN inserts. For the three-level experimental design using L_{27} Taguchi method the cutting speeds used were 100, 140, and 200 m min^{-1}, the feed rates were 0.08, 0.12, and 0.16 mm rev^{-1} while the depths of cut were 0.2, 0.4, and 0.6 mm. The authors investigated the combined effects of the process parameters on the performance characteristics using ANOVA. The optimization technique associated with the RSM quadratic models was used as the multi-objective optimization approach. The authors reported that the feed rate and cutting speed have strong influence on the surface roughness and tool life. About 64% of the total variation of the surface roughness was due to the feed rate. The depth of cut, however, had maximum influence on the cutting forces. Simultaneous optimization of the tool life, surface roughness, and cutting forces was achieved with a cutting speed of 168 m min^{-1}, feed rate of 0.08 mm rev^{-1}, and depth of cut of 0.22 mm.

Batish *et al.*[106] investigated the influence of five independent process parameters during the hard turning of EN31, SAE8260, and EN9 tool steels. The parameters considered were the material hardness, feed rate, cutting speed, and the combination of cutting tool nose radius and depth on the machining forces and surface roughness. Each factor was varied in three levels resulting in 10 degrees of freedom. The L27 orthogonal array was used to determine the combination of the parameters to be investigated. The hardness of the material were 50, 55, and 60 HRC, the cutting speeds were 75, 110, and 150 m min^{-1}, the feed rates were 0.03, 0.06, and 0.1 mm rev^{1}, nose radii-depth of cut combinations were 0.4–0.075, 0.4–0.15, and 0.8–0.15 (mm-mm). The GA method was used to optimize all the responses. The authors reported that only the feed rate significantly affected the surface roughness while the material hardness had no significant effect.

The surface roughness of the workpiece and the cutting forces are usually considered as the main quality attributes of a turned workpiece. Since in most of the optimization methods the researchers do not evaluate each parameter, Gok[107] applied variance analysis to grey relational grades (GRA) of the factor levels to discover interactions between the machining parameters relating to the surface roughness and cutting forces. Unlike the Taguchi method which is designed to optimize single response characteristics the GRA method is able to optimize multiple outcomes. The attributes evaluated by the author are R_a, R_t, F_f, and F_c where F_f and F_c are the feed force and cutting force, respectively. Prediction models for surface roughness and cutting force were developed using the response surface analysis. The author noted that the optimal combination of machining parameters using response optimization are the values of the largest cutting velocity (200 m min^{-1}), values of the smallest depth of cut (0.5 mm), and feed rate

(0.125 mm rev^{-1}). This finding agrees with those of many other researchers as well as that predicted by the theory, namely the lowest surface roughness is achieved by using a small feed rate.

The review of the optimization studies show that many researchers have attempted to optimize the three main cutting parameters, namely the cutting speed, feed rate, and the depth of cut, in order to achieve the best surface finish quality, i.e., minimum surface roughness. The only difference between their works is the choice of the workpiece material, the cutting tools, and the range of the parameters investigated. The approaches used are also similar, namely the Taguchi experimental design and ANOVA analysis, to carry out the experimental plan and to determine the most influential factor that affects the surface roughness. The prediction models have been developed mostly using the RSM, GA, or ANN or a combination of these methods. In most cases the researchers reported that high cutting speeds and low feed rates produced better surface finish. The effect of the depth of cut on the surface finish depends on other factors such as workpiece material and chip formation. In the machining of glass fiber reinforce plastic composite material, Palanikumar[108] reported that a high depth of cut produced lower surface roughness while in the machining of Al/SiC MMC Manna and Bhattacharyya[109] reported that an increase in the depth of cut increases the surface roughness. Radhika *et al.*[110] also reported that the surface roughness increases as the depth of cut increased during the machining of aluminum hybrid MMC. Nevertheless, in all the reported studies the optimization models developed by the researchers were able to predict the optimum combination of input variables in order to obtain the best surface finish quality.

1.1.7 Summary

The objective of the finish turning process is to avoid or reduce the secondary finishing processes such as grinding, lapping, and polishing. However, this chapter has shown that numerous and complex interrelated factors govern the final surface finish quality produced by the finish turning process. Although it is not possible to list these factors in the order in which they produce the best surfaces based on the published literature, it is possible to identify certain factors that can generally be considered as those contributing to a good surface finish. The combination of low feed rate, low depth of cut, large nose radius, an efficient lubricant, and turning using a very rigid machine tool will likely lead to good surface finish in most steels. The use of wiper inserts instead of the conventional inserts could also results in good surface finish. Harder materials can produce better surface finish but this depends on the microstructure of the material as well as the machining parameters. Some composites and metal-matrix materials appear to produce better surface finish when machined at greater depths of cut.

In spite of the extensive research carried out in the past, there are several areas that need further investigation in order to arrive at a more in-depth understanding of the effect of the various factors reviewed. The following areas are identified as examples of potential areas for further research:

a. Effect of the chip breaker design on surface finish
   Chip breakers can reduce cutting pressure and enable chips to be removed more easily during the turning process. In materials that produce long curly chip an effective chip breaker can break up the chips, facilitate easily chip removal thus avoiding interference with the machining process. An understanding of the effect of chip breaker design on surface finish in the cutting of different types of material under different machining conditions will provide significant insight into the effectiveness of chip breaker design. This type of study can be done using simulation software such as DEFORM 3D and can be verified experimentally.
b. Effect of BUE formation on surface roughness
   BUE is known to be detrimental to the surface finish. However, the direct influence of material, cutting parameters, and formation of BUE on surface roughness has not been studied in any depth. Since the formation and destruction of BUE are dynamic processes it will be interesting to see how the surface roughness changes during the machining. An in-process method of monitoring the various roughness parameters as proposed by Kumar and Ratnam[61] will be useful for such type of studies.
c. Investigation on factors affecting surface roughness using other roughness parameters
   A review of the available literature shows that the centerline average roughness (R_a) is the most common roughness parameter studied in the past. There are, however, over 70 amplitude, spacing, hybrid, and functional roughness parameters that can be used to characterize a surface more accurately that the most common R_a parameter.[111] The effect of the various factors on some or most of these roughness parameters have not been studied in the past. The conflicting observations made by researchers when studying the effect of the various factors on surface roughness could be overcome by selecting the parameter that is most suited to the turning process.
d. Effect of nanoparticle addition in vegetable oil-based cutting fluids
   The addition of nanoparticles in cutting fluids has shown to be effective in improving the surface finish in turning. Most researchers have used chemical or mineral oil-based cutting fluids in their studies. The effect of adding nanoparticle in vegetable oils as cutting fluids, however, has been relatively unexplored. The effect of the particle size and amount of nanoparticles added to the fluid on the machining performance is a potential area for further investigation.
e. Optimization of machining parameters to minimize tool nose wear
   It is well known that the tool nose edge plays a significant role in the surface finish quality of the workpiece. However, no previous work has been found where researchers attempt to optimize the machining or other parameters in order to minimize the tool nose wear.

1.2.1 Introduction

Boring is a process of enlarging a hole size that was already made by drilling, or casting to the designed dimension. The enlargement of hole can be made by means of a single point cutting tool or a boring head containing multiple tools. The boring of an engine cylinder or of a gun barrel is an example of such process. In boring, either the boring head/bar can be rotated or the workpart can be rotated. Boring machines or boring mills usually rotate the boring bar against a stationary workpiece. Also in turning machines, boring can be performed where the boring bar attached to the tool post remains stationary against a rotating workpiece held in the lathe chuck. The boring bar with insert attached to it is fed into an existing hole. Depending on material, type of tool insert, and cutting conditions, the chip formed may either be continuous or discontinuous. The surface produced is known as bore. Surface roughness in boring may vary between 0.0002 and 0.006 mm. With the advancement of machining technology, the limitations of boring with respect to geometric accuracy and material hardness have been diminishing. With new grades of carbide and ceramic tool inserts, the accuracy of boring and surface quality has increased. The hole produced may either be straight or tapered. The work holding devices used lathe could be either three-jaw chuck, the four-jaw chuck, the collet, or the faceplate. For round or hexagonal workpieces, three-jaw chuck is used while four-jaw chuck and collet are used for irregular-shaped workpieces.

In boring of steels, vibration of tool and workpiece are the important limiting factor for volume of metal removed and machining efficiency. In boring operations, the length of boring bar is kept long, resulting in vibrations leading to tool failure, poor surface finish, and chatter. The ratio of length to diameter of boring bar is one of the important factors that is responsible for tool vibration. It has been established that boring bars with a high length–diameter ratio tend to chatter.[1] In the industry where metal cutting operations such as turning, milling, boring, and grinding take place, degrading vibrations are a common problem. In internal turning operation, vibration is a pronounced problem, as long and slender boring bars are usually required to perform the internal machining of workpieces. Tool vibration in internal turning frequently has a degrading influence on surface quality, tool life, and production efficiency, and will also result in severe environmental issues such as high noise levels. Boring bar vibrations are usually directly related to the lower order bending modes of the clamped boring bar.[2,3]

The concern today in the manufacturing industry is the vibration induced by metal cutting, for example, turning, milling, and boring operations. Turning operation and especially boring operations are associated with serious vibration-related problems. To reduce the problem of vibration and ensure that the desired shape and tolerance are achieved, extra care must be taken with production planning and in the preparations for the machining of a workpiece. The vibration problem associated with metal cutting thus has considerable influence on important factors such as productivity, production costs, etc. Hence, the need for thorough investigation of the factors that cause vibrations in machining operation is therefore an important step toward solving the problem. In internal turning, the metal-cutting process is carried out in predrilled holes or holes in cast, etc. The dimensions of the workpiece hole generally determine the length and limit the diameter or cross-sectional size of the boring bar.

Usually, a boring bar is long and slender and is thus sensitive to excitation forces introduced by the material deformation process in the turning operation. The boring bar is generally the weakest link in the boring bar–clamping system of the lathe. The boring bar motion may vary with time. This dynamic motion originates from the deformation process of the work material. The motion or vibration of the boring bar influences the result of the machining in general, and the surface finish in particular. Tool life is also likely to be influenced by the resulting vibrations. The tool vibrations during turning are usually denoted 'self-excited chatter' or 'tool

 doi:10.1016/B978-0-12-803581-8.09148-7

vibration.' Depending on the driving force of the tool vibration, the vibration is generally divided into one of two categories: regenerative chatter and non-regenerative chatter (primary chatter).[4–7] Primary chatter may arise from different physical causes, for example, random excitation of the tool holder's eigen frequencies due to plastic deformation of workpiece material and/or friction between the tool and the cut material, the tendency of the cutting force excitation to change with the cutting speed, and the dynamic effects of the geometry of the cutting tool on the cutting process, etc.[4,7,8] Regenerative chatter is induced by the undulation on the surface of the workpiece which is produced during previous successive cuts.[4,9]

During an internal turning operation, the cutting tool and the boring bar are subjected to a prescribed deformation as a result of the relative motion between the tool and workpiece both in the cutting-speed direction and feed direction. As a response to the prescribed deformation, the tool is subjected to traction and thermal loads on those faces that have interfacial contact with the workpiece or chip. In the metal-cutting process, during which chips are formed, the workpiece material is compressed and subjected to plastic deformation. This results in considerable strain and strain rates in the primary deformation zone. **Figure 1** shows a typical boring operation process.

Also, the dynamic properties of a boring bar installed in a lathe are influenced by the boundary conditions imposed by the clamping of the bar.[2,10] A number of theories concerning the machine tool chatter and the behavior of the dynamic system have been developed explaining tool vibration during turning operations.[4,11–13] In 1946, the principles of the traditional theory of chatter in simple machine-tool systems was worked out by Arnold[11] based on experiments carried out in a rigid lathe, using a stiff workpiece but a flexible tool holder. In this way he was able to investigate chatter under controlled conditions. Later in 1965, Tobias[4] presented an extensive summary of results from various researchers concerning the dynamic behavior of the lathe, the chatter theory, and further developed the chatter phenomena considering the chip-thickness variation and the phase lag of the undulation of the surface. Also, in the same year, Merritt[12] discussed the stability of structures with *n*-degrees of freedom, assuming no dynamics in the cutting process; they also proposed a simple stability criterion.

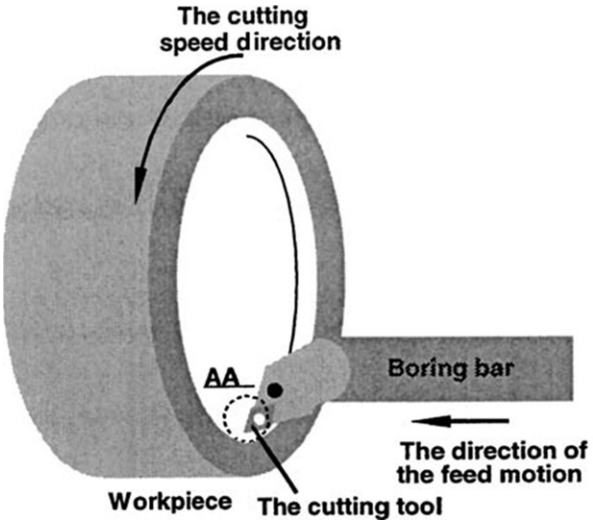

Figure 1 Boring operation.[2]

1.2.2 Factors Affecting Boring Operation

Like any other machining operations, output results are determined by the cutting conditions such as cutting speed, feed rate, depth of cut (DOC), type of tool, tool geometry, cutting fluid type, and method of application, machining type and materials. Hence, researchers have employed some of these cutting conditions to investigate how they affect the boring operation in terms of surface finish, cutting force, too wear, tool vibration, dimensional accuracy, etc. Akesson *et al.*[14] investigated the dynamic properties of boring bars concerning different clamping conditions. The experimental setup and subsequent measurements were carried out on a Mazak SUPERQUICKTURN – 250 M computer numerical control (CNC) turning center. The CNC lathe has 18.5 kW spindle power and a maximal machining diameter of 300 mm with 1005 mm between the centers, a maximal spindle speed of 400 revolutions per minute (rpm) and a flexible turret with a tool capacity of 12 as shown in **Figure 2**.

Two different boring bars were used in the experiment. The first boring bar used in the modal analysis was a standard 'non-modified' boring bar, WIDAXS40TPDUNR15F3D6G. The second boring bar used was a modified boring bar, based on the standard WIDAXS40TPDUNR15 boring bar with an accelerometer and an embedded piezo-stack actuator. The accelerometer was mounted 25 mm from the tool tip to measure the vibrations in the cutting-speed direction (y-). This position was as close as possible to the tool tip, but at a sufficient distance to prevent metal-chips from the material removal process from damaging the accelerometer. The standard WIDAXS40TPDUNR15 boring bar was manufactured using material 30CrNiMo8 (AISI4330), which is a heat treatable steel alloy (for high strength). Shaker excitation was used for the experimental modal analysis of the boring bars. The utilized spectrum estimation parameters and excitation signals' properties were determined. A frequency range covering the significant part near the resonance frequencies was selected, i.e., -100 to -200 Hz around the resonance peaks. The coherence values for the involved transfer paths at each eigen frequency were greater or equal to 0.996.

A number of different phenomena were observed during the experimental modal analysis of the boring bars for various configurations and setups. For instance, large variations were observed in the first resonance frequencies of the boring bar for different tightening torques of the clamp screws. Also, the order in which the clamp screws were tightened (first from the upper side of the boring bar or first from the underside of the boring bar) had a significant impact on, for example, the fundamental bending resonance frequencies. The results from the experimental modal analysis of the two boring bars demonstrate that the different controlled clamping conditions in the experiments yield different dynamic properties of the

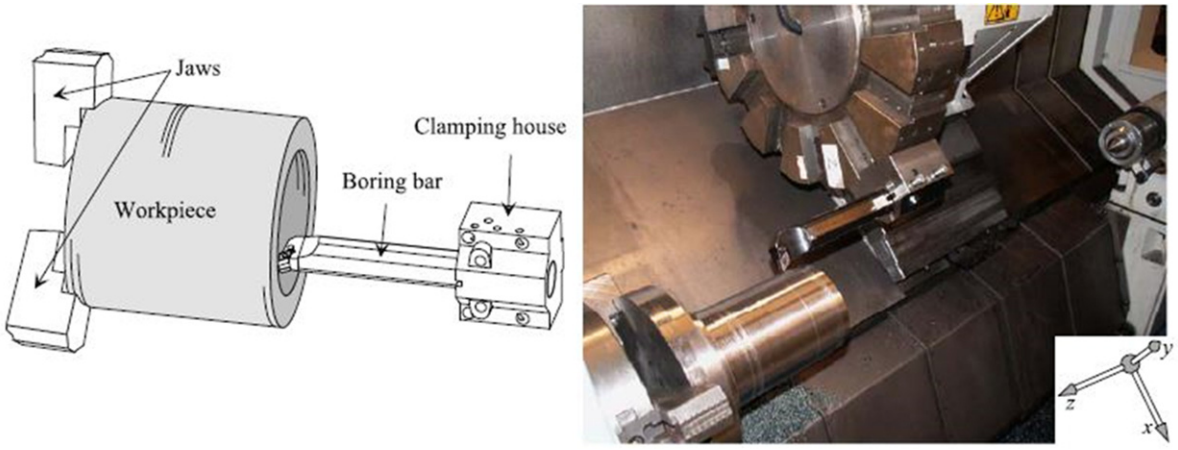

Figure 2 (a) An internal turning setup with a workpiece clamped in a shuck to the left and a boring bar clamped in a clamping housing to the right. (b) The room in the Mazak SUPERQUICKTURN – 250 M computer numerical control lathe where machining is carried out.[14]

clamped boring bars. Hence, the different clamping conditions result in different boundary conditions along the clamped part of the boring bar. It was also established that a boring bar clamped in a standard clamping housing with clamping screws is likely to have a nonlinear dynamic behavior. The standard clamping housing with clamp screws is the likely source of the nonlinear behavior. Multi-span Euler–Bernoulli models of a clamped boring bar incorporating pinned or elastic support boundary conditions approximating the flexibility of the actual screw clamping of the boring bar end inside the clamping housing provide significantly higher correlation with experimental modal analysis results compared to a traditional fixed-free Euler–Bernoulli model.

The fundamental boring bar resonance frequencies decrease with increasing excitation level. However, with regard to the behavior of relative damping as a function of excitation force level; the results from the standard boring bar indicate that the relative damping for the first mode increases with increasing excitation force level, while the relative damping for the second mode decreases with increasing excitation force level. Also, the results from the modified boring bar give an ambiguous indication of the effects on damping properties and the clamp screw tightening torque appears to affect the nonlinear behavior of the boring bar. The investigation shows that the number of clamping screws, the clamping screw diameter sizes, the screw tightening torques, and the order the screws are tightened has a significant influence on a clamped boring bars eigen frequencies and its mode shapes orientation in the cutting speed – cutting depth plane. The results indicated that multi-span Euler–Bernoulli beam models with pinned boundary condition or elastic boundary condition modeling the clamping are preferable as compared to a fixed-free Euler–Bernoulli beam for modeling dynamic properties of a clamped boring bar. It also demonstrated that a standard clamping housing clamping a boring bar with clamping screws imposes nonlinear dynamic boring bar behavior.

Rao *et al.*[1] evaluated the cutting tool condition monitoring by analyzing surface roughness, workpiece vibration, and

Figure 3 Workpiece.[1]

volume of metal removed for AISI 1040 steel in boring. The experiment was conducted on CNC lathe DX200 model, with tool inserts of DNMG150608 and DNMG150604 having nose radii of 0.8 and 0.4 mm respectively. The metal used in this experiment was AISI1040 with length of 90 mm, outer diameter of 100 mm, and inner diameter of 56 mm as shown in Figure 3.

The following sequential procedure was used to carry out the experiment under dry conditions.

1. Each test was started with a fresh cutting edge with one test condition (trials) and machining stopped at the end of each pass. After each pass the DOC was increased by 0.2 mm (fixed DOC was given in each pass) until the tool failed.
2. Vibration signals from the rotating workpiece were measured in the machining process using LDV.
3. After each pass the tool insert was removed and flank wear and crater wear were measured with machine vision system.
4. After each cut the workpiece was also removed and its surface roughness measured on Talysurf.

5. The steps one to four to be continued until the tool failed and beyond that two or three passes performed on the workpiece to observe the behavior of tool wear.
6. A new workpiece and new tool insert were loaded to the machine and the above steps were followed with a new working condition.
7. In each trial, surface roughness, volume of metal removed, and time and amplitude of workpiece vibrations were identified when the tool failed based on flank wear. The above procedure was followed for all the trials and in each trial the cutting parameters were changed as given in the **Table 1**.

Taguchi, analysis of variance (ANOVA) and regression analysis methods were used to analyze the experimental data to find out the effect and contribution of cutting parameters. According to selected orthogonal array eight experiments (trials) were conducted with two levels of cutting parameters such as workpiece rotational speed, tool insert nose radius, and feed rate. The results show that in each trial of experiment, a strong correlation among the dependent and independent variables was found. A noncontact monitoring system was used with Laser Doppler Vibrometer to observe vibration of workpiece during machining. Tool life was evaluated by analyzing surface roughness, amplitude of workpiece vibration, and volume of metal removed with the help of Taguchi, ANOVA, and regression analysis. The following results were observed during the experiment.

1. Vibration amplitudes of workpiece are found to be increased along with the progression of the tool wear.
2. Nose radius (45.81%) is the significant parameter for affecting the amplitude of workpiece of vibration.
3. Feed rate (55.57%) is the significant parameter for affecting the surface roughness.
4. Feed rate (51.26%) is the significant parameter for affecting the volume of metal removed.

Andren *et al.*[3] studied the identification of motion of cutting tool vibration in a continuous boring operation – correlation to structural properties. The experimental modal analysis and the operating deflection shape (ODS) analysis were carried out on a Mazak SUPER QUICK TURN – 250 M CNC turning center. It has 18:5 kW spindle power and a maximum machining diameter of 300 mm; with 1007 mm between the center. The cutting operations were performed as an external turning operation using the WIDAX S40TPDUNR15 boring bar. The measurements were divided into two different categories: modal analysis and ODS analysis of the boring bar. In the modal analysis measurement the following equipment were used: (1) 14 PCB 333A32 accelerometers, (2) OSC audio power amplifier, USA 850, (3) Ling Dynamic Systems shaker V201, (4) Bruel and Kjær 8001 impedance head, (5) Bruel and Kjær NEXUS conditioning amplifier 2692, (6) HP VXI E1432 front–end data acquisition unit, and (7) PC with IDEAS Master Series version 6. The ODS data were collected using less sensitive accelerometers than those used in the modal analysis measurement. For the ODS analysis, the boring bar vibration was measured during a continuous cutting operation and data were collected using the following measuring equipment: (1) 14 PCBU353B11 accelerometers, (2) HP VXI E1432 front–end data acquisition unit, and (3) PC with IDEAS Master Series version 6.

Table 1 Test trails for boring[1]

S/N	*Speed (m min^{-1})*	*Feed (mm rev^{-1})*	*Nose radius (mm)*
1	210	0.10	0.8
2	210	0.16	0.8
3	170	0.10	0.8
4	170	0.16	0.8
5	210	0.10	0.4
6	210	0.16	0.4
7	170	0.10	0.4
8	170	0.16	0.4

The experimental modal analysis of the boring bar with modified clamping resulted in two identified modes. The first mode in the cutting depth direction had a resonance frequency of 570 Hz; and a relative (viscous) damping of 1.85%. The second mode in the cutting-speed direction had a resonance frequency of 595 Hz and a damping of 0.84%. The damping of the first mode was noted to be slightly larger than prior to the modification of the clamping. The two modes were well separated as defined by the cross MAC value and the synthesized frequency response functions corresponded well with the measured functions. From the ODS results, it was apparent that vibrations of the boring bar were dominating in the cutting-speed direction during a continuous cutting operation. The deformation pattern of the boring bar was according to the ODS measurement dominating in the cutting-speed direction at both resonance peaks. The ODS resulted in eigen frequencies at a somewhat lower frequencies compared with the modal analysis.

Saindane *et al.*[15] investigated the effect of vibration damping in boring operation using passive damper. Boring bar of 16 mm × 16 mm cross section and 200 mm long of WIDAX make was used. The boring operations were carried out on a lathe machine as shown in **Figure 4** using EN9 as workpiece material. The workpiece was mounted on the lathe using a four-jaw chuck. The machining parameters were selected based on the manufacturers recommendations and were changed according to the proposed conditions. Also the cutting speed, length of passive damper on boring bar, and overhang length were varied as shown in **Table 2** and experiments were conducted to analyze the effect of vibration on deflection of boring bar.

The boring operation was carried out for 51 mm internal diameter using passive dampers of nylon and polyurethane. Fast Fourier transform (FFT) analyzer and accelerometer were used to obtain various results for the experiments and the deflections were measured in terms of acceleration by accelerometer as shown in **Table 3**.

It was observed that the proposed method was an innovative to reduce the deflection of the boring bar in boring operation. The results proved the passive damping technique has vast potential in the reduction of deflection and depend on the DOC. Passive dampers are also relatively cheaper than other damped boring bars.

Khatake and Nitnaware[16] studied the mitigation of vibration using passive damper in machining. The study involved the use of particle damper, which is a passive damping concept

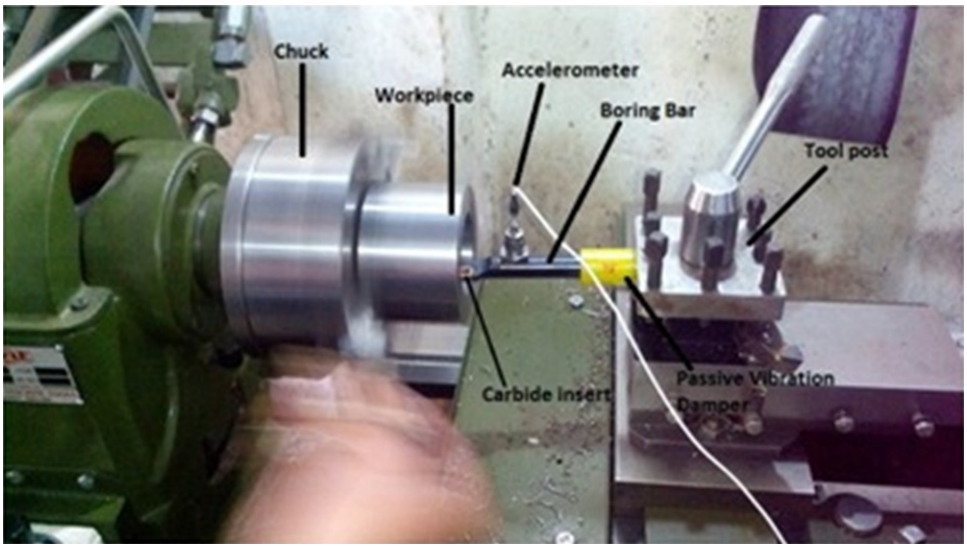

Figure 4 Experimental set up of boring bar with passive damper and accelerometer.[15]

that uses metal or ceramic particles or powders of small size that are placed inside cavities within or attached to the vibrating structures. Metal particles of high density such as lead or tungsten steel are the most common materials for better damping performance. In contrast to viscoelastic materials which dissipate the stored elastic energy particle damping treatment focuses on energy dissipation in a combination of collision, friction, and shear damping. It involves the potential of energy absorption and dissipation through momentum exchange between moving particles and vibrating walls, friction, impact restitution, and shear deformations. It is an attractive alternative in passive damping due to its conceptual simplicity, potential effectiveness over broad frequency range, temperature, and degradation insensitivity and very low cost. The principle adopted in the study was to enhance the damping capability, minimizing the loss in static stiffness through implementation of passive damper.

Boring bar of 20 mm × 20 mm cross section and 200 mm long of WIDAX make was used on EN9 workpiece material. The boring operations were carried out on CNC center lathe. The workpiece was mounted using a pneumatic chuck. The machining parameters such as feed rate (0.09 mm min^{-1}), DOC (0.6 mm^{-1}), clamping pressure (10 bar), etc., were selected based on the manufacturers recommendations and were kept constant for all the samples used. Only the cutting speed, passive damper position on boring bar, and overhang length were changed as shown in **Table 4**. Boring was carried out for 110 mm internal diameter using newly designed tool and conventional tool. The evaluation criteria were the dynamic characteristics, frequency, and damping ratio, of the machining system, as well as the surface roughness of the machined workpieces.

Table 5 shows the results obtained for cutting speed of 210 rpm, DOC of 0.6 mm and feed rate of 0.09 mm min^{-1}.

Table 4 Experimental conditions[16]

Boring tool	*BT1*	*BT2*	
Overhang length L (mm)	30	60	90
Position of passive damper	Vertical	Horizontal	
Cutting speed (rpm)	70	140	210

Table 5 Experimental results[16]

S/N	*Overhang length of boring bar (mm)*	*Surface finish (μm) without passive damper*	*Surface finish (μm) with passive damper*	
			Vertical	*Horizontal*
1	30	2.63	2.41	2.63
2	60	2.59	2.51	1.46
3	90	2.80	3.19	3.25

The result shows that the results prove the passive damping technique has vast potential in the reduction of tool chatter. It is therefore concluded that passive damping has a good effect in improving surface finish in boring operation and significant improvement was observed between the results of surface finish obtained using boring bar without passive damper and boring bar with passive damper.

Kadu *et al.*[17] formulated a mathematical model for the investigation of tool wears in boring machining operation on cast iron using carbide and cubic boron nitride tools. The process of formulation of mathematical model for optimizing the tool life in casting machining operation and its analysis in this study involved two levels for each independent parameter taken. In tool life optimization process, the objective of the experiment was used to gather information through experimentation for formulation of mathematical model for cast iron machining operation. During cast iron machining operations, the measurement of tool life, surface finish, bore size variation, operation time, and spindle load was measured using meter scale, surface finish tester, digital dia. test plug gauges, digital stopwatch, and current in percentage amp. Energy and time were measured using energy meter and stopwatch respectively. Pilot experiments were performed to select test envelope and test points of process parameters for experimental design. These process parameters as shown in **Table 6** were used in experimental design for the investigation of process parameters like cutting speed, nose radius, length, diameter, and material of the cutting tool, cutting fluid pressure, and concentration and DOC for casting machining operation. The observed values for tool life, surface finish, bore size variation, operation time, and spindle load were recorded for formulation of mathematical model. In casting machining operation observations were taken out at two levels for each independent parameter.

One hundred and twenty-eight experiments were designed on the basis of sequential classical experimental design technique that has been generally proposed for engineering applications.[18] The basic classical plan consists of holding all but one of the independent variables constant and changing this one variable over its range. The main objective of the experiments consists of studying the relationship between 09 independent process parameters with the 05 dependent responses for tool life optimization. Simultaneous changing of all 09 independent parameters was cumbersome and confusing. Hence all 09 independent process parameters were reduced by dimensional analysis. Buckingham's π theorem was adapted to develop dimensionless π terms for reduction of process parameters. This approach helps to better understand how the change in the levels of any one process parameter of a π terms affects 05 dependant responses for cast iron boring machining operation. Out of five response/dependant variables two dependant variables cutting time and surface roughness were evaluated. A combination of the levels of parameters, which lead to maximum, minimum, and optimum response, can also be located through this approach. Regression equation models of tool life were optimized by mini–max principle.[19]

The authors observed that (1) the dimensionless π term have provided the idea about combined effect of process parameters in that π terms. A simple change in one process parameter in the group helped the manufacturer to maintain the required torque (*To*) and surface roughness (*Ra*) values so that to get increased tool life. (2) The mathematical models developed with dimensional analysis for different combinations of parameters for cutting speed, nose radius, length, diameter, and material of the cutting tool, cutting fluid pressure and concentration, and DOC can be effectively utilized for cast iron boring machining operations. (3) The computed selection of cast iron boring machining operation parameters by dimensional analysis provides effective guidelines to the manufacturing engineers so that they can minimize *To* and *Ra* for higher performances. (4) The models have been formulated mathematically for the Indian conditions. The comparison of values of dependent term obtained from experimental data, mathematical model, and ANN. From the values of percentage errors, it seems that the mathematical models can be successfully used for the computation of dependent terms for a given set of independent terms. Indian industries can use the data for calculation cutting time, tool life, surface roughness, bore size variation, and spindle load estimation for cast iron boring machining operations.

Badadhe *et al.*[20] conducted an experiment to optimize the cutting parameters in boring operation. Four parameters, i.e., spindle speed, feed, DOC, and length–diameter (L/D) ratio of boring bar were considered as input variables. **Tables 7** and **8** show the input factors and levels used in the experimental design and experimental matrix of 3^4 orthogonal array respectively. Total nine runs (L_9) were conducted during one trial. Trials were repeated to check the consistency in the output. Cutting trials were conducted on Kirloskar make (Enterprise-500) center lathe machine. AISI 1041 carbon steel cylinders with 100 mm outside diameter, 85 mm inside diameter, and 75 mm length were used as workpieces.

Standard boring bars with Widax tool holder S25TPCLNR12F3, S20SSCLCR09T3, and S16QSCLCR09T3 along with cemented carbide inserts having radius 1.2 mm were used for metal cutting. Surface finish was measured offline by using HOMMELWERKE TURBO RAUHEIT V 6.14, Swiss make surface recorder having 0.8 mm cut-off and 4.8 mm sample length. The ANOVA was carried out to find the significant factors and their individual contribution in the response function, i.e., surface roughness.

5	2	2	3	1
6	2	3	1	2
7	3	1	3	2
8	3	2	1	3
9	3	3	2	1

The averages of surface roughness values obtained during each trial (Ra_1 and Ra_2) and the Signal-to-Noise (S/N) ratio calculated for the criteria of lower-the-better are shown in **Table 9**.

The optimal values of the input factors *A*, *B*, *C*, and *D* were obtained from S/N ratio as shown in **Table 10** using the lower the better characteristic. The S/N ratio for spindle speed is higher at level 3, similarly for others the values are feed 1, DOC 2, and L/D ratio 1. Hence the optimal combination of control factors were given as 3-1-2-1 and this is represented on the plot of **Figure 5**.

ANOVA was carried out to check the significant contribution of each input factor in response function. **Table 11** shows the results of the ANOVA for surface roughness. It can be observed from the ANOVA result, that the parameters A, B, and D are having significant contribution of 28%, 30%, and 36% respectively in the response function (*Ra*) whereas the parameter C has relatively less contribution and thus is of less importance.

The study shows that the control factors had varying effects on the response variable and the use of the Taguchi parameter design technique was considered successful as an efficient method to optimize machining parameters in a boring operation.

Moetakef-Imani and Yussefian[21] studied the dynamic simulation of boring process. The study involved the use of a boring bar with 20 mm diameter and 140 mm length ($L/D=7$) to implement the machining tests. Carbide inserts with 0.4 mm nose radius and flat rake face were used to machine the aluminum 6061 tubes. The dynamic properties of boring bar and geometrical properties of the cutting tool are presented in **Tables 12** and **13** respectively.

The cutting speed, feed rate, and radial DOC were in the range of 70–110 m min^{-1}, 0.08–0.24 mm rev^{-1}, and 0.2–4 mm respectively. Cutting force components were measured in three orthogonal directions by a KISTLER9255b dynamometer. The dynamic simulation program was also implemented for every corresponding machining experiment. For the sake of comparison between the experimental measurements and numerical simulations, two different cutting tests were presented. The cutting conditions for these two cutting experiments are shown in **Table 14**.

The DOC was set to 0.5 and 4 mm for tests *A* and *B* respectively. All other conditions for these tests are equal. In order to validate the proposed method, 30 boring experiments were conducted. **Figure 6** shows the algorithm for dynamic simulation of boring process.

Measured and predicted cutting force components for boring with machining conditions of test A are depicted in **Figure 7**. When the tool first engaged the cut, it undergoes transient vibrations. But after several revolutions, the cutting process becomes stable and the tool continues to vibrate periodically with relatively constant amplitude.

So the condition of test A was stable and chatter-free cutting machining operation. The simulated peak frequency occurred at 672 Hz with a deviation of 12.94% above the measured value of 594 Hz. It was observed that the deviation resulted from the over estimation of the eigen frequencies by the Euler–Bernoulli beam equation. When the results of cutting force components measured by a dynamometer was compared with the simulated results by the proposed algorithm. The measured values of the cutting force components in x, y, and z direction were predicted by 9%, 2%, and 12% errors in magnitude. This amount of error was consistent with the validity interval of $\pm 10\%$ for the cutting force computation[22] which could be due to the cutting force coefficient computations.

Experimental and simulated cutting force components in time domain for the condition of test B are shown in **Figure 8**. It was observed from the measured data that the machining process was unstable with chattering frequency around 573 Hz. In case of chatter, measured force components oscillate randomly and grow rapidly to large amplitudes. It could be seen from **Figure 8** that the simulated results had also predicted the incidence of chatter vibrations. Although the model was capable of truly predicting the chatter occurrence for the conditions of test B, the variation of simulated and measured cutting force amplitudes is increased.

This is due to the fact that the measured cutting force components have been amplified by chatter frequency.[23] As a consequence of high-vibration amplitudes, the actual geometrical angles of the cutting tool will change from their nominal values. It is well known that the variation of cutting tool angles will affect the cutting force components significantly.[22,24] The high-reciprocating velocity of the tool tip makes the cutting process be accompanied with the plunging of the tool in to the workpiece. The high acceleration of the tool increases the effect of the tool inertia forces on dynamometer measurements. All of these will make the prediction of dynamic characteristic of the process under chatter vibration almost impossible. However, for any dynamic model the correct prediction of chatter onset is enough since no practical machining operation will be carried out under chatter conditions.

The researchers were able to develop a model to simulate the dynamics of boring process. The developed model relies on the novel algorithms of geometrical modeling. In contrast to the previous models that were only able to predict the stability region, this model computes the dynamic cutting force components and frequencies in stable boring operation. The performed cutting experiments have shown that the cutting force components and the vibration frequencies in chatter-free dynamic boring operation could be predicted within $\pm 15\%$ error margin. The model is valid for both finishing (DOC$<r$) and roughing (DOC$>r$) boring processes. The model is also able to predict the chatter onset in boring

operation. Due to the nonlinear geometry of the edge, the influence of DOC and feed rate is interrelated and should not be separately investigated. The instantaneous chip load is computed to incorporate the effect of DOC and feed rate. The influence of geometrical properties (like tool angles and nose radius) as well as structural and process parameters could be investigated using this model. The stability and efficiency of the process depends on the combined effect of all these

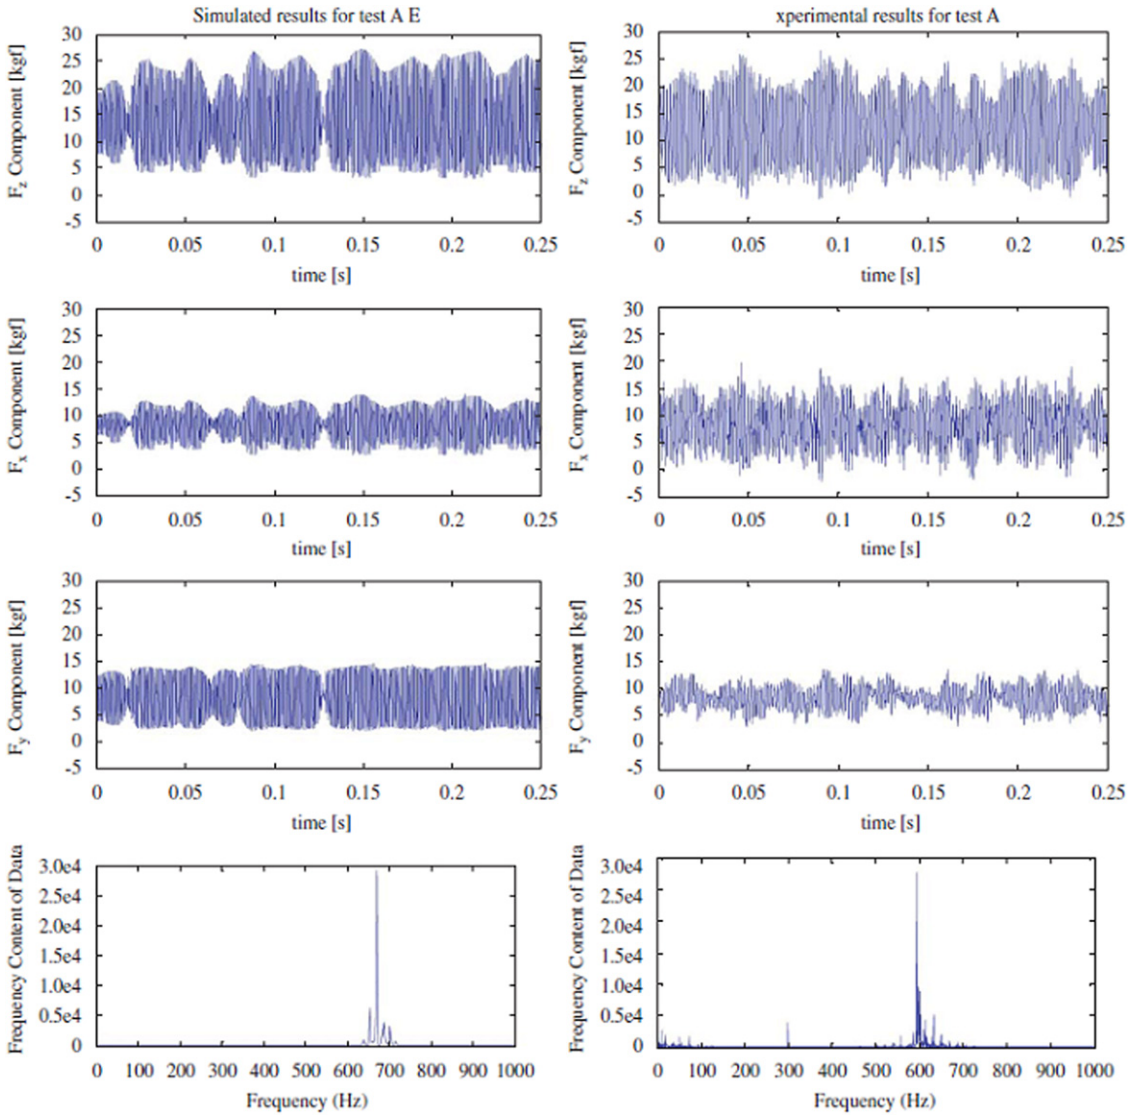

Figure 7 Experimental and simulated cutting force values for test A.[21]

parameters. Hence, the proposed model provides a better understanding of a certain boring process.

Byung-Kwon Min *et al.*[25] studied the use of smart boring tool for process control. The experiment involved the evaluation of the performance of the tool tip servo under real machine tool operating conditions, cutting tests were performed using a stationary Smart Tool boring bar and rotating workpiece. For the cutting test, an aluminum workpiece made from thick wall tube with a 180 mm diameter hole was used. The Smart Tool boring bar was attached to a turning machine tool post and the workpiece was attached to spindle. The tool tip position measurement was recorded to the memory of the controller computer. The spindle speed was 510 rpm corresponding to a cutting speed of 4.8 m s^{-1}. The feed rate was 0.21 mm rev^{-1}. Step response and sine wave tracking were conducted. The purpose of the step response experiment was to determine what tolerances could be maintained in the position of the tool tip relative to the fixture, as well as the effects of cutting on the transient response of the tool tip servo. The purpose of the sine wave tracking experiment was to verify the ability of the system to follow sinusoidal references during cutting. This is similar to the objective of isolating the tool tip motion from boring bar vibration. The model parameters and monitoring variables for the experiments are shown in **Tables 15** and **16**.

Figure 9 illustrates the geometry of finish boring process. As can be seen, if the center of the pre-boring hole and the finish boring tool position are offset due to fixture misalignments, the DOC of the boring process becomes a periodic function that is repeated with every revolution of the spindle.

Tool breakage also results in the deviation of the cutting force from the normal cutting force generated by the boring process. Cutting force is a monotonic function of the DOC and feed rate.[26] Consequently, if the feed is maintained constantly and if the cutting force is accurately measured, the geometric profile of the cutting surface can be estimated from the force data. Cutting tool insert breakage can be monitored in a cutting force changes. For a boring process, the radial direction

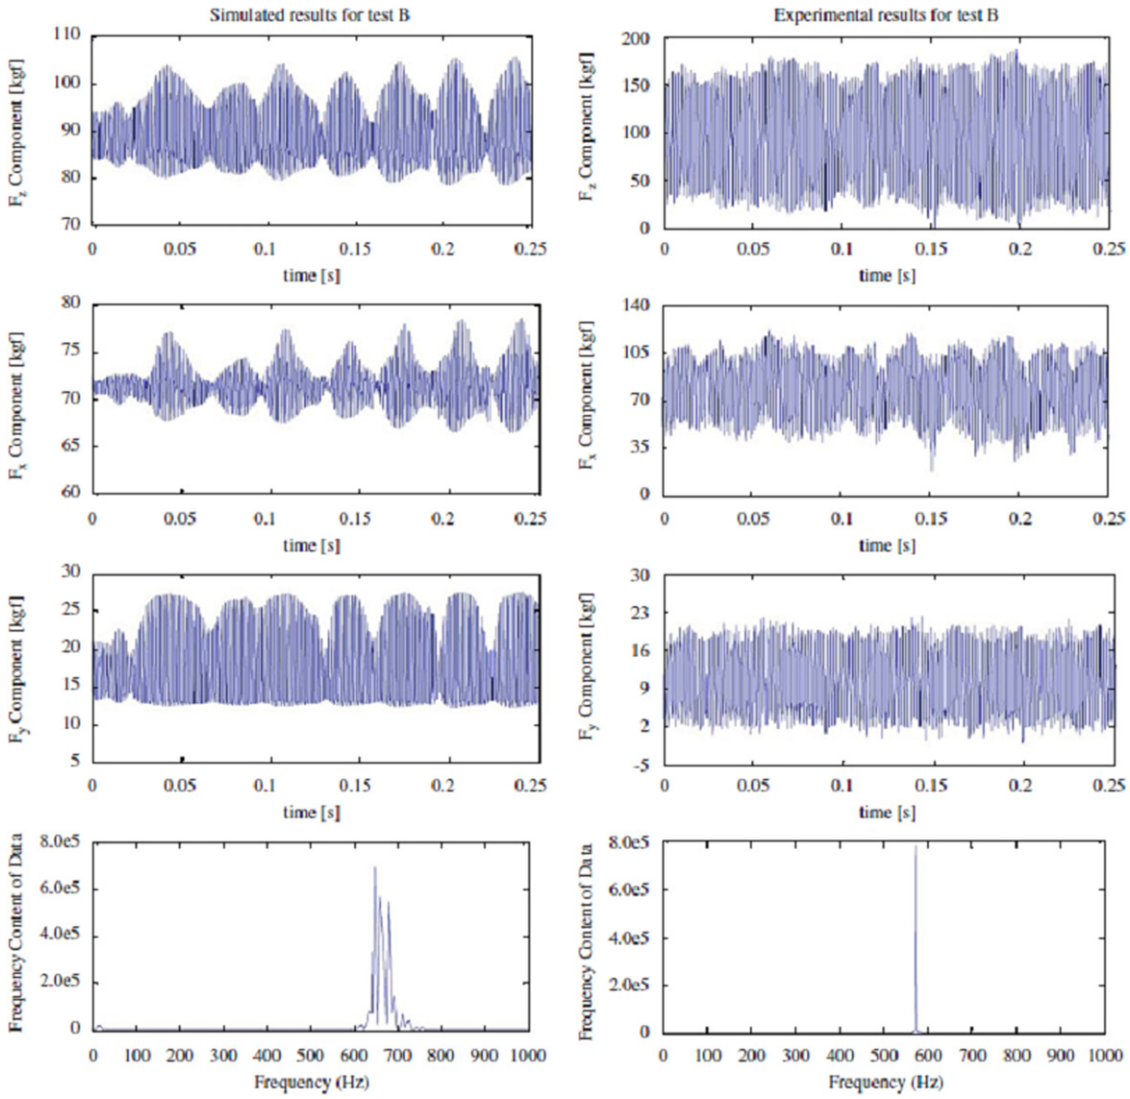

Figure 8 Experimental and simulated cutting force values for test B.[21]

component of the cutting force dramatically increases immediately after tool fracture or chipping.[27] Considering the small cutting force generated by finishing process, an excessive rise in the radial cutting force generally indicates finish tool breakage, if the force is bigger than that observed in workpiece misalignment error which will be detailed in the rest of this section.

Based on above observation, the monitoring of fixture misalignment and tool breakage of the Smart Tool boring process can be carried out with force pattern recognition. The radial cutting force estimation described in the previous section has been considered as a method for the monitoring of the Smart Tool boring process. The cutting force estimated by Smart Tool during a single rotation is compared with the radial cutting force measured by a tool dynamometer. The cutting force estimated by Smart Tool during a single rotation is compared with the radial cutting force measured by a tool dynamometer in a polar plot in **Figure 10(a)**. Cutting speed was 2.0 m s^{-1} and feed rate was 0.083 mm per revolution. A random cutting profile was used to evaluate dynamic performance of the estimator. The difference between the Smart Tool estimation and the tool dynamometer measurement was less than 10% of the cutting force and, thus, the cutting force based on disturbance estimation could be used to detect both the dynamic and the static cutting forces.

Figure 10(b) shows the polar plot of cutting force during a normal boring process operation. **Figures 10(c)** and **10(d)** show the case of workpiece misalignment error and the event of tool breakage respectively. Cutting condition of 2 m s^{-1} cutting speed and 0.083 mm per revolution federate was used for all experimental data. 0.25 mm DOC is used for normal cutting and 0.25 mm desired DOC with 1.27 mm offset was used for misalignment experiment. For the tool breakage experiments, inserts with a 2.0 mm notch was used to expedite breakage. For the normal operation, as can been in **Figure 10(b)**, the cutting force has not deviated more than 10 N from its mean value of 25.96 N and the center of the force plot is close to the center of the graph. The response from misaligned cutting

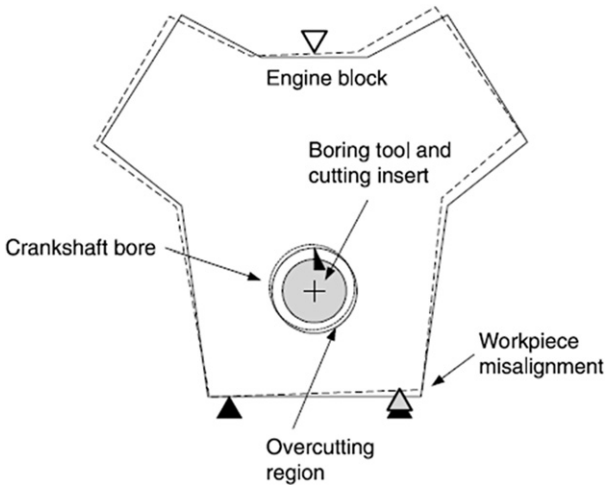

Figure 9 Nonuniform depth of cut due to workpiece misalignment error.[25]

plotted in Figure 10(c) also shows regular cutting force, but the center of the force plot is shifted from the graph center. The small partial circle in the plot is due to the negative reaction force of the tool when the cutting insert lost the contact with workpiece. The tool breakage recorded in Figure 10(d) shows the chaotic behavior of the cutting force with huge force value. As can be seen the plots in Figure 8, it is obvious that the different process failures have different force patterns. Therefore, if the difference between the force patterns can be specified quantitatively, monitoring of these failures is possible.

In this experiment, the R and r values calculated from 10 most recent revolutions are used. The R is equal to mean value cutting force. Therefore, regardless of existence of workpiece misalignment error, the excessive R value bigger than critical value is due to tool breakage. The critical cutting force of the tool breakage must be determined by experiment. In this experiment, it is set to 129.80 N which is 500% of measured cutting force, 25.96 N, from normal operation plotted in Figure 10(b). As far as the mean cutting force R is smaller than critical value, the bigger r value indicates workpiece misalignment error. The threshold of r value is also determined by experiment. In the experiment, it is set to 5.19 N which is 20% of normal operation cutting force. This also means threshold of the offset is approximately 20% DOC, even though that is not exact number due to nonlinear relation between cutting force and DOC. From a and b values, which are x and y-directional components of the radial cutting force, the misalignment direction of the hole can be found. The a, b, R, r, and direction of least square center.

The authors were able to develop a mechatronic metal cutting tool to improve the accuracy and flexibility of line boring machining in the automotive industry. Laser position sensors and piezoelectric actuator were integrated into the rotating body of the boring tool, and to compensate the boring bar droop and effects of cutting forces, a fast tool servo utilizing feedback control of the boring tool insert position was designed and embedded in the rotating tool assembly. In addition to position control, a self-monitoring algorithm that utilizes disturbance estimator was put together in the controller. Self-monitoring capability is an important feature in automated machine tool systems and it is more critical when sophisticated mechatronics is used to control the process. This chapter has proposed a tool monitoring method that utilizes the process information and estimated cutting force during tool tip servo control. A new measurement technique of the cutting force based on disturbance estimation was developed and integrated into a sensorized boring tool. The proposed cutting process monitoring method was effective to detect tool failure as well as process failure due to workpiece misalignment errors which occurred in the boring process. The force measurement by the proposed method matches well with the conventional force measurement using a tool dynamometer. The developed accurate cutting force estimation method is not only useful for process failure monitoring, but it is also useful as a substitute for tool dynamometers, especially in cases where the tool dynamometer is difficult to be placed, such as in a rotating tool tip.

Kanase Sandip *et al.*[28] conducted an experiment on the improvement of surface roughness (*Ra*) value of boring operation using passive damper. The workpiece was mounted using a pneumatic chuck in CNC turning center and the clamping pressure was set at 10 bars. The machining parameters like feed, DOC, clamping pressure, etc., were selected based on the manufacturers recommendations and were kept

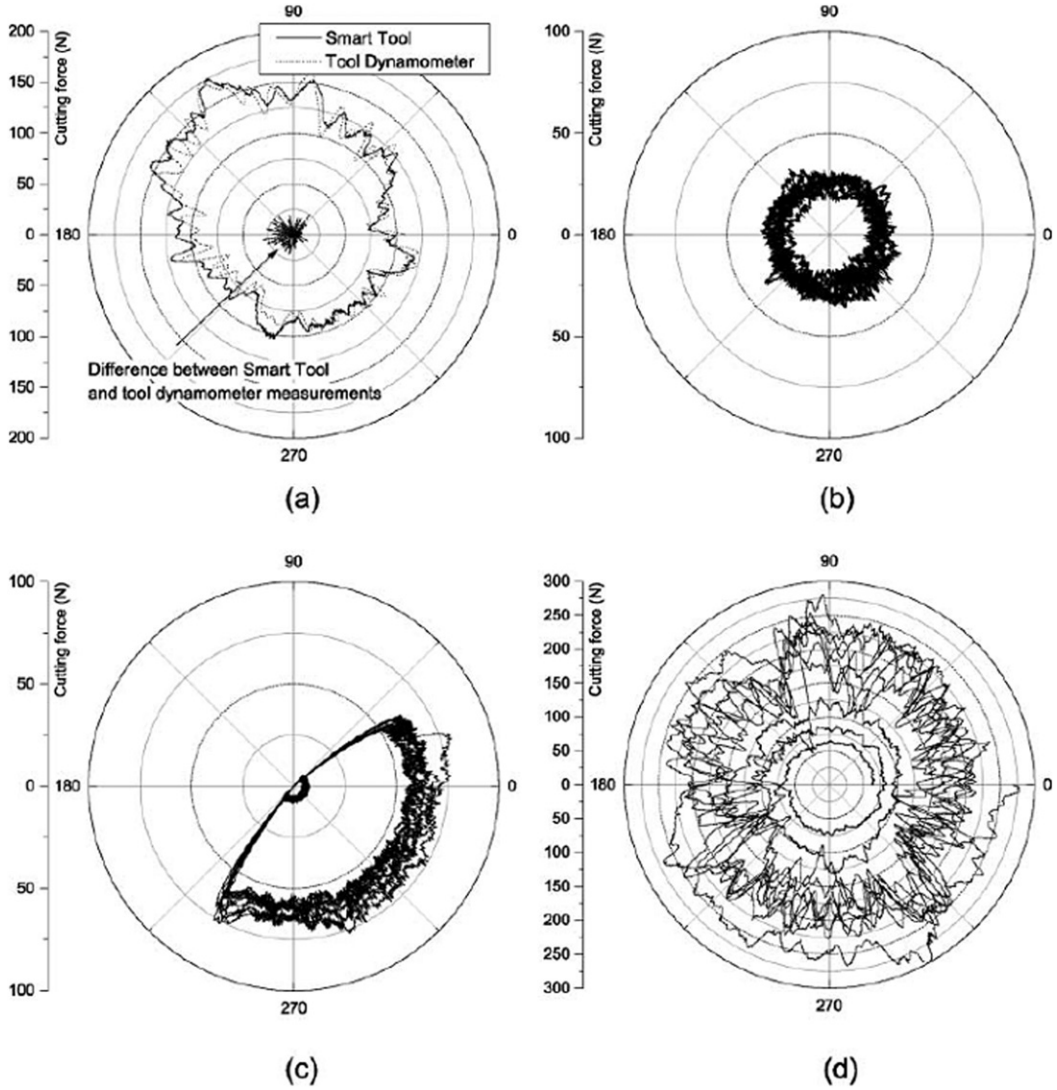

Figure 10 Cutting force measured at Smart Tool. Depth of cut 0.25 mm; feed rate 0.083 mm rev^{-1}; cutting speed 2 m s^{-1}. (a) Comparison with tool dynamometer measurement, (b) normal cutting, (c) workpiece misaligned (tool offset 1.27 mm), and (d) tool breakage.[25]

Table 17 Experimental parameters[28]

Boring tool	BT_A	BT_B	
Overhang length L (mm)	40	80	120
Impact damper position	Vertical	Horizontal	
Clearance CL (mm)	0.4		
Spindle rotation N (rpm)	80	160	240
Feed rate S (mm min^{-1})	0.9		
Depth of cut t (mm)	0.6		

Figure 11 Sample workpiece.[28]

constant for all the samples used. Only the cutting speed, passive damper position on boring bar, and overhang length was changed. The recommended cutting speed, feed, DOC, etc., are shown in **Table 17**. Boring was carried out for 105 mm internal diameter as shown in **Figure 11**.

Twenty five numbers of experiments were conducted to analyze the effect of vibration on surface finish. Boring bar of 20 mm × 20 mm cross section and 200 mm long of WIDAX make was used. The boring operations were conducted on CNC turning center of ACE make using EN9 workpiece material. A Mitutoyo SJ-201P apparatus was used to determine the surface roughness of the bored surface. **Tables 18–21** show the results obtained for all the experiments conducted under different conditions.

Table 18 Surface roughness without passive damper (cutting speed 240 rpm, doc 0.6 mm and feed rate 0.09 mm min^{-1})[28]

S/No	Test A	Overhang length (mm)	Response (surface roughness, R_a)		
			1	2	3
1	3	40	2.72	2.72	2.73
2	2	80	2.37	2.47	2.69
3	5	120	2.82	2.90	2.60

The results proved the passive damping technique has vast potential in the reduction of tool chatter. Also the suppression in tool chatter by using impact damper boring bars was very significant. Boring bars with impact damping are also relatively cheaper than other damped boring bars. It is therefore concluded that impact damping has a good effect in improving surface finish in boring operation.

Pardeep Kumar *et al.*[29] conducted an experiment to analysis and optimized the parameters that affect bore deviation (BD) in boring process. A systematic method as outline in the form of flow chat as shown in **Figure 12** was used to optimize the cutting parameters to achieve minimum BD of the Crankcase made up of grade FG 260 of IS: 210–1978.

Randomization of the run order and analysis sequences was carried out according to the run order by Design Expert software 9.0. Full factorial design of three factors with two having three levels and one factor having two levels which consist of 18 runs were adopted. The overall experimental results corresponding to each run generated by the software are shown in **Table 22**. The machining response that was analyzed was BD. All data obtained was then used as input to the Design Expert software 9.0 for further analysis, according to steps outline for full factorial with optimal design.

Design Expert software was used to analyze the results obtained in order to identify the significant factors and interactions between the factors under studied. ANOVA provides information of analysis of variance and case statistics for further interpretation as shown in **Table 23**. Normal probability plot, main effect plot, and interaction plot for the dependent parameters that significantly affect the response were obtained to show the reliability of the results obtained from the experiment.

From the experiment, it has been observed that the existing parameters for finish tappet bore was cutting speed (137 m min^{-1}), feed rate (0.1 mm rev^{-1}), and cutting allowance (0.5 mm^{-1}), whereas for the same dimensions the optimum cutting parameters was cutting speed (160 m min^{-1}), feed rate (0.3 mm rev^{-1}), and cutting allowance (0.3 mm^{-1}). Further, on comparing the values of BD of existing and optimum parameters, the BD was 0.021 mm when the experiments were performed with existing cutting parameters whereas BD obtained with optimum parameters was about 0.015 mm. Therefore there was an approximately 40% of reduction in BD by employing the optimum parameters.

1.2.3 Application of Boring Process in the Building of Tunnel

Boring process is not only restricted to workshop, in fact, it has been applied in the building of tunnels for transportation purpose. Since the need for infrastructure to handle the intercity transportation of people and goods has steadily increased. The construction of such facilities often requires the excavation of long, deep tunnel such as the base tunnels of the Alptransit Project in Switzerland,[30] the Brenner Base tunnel between Austria and Italy,[31] the Lyon-Turin tunnel between France and Italy,[32] or the Gibraltar Strait tunnel between Spain and Morocco.[33] The application of boring process in this complex operation involved a large special engineering machine for tunnel boring known as tunnel boring machine (TBM). In using TBM, it has been observed that several factors affect its operation. Robbins[34] stated that, it was always impossible to find a route that will avoid the problem of excavating in difficult geological zones with a sufficient degree of certainty. The extent and frequency of the difficulties encountered can be decisive in terms of economical viability or even in terms of the technical feasibility of a TBM drive. And in some cases, a very great potential damage, a single event can cast the entire project into doubt. The length and the number of critical stretches are very important in this respect. Short tunnel stretches with unfavorable but well-known geological conditions are not particularly risky for the economic success of a TBM drive provided that adequate countermeasures are planned in advance.[35]

TBM performance can be affected by geological conditions in a great variety of ways.[36] For instance, boreability problems in hard rock, steering difficulties or severe vibration of the cutter head due to mixed face or blocky rock conditions, major water inflows, cave-ins ahead of the tunnel face, or unstable excavation walls in highly fractured or weathered rock as well as crossing fault zones may represent difficult tunneling conditions. ITA[37] observed that squeezing ground conditions may also slow down or obstruct TBM operation and sometimes even call into question the feasibility of a TBM drive. Because of the nature of this complexity in mechanized tunneling, the need for well funded, thorough investigation of the risks, the technical feasibility, and the cost of TBM application cannot be overemphasized. Hence, it is not surprising that the question of TBM applicability in squeezing conditions has kept engineers busy for more than 30 years.[38–40] Due to the increased economic importance of mechanized tunneling associated with the demand for long-deep tunnels, the application of boring operation is particularly relevant today.

Ramoni and Anagnostou[41] carried out a comprehensive literature search on case histories involving TBMs under squeezing conditions in order to identify the specific problems associated with the use of TBMs. They observed that squeezing behavior may become problematic at different distances behind the tunnel face. Hence, the specific potential hazards concern both the machine area (sticking of the cutter head, jamming of the shield) and the back-up area (e.g., jamming of the back-up equipment, inadmissible convergences of the bored profile, damage to the tunnel support). In addition to the difficulties that are directly caused by squeezing behavior, adverse events such as clogging of the cutter head, insufficient bracing of the grippers, or instabilities of the face or the tunnel wall may also occur when boring through weak ground. It was equally difficult or even impossible to distinguish the different phenomena from each other. For example, when driving through poor-quality ground it may remain uncertain if the

ground pressure acting upon the TBM is due to squeezing or raveling behavior.[35]

A marked difference exists between conventional and mechanized tunneling as a result of the magnitude of the potentially problematic deformations. Due to the geometrical constraints imposed by the equipment, even convergences as small as one or two decimeters may lead to difficulties in the machine or in the back-up area of a TBM drive Kovári.[42] Again, experience in some stretches of the Gotthard Base Tunnel has shown that hard but highly fractured rocks may also exhibit relevant deformations and challenge TBM tunneling, particularly if encountered at great depths. Tunneling experience shows that the ground deformations may develop very rapidly and very close to the working face. In such a situation, the achieved gross advance rate would play a secondary role (the TBM would become jammed even if operated at the highest feasible speed). Furthermore, standstills of TBM operation cannot be completely avoided.[39,43] Besides adverse ground conditions, unpredictable stops due to technical problems (e.g., electric power stoppages, mechanical breakdowns of the TBM, problems in the back-up system) have to be considered. For example, during the excavation of the Evinos–Mornos Tunnel (Greece) the cutter head of one of the gripper TBMs ($D=4.20$ m) became jammed during an excavation standstill which was caused by an interruption of the electric power supply.

When tunneling by a single shielded TBM (or a double shielded TBM in the so-called (auxiliary mode), the tunnel support (lining by precast segments) forms part of the thrusting system. There have been negative experiences in cases where a proper backfilling of the segmental lining was not achieved. For example, the double shielded TBM ($D=2.91$ m) that excavated a part of the Stillwater Tunnel (USA) probably became trapped in squeezing ground because of the impossibility of fully utilizing its installed thrust force. Firstly, it was not possible to drive the double shielded TBM in the 'gripper mode' and secondly, the improperly backfilled segmental lining was not able to withstand the combined loading of ground pressure and thrust force generated in the 'auxiliary mode.' In this case there was a further difficulty in relation to the telescopic part of the shield, which had a smaller diameter than the front and the rear shield, favoring the accumulation of loose material in this area, and thus leading to an increase in the friction that had to be overcome when moving the double shield. Similar problems also arose with gripper bracing, the backfilling of the segmental lining, and the telescopic part of the shield during the excavation of the Los Rosales tunnel (Colombia, double shielded TBM, $D=3.54$ m). Possible problems in the back-up area include inadmissible convergences of the bored profile or damage to the tunnel support. Such problems are basically the same as in conventional tunneling, the main differences being that in conventional tunneling (1) there is the option of excavating a considerably larger profile in the critical stretches (in order to accommodate the deformations) and (2) there is also more flexibility concerning the location of support installation (stabilization measures can be taken practically wherever and whenever required).

In TBM tunneling, the space available for ground deformations and tunnel support is largely predetermined by the fixed geometry of the excavated cross section. The possibility of enlarging the boring diameter locally is very limited (up to 30 cm, if at all possible). Besides the typical problems mentioned above, jamming of the back-up equipment is an additional hazard scenario to be considered, particularly for gripper TBMs. This has been experienced, for example, during the excavation of the Strada Section of the Tavanasa–Ilanz Tunnel (Switzerland, gripper TBM, $D=5.20$ m), in the Northern Section of the Vereina Tunnel (Switzerland, gripper-TBM, $D=7.64$ m), and, recently, in the Faido Section of the Gotthard Base Tunnel (Switzerland, gripper-TBM, $D=9.43$ m).

In furtherance of their research, Ramoni and Anagnostou[44] extensively studied the TBMs under squeezing conditions under the following subheadings:

1.2.3.1 Ground–Equipment–Support Interactions

They identified the relevant interfaces between the main system components and understanding their interactions was very important to an assessment of the critical situations. This might affect the performance, or even the feasibility of a TBM drive taking into consideration the peculiarities of existing TBM types with respect to thrusting systems, tunnel support, the presence or absence of a shield, and the achievable gross advance rate. They observed that the large number of interfaces between ground, tunneling equipment, and support in combination with the possibility of conflicting requirements and feedback effects introduces a high level of complexity, which necessitates an efficient mapping of the system and of its interfaces in order to identify and analyze the relevant interactions.

1.2.3.2 Boring and Thrusting

They have observed that the jamming of the TBM represents a major hazard as it may lead to serious damage, necessitating lengthy standstills for freeing or repairing the machine. Besides being important from a practical point of view, this potential problem is also theoretically very interesting and has attracted several research efforts over recent years. The researchers that have work in this area includes Graziani *et al.*,[45] Ramoni and Anagnostou,[46,47] and Sterpi and Gioda.[48] Ramoni and Anagnostou[44] further investigated the following conditions as it affects boring and thrusting.

1.2.3.2.1 Restart after standstill

If the ground behavior is time dependent, which is very common for squeezing conditions, a radial ground pressure may develop upon the machine during a standstill. In order to resume TBM operation, i.e., to move the TBM forwards and to rotate the cutter head, the thrusting system must be able to cope with the frictional forces acting upon the cutter head and the shield (Figure 13). In order to move the TBM forwards, both the installed thrust force and the bearing capacity of the thrusting system must be higher than the frictional resistance (static friction).

The frictional resistance was observed to increase with the radial pressure acting upon the machine (which may be high in the case of squeezing ground) and with the size of the loaded area (i.e., with the diameter and length of the cutter head and of the shield). However, it depends on the type of the ground and on the surface roughness of the cutter head and of the shield as they are relevant with respect to the skin friction coefficient.

1.2.3.2.2 Immobilization during ongoing excavation

TBM immobilization during the boring process can be seen as equivalent to the borderline case of a zero net advance rate. In the case of intensively squeezing ground, however, one should bear in mind that before the machine moves forwards the extrusion of the core has first to be compensated. Under normal conditions (characterized by the usual values for penetration and rotational speed), the effect of the core extrusion is small, but it may become relevant in the case of a low-penetration rate or a low-rotational speed. In extreme cases, the cutter head penetrates and rotates without moving forward (the penetration is used-up just for removing the axially deforming ground at the working face).

1.2.3.2.3 Tunnel support

Maidl *et al.*[49] stated that the application of tunnel support usually took place at two locations: in the machine area and later in the back-up area at a distance of 30–60 m behind the tunnel face. The locations of the support installation are determined by the design of the tunneling equipment. In the back-up area it is generally possible to install the tunnel support without slowing down the rate of TBM progress. Support application in the machine area, however, interferes considerably with TBM operation because, as a rule, it necessitates a halt of the machine. Furthermore, the support in the machine area may influence the ground pressure acting upon the shield. According to Schneider *et al.*,[50] particularly critical in this respect is the zone between the first and the second tunnel support installation points. In order to reduce the risk of problems in this area (e.g., jamming of the back-up equipment, inadmissible convergences of the bored profile, damage to the tunnel support) the installation of a higher quantity of tunnel support may be needed in the machine area, and this, as said before, will affect general TBM performance.

1.2.3.2.4 Single and double shielded TBMs

The differences between single and double shielded TBMs include the TBM length, the thrusting system, the tunnel support, and the advance rate. Single shielded TBMs are longer than gripper machines. As the area exposed to the squeezing pressure is larger, a higher frictional resistance has to be overcome and, consequently, all other parameters being equal, the risk of shield jamming is higher. The disadvantage of a longer shield is, nevertheless, not of absolute significance because single shielded TBMs usually have a higher installed thrust force than gripper TBMs.

1.2.3.3 Counter Measures

In order to influence system behavior, counter measures are as follows (1) cutter head, (2) geometry, (3) overboring, (4) shield, (5) thrust force and torque, (6) back-up equipment, and (7) tunnel support. While the tunnel support was studied under (1) practically rigid supports, (2) yielding supports, (3) deformable longitudinal joint elements, and (4) on the appropriate support concept.

In conclusion, the authors observed that, the result of a complex interaction between the ground, the tunneling equipment (TBM and back-up) and the support affect the TBM performance. Hence, the factors resulting from the three main

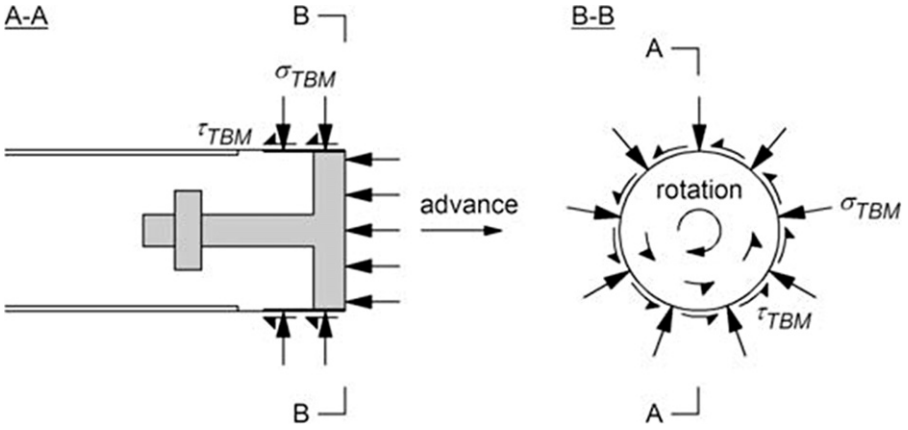

Figure 13 Loads acting on the TBM at restart (the shear and normal stresses at the face apply only in the case of a significant core extrusion). Ramoni, M.; Anagnostou, G. Tunnel Boring Machines under Squeezing Conditions. *Tunn. Undergr. SP. Technol.* **2010**, *25*, 139–157.

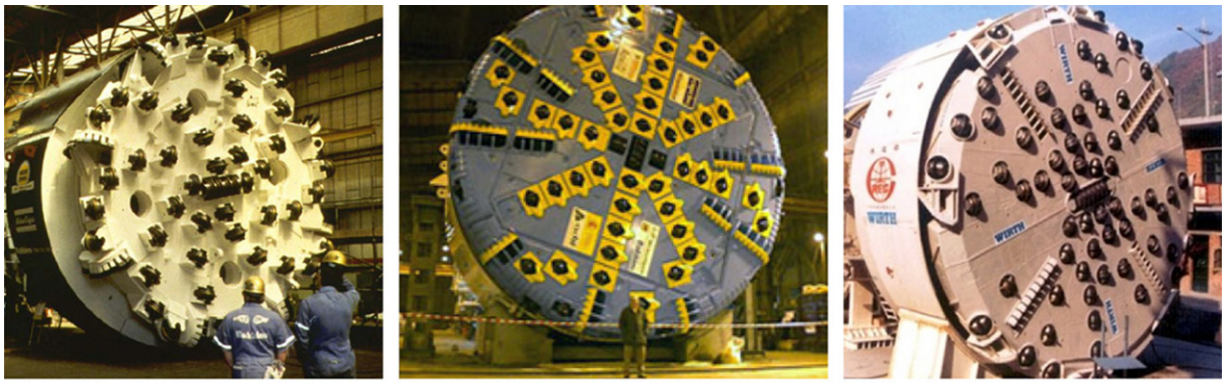
components of the system affect the TBM drive simultaneously and are usually coupled with each other.

Huo *et al.*[51] investigated the effect of disk cutters plane layout design of the full-face rock TBM based on different layout patterns. The study involved formulation of a nonlinear multi-objective mathematical model with multiple constraints for the disk cutters plane layout design, and analyses the characteristics of a multi-spiral layout pattern, a dynamic star layout pattern, and a stochastic layout pattern. The emphasis was put on the study of superiority of three different layout patterns as shown in **Figure 14**.



Different layout patterns were adopted in practice during the layout design of the disk cutters, while taken into consideration the engineering technical requirements and the corresponding structure design requirements of the cutter head. Genetic algorithm was employed to solve a disk cutter's multi-spiral layout problem and a cooperative coevolutionary genetic algorithm (CCGA) utilized to solve a disk cutter's star or stochastic layout problems. An instance of the disk cutter's plane layout design was solved by the proposed methods using three different kinds of layout patterns. Experimental results showed the effectiveness of the method of combining the mathematical model with the algorithms, and the pros and cons of the three layout patterns. Some of the observations made were as follows (1) the quality of plane layout design of the disk cutters for the full-face rock TBM directly affects the balance of force distribution on the cutter head during excavation, (2) the layout design of the disk cutters belongs to a complex optimization problem, so there was a need to make use of the advanced optimization methods to solve the problem, (3) the multi-spiral layout pattern can make the disk cutters distribute more evenly on the cutter head and can improve the stress distribution of the cutter head, and (4) the stochastic layout pattern can provide infinite possible solution space for the layout of the disk cutters and can produce the best solutions with the best performance indices.

1.2.4 Future Research Direction in Boring Operation

Available literatures in boring operation have shown a gap that needs to be investigated in order to fully appreciate how the various input factors affect the output factors or variables. Studies have shown that cutting fluid types and method of its application could affect the outcome of an investigation during machining processes.[52,53] Efforts have been concentrated on how vibrations, ratio of length to diameter affects the results of boring operation and not much have been reported on how cutting fluids type or it methods of applications affect boring operation. Even when cutting fluids are used, it is never discussed as a factor that could affect the outcome of the result. For instance, Chang[54] used two nose radii in his work to evaluate the effect of vibrations on tool life and surface roughness. He found that surface roughness and tool wear were strongly affected by the vibration amplitude and frequency and that improper tool geometry and nose radius will produce more vibrations than the DOC. Huang and Chen[55] discovered that two types of vibrations may occur in machining, such as forced vibration and self excited vibration. Forced vibration was noted to be associated with bad gear drives, unbalanced machine-tool components, misalignment, or motors and pumps, etc., while self-excited vibration occurred due to chatter which was caused by the interaction of the chip removal process and the structure of the machine tool and resulted in disturbances in the cutting zone.

Similarly, Lin and Chang[56] studies show that vibrations have strong correlation with surface roughness, when effects of vibration signals on tool wear, surface quality, and machining time were studied. Bernardos and Vosniakos[57] investigated the relative motion between cutting tool and workpiece on the surface finish profile, using the ratio between vibration frequency and spindle rotational speed. While, Salgado *et al.*[58] studied the cutting parameters such as feed rate, spindle speed, DOC, tool nose radius, nose angle, and vibration data which are the input information for evaluation of tool life by adopting two levels of spindle speed, feed rate, and nose radius. Korkut and Kucuk[59] had proved that the best length to diameter ratio that results in less vibration in boring process is three. They obtained minimum vibration of tool and workpiece when the value of L/D ratio was taken as three. Tool failure in boring was identified by observing higher power consumption, poor surface finish, dimensional inaccuracy, appearance of a burnishing band on machined surface, tool vibrations, workpiece vibration, etc.

A lot of experimental and analytical studies have been employed to study boring bar dynamics and most researches

(a) Multi-spiral layout pattern (b) Star layout pattern (c) Stochastic layout pattern

Figure 14 Different layout patterns of the disk cutters.[51]

were usually carried out on dynamic modeling of cutting dynamics and concentrated on the prediction of stability limits. Parker[60] investigated the stability limit of a slender boring bar in external longitudinal turning, experimenting with alternative regenerative cutting conditions at different cutting speeds and inclination angles. The vibration was measured in the cutting-speed and cutting-depth direction. He developed a two-degrees-of freedom analytical model of the boring bar with two input forces, one proportional to the variation of chip thickness and the other proportional to the penetration velocity. Based on boring bar point receptance estimates, the modal constants of the model were determined. Stability limits were predicted with the aid of the model; these were then compared with the experimental results. However, there was a wide range of cutting speeds resulting in extensive vibration in the cutting-speed direction, which was not predicted by the model. The experimental results indicated that the direction of vibration was either in the cutting-speed direction or in between the cutting speed and cutting depth direction.

Rao *et al.*[61] introduced an analytical dynamic boring force model which included the instantaneous variation of chip cross-sectional area under dynamic conditions. They produced a continuous system model of boring dynamics based on their dynamic boring force model and an uniform Euler–Bernoulli cantilever beam with a circular cross section. They studied boring with a zero side cutting edge angle and calculated chatter frequencies (fundamental eigen frequency of the boring bar) and amplitudes; these were then compared with the experimental results. They claim that their model correlates well with the experimental results.

Jayaram *et al.*[62] attempted to model the chatter stability limit in boring using a simplified analytical model of boring bar dynamics based on the direct point receptance functions and a linear regenerative cutting force model for three orthogonal directions. Jayaram *et al.*[40] claimed that estimates of the direct point receptances were produced based on hammer-excitation. Moreover, they experimentally determined stability limits for turning to validate their model. Kuster *et al.*[63] developed a computer simulation model of boring bar dynamics based on a three-dimensional model of regenerative cutting. Using the knowledge of the radius of curvature of the cutting tool tip as a base, their model differentiates between roughing and finishing in boring.

Marui *et al.*[64] investigated primary chatter of boring bars (with a rectangular cross section) and a tool holder shank using experiments in which they cut the top of a square thread in external longitudinal turning operations. The displacement of the boring bars was measured in both the cutting-speed and cutting-depth direction. With respect to the tool holder shank, both the cutting force and the displacement were measured in the cutting-speed direction. They used displacement and force as a function of time and chatter mark on the workpiece as well as displacement versus displacement to study primary chatter. They found that the vibration of the tool was dominating in the cutting-speed direction. The frequency of this self-excited vibration was slightly lower than the first natural frequency in the cutting-speed direction of both the boring bars and the tool holder shank. While, Taskesen[65] used a closed-loop feedback circuit in on-line vibration control system to measure the relative vibration between workpiece and cutting tool. He used root mean square of workpiece vibration velocity to evaluate the tool life.

1.2.5 Conclusions

It has been established that one of the important factors that affect manufacturing cost is the cost of tooling; therefore any reduction in tooling cost will result in the reduction of manufacturing cost. This reduction in tooling cost can be achieved through proper selection of tool material, tool geometry, cutting speed, feed rate, DOC, and cutting fluids. Following the literature review on effect of cutting parameters during boring operation, it is observed that experimental investigation of the effect of cutting fluid types and its method of application in boring operation still remain an area of research that has not been studied.

Thus, it is of importance to investigate the effect of cutting fluids on the dynamic properties of the clamped boring bar, surface roughness, and tool wear during boring operation in order to gain further understanding of the dynamic behavior of clamped boring bars in the boring process. It is equally observed from literature that the TBM performance depends on a very complex interaction between the ground, the tunneling equipment (TBM and back-up), and the support. Hence, these factors resulting from the three main components of the system affect the TBM drive simultaneously and are usually coupled with each other.

1.3.1 Introduction

Higher production rates in shorter lead-times with continuous quality improvement, dry machining techniques, and constant demand for increased metal cutting performance from difficult-to-machine workpiece materials are continuously increasing. Among users in recent years, demands for extremely tough and hard steels also known as ultrahigh strength steels (UHSS) are continuously increasing. These grades of steel finds application in landing gear components, rocket cases, air frame fittings, heavy vehicle crank shafts, connecting rods, spindles, and power transmission gears. A significant research being undertaken to consider replacing Inconel engine shafts with UHSS in the aerospace industry. However, in the hardened state, these steels are amongst the difficult-to-machine workpiece materials which create ever new challenges for machining operations and place very high demands for high performance cutting tools. The hardness and alloying content makes these grades of steel difficult to machine, the generated temperature being high.

1.3.1.1 Soft-Part and Hard-Part Machining

The term hardened steel is often used for medium or high carbon steel. Hardened steel is designed to be resilient and tough to penetrate by suitable heat-treatment process, namely hardening and tempering processes. Both these processes are used hand in hand when hardening steel. The process begins

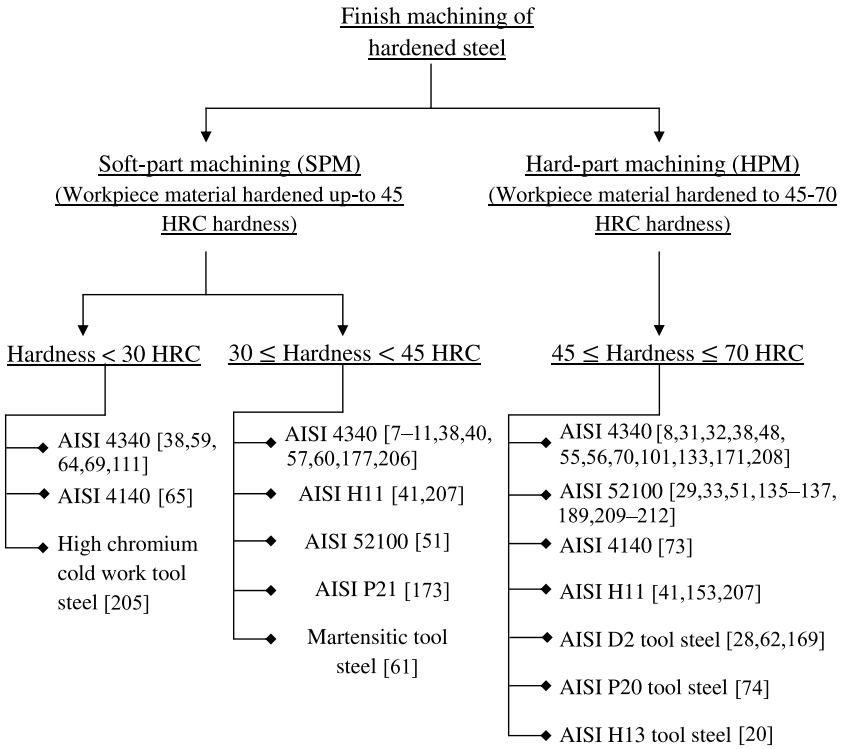

Figure 1 Attempts made by various researchers while soft and hard machining of hardened steel. Modified from Ref. [3].

with hardening wherein a piece of metal is heated gradually until it reaches a high temperature (a temperature that causes it to turn red). Next, the piece of metal is removed and placed directly into cool water. The steel is now very hard, but many times this process leaves the steel very brittle and susceptible to breaking during use. Tempering reduces the hardness of the forged steel very slightly but improves the toughness. In tempering process, steel is heated until it turns the indicative blue color and then allowing the new hardened and tempered steel to cool on its own. The final result of exactly how hard the steel will become depends on the amount of carbon present in the metal.[1]

Today, finish machining of hardened steel which is being stimulated interactively by new cutting tool materials and improved machining processes is categorized as soft-part machining (SPM) and hard-part machining (HPM). SPM is a process wherein a workpiece material hardened up to 45 HRC hardness is easily machined with the advancement in the cutting tool materials and machine tools. On the other side, machining of hardened steels having hardness in the range of 45–70 HRC is considered under HPM.

Sandvik Coromant, the world-leading manufacturer of cutting tools, commented that HPM has become a viable manufacturing process for mass production and is able to meet industry productivity goals of higher quality and shorter cycle times with advent of super-hard cutting tool materials such as cubic boron nitride (CBN) and aluminum oxide ceramics and new optimized machines.[2] Although, HPM has been mostly attempted by various researchers with CBN and ceramic tools, attempts also have been made using coated carbide tools with the development in the cemented carbide grades, coating materials and coating deposition technologies as an economical alternative to costly CBN and ceramic tool materials.[3] A summary of various researchers work which were performed at different levels of work material hardness categorized as SPM and HPM is shown in **Figure 1**.

Researchers have tried to investigate the specific cutting characteristics in terms of cutting forces, surface roughness, tool life, chip morphology, residual stresses (RSs), the changes of subsurface microstructure (so-called white layer), and the tool–chip interface temperature considering the effects of cutting parameters, tool materials, different coatings, and tool geometry under dry and/or semidry and/or flood cooling environment during finish machining of hardened steels while many of them have ventured to characterize the wear phenomenon. Important conclusions of their work for a given tool–workpiece combination are given in Section 1.3.3.

1.3.1.2 Qualitative Comparison of Hard-Part Turning with Grinding

Hard-part turning (HPT) in comparison to grinding offers many advantages. Traditionally, grinding processes are employed for finishing operations on the machine parts with hardness value in excess of 60 HRC. However, HPT using tools with geometrically cutting edges can produce comparable surface finish with the desired accuracy. HPT with a single point cutting tool can produce complex contours as against the costly form wheels are required in case of grinding. Moreover, it is possible to perform multiple operations with single

setup when using HPT resulting in excellent positional accuracy, reduced part handling, and less risk of part damage in comparison to grinding. Further, HPT is mostly carried out under dry cutting condition which reduces costs for coolant, its maintenance or disposal as against grinding waste while grinding.[2,4]

In particular, better production control in terms of reduced manufacturing costs, production time, and higher product quality can be achieved while HPT by employing proper tool geometry, using rigid and stable machine tools and by providing proper clamping to workpiece, tool holder and insert for maximum rigidity. Depending on part geometry, a reduction of machining time and cost of well over 70% can be achieved while maintaining accuracy and surface finish when employing HPT in comparison to grinding.[2] Qualitative comparison of HPT with grinding in terms of overall product quality, process flexibility, material removal rate, subsurface damage, RSs, process reliability, setup time, environmental compatibility, and shape and dimension accuracy is shown in Figure 2.

HPM is widely used in automotive, roller bearing, hydraulic, and die and mold industries. HPT finds application in finish turning of gearwheels, gear shafts, bearing rings, and other transmission parts. Hard milling, hard broaching, and hard reaming processes are widely used in the die and mold industry. In general, HPT is widely accepted as a best replacement to costly grinding operations as it provides a relatively high accuracy for many hard parts and cost benefits. However, issues related to surface integrity, especially undesirable patterns of RSs and the changes of subsurface microstructure, so called white layer, which reduces fatigue life of turned surfaces are need to be considered for hard-part turned surfaces.[6] A group of researchers experimentally investigated and mathematically modeled the performance measures such as surface roughness, RSs, and the changes of subsurface microstructure (so-called white layer) considering the effects of cutting parameters, tool materials, different coatings, and tool geometry during finish machining of hardened steels. Important conclusions of their work are given in Sections 1.3.3 and 1.3.4.

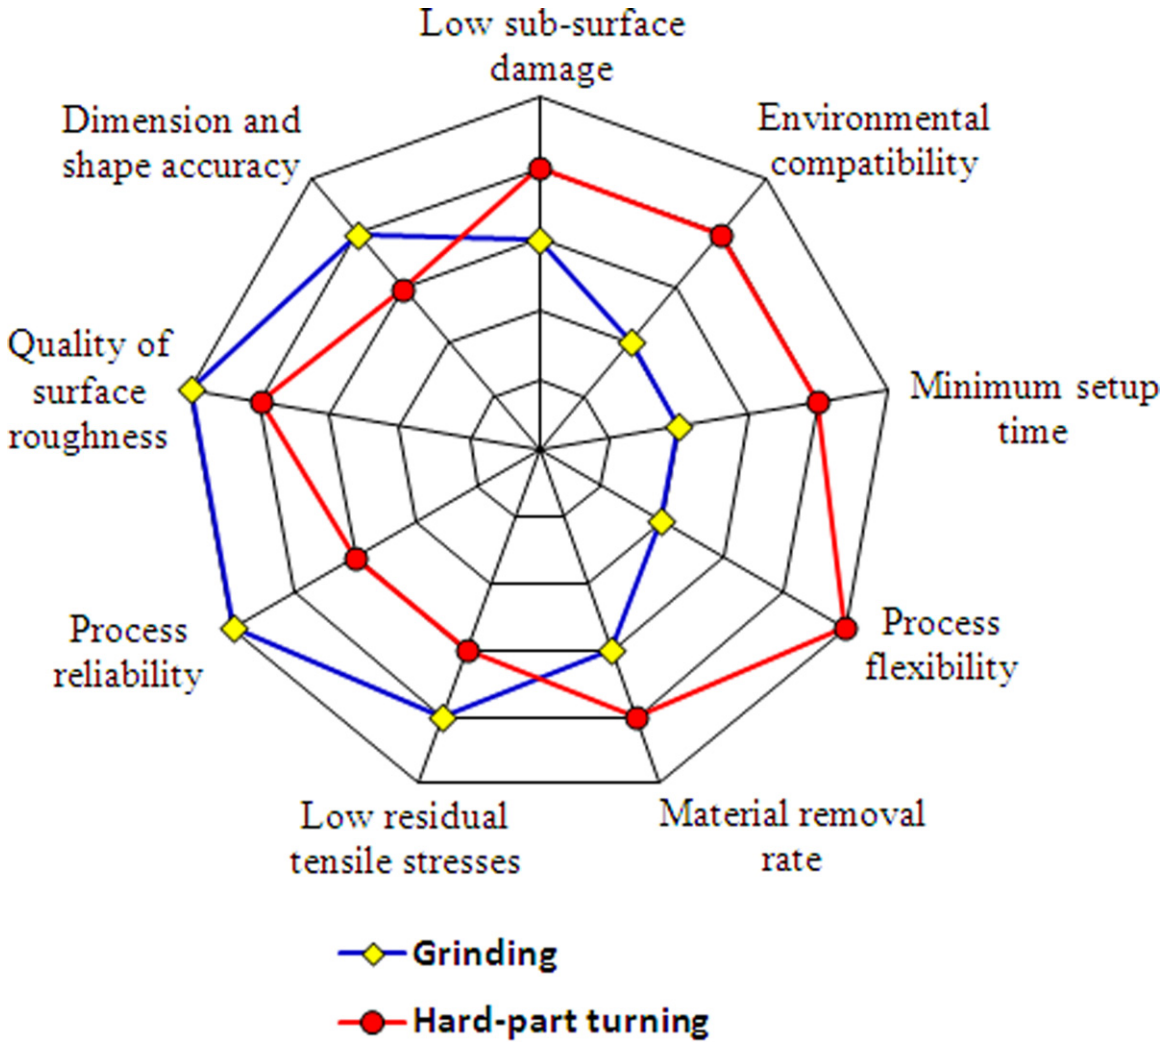

Figure 2 Qualitative comparison of hard-part turning (HPT) with grinding. Modified from Ref. [5].

1.3.1.3 Applications and Machining Characteristics of Hardened Steels

Finish machining of hardened steels is greatly affected with the type of cutting tool material and macro- and micro-geometry employed for the cutting inserts. It has been reported that higher workpiece hardness imposes certain restrictions on cutting conditions to be employed during machining to have better tool life, dimensional accuracy, and surface finish. Further, machining performance largely depends upon the physical properties and chemical compositions of the workpiece and the cutting tool materials, especially the coating materials and their characteristics in case of coated tools. The machining aspects such as chip formation, heat generation and tool wear differ substantially while machining of hardened steel at different levels of hardness.[7–11] Applications of hardened steels at different levels of hardness are given in **Table 1**.

1.3.1.3.1 Hardened steels: Hardness ≤ 45 HRC

With the advent of the new cutting tool materials and improved machining processes, today, machining of hardened steel having hardness up to 45 HRC is being considered as SPM. Sufficient research has been carried out to investigate the effect of work material hardness and cutting parameters on the machining performance using uncoated/coated carbide, ceramic, and CBN tool inserts. Attempts also have been made by various researchers to predict worn tool cutting forces and tool wear progression given the cutting conditions, tool geometry, workpiece, and cutting tool material properties. In view of increasing laws and directives governing industrial safety and environmental protection, a group of researchers evaluated machining performance of hardened steel under dry and/or near-dry and/or flood-cooling environment. Based on the literature review on machining of hardened steel and leading tool manufacturer catalogs, machining characteristics of various types of hardened steels having hardness in the range of 20–45 HRC is given in **Table 2**.

1.3.1.3.2 Hardened steels: Hardness in the range of 45–70 HRC

The concept of HPT (45–70 HRC) has gained considerable attention in the recent past in metal cutting as it can apparently replace the traditional process cycle, which comprises rough turning, heat treatment, and finish grinding. HPT was introduced to increase the flexibility and ability to manufacture complex geometries. Gearwheels, bearing rings, and other transmission parts are typical applications for HPT. Machining characteristics of hardened steels which include high speed steels (HSS), die steels, bearing steels, alloy steels, and case hardened steels having hardness in the range of 45–70 HRC is given in **Table 3**.

Hardened steels have good dimensional stability combined with high resistance to tempering. However, machining of these materials is considered as difficult-to-cut materials and care must be taken to select the correct cutting conditions. In order to withstand higher cutting forces and higher cutting temperatures in the HPM, rigid machine tools with adequate power, very hard and tough tool materials with appropriate tool geometry, tool holders with high stiffness and appropriate

Table 1 Applications of various types of hardened steels[3,12]

Type of hardened steel	*Applications*
Case hardened steels (55–62 HRC)	Gears, shafts, bearings, nozzles, bushes, clutch sleeves, and constant velocity (CV) joints
Bearing steels (58–62 HRC)	Bearing housings, roller bearings, fuel injector nozzles, ball bearings, and hub units
Cold work tool steels (45–65 HRC)	Cold extrusion tools, stamping tools, dies, punches and tools for the manufacture of screws, nuts, and bolts
Hot work tool steels (45–58 HRC)	Extrusion dies, tool and dies, punches, and drop forging die
High manganese steels (200–400 BHN)	Crushing cones, railway components, deflector plates, and mineral processing equipment
High tensile steels (45–56 HRC)	Jet engine mounting, helicopter camshaft gears, landing gear components, and air frame fittings
High speed steels (HSS) (58–66 HRC)	Tool and dies, thread rolling dies, pressure rolls, high temperature bearings, metal cutting tools such as milling cutters, drills, taps, and threading dies

Table 2 Machining characteristics of hardened steels: Hardness ≤45 HRC[3]

Type of steel	*Machining characteristics*
Low-carbon (<0.3% C)	Soft and gummy, difficult chip control, and high-speed machining is possible
Free-machining steels (<220 HB)	Easy to machine using higher cutting speed and high depth of cuts, difficult chip control
Medium and high carbon steels, alloy steels, and tool steels (≤35 HRC)	Higher content of chromium, nickel, and molybdenum: greater tendency to work harden Higher nickel content: more difficult to control chip Higher carbon and alloy content: generally difficult to machine Higher carbon content: more abrasive, achieves good surface finish, and lower speeds
Alloy steels and tool steels (36–45 HRC)	Greater tendency to work harden, more difficult to control chips, hard to break chips, and increased abrasive wear

Table 3 Machining characteristics of hardened steels: hardness in the range of 45–70 HRC[3,12]

Type of hardened steel	*Machining characteristics*
Case hardened steels (55–62 HRC)	While machining of these steels it is important to make sure that machining is taking place in the hard case zone as machining into the soft core may reduce the cutting tool performance. Mostly, polycrystalline cubic boron nitride (PCBN) and ceramic tools are preferred for machining
Bearing steels (58–62 HRC)	Bearing steels are slightly hyper eutectic with a carbon content of about 1%. The microstructure is martensitic with embedded carbides. Due to the abrasiveness of the material, wear resistant grades, mostly, PCBN and ceramic tools are preferred for machining
Cold work tool steels (45–65 HRC)	Cold work tool steels are highly abrasive and the embedded carbides lead to increase crater wear on cutting tools. These steels are difficult to machine as they are wear resistant and a lot of heat is generated during machining
Hot work tool steels (45–58 HRC)	These steels are known for high hot tensile strength, toughness, and wear resistance. Most of the alloying elements in these steels are carbide formers. Tool wear is mostly dominated by crater wear and edge chipping
High manganese steels (200–400 BHN)	These steels have a tendency to work harden. Always machine beneath the skin of the component as tool wear accelerates during machining of the actual skin. Tool life reduces by using too low feed rates and notching occurs when using higher feed rates
High tensile steels (45–56 HRC)	These steels are known for their toughness and capability of obtaining high tensile strength in the heat-treated condition. It is suggested to use low cutting speeds and sharp positive tool geometries to prevent surface abuse and carbon depletion
High speed steels (HSS) (58–66 HRC)	These steels known for high strength, hardness, good wear resistance, and high edge sharpness. A high abrasion resistance and toughness characteristic of these steels generates high temperatures at the cutting edge. Most dominant wear modes are crater wear and notching which can be reduced by lowering the cutting speed and the feed rate, respectively

cutting conditions are some of the prerequisites.[2] Sufficient research has been carried out by the researchers using uncoated/coated CBN, polycrystalline cubic boron nitride (PCBN), and ceramic and carbide tool inserts while HPM. However, CBN inserts win the race in all respects as they exhibit better tool life at toughest cutting conditions due to their high and stable hardness,[13] and its lower solubility for steel material of the machined workpiece.[14] The next section describes the equipment and tooling requirement, especially, the macro- and micro-geometry of the cutting insert for various operations (turning, milling, drilling, broaching, reaming, and threading) while finish machining of hardened steel.

1.3.2 Equipment and Tooling

1.3.2.1 Machine Tools: Applications of Hard Machining Processes

Machining of the steels in the hardened/soft condition primarily depends upon the workpiece configuration, production volume, and amount of the material to be removed. In general, roughing operation wherein up to 30% of the work material is removed from the blank is carried out under soft-state condition. After a workpiece is roughed in the soft state, it is heat-treated to get the required hardness. However, heat treatment usually creates problems with workpieces being twisted, bent, or otherwise out of shape. Machining to the finished size in hardened state allows making a part with higher accuracy and better dimensional characteristics compared to parts heat-treated after machining.[15]

With the advent of the modern machine tools and advanced cutting tool materials, nowadays, it is feasible to machine the workpiece entirely from a hardened state. However, the degree of machine rigidity, rigid spindle tooling and tool holders, hydrostatic guideways, polymer composite reinforcement bases, and high dynamic stiffness, which determines low levels of vibration over a wide frequency range dictate the degree of hard machining accuracy and the quality of surface finish.[16] A solid machine tool, one with bridge construction and a rigid spindle and hand-scraped machine surfaces as they are more accurate and better at dampening vibration than conventionally ground surfaces plays a large part in the level of success of hard machining. High machine rigidity and stability will minimize the impact of variable cutting force on the surface profile produced. This results in a better process capability. All vertical pick-up turning machines from EMAG have a machine base made of MINERALIT® polymer concrete which has eight times better damping properties than gray cast iron. In particular, in case of hard machining small depths of cut (0.05–0.3 mm) and feed rates (0.05–0.2 mm rev^{-1}) are used resulting in small undeformed chip thickness and the ratio of the undeformed chip thickness to the radius of the cutting edge. The geometrical relationship leads to larger effective negative rake angle and as a result extremely high pressure is generated to remove material in the vicinity of the cutting edge. Moreover, a large corner radius causes the components of the resultant cutting force to be high in conjunction with extreme high thermal stresses which demands for an absolute stable and rigid process.[17]

Machining operations performed on hardened steel (turning, milling, drilling, boring, reaming, and threading) found applications in automotive, aerospace, bearing, and die/mold industries as shown in **Figure 3**. Today, HPM is often combined with high-speed machining (HSM) using computerized numerical control (CNC) machine tools.[6] A stable machine structure and dynamic axes based on a completely new modular machine concept are the outstanding features of the modern CNC vertical turning machines which make it possible to utilize various production technologies for soft and hard machining with integrated automation and a pick-up spindle.

Not only machine stability, but also rigidity and thermal stability are vital components in producing an accurate and

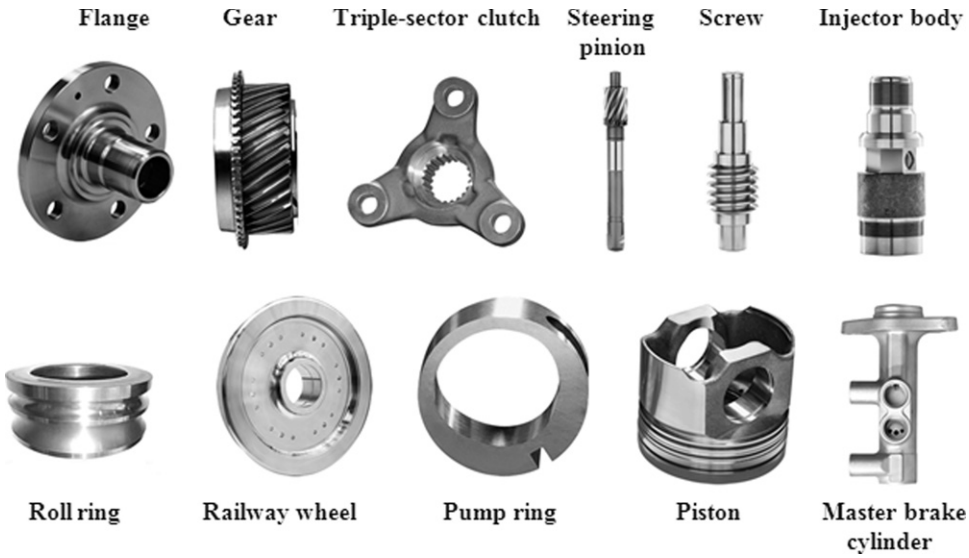

Figure 3 Industrial applications of hard-part machining. Modified from Ref. [17].

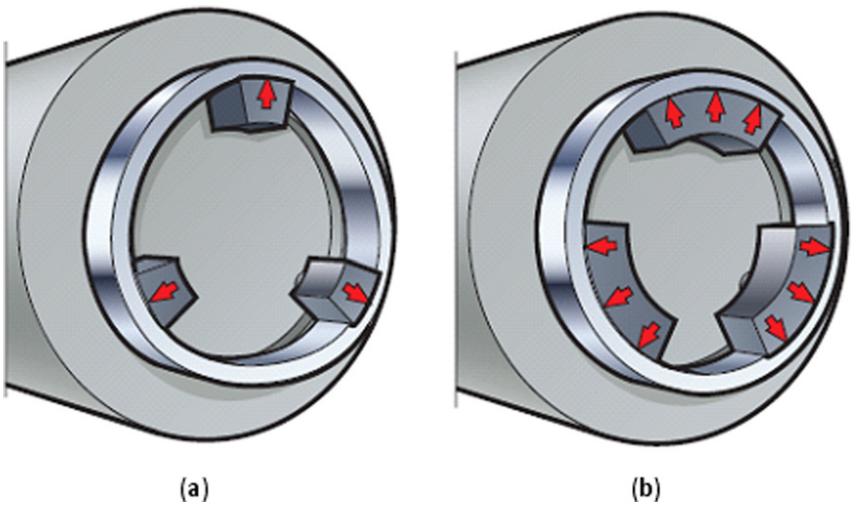

Figure 4 Clamping of thin-walled parts using (a) ordinary three-point jaws and (b) wide jaws. Modified from Ref. [2].

high-quality finished part. Heat generated at any place in the machine affects the tolerance of the workpiece, so it must be controlled accurately. Removing heat by cooling the spindle or transporting it away in heat-containing chips will pay dividends in better tolerances. In this respect, vertical lathes (pick-up machines) with no resting place for chips to accumulate are good examples of 'thermostable machining systems'.[2] In order to control thermal distortion of the machine tool structure, nowadays, machine tools are equipped with a thermal distortion stabilizing system which circulates a temperature-controlled fluid through the main components of the machine. This system is usually employed for high-precision machining applications such as die and mold parts that require long duration cutting. To isolate heat and vibrations from spindle drive, spindle and drive motor are connected coaxially by the diaphragm coupling that provide the spindle carriage with a smooth, vibration free, and rotationally accurate ride.[16] Guiding accuracy and positioning accuracy of the carriage are also become vital and an important criteria to consider in case of hard machining processes.

The ability to accurately rotate the workpiece is vital for achieving close dimensional tolerances. Workpiece clamping especially, thin-walled components place very stringent requirements on clamping. Hard machining of thin-walled parts is often subjected to part distortion which can be eliminated by gripping the part using multiple contacts on the chuck.[16] Ordinary three-point jaws can distort the roundness of thin-walled work-piece due to local excessive clamping forces (**Figure 4(a)**). As against, gripping thin-walled work-piece using wide jaws distribute clamping forces over a larger area for better machining with narrower dimensional tolerances (**Figure 4(b)**).[2] Magnetic work-holding devices are also

more commonly used due to sufficient clamping force and consistent part location for complete 3D machining in a single setup with improved accuracy and better surface finish.[16]

Usually, a length-to-diameter ratio of up to 2:1 is used for workpieces supported on one end only. However, with additional tailstock support, this ratio can be extended. Properly aligned headstock and tailstock promotes maximum rigidity and add extra dimensional stability as shown in Figure 5.[2]

Further, added strength for tool holder and insert clamping brings additional rigidity to process while machining of hardened steels. It is always desired to keep the overhang as short as possible or, if feasible, use a rigid tool with a large cross-section as deflection of the tool holder increases by the cube of the added overhang. In addition to a requirement of strong tool holder, hard machining also requires a rigid means of clamping inserts to tool holder. CoroTurn® RC clamping for negative inserts and CoroTurn® 107 for positive inserts provide this rigidity by clamping the insert in two directions, combining downward forces with insert positioning accuracy as shown in Figure 6.

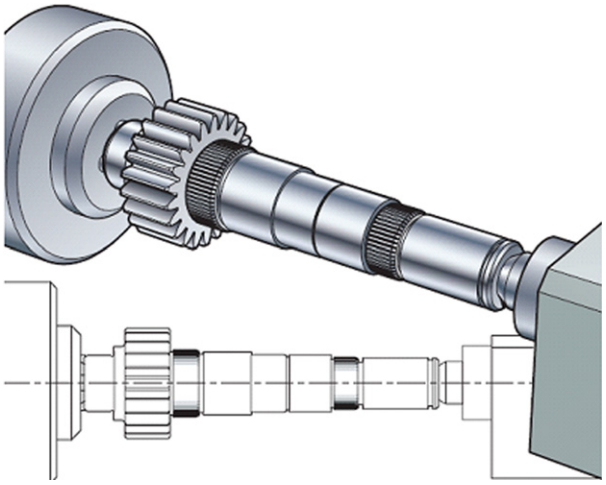

Figure 5 Properly aligned headstock and tailstock promote rigidity. Modified from Ref. [2].

1.3.2.1.1 Industrial applications

1.3.2.1.1.1 Complete machining of flanges

'Downsizing' remains the focus of industrial production, in regards to car engines, in the energy industry or also general mechanical engineering. Machining of ever smaller and more precise components in the hardened/soft state, such as flanges has become possible with modern CNC machine tools such as EMAG's vertical turning lathes as shown in Figure 7(a).[17] The design of these machines provides a high degree of flexibility to apply different production technologies for soft and hard machining which has become the basis for success when machining a wide range of flanges.

1.3.2.1.1.2 Machining of gears: compact manufacturing system

A demand on the manufacture of transmission components such as shafts, gears, planetary gears, and plate carriers at the highest precision continues to increase. Modern gearboxes are becoming smaller while the number of speed-gears increases, leading to a general increase in the quantity of all gears and toothed components. With innovative machine designs by the gearing specialists from EMAG have expedited developments in the production of transmission systems such as, vertical pick-up turning machine (VL 2) for the fast and precise machining of gears, pick-up gear hobbing machine for the fast hobbing and deburring of gears (VLC 200 H) (Figure 7(b)), vertical chamfering machine (VLC 100 C), and laser-welding machine (ELC 160) for the joining of synchronizing ring and transmission gear.

The integrated automation system, using a pick-up spindle in VLC 200 H, ensures short idle times and reduced cost-per-piece. It is perfectly prepared for integration into manufacturing systems. These machines have a body made of high-grade MINERALIT® polymer concrete, which is thermally stable and provides excellent damping properties, resulting in extended tool life and super surface finishes. The KOEPFER gantry loader, equipped with V-grippers, forms the basis of the automation system of these machines. Long-time magazines, like the recirculating storage conveyor, make sure that machines are running for a number of hours and are not only suitable for both wheel- and shaft-type components, but can also be reset without much effort. The capacity of a gravity-based magazine and thus the

(a) (b)

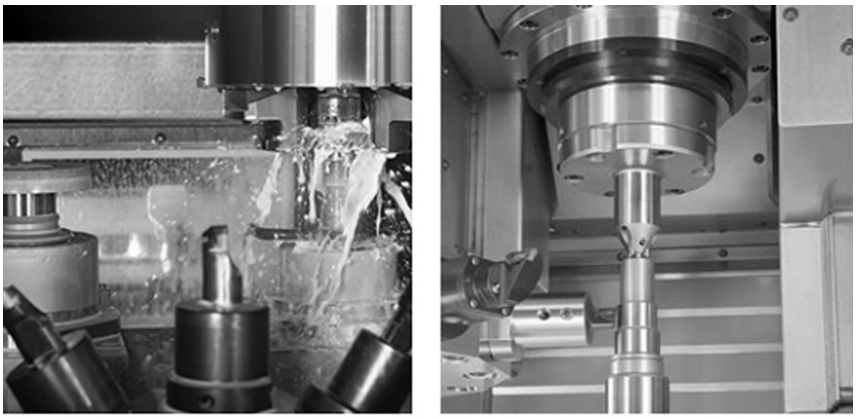
Figure 8 (a) Compact shifting milling head for processing of screws (b) vertical machining center: drilling. Modified from Ref. [17].

autonomy of these machines can be greatly enhanced with the use of multiple feeding rails.[17]



1.3.2.1.1.3 Vertical pick-up turning machines

Vertical turning with suspended spindle also called vertical pick-up turning machines are primarily used in the manufacture of large batches of high-quality metal components. In these machines the work-spindle takes over both the work-holding function for the machining process and the automation process. The highly stable vertical turning machines are being used in the production of gearwheels, sprockets, sliding sleeves, components for CVTs, link pins, connecting rods, rockers, bearing rings, and piston rings as shown in **Figure 8**. This vertical design of the machine offers ideal chip-flow conditions and makes dry machining, an uncomplicated process. Another advantage of these machines is its stability and their vibration resistant design which is obtained through their polymer concrete base and the firmly integrated tooling system to the machine base.[17]

1.3.2.1.1.4 Combination (hybrid) technology

Every year up to two billion gears are produced worldwide, the larger part by gear cutting for transmission systems for the automotive industry. Earlier, requirements of complex gear geometries and exceptional geared components quality was attained with a relatively long process chain, namely turning, gear cutting, and deburring, with each process allocated to a different machine. However, today, gear cutting, turning and deburring operations are integrated in a single setup which offers customers a much quicker alternative for gear production. The vertical machines EMAG VSC 400 WF and VLC 250 WF have all processes integrated in a single setup, resulting in increase in productivity dramatically.[17]

These days, the combination of hard turning and grinding is performed on a single machine, to great effect, to reduce cycle times. Moreover, the process combination (hard turning and grinding) allows greater flexibility and improved component quality. A typical example of combination machining is the machining of gearwheels as shown in **Figure 9(a)**. The shoulders are finish hard turned and the bore and cone are pre-turned and finish-ground because of the high demands made on their quality. To achieve this, the machine has been equipped with two grinding spindles, one of which is designed to machine the bore, with the second one machining the external sections of the component. Another example of the

(a) (b)

Figure 9 (a) A combination of hard turning and grinding and (b) scroll-free turning. Modified from Ref. [17].

combination technology is the machining of scroll-free seats of a pressure ring. To have its outside diameter scroll-free surface it is pre-turned and then finish-ground and its face is hard finish-turned. Another interesting example of this technology is the machining of nuts with internal ball tracks, as used in ball screws. The EMAG VSC, equipped with *Y*- and *B*-axis allows the hard turning of the face, the O/D and the shoulder of the nut and grinding of the internal thread on the ball track. The high-precision *B*-axis allows the setting of the lead angle of the thread, whilst the *Y*-axis serves as in-feed axis for the machining of the ball track. The advantage of this concept over conventional, sequential processes is that all quality-defining surfaces can be machined in a single setup. Re-clamping errors that affect in particular the alignment of face and O/D to the center line of the ball groove are thus avoided.[17]

1.3.2.1.1.5 Scroll-free turning

The Scroll-free Turning process is a process wherein turning tool carries out a rolling motion which offers new opportunities in the machining of precision components. The cutting edge of an inclined CBN wheel moves over the rotating workpiece and the cutting speed is generated by the workpiece rotation as shown in **Figure 9(b)**. With the movements of tool and workpiece overlaid, the contact point of the cutting edge continuously moves along the component surface. The process is very fast, about five to six times faster than that of hard turning processes and about two to three times that of grinding, and impresses with outstanding surface finishes without any trace of scoring marks.[17]

1.3.2.2 Cutting Tool Materials

Machining is a major manufacturing process that is being stimulated interactively by new cutting tool materials, improved machining processes, and government regulations. Diminishing component size and weight, enhanced surface quality, tighter tolerances, and high manufacturing accuracies and reduced costs are the key drivers to the progress of cutting technology.[6] These key drivers have a direct influence on the primary inputs to the cutting process, namely, the cutting tool material, cutting tool geometry and its design, cutting parameters, the workpiece material, and the cutting fluid.[18] A wide range of cutting tool materials is available with the variety of properties, performance capabilities, and cost. These include HSS, cemented carbides (WC), cermets, ceramics (alumina and silicon nitrides), PCBN, and polycrystalline diamond (PCD).

Cemented carbides are the most common cutting tool materials currently in use and are now the material of choice for more than half of all cutting tools produced worldwide, particularly for machining harder materials at higher speeds. HSS are used in a wide variety of cutting operations requiring complex tool shapes such as drills, reamers, taps, broaches, and milling cutters. Cemented carbides are made by powder metallurgy methods using a number of different carbides, namely, tungsten carbide, titanium carbide, tantalum carbide and niobium carbide, and tough metals of the iron group as binders, mostly, cobalt. The percentage of hard particles in carbide tool materials can vary from about 60 to 90%. Some of the developments in the field of carbides are cobalt enrichment, i.e., increasing the concentration of cobalt binder phase near the surface to improve the toughness within the layer keeping the core material hard. Cermet is the collective name for cemented carbides (CERamic plus METal) that have hard particles based on titanium carbide, titanium carbonitride, and/or titanium nitride rather than tungsten carbide. In comparison to cemented carbides, cermets have higher abrasive wear resistance, high hot hardness and better chemical stability, and low tendency for oxidation wear. However, strength and toughness are lower than cemented carbides.[6]

Ceramic tool materials have found applications principally in turning and milling of cast irons, super-alloys, and in finishing of hardened materials. For cutting tools, two kinds of ceramic composite materials based on aluminum oxide and silicon nitride are used. In general, ceramics exhibit high hardness and chemical inertness and hence, wear by adhesion and chemical erosion is almost eliminated except for few selected materials. PCBN which is also termed simply as CBN is significantly harder than cemented carbide or ceramics and is the only material having exceptional hot hardness. CBN has found its main application in the machining of hard ferrous

materials where temperature in the cutting zone is relatively high due to its high hot hardness. PCD is the hardest material we know of and possess superior abrasive resistance compared to any other cutting materials. However, the biggest limitation of PCD inserts is its chemical affinity to ferrous materials. PCD inserts provide premium performance mainly in the machining of highly abrasive aluminum alloys with higher silicon content, low tensile strength nonferrous or nonmetallic material and magnesium, copper, zinc, and the alloys of these metals.[6]

However, in practice no single material exhibits all of the desirable properties for a tool material as the surface and bulk requirements of a cutting tool during machining are entirely different and conflicting. The surface of the cutting tool should be hard, should have low thermal conductivity and low coefficient of friction and should be chemically inert. On the other hand, the bulk should have high thermal conductivity to quickly carry away the heat penetrated into the cutting tool. The bulk material of cutting tool should be sufficiently stronger and tougher to prevent chipping or fracture of the tool under impact forces. Moreover, temperature generated during dry machining is very high, which the uncoated cutting tools cannot sustain. In order to satisfy the conflicting and different requirements of the tool surface and core, coated cutting tools were developed. Coated cutting tools highly contributed in conservation of coating materials as coating generally requires a very thin film to be deposited on cutting tool substrate, which are generally a few microns thick.

Different types of cutting tool materials employed by the researchers while machining of hardened steels at different levels of work material hardness is shown in Figure 10. It can be seen that mostly coated carbide tools were employed by the researchers while machining of hardened steel having hardness up to 45 HRC. However, it can be seen that machining of hardened steel having hardness beyond 45 HRC were mostly attempted by the researchers under dry cutting conditions using ceramic and PCBN tools. A significant contribution of coated carbide tools can also be seen to machine tough and hard steels having hardness in the range of 45–65 HRC.[3]

1.3.2.3 Cutting Edge Geometry: Macro- and Micro-Geometry of the Insert

From last decade, demands for the precision cutting tools which can enhance productivity and quality of workpieces while finish machining of hardened steels are increasing. For an integral and systematic development of a precision cutting tool, four aspects are considered, namely cutting tool material (substrate), coating technology which can enhance the properties of the substrate, macro-geometry which can ease chip transportation, chip breaking and handling, and cutting edge preparation for specific application.[19] The geometry of the cutting edge, in terms of nominal radius and the microstructuring of the tool face and tool flank has relevant influence on the performance of the precision cutting tool.

In order to define the adequate cutting edge geometry and preparation for a specific application, it is required to consider the following aspects, namely, initial condition of the cutting edge, type of machining process, process parameters, size effect and/or micro-machining aspects, workpiece material, tool material (substrate), cutting tool macro-geometry, and required coating as shown in Figure 11.

For finish machining of hardened steel, the cutting geometry is generally characterized by a large negative rake angle, a reinforced edge chamfer to avoid the chipping off of the cutting edge due to large compressive stresses, and the cutting edge radius which is generally obtained by honing. The tool geometry is generally divided in macro- and micro-geometry of the insert. The macro-geometry of the cutting tool is related to the design and optimization of cutting angles, tool flank and tool face angles, corner radius of the tool, radius of the chamfered corner, and chip-breakers to facilitate the chips flow and evacuation, to support the mechanical and thermal loads generated in the cutting process with adequate lubrication during machining. Cutting edge preparation (micro-geometry of the tool) consists of modifying the micro-topography of the cutting edge in terms of roughness and texture of the flank and face surfaces of the tool so as to enhance the performance and reliability of the cutting tool and the quality of the workpiece.[19]

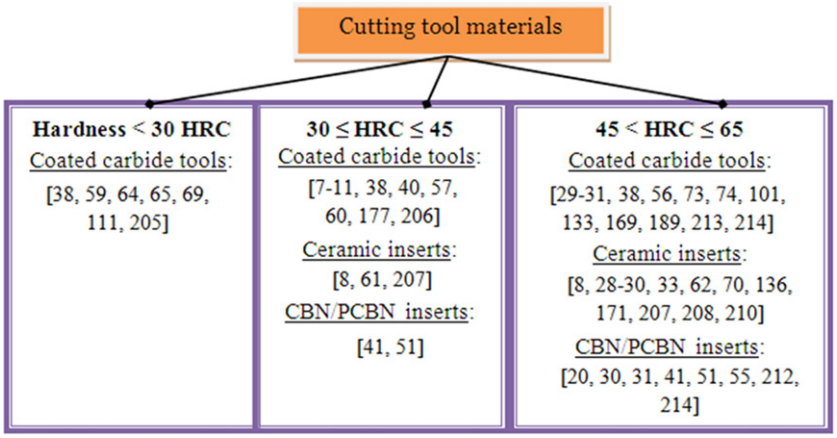


Figure 10 Attempts made by researchers while machining of hardened steel at different levels of hardness using different cutting tool materials. Modified from Ref. [3].

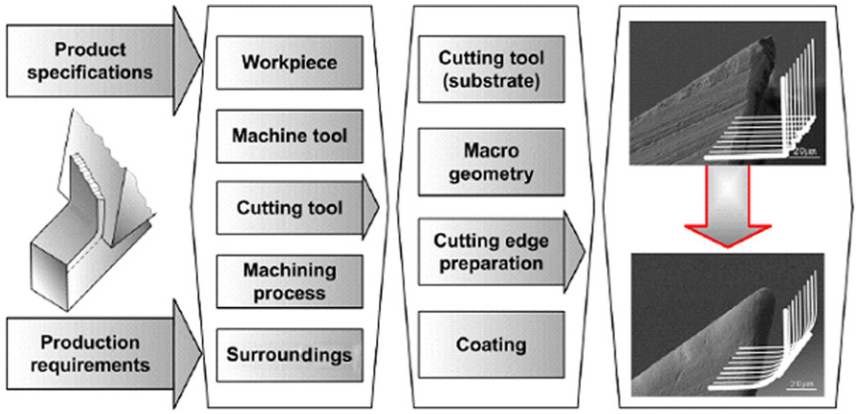

Figure 11 General aspects of cutting edge preparation.[19]

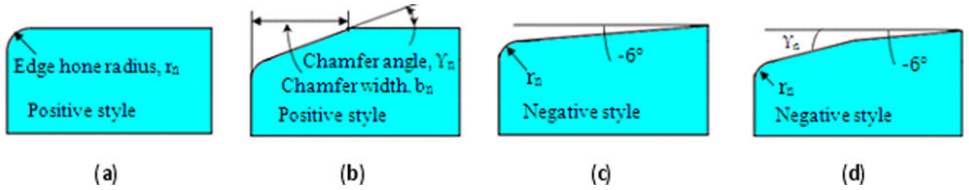

Figure 12 (a) Honed edge, positive insert (b) chamfered and honed edge, positive insert, (c) honed edge, negative insert, and (d) chamfered and honed edge, negative insert.[3]

Macro-geometry comprises of insert size, shape/point angle, and corner radius which is usually determined based on requirement of cutting edge strength (higher corner radius provides more toughness to cutting edge), entering angle versus requirements regarding versatility and cutting power. The micro-geometry usually refers to cutting edge geometry. Two edge geometries are more commonly used while machining of hardened steel, especially when using PCBN inserts. They are honed edges and chamfered and honed edges. In honed edges a small radius is applied to cutting edge and in chamfered and honed edges a chamfer is ground along the edge and the edge is honed afterwards. For PCBN inserts, usually, chamfer angle varies between 10° and 30°, chamfer width varies between 0.05 and 0.25 mm and corner radius varies between 0.015 and 0.050 mm. To have a strong edge, generally, PCBN inserts having negative top rake angle are used. However, to have a stronger cutting edge while machining a hardened steel additional chamfer and edge hone is provided as shown in **Figures 12(a)–12(d)**.[3]

Proper selection and application of cutting edge preparation is one of the basic ingredients as edge geometry and micro-topography of tool surfaces play an important role for a successful development of precision cutting tools.[19] With this view, in recent years, substantial efforts have been made by the researchers in understanding the effects of the edge preparation during finish machining of hardened steels and micro-machining. It has been observed that insert micro-geometry has significant impact on the workpiece surface properties and performance of the cutting tool.[20–24] Ozel *et al.*[22] during their investigations on hard turning with uniform and variable edge design PCBN inserts while turning of hardened AISI 4340 steel observed that variable micro-geometry tool design reduces the heat generation along the tool cutting edge. Further, they observed that lower values of tool wear and plastic strain on the machined workpiece with the use of a variable micro-geometry insert in comparison to uniform micro-geometry insert as shown in **Figure 13**. In another study, Karpat and Ozel[25] experimental and simulation study of analysis concluded that a honed micro-geometry insert results in lower cutting forces, hence lower flank wear values as against chamfered micro-geometry inserts.

Selection of different micro-geometries, namely wiper, chamfer, and hone is depending upon specific application while deciding HPM strategy. In general, a standard radius produces a certain surface finish at a certain feed rate. As against, a wiper radius can produce the same finish profile at twice the feed rate, or twice as good a finish profile at the same feed rate. Leading tool manufacturers have optimized wiper geometry of CBN inserts in terms of lower cutting forces and better surface integrity for specific applications. Virtually, for finish inserts with a chamfer micro-geometry is preferred to enhance the machining performance during machining of hardened steel. In addition, chamfered with a honed edge is less sensitive to chipping and generally performs more consistently.[2] It is reported that high surface quality can be achieved by using wiper insert geometry.[26,27] Galoppi *et al.*[14] observed that PCBN inserts provided with wiper geometry result in lower tool life as against conventional ones. Similar observation was reported when using ceramic inserts.[27] However, Gaitonde *et al.*[28] observed that ceramic inserts provided with wiper geometry result in better tool life and surface finish as against conventional ones.

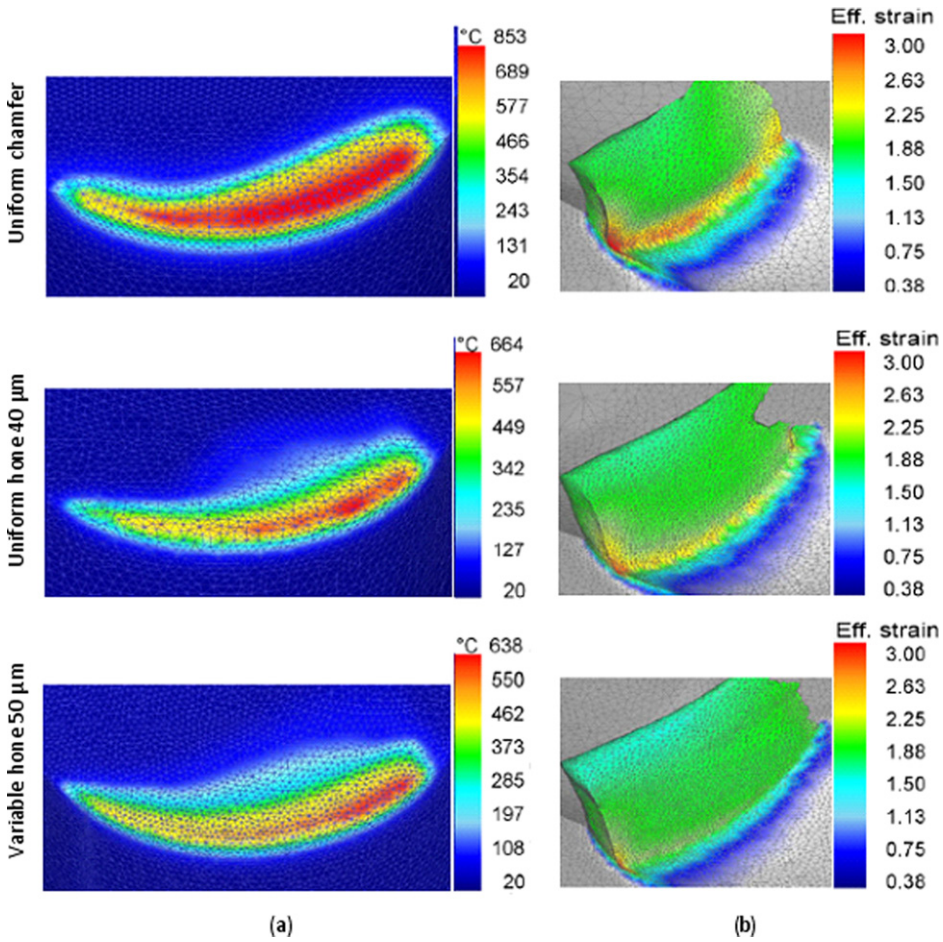

Figure 13 Simulated results of (a) temperature distributions and (b) chip formation and strain fields using PCBN inserts with different micro-geometry.[22]

From **Figure 10**, it can be seen that the researchers performed hard machining (45–65 HRC) using mostly PCBN and ceramic tool materials. However, in view of inflexibility of fabricating PCBN inserts with complex tool geometries and the prohibitive cost of PCBN inserts, a group of researchers performed hard machining using coated carbide tools.[3] Attempts also have been made by the researchers to compare the machining performance of coated ceramic and carbide inserts with uncoated CBN and ceramic inserts when machining hardened steels.[29,30] The work reported shows that the sintered carbide tool is more suitable for turning a workpiece of lower hardness ($\leq$45 HRC). However, coated carbide inserts designed with proper macro- and micro-geometries could become a viable alternative to costly ceramic and CBN inserts while finish machining of hardened steel which is discussed in detail in next section.

1.3.3 Finish Machining of Hardened Steel: Physical Aspects

The researchers have worked on many facets of machining of hardened steel to investigate the effects of cutting parameters, tool materials, and tool geometry on different machinability aspects like, the tool life, surface integrity, cutting forces, chip morphology, and the tool–chip interface temperature. Many of the researchers have ventured to characterize the wear phenomenon under dry and/or semidry and/or flood cooling environment. Compared to SPM, in HPM, the uncut chip thickness is often on the same order of magnitude as tool edge dimension which directly influences the physical aspects of the machining process in terms of cutting forces, the quality of the workpiece (surface finish, surface and subsurface material structure, and RSs), and tool wear and wear mechanisms. With a view to have clear understanding of the changing behavior of physical aspects of finish machining of hardened steel considering the effect of work material hardness, cutting parameters, and tool materials is discussed in following subsections.

1.3.3.1 Cutting Forces

In general, the cutting forces in HPM of a steel component are about doubled than the forces employed while SPM at the same cutting data. High cutting forces also means higher specific cutting force, but, in the context of conventional

machining, in finish HPM, the depth of cut is only of 0.1–0.2 mm which is lower than the tool nose radius, cutting forces are rather low, typically in the range of 50–200 N. However, in roughing of hardened steel the forces are considerably higher, and can reach up to several thousands Newton. There is almost a linear relationship exists between cutting forces and both feed rate and depth of cut.[2,31,32]

Normally, the force conditions in hard turning were different from those in conventional turning, i.e., the radial force was dominant in comparison to the tangential force.[25,33–36] But with variable hone edge radius, the tangential force becomes more than radial force thus increasing the efficiency of cut.[22] However, while finish hard turning of AISI 52100 (100Cr6) steel with CBN 7020 insert, when cutting was limited within the tool nose, radial force component was found to be predominant.[34] Such finding is in contradiction with what is known from conventional turning that the radial force component is 0.3–0.5 times the cutting force component. Consequently, the radial force cannot be neglected in characterizing static and dynamic behaviors of such machining system.[37]

Aneiro *et al.*[31] observed that the depth of cut had the greatest influence on force and temperature. Tool life observed was particularly long for the TiCN/Al_2O_3/TiN-coated carbide tool. However, it was about half of the tool life of PCBN tool at similar cutting conditions, but, claimed that hard machining with coated carbides is justified as PCBN tool prices are, probably, more than twice that of coated carbide price. Suresh *et al.*[32] claimed that hard turning of AISI 4340 (48 HRC) with multilayer CVD-coated TiN/TiCN/Al_2O_3 cemented carbide tool has several benefits over grinding process such as, reduction of processing costs, increased productivity, and improved material properties. The analysis of results concluded that the optimal combination of low feed rate and low depth of cut with high cutting speed is beneficial for reducing machining force. Higher values of feed rates are necessary to minimize the specific cutting force.

Lima *et al.*[38] evaluated the performance of multilayer TiCN/Al_2O_3/TiN-coated carbide inserts in order to investigate the applicability of these inserts to machining of hardened AISI 4340 steel at different levels of hardness 23, 35, 42 and 50 HRC, respectively. Their study concluded that coated carbide tools were unable to machine 50 HRC workpiece, even at light metal removal rates. Experimental results indicated that the relationship between the hardness of the work material and the machining force was not straightforward. The cutting force presented higher values followed by the thrust and feed force. Luo *et al.*[39] observed higher cutting forces for the ceramic tool than those of the CBN tool during their investigation of the variation of the cutting forces with the hardness of the work material. They found that the principal cutting force and thrust force decreased with the increase of hardness, and at about HRC50, the cutting force starts to increase.

Chinchanikar and Choudhury[9,11,40] also observed higher cutting forces for harder workpiece and for CVD-applied multilayer MT-TiCN/Al_2O_3/TiN-coated carbide tool in comparison to PVD-applied single-layer TiAlN-coated carbide tool during machining of hardened AISI 4340 steel at different levels of hardness (**Figure 14**). However, cutting forces were observed by them to be reduced and become nearly equal to that of the softer material at higher cutting speed when coupled with higher feed and higher depth of cut. Their study of analysis concluded that lower cutting forces employed for PVD-coated tools could be attributed to a positive cutting edge style employed for PVD-coated tool in comparison to negative, stable cutting edge style for CVD-coated tool (**Figure 15**) and the characteristics of the PVD-applied coating process which produces very smooth and bright coating surface with a low coefficient of friction between the tool face and the chips.

Aouici *et al.*[41] experimental study on hard turning of AISI H11 steel, hardened to 40, 45, and 50 HRC, respectively, using CBN tools also showed that the cutting force components were influenced principally by depth of cut and workpiece hardness. In HPT, higher cutting forces employed at low cutting speeds were observed to be reduced when cutting speed was increased.[42–45] This may be due to the fact that at high speeds the cutting temperature is very high that results in thermal softening of the workpiece material thereby reducing the cutting forces required for machining. Gaitonde *et al.*[28] explored the consequences of machining parameters on various machining responses in view of hard turning as a potential alternative to costly grinding operations. Results of their experimental analysis during turning of high chromium AISI D2 cold work tool steel using wiper ceramic inserts concluded that the machining force was highly sensitive to feed rate and machining time. The specific cutting force was highly sensitive to machining time while higher values of feed rates were necessary to minimize the specific cutting force.

In finish machining of hardened steel, the undeformed chip thickness is comparable to the cutting edge radius of the

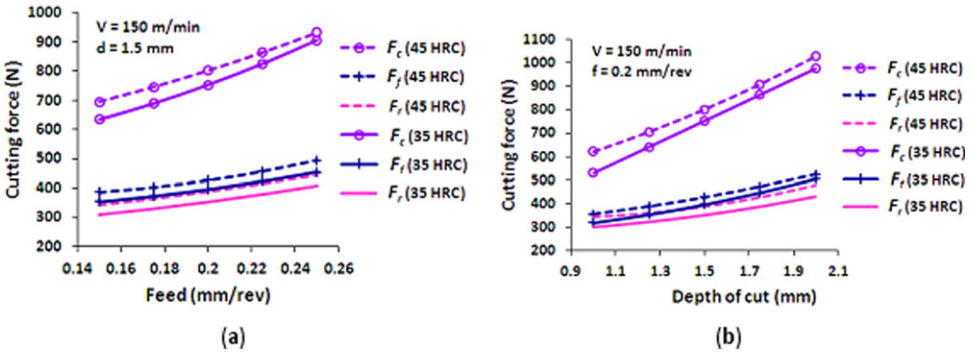

Figure 14 Effect on cutting forces (F_c: tangential force, F_f: feed force and F_r: radial force) by (a) feed and (b) depth of cut.[11]

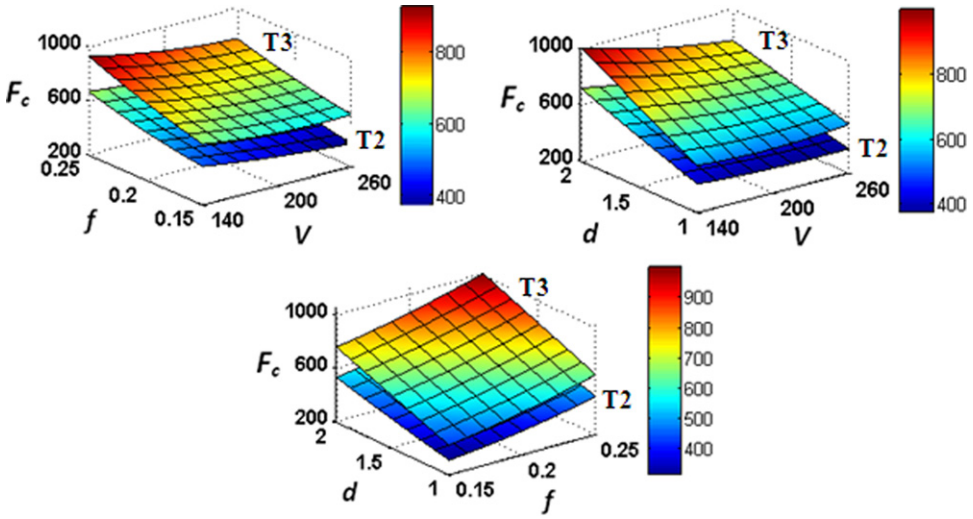

Figure 15 3D response surfaces showing effect of cutting conditions on tangential force (letter T2 and T3 shows response surfaces for PVD-coated and CVD-coated tools, respectively).[40]

tool and grain size of the material which consumes more energy as a round cutting edge of the tool tends to remove a solid grain of the workpiece material. As against, in macroscale machining, the cutting edge of the tool is assumed to be perfectly sharp. Furthermore, it is assumed that there is no contact between the cutting tool and workpiece at the tool flank due to sharp cutting edge and hence, frictional force at the interface is therefore neglected. However, there exists a friction zone at the tool flank in case of finish machining of hardened steel due to elastic recovery of the newly machined surface of the workpiece at the tail end of the of the cutting edge. Hence there exist three deformation zones named primary, secondary, and tertiary deformation zones as against primary and secondary deformation zones in case of macroscale machining.[46]

The force required to overcome tertiary deformation zone does not contribute to the chip removal and hence is commonly named as plowing force. The plowing force is proportionally very small compared to the forces generated in the primary and secondary deformation zones due to the large values of the undeformed chip thickness employed in the macroscale machining. However, in case of finish machining of hardened steel, the magnitude of the plowing force becomes proportionally considerable due to the lower value of overall cutting force and hence can no longer be neglected.[46] With this view, Bhokse *et al.*[47] investigated varying contribution of chip formation and plowing cutting forces at different cutting conditions during hard turning of AISI 52100 alloy steel. They found contribution of chip formation cutting force in the range of 60–70% in total cutting force in comparison to plowing force. However, at lower values of depth of cut, they observed plowing forces has become predominant as compared to chip formation forces. Further, they found that variation in the chip formation force was more prominent in comparison to plowing cutting force with the increase in cutting speed, feed, and depth of cut.

From the available literature it has been observed that sufficient studies were made on the machining of hardened steel alloys. Several studies are available wherein cutting parameters were optimized for surface roughness or cutting force(s) or both. However, in most of the studies, tool life being an important factor was not considered while optimizing the cutting conditions. Experimental observations from several studies indicate that all the three components of cutting forces are higher for harder work material. However, forces were observed to be reduced and become nearly equal to that of the softer material at higher cutting speed when coupled with higher feed and higher depth of cut. In almost all the studies cutting forces get affected mostly by depth of cut (nearly 60–70% contribution) followed by feed (nearly 25–30% contribution) and cutting speed has little influence. In finish machining of hardened steel (depth of cut: 0.1–0.3 mm, less than tool nose radius), the radial component of cutting force has been observed to be largest in magnitude followed by the tangental and feed forces. Moreover, the magnitude of the plowing force becomes proportionally considerable in case of finish machining of hardened steel. The contribution of chip formation cutting force observed in the range of 60–70% in total cutting force. However, at lower values of depth of cut, plowing force has become predominant as compared to chip formation force. More investigations on force and friction conditions through modeling attempts are required to be taken up to characterize the static and dynamic behaviors of HPM process.

1.3.3.2 Chip Formation

Chips produced during machining significantly influence the surface finish of the workpiece, tool life, and overall cutting operation. A group of researchers reported that the formation of chips (form of chip) was strongly influenced by the work material hardness, type of tool, and cutting conditions, especially the feed rate.[9,39,48,49] More closely curled chips are produced in case of harder workpiece, which are hard to break and might be one of the reasons for employing higher cutting

forces for harder workpiece as discussed in Section 1.3.3.1.[9] Jerold and Pradeep Kumar[50] also observed higher cutting forces for closely curled chips in comparison to loose arc chips while turning AISI 1045 steel. In general, snarled long ribbon-chips or snarled tubular-chips are produced at low feed rate when turning steel hardened to 35 HRC and at higher feed rate, short spiral or loose arc chips are obtained when turning softer workpiece (35 HRC) and short helical chips when turning harder workpiece (45 HRC).[9]

Chips form and shape (morphology) produced during machining also significantly changes with the machining time or with the progress of tool wear and has a prominent effect on the quality of the workpiece produced.[48] Attainment of surface finish during machining of hardened steel can be explained in terms of chip morphology. The typical free and back surfaces of the chip produced using two different coated tools (T2 and T3) are shown in **Figures 16(1)–16(8)**. More or less polished back and smooth free surfaces can be seen on the chip produced when using PVD-coated tool T2. However, rough back surface showing some parallel stripes and damaged free surface of the chip can be seen when using CVD-coated tool T3. Polished and bright back surface of the chip obtained when using coated tool shows that minimum friction was offered by tool T2 during machining, which resulted in lower cutting forces and hence, better surface finish as against the higher values of cutting forces and surface roughness when using CVD-coated tool (T3).[9]

It has been observed that when steel in the hardness range of 10–50 HRC were cut, continuous chip was produced with a decrease in cutting forces with increase in hardness in this range of hardness.[51] Increase in steel hardness (10–50 HRC) raises the chip–tool interface temperature which softens the steel resulting in an increase in the shear angle in turning. This leads to a decrease in the chip thickness reducing the tool/chip contact area and hence, contributes to the reduction in cutting force. However, when the hardness exceeds 50 HRC, chip segmentation appears and the cutting forces increase. When harder material is machined, the fracture strain becomes lower, and when it becomes lower than a certain limit, fracture becomes predominant and concentrated shear occurs intermittently at the shear area.[51] Segmented chips are also produced when machining softer material at higher cutting speeds as shown in **Figure 17**. SEM micrographs of the chips of the EN 24 steel of hardness 40 and 45 HRC are shown in **Figures 18(a)** and **18(b)**. It can be seen that the chip of EN 24 steel with 40 HRC is smooth and without serrations whereas the chip of EN 24 steel with 45 HRC has serrations.[49]

1.3.3.3 Tool–Chip Interface Temperature

Heat generated in machining operation is an important factor in addressing metal cutting issues like dimensional accuracy, surface integrity, and tool life. In machining of hardened steels, higher workpiece hardness generates higher temperatures in the cutting zone which have a very strong influence on the workpiece surface quality and the tool wear rate. Therefore, measurement of the chip–tool interface temperature during machining and develop a mathematical model to establish the effect of various key factors of machining on temperature will be extremely valuable and represents a key issue.[10]

Over the past century, several conduction techniques like tool–chip thermocouple, embedded thermocouple, thermocolors, and radiation techniques like infrared thermometry, pyrometry have been developed to evaluate the chip–tool interface temperature arising in the cutting zone during machining. However, tool–work thermocouple technique is widely used during metal cutting due to its ease of implementation and low cost as compared to other techniques as shown in **Figure 19(a)**.[10,31,52,53] In order to establish the relationship between the electromotive force (emf) generated and the corresponding temperature, a schematic of calibration setup is shown in **Figure 19(b)**. A tool–work thermocouple

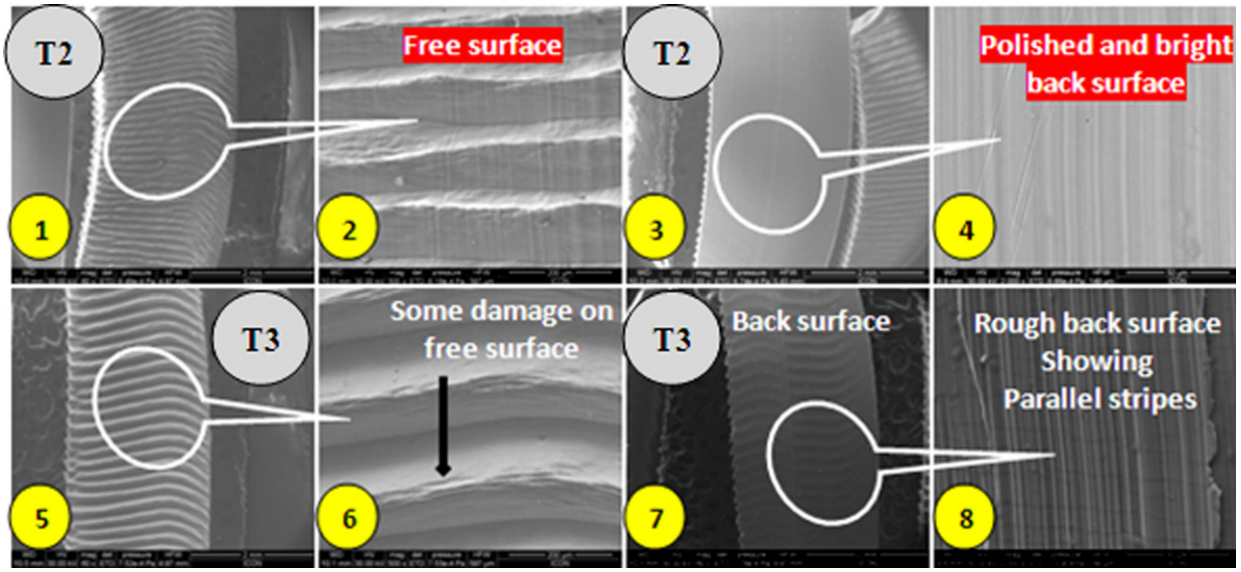

Figure 16 SEM images of the chip surfaces (1) (2) free surface (using T2), (3) (4) back surface (using T2), (5) (6) free surface (using T3), and (7) (8) Back surface (using T3).[9]

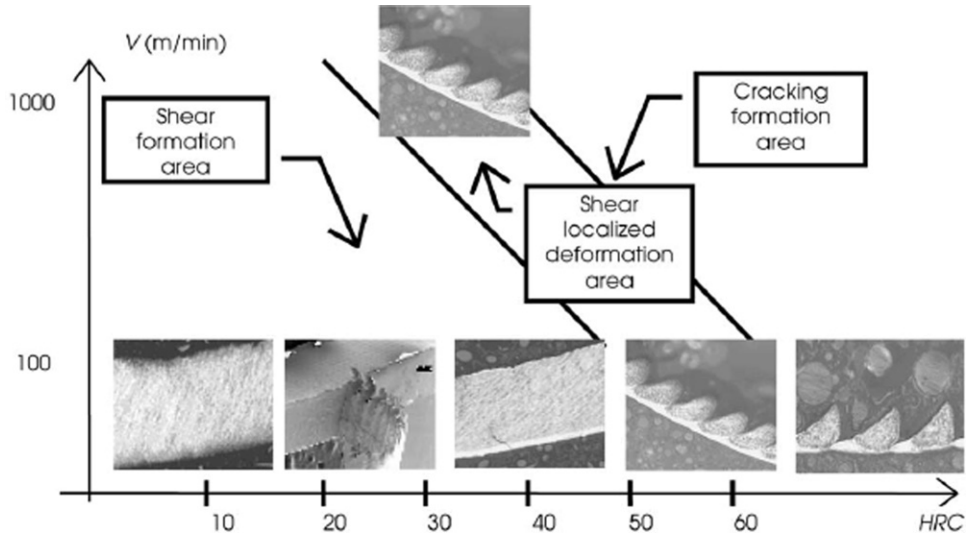

Figure 17 Chip morphology according to the hardness and the cutting speed.[51]

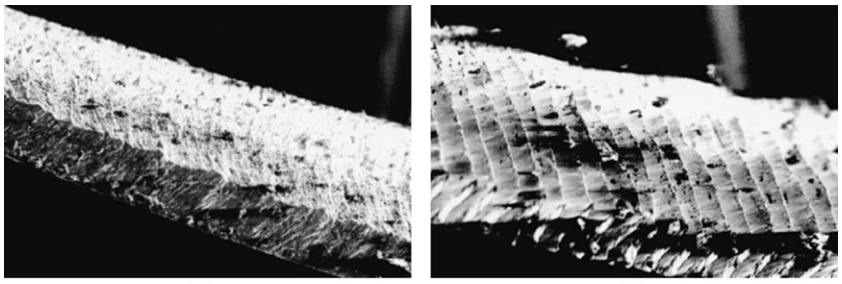

Figure 18 SEM micrograph of the chip of EN 24 steel with (a) 40 HRC and (b) 45 HRC.[49]

junction is formed using a tool and a long continuous chip. The tool and chip junction is heated at different temperature which can be measured by using standard K-type thermocouple wire connected to temperature indicator. Emf generated between the hot and cold junction can be monitored by a digital multimeter. The linear relationship obtained for AISI 1045 and AISI 304 workpieces when using different cutting tools is shown in **Figure 20(a)**.

The chip–tool interface temperature was observed to be more influenced by thermal properties of the workpiece and tool coating.[10,53,54] Most of the studies concluded that the tool–chip interface temperature increases with the increase in cutting speed, feed, and depth of cut. However, interface temperature decreases with the increase in tool nose radius.[31,36,52] Chinchanikar *et al.*[10] observed that the tool–chip interface temperature is higher for harder work material which gets affected mostly by cutting speed followed by feed and depth of cut having the negligible influence on chip–tool interface temperature. In cutting process analysis, values of the cutting speed are often replaced by corresponding values of the thermal number. This is because the cutting speed influences the contact temperature and cutting energy more intensively than other process variables.[54]

It can be seen (**Figure 20(b)**) that the temperatures calculated for the same values of thermal number differ substantially for uncoated and coated tools, especially in the case of stainless steel. At higher values of the thermal number, the reduction of the average tool–chip interface temperature occurs more intensively when a fourfold coating is applied. The main reason why the maximum temperatures occur at different thermal numbers is that the diffusivities of steels used are different.[54]

Noncontact radiation techniques like infrared thermometry, pyrometry have been used to evaluate the chip–tool interface temperature. However, accuracy of the results depends upon the exact values of the emissivity of the cutting tool material and temperature of the radiating surface. Further, when the chip flows at a high speed along the rake face, these methods give erratic results during the measurement of exact temperature on the rake/flank face with the help of infrared rays due to accessible issue. Metallographic techniques like observing the microstructural changes of the cutting tool/workpiece after cutting can be used to find the temperature near the rake face. However, this technique is laborious and time consuming. Further, this technique is applicable to only those tool materials that exhibit a change in the microstructure with temperature.[10]

The finite element method (FEM) simulations of Cohelo *et al.*[55] study showed that temperature at the tool–chip interface was stable and as high as 800 °C when using TiAlN-based

coated and uncoated PCBN tools (Figure 21) while finish turning of hardened AISI 4340 steel (52 HRC).[55] The simulation results of their study indicate that the temperature at the PCBN substrate is always lower than at the surface. The coating layer not only prevents heat from going to the substrate, but it works as an additional barrier to keep the substrate at lower temperature. As the presence of coating layer creates an additional thermal resistance between workpiece and the tool, resulting in lowering temperature at the substrate, demands for coated cutting tools while finish machining of hardened steels are continuously increasing. However, tool wear patterns and wear mechanisms of different coated tools have significant effect on quality of workpiece machined while machining of hardened steels is discussed in the following section.

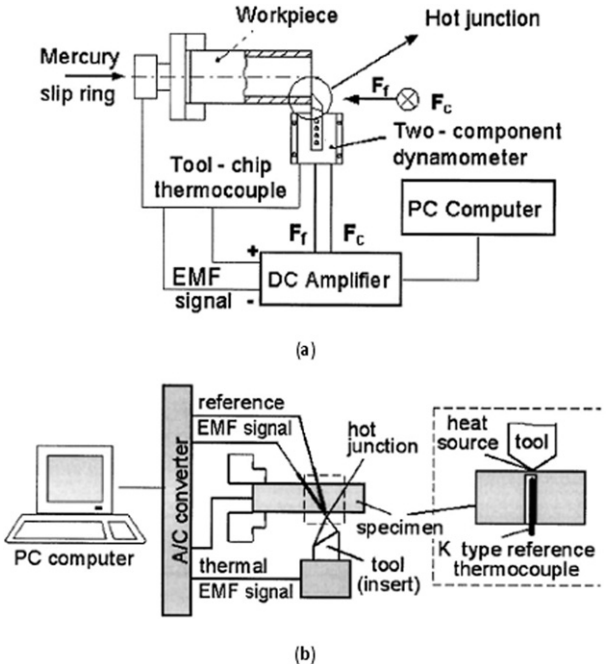

Figure 19 (a) Tool–work thermocouple setup and (b) thermoelectric calibration setup.[54]

1.3.3.4 Tool Wear Patterns and Mechanisms

Finish machining of hardened steels having hardness in the range of 50–65 HRC is mostly carried out using uncoated/coated PCBN tools as they exhibit better tool life at toughest cutting conditions due to their high and stable hardness,[13] and its lower solubility for steel material of the machined workpiece.[14] However, in view of inflexibility of fabricating PCBN inserts with complex tool geometries and the prohibitive cost of PCBN inserts, More *et al.*[56] investigated and compared the machining performance in terms of tool wear, surface roughness, and cutting forces of the cBN–TiN-coated carbide inserts with commercially available PCBN-tipped inserts during turning of hardened AISI 4340 steel (53 HRC). They observed less crater wear when using cBN–TiN-coated inserts than that of the PCBN inserts because of the lubricity of TiN coating layer on the cBN–TiN inserts. They also observed a good surface finish and a tool life of about 18 min per cutting edge as against 32 min with PCBN inserts. The cutting forces for the cBN–TiN-coated carbide inserts were observed slightly higher than those of the PCBN inserts due to a slightly larger nose radius and a rough surface associated with the cBN–TiN-coated inserts. A cost analysis performed by them, based on a single cutting edge, shows that the cBN–TiN-coated carbide tools are capable of reducing machining costs, and, therefore, will be an important complement to PCBN compact tools for finish machining of hardened steels.

Chinchanikar and Choudhury[9,57] also observed better tool life by CVD-applied multilayer MT-TiCN/Al_2O_3/TiN-coated carbide tool due to thick coating and claimed that the protective Al_2O_3 oxide layer formed during cutting has protected the CVD-coated tool from severe abrasion at elevated temperatures. In HPT with PCBN tools, the wear mechanisms

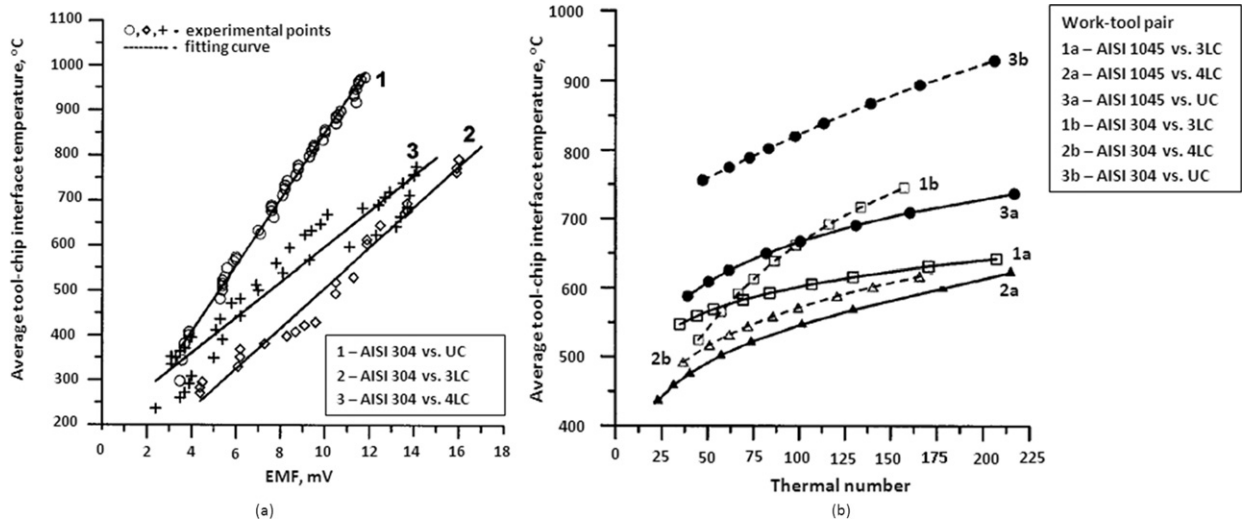

Figure 20 (a) Thermoelectric calibration plots for AISI 304 and (b) dependence of tool–chip interface temperature on thermal number (tool codes: P20 uncoated carbide-UC; TiC/Al_2O_3/TiN-3LC: TiC/TiCN/Al_2O_3/TiN-4LC.[54]

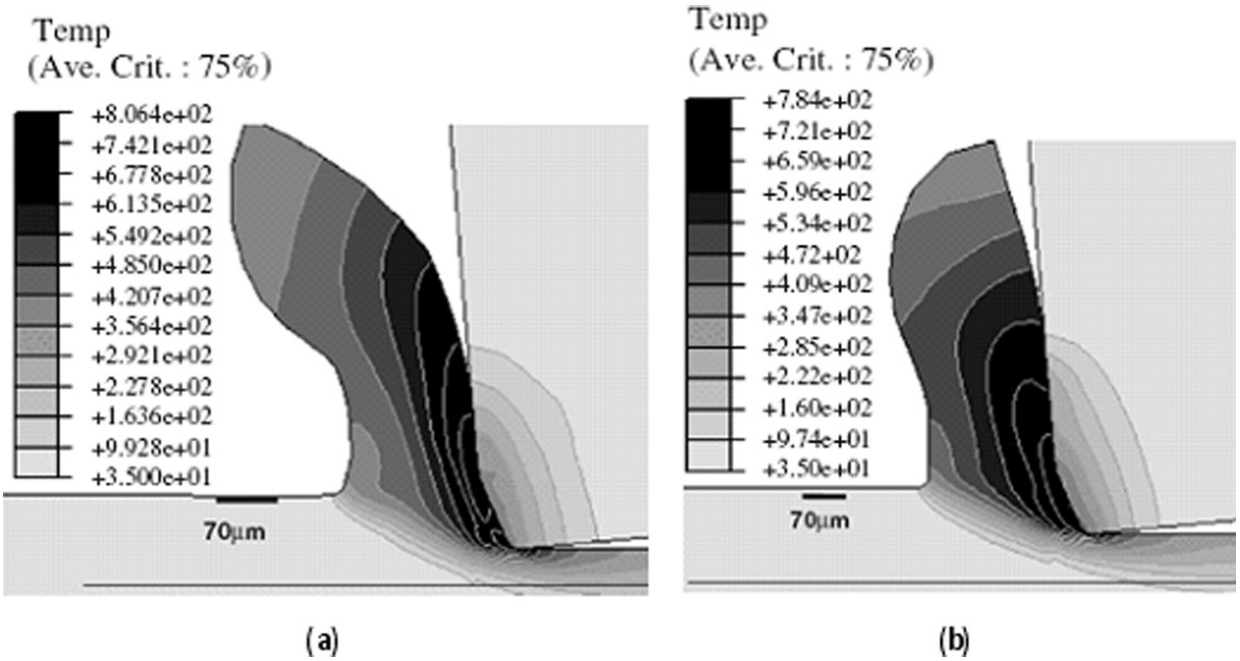

Figure 21 Temperatures obtained from finite element method simulation for (a) uncoated PCBN tool and (b) TiAlN-coated PCBN tool.[55]

depend not only on the chemical composition of the PCBN, and the nature of the binder phase, but also on the hardness value and above all on the microstructure (percentage of martensite, type, size, composition of the hard phases, etc.) of the machined work material.[51] Park and Kwon[58] experimental study also concluded that the hardness of the coating is the most important requirement to resist flank wear against abrasion. A group of researchers proposed the tool life model in a generalized form of the extended Taylor's law as a function of the cutting parameters and of the workpiece hardness. They found that cutting speed followed by the work material hardness as having the most significant effect on flank wear progression during machining of hardened steel.[7,40,48,51,57,59,60]

Coelho *et al.*[55] claimed that TiAlN-nanocoated PCBN tool is a better choice while finish turning of hardened AISI 4340 due to a combination of high hardness and the presence of an oxidizing layer produced by TiAlN coating at the lower cutting temperature range as against cutting temperature range of higher than 1000 °C required for AlCrN coated PCBN tool. They observed that the use of coatings on PCBN substrate bring benefits to tool life, extending it up to 38%, from 17.8 to 24.5 km, using TiAlN-nano coating, within the tested cutting conditions. With the other coatings employed by them, TiAlN and AlCrN, the tool life was extended up to 21 and 11.8%, meaning to 21.6 and 19.9 km, respectively, within the tested cutting conditions. The higher hot hardness of the TiAlN-nano at the temperature on the interface, have delayed tool wear, lasting longer than TiAlN. They found that the performance of AlCrN was not as good as the other coatings, since within the cutting conditions; temperature was below its oxidizing range. The typical wear pattern observed by them for different tools is shown in **Figure 22**.

Several attempts have been made by machining of hardened steels using cermet and ceramic tools. Noordin *et al.*[61] obtained longest tool life when cutting with cermet insert at low cutting speed and feed rate during dry turning of martensitic stainless tool steel (43–45 HRC). However, in all other instances, multilayer carbide inserts outperformed cermet inserts. Lima *et al.*[62] observed higher flank wear rate with mixed alumina inserts when using a cutting speed of 220 m min^{-1} and feed rate of 0.15 mm rev^{-1}. Further, they observed in contrast to the coated carbide and PCBN tools tested against AISI 4340 steel, that the mixed alumina tool failed by spalling when machining under higher cutting conditions. Ghani *et al.*[63] observed that the cutting edge of TiN-coated carbide tools take longer time from the crack initiation to fracturing than that of uncoated cermets tools, especially at higher values of cutting speed, feed, and depth of cut. However, at lower values of cutting speed, feed, and depth of cut, uniform and gradual wear on the flank face of uncoated cermets was observed by them in comparison to the TiN-coated carbide tools during end milling of hardened AISI H13 tool steel (50 ± 3 HRC).

Sufficient efforts have been made by the researchers to understand the wear mechanisms of cutting tools while machining of hardened steel. Avila *et al.*[64] experimental results during turning of quenched and tempered AISI 4340 steel with coated tools showed the presence of three wear mechanisms, namely, one possessing a lower wear rate, related to the wear of the coating; the second one, more severe, associated with the wear in the absence of the coating in the crater wear region, and the third one associated with the wear of the uncoated tool. They found the highest wear rate with the TiAlN followed by TiN- and TiCN-coated carbide tools and claimed that the high amount of aluminum in the coating, which resulted in a high hardness and low toughness film, is mainly responsible for the high wear rate. Moreover, they claimed that comparatively lower adhesion of the TiAlN film to the substrate also contributed to its poor performance.

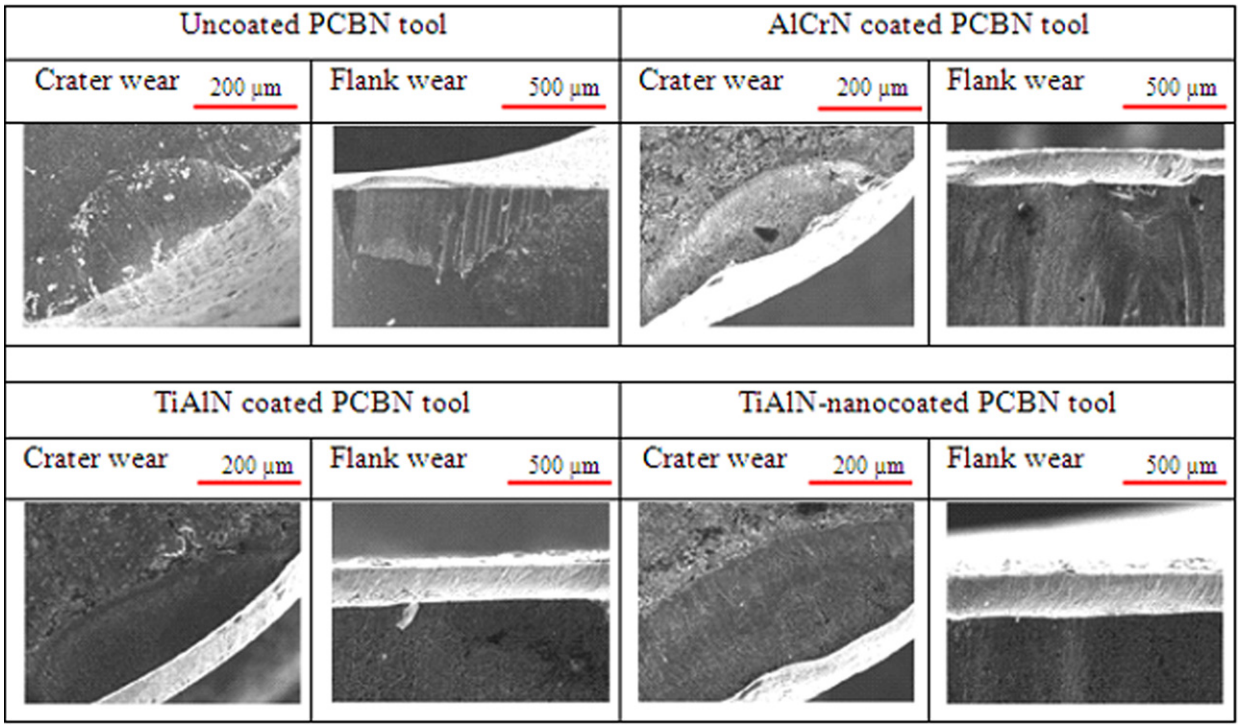

Figure 22 Aspect of cutting edges after wear (finish turning at cutting speed of 150 m min^{-1}, feed and depth of cut of 0.07 mm rev^{-1} and 0.2 mm, respectively).[55]

Khrais and Lin[65] also observed that flank wear proceeded through three levels: initial break-in wear, gradual wear, and catastrophic wear and claimed that the TiAlN-coated carbide inserts demonstrate best performance under dry condition with any cutting speeds less than 260 m min^{-1} while turning of hardened AISI 4140 steel. Chubb and Billingham[66] systematic examination of worn inserts using optical and scanning microscopy revealed that the cutting performance was initially controlled by wear on the flank face which was predominantly of an abrasive type, but was superseded on coating breakthrough by a combined diffusion/abrasion mechanism. On the rake face they observed coating breakdown due to thermal cracking that resulted in removal of small regions of the coating, which in turn allowed direct substrate–metal interaction and hence, enhanced diffusion wear.

Poulachon *et al.*[51] during their study on wear mechanisms of PCBN tool, obtained the progression of the tool wear for different cutting conditions as shown in **Figure 23**. They observed crater wear appears first when the cutting speed is higher. They claimed that the binder of the tool is abraded by hard carbide particles of 100Cr6 steels (i.e., chromium carbides) which leads to CBN grains detachment from the bond. Moreover, an increase in cutting speed leads to an increase in cutting temperature which thus, accelerates the tool wear rate.

Luo *et al.*[39] experimental results of analysis during dry turning of AISI 4340 also concluded that the main wear mechanism for the CBN tools was the abrasion of the binder material by the hard carbide particles of the workpiece. However, adhesive and abrasive wear were observed by them as dominant wear mechanisms when using the ceramic tools. They observed that the carbide tool was unable to cut for more than 5 min due to fracture of the cutting edge while turning a workpiece having hardness above 45 HRC. Moreover, they observed usable cutting time of less than 1 min as carbide tool failed almost immediately at a higher work hardness of 55 and 60 HRC. The work reported shows that the sintered carbide tool is more suitable for turning a workpiece of lower hardness.

Chinchanikar and Choudhury[9,57] investigated the tool wear patterns and wear mechanism(s) considering the effect of workpiece hardness, cutting parameters, and type of coating. They observed a severe damage at the nose of the tool, pitting on the rake and flank faces resulting in exposing the tool substrate, coating delamination, crater wear and metal adhesion at the end of cutting when turning AISI 4340 steel (45 HRC) using CVD-coated MT-TiCN/Al_2O_3/TiN-coated carbide tool (**Figure 24(a)**). The fine abrasive marks and metal adhesion can be seen from the magnified view of **Figure 24(a)** as shown in **Figure 24(b)**. After a brief cutting, this adhered metal gets dislodged and comes out as a loose fragment along with the coating material, resulting in pitting on the flank and rake faces, subsequently exposing the tool substrate.

However, adhesion was observed as a prominent wear mechanism when turning comparatively softer AISI 4340 steel (35 HRC).[9,57] Removal of the adhered workpiece material from the tool surface due to fast flowing chips is responsible for fragmentation of tool material. On the other hand, abrasion was observed as a prominent wear mechanism when turning softer material at higher cutting speeds.[9] **Figure 24(c)** reveals deep abrasion marks covered with metal adhesion on flank face of MT-TiCN/Al_2O_3/TiN-coated carbide tool. This adhered metal eventually being plucked from the tool surfaces

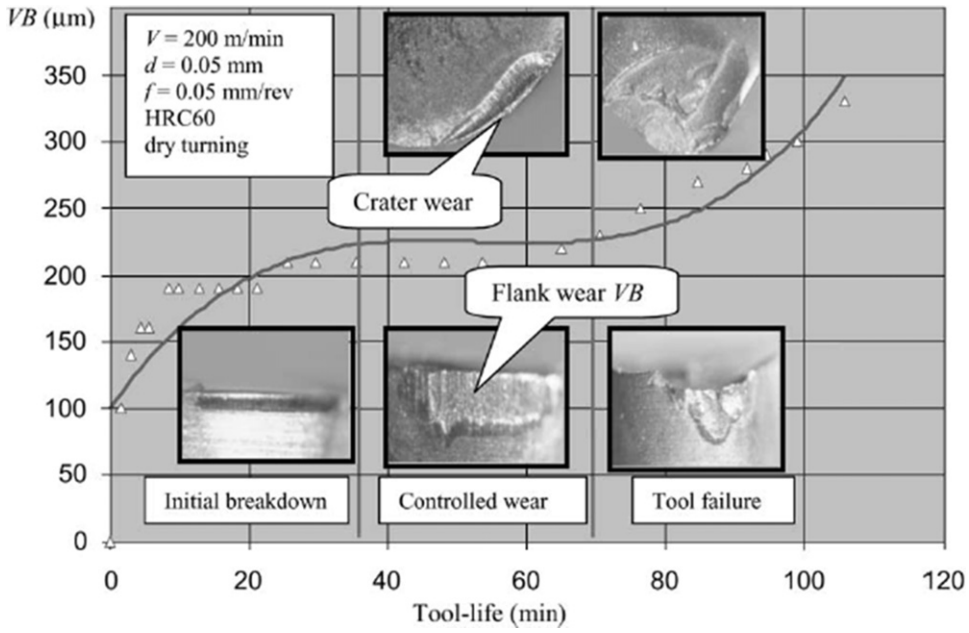

Figure 23 Tool wear rate progression.[51]

under high sliding speed resulted in forming shallow pockets as seen in Figure 24(d). Removals of the hard particles from the tool flank surface which are responsible for cutting are shown by marked circles in Figure 24(e). These hard particles get entrapped between the machined surface and the tool while machining, subsequently rub the flank surface of the cutting tool indicating the signs of three-body abrasion wear.[9]

Rapid deterioration of the cutting edge, eventually leading to catastrophic failure, is normally observed just after the removal of the coating layer(s), especially, when using PVD-applied single-layer TiAlN-coated carbide tool.[9,57] Comparatively smooth flank surface of PVD-coated single-layer TiAlN carbide tool (Figure 24(f)) as against the rough flank surface of CVD-coated multilayer MT-TiCN/Al_2O_3/TiN carbide tool after delamination of the coating (Figure 24(e)), shows better adhesion strength of the MT-CVD TiCN (bottom most) coating layer to the tool substrate. Complete spalling of the coating from the flank and rake faces and plastic deformation of the cutting edge can be seen from Figure 24(f). High compressive stresses clubbed with high cutting speed results in plastic deformation of the cutting edge which affects the dimensional accuracy and quality of the machined surface. A rough surface in the crater wear region (Figure 24(f)) indicates a severe wear mode which might have occurred by diffusion and adhesion wear mechanisms that are active on the rake face. Moreover, interdiffusion of tool and workpiece elements (Fe and Co) resulting in weakening of the binder. This causes fracturing of small elements of the tool which are being carried away along with the chips resulting in the formation of rough surface in the crater.

In the machining of hardened steel alloys, tool wear adversely affects the surface integrity of the machined surface and dimensional accuracy and is need to be considered while optimizing the cutting conditions for cutting forces and surface finish. Surface integrity of the machined surface in terms of the surface finish achieved, RSs, white layer effect, dimensional accuracy, and optimization studies are discussed in following sections.

1.3.3.5 Surface Integrity

It is well acknowledged that the functional performance of a manufactured component is heavily influenced by the quality and reliability of the surface produced in terms of topography and surface layer characteristics. With a view to address the growing demand on component performance, reliability and durability, sufficient efforts have been made by the researchers to investigate the effect of the process parameters and type of tool on the nature of the surface alterations produced and hence, on product's functional performance during machining of hardened steel.[67] Surface integrity is the surface condition of a workpiece after being manufactured and is generally expressed in terms of topography characteristics and surface layer characteristics. The topography includes surface roughness, waviness, form errors, and surface flaws. The surface layer characteristics include local plastic deformation, RSs, cracks, hardness, and phase changes. Surface integrity of the machined component is drastically deteriorated with the use of improper selection of process variables during machining, dull tools, improper amount, and type of coolant or lubrication.[68]

1.3.3.5.1 Surface roughness

Surface roughness is the measure of the finely spaced micro-irregularities on the surface texture which is composed of three components, namely roughness, waviness, and form. Every machining operation leaves characteristic evidence on the machined surface. Ideal surface roughness is a function of only feed and geometry of the cutting tool which can be achieved in the absence of the built-up edge, chatter, and inaccuracies in the machine tool movements. The theoretical surface

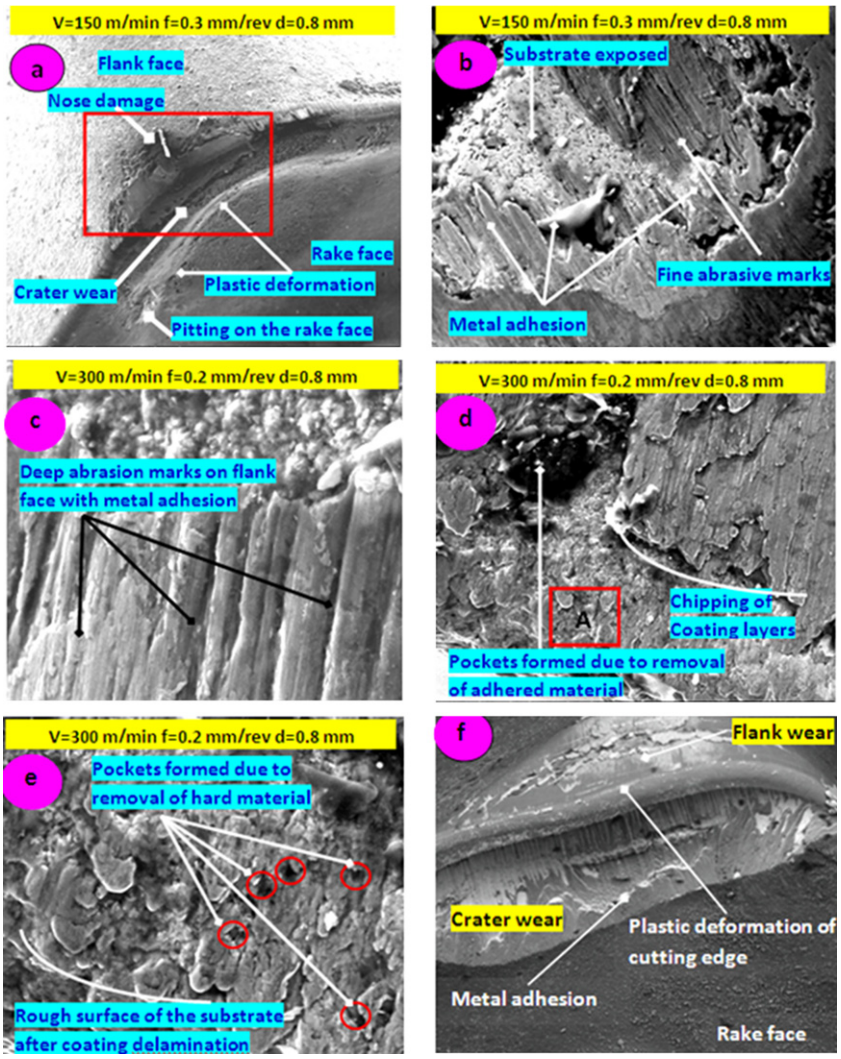

Figure 24 SEM images of (a) (b) CVD-coated tool and its magnified (workpiece with 45 HRC), (c), (d), and (e) flank face, clearance face and its magnified view (workpiece with 35 HRC hardness), and (f) PVD-coated single-layer tool (workpiece with 35 HRC hardness).[9]

roughness parameter, R_a, can be given as $R_a = (0.0321\ f^2)/r_\varepsilon$, where, '$f$ 'is the feed rate in mm rev^{-1} and 'r_ε' is the insert radius.[56]

The ability of a manufacturing operation to produce a surface roughness depends on many factors such as the machining variables (cutting speed, feed, and depth of cut), the tool macro- and micro-geometries (nose radius, rake angle, side cutting edge angle (SCEA) and type of cutting edge such as chamfered, honed, and a combination of chamfered and honed), workpiece and tool material combination and their mechanical properties, quality and type of the machine tool used, auxiliary tooling and the amount and type of lubrication at the point of cutting and vibrations present between the workpiece, machine tool and cutting tool. A small change in any of the above factors can have a significant effect on the surface produced.

Surface roughness is an important characteristic of the surface integrity of machined parts, and correlated to the tool wear as well as feed rate.[69,70] Dogra *et al.*[71] during their investigation on continuous and interrupted finish hard turning observed that the R_a values with the CBN tool were in the range of 0.3–0.7 μm and with carbide inserts they were in the range of 0.35–1.3 μm with the selected tool wear criterion ($VB_{max} = 200$ μm), indicating that the roughness values are comparable with grinding (less than 1.6 μm). **Figures 25(a)** and **25(b)** show the values of surface roughness obtained by them with progression of machining time in continuous and interrupted turning, respectively, at different cutting speeds. It can be seen that the roughness obtained with CBN inserts in continuous turning increased marginally with the progression of machining time, while with carbide inserts it increased rapidly just after the tool wear criterion reached. However, at higher cutting speed ($V = 190$ m min^{-1}), significant increase in the surface roughness can be seen when using CBN tool. At higher cutting speed, formation of shallow pockets on the cutting edge was observed by them, which altered the shape of the tool nose, causing increase in roughness value. As against, at higher cutting speed, a drastic increase in the roughness

value can be seen with carbide tool due to rapid wear and chipping off of the tool. Under all the cutting conditions tested, they observed higher values of the surface roughness with carbide tools than those produced with CBN tools. However, this effect can be seen as more prominent for interrupted surface in comparison to continuous surface. Their study of analysis concluded that the difference in roughness obtained was mainly dependent on tool wear.

Asilturk and Akkus[73] observed that the feed rate together with the interaction effects of the feed rate and cutting speed as well as the depth of cut and cutting speed had the most significant effect on surface roughness during turning of hardened AISI 4140 steel (51 HRC) with Al_2O_3 and TiC-coated carbide tools. Cakir *et al.*[74] also found that feed rate had the greatest influence on surface roughness, followed by cutting speed and depth of cut had no significant effect during turning of AISI P20 tool steel (52–55 HRC). They observed higher values of surface roughness, which further increased at higher cutting speed when using CVD-applied multilayer TiCN/Al_2O_3/TiN carbide insert in comparison to PVD-applied single-layer TiAlN-coated carbide insert which showed almost no variation in surface roughness at higher cutting speeds.

When machining hardened steel at comparatively lower hardness (35 HRC), it is reported that the surface roughness gets affected significantly at higher values of feed and depth of cut. However, this effect was less prominent in case of harder workpiece. This may be because of reduction in cutting forces occurred due to softening of the harder material at higher feed and depth of cut. As against, this effect was more prominent when using PVD-coated tool as growing crater wear observed for these tools reduces the metal available to support the tool, which promotes more chatter. Surface roughness presented lower values when using PVD-coated tools (**Figure 26**), which can be attributed to minimum friction offered by these tools to flowing chips. Chips produced when using PVD-coated tool showed more or less polished back and smooth free surfaces as against chips produced showed a rough back surface showing some parallel stripes and damaged free surface when using CVD-coated tool as shown in **Figure 16**. Polished and bright chip back surface obtained with PVD-coated tool shows that minimum friction was offered by these tools during cutting which resulted in lower cutting forces and hence, produced better surface finish.[9,11,40] The typical surface roughness contours for PVD (T2) and CVD-coated (T3) tools as shown in **Figure 27**.

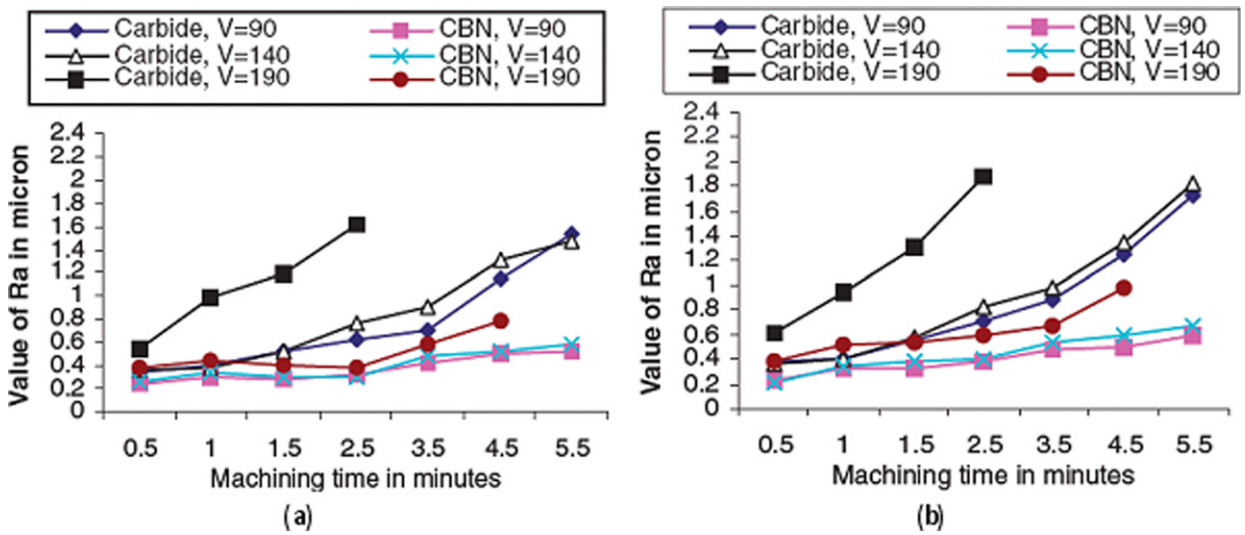

Figure 25 Progression of roughness for (a) continuous surface and (b) interrupted surface.[72]

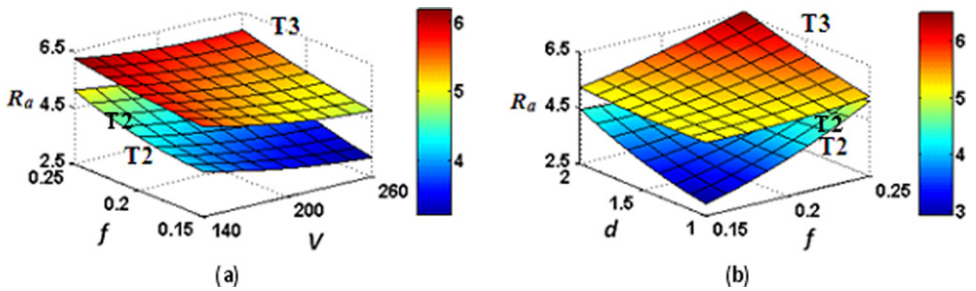

Figure 26 3D response surfaces showing effect of cutting conditions on surface roughness (letter T2 and T3 shows response surfaces for PVD-coated and CVD-coated tools, respectively).[40]

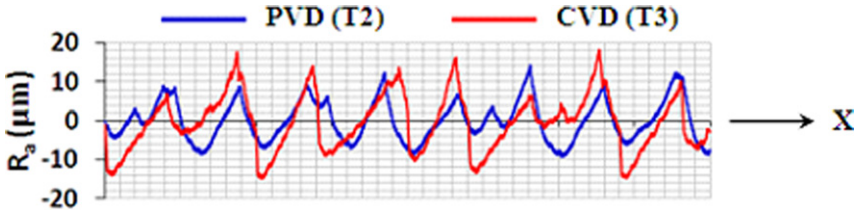

Figure 27 Surface contour plots obtained by T2 and T3 at $V=200$ m min^{-1}, $f=0.2$ mm rev^{-1}, and $d=1.5$ mm (X-axis shows evaluation length of 4 mm).[40]

From Figure 26, it can be seen that surface roughness decreases with increase in cutting speed. However, this effect can be seen as more prominent for PVD-coated tools (T2). However, surface roughness increases with increase in the values of feed and depth of cut, which is in line with the classical theory of metal machining. Interaction effect of $f \times d$ can be seen as more prominent for T2, indicating that surface roughness obtained with this tool is more sensitive to cutting conditions, especially feed and depth cut. At higher feed and depth of cut, the force components increase sharply resulting into more vibrations and hence chatter marks remaining on the machined surface. However, this effect can be seen as more prominent when using T2 as growing crater wear observed for these tools reduces the metal available to support the tool, which promotes more chatter. In summary, when surface finish is a criterion for tool selection, PVD-applied single-layer TiAlN-coated carbide tool is the better option during finish machining of hardened AISI 4340 steel. However, values of higher feed and depth of cut is to be avoided in this case.[40]

Yusuf and Motorcu[72] developed the first- and second-order surface roughness models for turning with TiN-coated carbide tools using response surface methodology (RSM). They observed feed rate followed by cutting speed are the main influencing factors on the surface roughness while depth of cut was insignificant. Noordin *et al.*[75] investigated the effects of cutting speed, feed, and SCEA of the cutting edge, on cutting force and surface roughness, while machining with coated carbide tools. They observed that feed is the most significant factor on the surface roughness. However, secondary contributions by the second order of SCEA^2 and the interaction effect of feed and SCEA, was also observed by them during turning of AISI 1045 steel. Lalwani *et al.*[76] investigated the effect of cutting parameters on surface roughness in finish hard turning of MDN250 steel using coated ceramic tool. They observed that surface roughness do not vary much with cutting speed. However, feed rate, interaction effect between feed rate and depth of cut and interaction effect between speed and depth of cut were observed as having prominent effect on surface roughness.

Senthil kumar *et al.*[49] observed better performance of the Ti [C,N]-mixed alumina inserts in terms of surface finish than that of zirconia toughened alumina (zirconia particles dispersed in alumina matrix) ceramic cutting tool during machining of hardened steel EN24 steel. They found that the flank wear generally does not affect the performance of the surface finish while using ceramic cutting tools, until it does not affect the nose region of the tools. Further, they observed that the surface roughness exhibited a rising trend, up to certain time of machining beyond which there was an improvement in surface finish which could be attributed to the nose-associated transformation toughening of zirconia toughened alumina ceramic cutting tool.

If hard turning is to be a viable replacement for finish grinding operations, it must be capable of producing surface finishes comparable to grinding with the R_a and R_z parameters in the range of 0.1–1 μm and 2–4 μm, respectively.[77–79] From Figure 28, it can be seen that the Rz values provided that CBN-based tools produce more stable surface finish in comparison to Al_2O_3–TiC composite based ones while continuous turning of different steels at depths of cut of 0.1–0.3 mm and for feed rates ranging from 0.04 to 0.15 mm rev^{-1}.[79] Depending on the steel grade machined the peak-to-valley height varies approximately between 2 and 7 μm for ceramic tools (Figure 28(a)) and from 1.5 to 3.5 μm for CBN tools (Figure 28(b)). Figure 29 shows the scanning electron microscopy (SEM) images of the quality of the surface observed during turning of AISI 4340 alloy steel using coated carbide tool for two different depth of cuts (0.8–1 mm) at cutting speed of 260 m min^{-1} and feed of 0.1 mm rev^{-1}. The improved surface finish for lower depth of cut of 0.8 mm can be clearly evidenced from Figure 29(a) as compared to surface finish obtained at higher depth of cut of 1 mm (Figure 29(b)). The study of analysis while hard turning using coated carbide tool concluded that the surface roughness is sensitive to variations in feed rate and depth cut at lower values of cutting speed it is found to be insensitive to variations in machining time.[80]

In hard turning, it is reported that the built up edge is never observed due to the poor ductility of the workpiece material and the high cutting temperature generated by the cutting process. Thus, the profile of the generated on the workpiece surface is the conjugate profile of the cutting edge.[51] High abrasiveness of the hardened workpiece combined with the higher cutting temperatures employed during machining of hardened steel induce a rapid tool wear. It has been reported that the worn flank surfaces of the tool increases the cutting forces and particularly the thrust force as the tool penetration in the work material becomes difficult due to the flank wear.[51,57] Usually, cutting forces and surface roughness get affected with the progression in tool wear. Many of the cases, especially in finish machining of hardened steel, tool life is considered to be over when surface roughness exceeds beyond the specified limit. However, Poulachon[51] reported that the increase in surface roughness due to tool wear appears later than the increase in thrust force as shown in Figure 30, i.e., the thrust force is more prominently get affected with the tool wear and could be a better choice for tool wear monitoring in comparison to surface roughness.

1.3.3.5.2 RSs

In general, machining (turning, milling, grinding, drilling, broaching, etc.) is a term used to describe the removal of material from a workpiece. Machining processes are known for being complex due to the diversity of physical phenomena involved, such as large elastic–plastic deformation, complicated contact/friction conditions, thermo-mechanical coupling and chip separation mechanisms.[81,82] The stress produced in the workpiece surface as a result of machining is called RSs, which especially tensile in nature significantly affect the fatigue life, fracture resistance, and stress corrosion of the component. The level of generated RSs depends on the machined material, tool flank wear, shape of the cutting edge, and the process parameters used. In hard turning, RS can be generated by mechanical, thermal, and phase transformation changes.[71]

HPM is mostly used as a finishing process and hence, it is imperative to study about the machining parameters which affect the magnitude and nature of the RSs as they can enhance or impair the functional behavior of a machined part. It is possible to generate tailor-made stresses on hard turned surfaces by effectively controlling cutting parameters so as to get prolonged service life of component.[83] Hard turning with a sharp cutting tool generates a unique 'hook' shaped RS profile characterized by compressive RS at the surface and maximum compressive RS in the subsurface,[84,85] but as tool wears out, the nature of the surface RSs changes to tensile that reduces

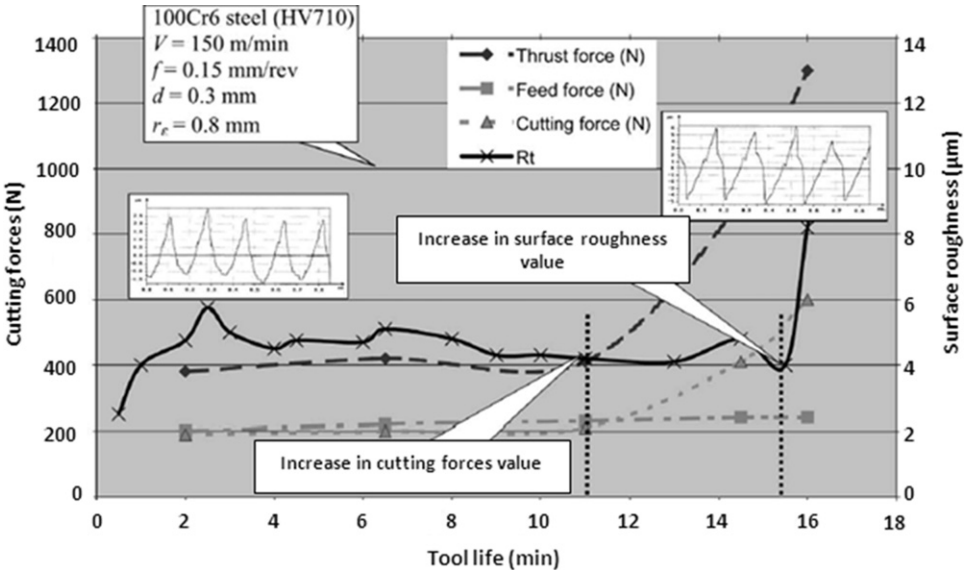

Figure 30 Cutting force and surface roughness progression as a function of the tool wear.[51]

fatigue life of component. This is one of the major areas of concern in hard turning.

Matsumoto *et al.*[86] also observed compressive RSs in a deep subsurface, contributing a long fatigue life of hard-part component. They found that the tool edge geometry was having the most dominant factor in deciding the RS profile while hard turning of case carburized steel (58–62 HRC) using PCBN tool. Further, they observed that increase in cutting speed increases the tensile RSs on the surface. As against, higher feed generated compressive stresses while a high negative rake angle produced more compressive stresses. Javidi and Rieger[87] found that the nose radius and feed rate as most critical parameters to control RSs. They observed that RSs became more compressive with the increase in feed rate. However, decrease in compressive RSs was observed by them with increase in the tool nose radius. However, ploughed depth also found as a major influencing factor in producing the machining-induced RS profile and a unique hook shaped RS profile is produced when the ploughing depth reached a threshold (critical) value.[85]

It has been observed that the microstructural phenomena associated with white and dark layers formation influenced the RS distribution. Further, it is claimed that better prediction of RS could be achieved by incorporating such microstructural changes in the RS model.[88] Thiele *et al.*[89] investigated the effects of tool edge preparation and material hardness on surface RS during finish hard turning of AISI 52100 steel with PCBN tool. Their study of analysis concluded that a large edge hone radius (~120 μm) and a chamfer tool (24.5 μm) produces more compressive RSs than small edge hone tools (~20 μm). They found low residual tensile stresses with small edge hone tools for workpiece hardness of 41 HRC and compressive RS for higher workpiece hardness of 57 HRC. Hua *et al.*[90] during their investigation on RSs considering the effect of tool geometry, cutting process parameters, and material hardness show that an optimal combination of a large-hone edge with a chamfer at an aggressive feed rate favors an increase in compressive RSs in both axial and circumferential directions.

Figure 31 shows the RS generated during turning of continuous (c), interrupted (I), and fully interrupted (FI) surfaces at cutting speed of 190 m min^{-1} with the carbide and CBN tools. It can be seen that with both the tools (190-C condition), the maximum compressive RS observed beneath the machined surface was larger in magnitude and also deeper in the subsurface. A tensile RSs can be seen only for a few microns beneath the machined surface which can be removed by any super-finishing process to avail the advantage of fatigue life of the component.[71,87] However, for compressive RS on the surface, the magnitude of the compressive RS beneath the machined surface and its penetration in the subsurface can be seen low.

The circumferential RSs observed on the exposed surface with varying flank during turning of continuous and fully interrupted surfaces with both tools as shown in **Figure 31(c)**. For all the cases with fresh tools or when maximum flank wear reached 100 μm, compressive RS was observed on the surface of the machined workpiece. With increase in the flank wear, shifting of compressive RSs to tensile stresses can be seen which could be attributed to an increased thermal effect due to rubbing between the worn tool flank and the workpiece surface.[91] It can be seen that almost zero RS on the surface could be obtained by limiting the maximum flank wear up to 100 μm.

It is reported that turning with CBN tool results in tensile RS of lower magnitude in comparison to carbide tools which could be attributed to high thermal conductivity of CBN tools and thus low thermal damage on the machined surface in comparison to carbide tools. Moreover, the chamfer and honed edge geometry of CBN tools resulting in reduction of tensile RS produced on the surface.[91,92] At higher cutting speed higher cutting temperatures generated in the cutting zone either shifts the nature of the RSs from compressive to less compressive or toward tensile. However, this effect was observed more prominently with carbide tools in comparison to CBN tools.[71] Previous investigations on the effects of flank

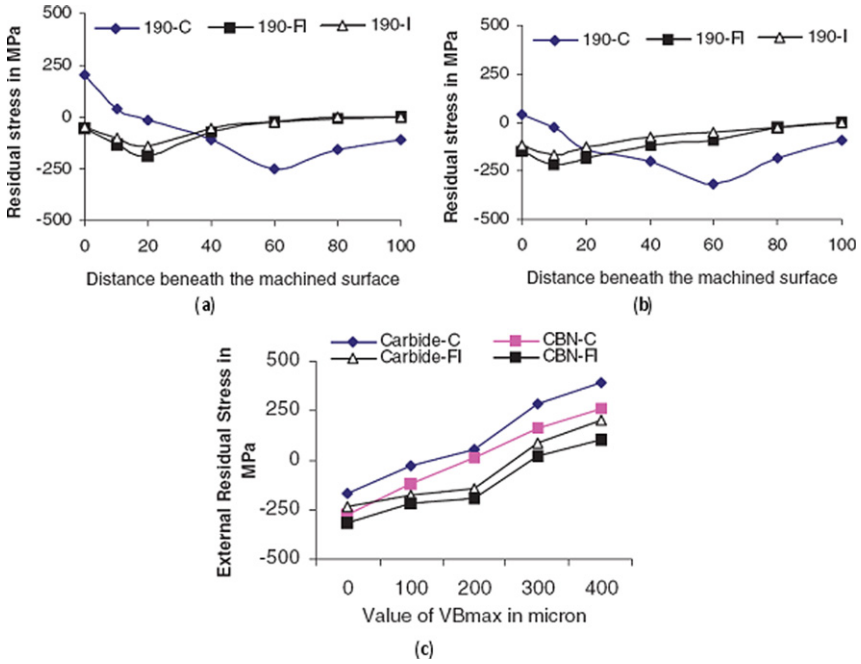

Figure 31 Residual stress generated at $V=190$ m min^{-1} as VB_{max} reaches 200 μm with (a) carbide tool, (b) CBN tool, and (c) effect of flank wear on external residual stress generated.[71]

wear indicate that an increase in flank wear results in a shifting of the surface RS toward tensile stress values. Also, increasing flank wear shifts the maximum compressive stress deeper in the subsurface layer.[93,94]

From above it can be deduced that a favorable surface integrity in terms RSs is very important in finish machining of hardened steel as it can be decisive for tool change. Components requiring good fatigue strength can be severely affected if the HPM process is not controlled effectively. A worn tool and a high cutting speed generate tensile RSs which can be detrimental while deciding the fatigue life of the component. Hard turned surfaces are more repeatable while the ground surface are more random in nature due to random distribution and shape of cutting edges of the abrasive grains that gives a upper hand to the hard turning.[37] In general, the performance of carbide tools was comparable with that of CBN at low and medium cutting speeds in terms of the type of RS observed on the surface.

1.3.3.5.3 White layer effect

Workpiece surfaces, especially hard-part machined surfaces, usually exhibit surface alterations under the circumstance of excessive flank wear or aggressive cutting conditions that are referred as white layers.[93,94] White layers can be resulted from severe plastic deformation and grain refinement or by phase transformations as a result of rapid heating and quenching.[95] White layer is denominated due to their white appearance, has a high hardness, ultrafine grains, and resists metallurgical etching. It is basically a rehardened structure, which can reach up to 10 μm deep increasing with the size of the flank wear land.[96]

White layers are produced due to the occurrence of martensitic phase transformation, particularly at higher cutting speeds. However, occurrence of mechanically induced grain refinement at low cutting speeds owing to severe deformation.[97] Tool flank wear and cutting speed which led to an increase in temperature at the cutting zone are dominant factors for formation of white layer in hard turning.[98] Therefore, chances of white layer generation can be minimized by controlling the temperature in the cutting zone. It has been observed that the thickness of the white layer generated with CBN tools was somewhat less than that produced with carbide tools. This effect could be attributed to greater thermal conductivity of CBN tools in comparison to that of carbide tools.[71] It has been found that the thickness of the white layer generated for continuous surfaces increases with cutting speed.[98,99] However, white layer was not observed while machining of interrupted and fully interrupted surfaces which could be attributed to discontinuity in heat propagation through the workpiece surface due to interruptions and generation of an air flux through the slots on the surface, which helps in limiting the temperature of the workpiece and the tool.[71]

A typical white layer obtained during hard-part of machining is shown in **Figure 32**. A white layer followed by dark-etching layer having thickness of about 13–17 μm, respectively can be seen. It can be seen that the white layer has an unresolvable feature, the dark-etching layer has very fine precipitates and the bulk exhibits a pearlite microstructure. Rough surface profile observed could be attributed to machining-induced vibration due to an imperfect workpiece holding device used.[96,100]

A thin white layer formed during hard turning of AISI 4340 steel (50–52 HRC) using cBN–TiN-coated carbide tool can be seen from SEM micrograph (**Figure 32**). The white layer formed approximately of 1 μm thick shows that the intensive

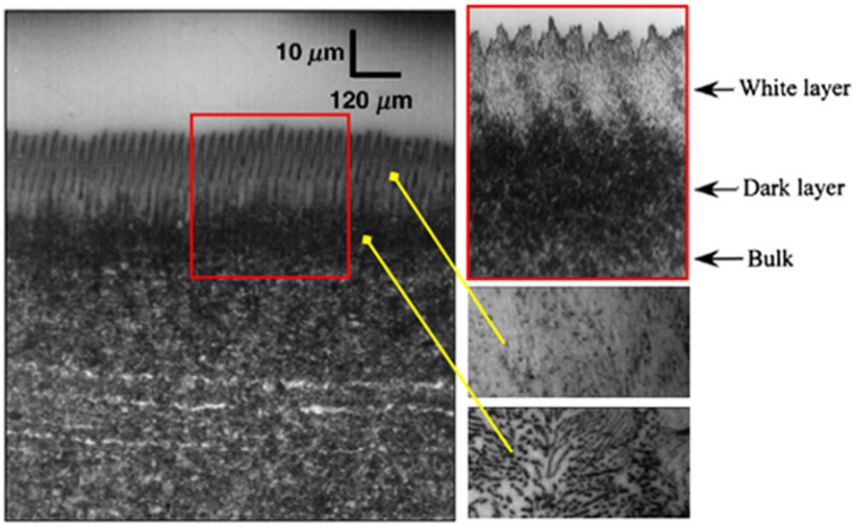

Figure 32 Phase transformed structures of a machined hard surface.[96,100]

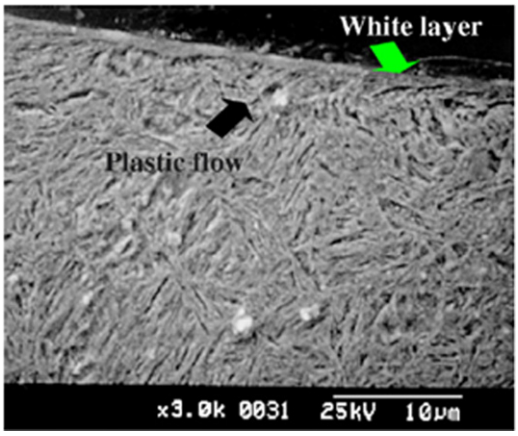

Figure 33 SEM micrograph showing the white layer and plastic flow in the subsurface (5% nital etchant).[101]

heating which was sufficient to produce a phase change at the surface followed by subsequent rapid cooling occurred at the workpiece–tool interface. Heating occurred due to the high energies involved in the hard turning and rapid cooling occurred mainly from conduction and partially from convection. A subsurface plastic flow in the circumferential direction of the workpiece can be also seen from **Figure 33**. This effect could be attributed to excessive shear associated with the negative rake angle (-5°) and nose radius (0.8 mm) of the tool.[101]

White layers are formed as a consequence of high friction energy and heat generated during machining which significantly influenced by the tool wear and magnitude of cutting speed employed during the process. At higher cutting temperature, martensite present in steel structure gets transformed into the austenite forming the white layer. Tool wear increases with increase in cutting speed and hence, thickness of the white layer. However, a group of researchers observed at higher cutting speeds, decrease in the white layer depth and its hardness. This may be due to the fact that at high cutting speeds the temperature of the workpiece material reduces as maximum heat is carried away with fast flowing chips.[34,102] Ramesh *et al.*[97] found that white layers produced were largely due to grain refinement induced by severe plastic deformation when using low-to-moderate cutting speeds. As against, at higher cutting speeds, the white layer formation was mainly due to thermally driven phase transformation. They observed that white layers found to be comprised of very fine (nano-scale) grains compared to the bulk material which increases the hardness of the layer.

Properties of white layers produced from HPT and grinding processes are fundamentally different in terms of surface structure characteristics, micro-hardness, microstructure, and chemical composition. A turned white layer is etching resistant, has much more strained and retained austenite than the ground white layer. The micro-hardness profile obtained from HPT and grinding processes is almost same. However, ground white layer observed to be 40% harder and the thickness ratio of dark to white layer is much larger than the white layer in turning.[98] Smith *et al.*[103] observed that the presence of white layer did not adversely affect fatigue life and that, on average, the hard turned surface performed as well or even better than the ground surface. The results of analysis of their study concluded that the effect of RS on fatigue life was more significant than the effect of white layer during hard turning of AISI 52100 steel.

However, Schwach and Guo[104] observed that a white layer induced by hard turning was very detrimental to rolling contact fatigue (RCF) as it increased tensile RSs. They found almost six times more life for a component which was free of white layer than life obtained with a white layer component. Steel with fine microstructure showed thicker white layer in comparison to steels with coarse microstructure. Moreover, the carbon content in the white layer was observed to increase with time and with increasing layer thickness.[105] A negligible white layer was observed at higher cutting speeds while hard turning of H13 steel with CrTiAlN and CrTiAlN/MoST-coated carbide tools. This could be attributed to lower workpiece and tool temperatures due to low friction coefficient of coated tools. Moreover, coated tools resulted in reduced and more

homogeneous hardening effects compared to uncoated tool.[106] It is reported that white layer increased with increase in both cutting speed and feed rate. As against, dark layer decreased with increase in cutting speed, while it remained almost constant or slightly decreased when feed rate was increased.[99]

The white layer formation occurring only with a worn tool in service is undoubtedly a phase transformation process at near austenizing temperature or even below when accompanied with high strain rates. Negative tool geometry and high feed rates tend to increase white layer formation. A group of researchers observed that the surface integrity (white layer formation, micro-hardness and surface roughness) achieved with carbide tools was comparable with that of CBN tools and they found no discernible difference in hardness between the white layer and bulk material using coated carbide tool in comparison to CBN tool[107] which shows that the coated carbide tools could be complementary to PCBN tools in finish hard turning. According to some researchers white layer does not have any significant effect on fatigue strength but it is RSs on the machined surface which were detrimental while some have directly observed white layer as the culprit for reducing fatigue strength of component.[37]

1.3.3.5.4 Cutting errors and dimensional accuracy

Finishing operations are carried out to achieve the desired surface finish and dimensional accuracy of a machined component. Deflections caused by cutting forces are generally the main source of dimensional error in machining. This is especially the situation when long and flexible tools are used. As the machining operations are the last operations in the process chain, the cost of scrapping the workpiece in the finishing stage due to dimensional inaccuracies is high. Tool wear, cutting forces, and cutting temperature are the key factors that affect the part accuracy and process stability and reliability. To achieve high surface finish and high dimensional accuracy a rigid setup of the machine tool system is recommended. The stiffness of the machine tool and the tool holders should be high enough to avoid static and dynamic deflections.[108]

In an attempt to analyze the geometrical accuracy, investigations on the parts produced in series in terms of measurement of size deviations, out-of-roundness, cylindricity error, and parallelism error. It was observed that as compared to grinding, cylindricity error obtained was on the higher side for hard turning, but, still workable. However, the parallelism was better in hard turning. Flatness error obtained was observed to be adequate in hard turning. As against, it was very high in grinding. Also, the axial run-out was much higher in grinding in comparison to hard turning. Thus hard turning seemed to be a better option while the ground gear did not fulfill the requirements prescribed in the drawing because of its large flatness error.[109] Cutting parameters such as cutting speed, feed rate, and depth of cut have significant influences on the three quality characteristics, namely dimensional error, surface roughness, and circularity. A hybrid predictive model recently proposed by Jawahir and Wang[110] for optimum cutting parameter selection could be a viable option to optimize all three quality characteristics during finish machining of hardened steel.

For any process to be accepted by the industry it should be robust and accurate as far as the performance is concerned. Attempts have been made by the researchers to investigate process accuracies and the sources of errors to establish the reliability of the hard turning process as a substitute to finish grinding. Zhuo *et al.*[71] observed that the tool wear, cutting forces and temperature induced by the cutting process on the cutting tool and workpiece are the major error drive factors in a precision hard turning as shown in Figure 34.

In plain turning, the diameter of the machined component generally deviates from its desired value along the length of job. This could be attributed to change in the effective depth of cut due to several reasons which include wear taking place at the tool nose, overall compliance of the machine–fixture–tool–work (M–F–T–W) system and thermal expansion of the job during machining followed by cooling. Therefore, variation in diameter produced would be governed by limiting the cutting temperature with effective design of M–F–T–W system. With the increase in cutting temperature, the rate of flank wear and thermal expansion of the workpiece increases resulting in more dimensional inaccuracy. By properly selecting the type of cooling technique dimensional deviations of the machined component can be controlled.[111] Cryogenic cooling provided remarkable benefit in respect of controlling the increase in diameter of the finished job with machining time, as can be seen in Figure 35.

It has been reported that the use of machine tool with polymer concrete bed improved the machining performance in terms of reduced tool wear and better surface finish due to its outstanding damping and high rigidity in comparison to cast iron bed.[112] Tool wear, especially flank wear has a significant effect on the quality of the surface produced. In general, while machining of hardened steel, the dimensional errors measured in axial/radial directions can increase up to 25 μm for the flank wear of 0.2 mm. Moreover, higher cutting temperature employed during process (800–1000 °C) resulting in substantial thermal expansions of cutting edge of the tool and the workpiece. In particular, at cutting speed of 160 m min^{-1} and feed and depth of cut of 0.05 mm rev^{-1} and

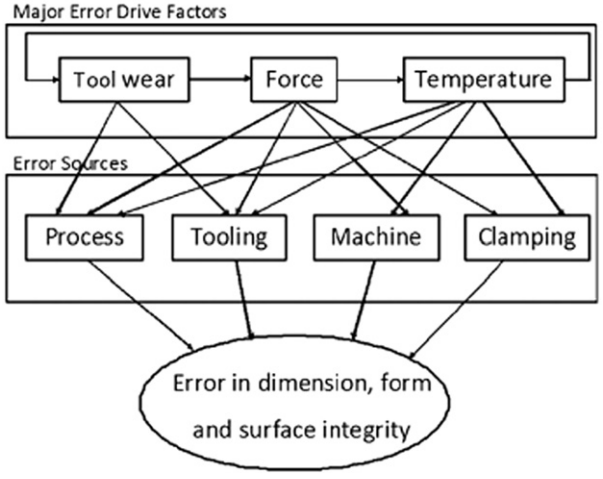

Figure 34 Major error driver factors and error sources in precision hard turning.[107]

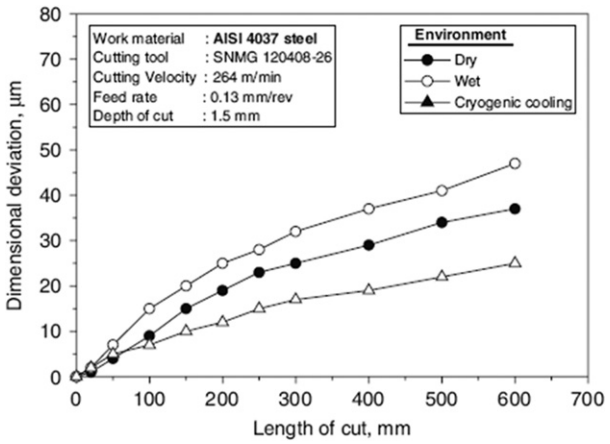

Figure 35 Variation in change in dimension with cutting-length under different conditions.[111]

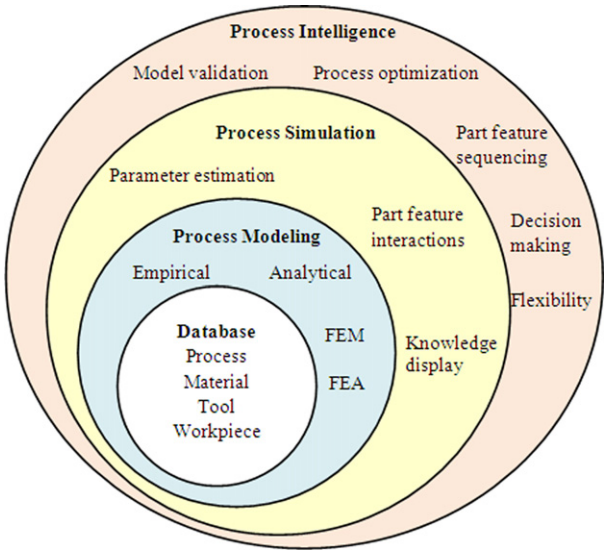

Figure 36 Process data and models drive design and manufacturing decisions with increasing levels of complexity.[115]

0.05 mm, thermal expansion of the CBN tool tip and workpiece can reach up to 10–15 µm, respectively.[107]

It is important to choose a nose radius that is smaller than the cutting depth as this has the same effect as choosing the correct entering angle. If the nose radius is too large it will push the tool in the radial direction and affect the dimensions of the component. Wiper inserts act as a large nose radius and will generally need a bit more care when applying it to internal turning.[113] In manufacturing of the bores, heat removal is more difficult than when machining external surfaces. So there may be chances of thermal distortions. A finite element based model which was developed for the simulation of thermal deformation in the hard turning of small bores indicated that thermal distortion did not have a significant effect on the machining accuracy, as the deviation in diameter caused by the heat remained below 0.001 mm.[114]

However, in internal turning operations and specially in finishing, the machining conditions are difficult. The workpiece is sometimes thin-walled and flexible, and the internal turning is often performed by using long boring bars with relatively low stiffness. Machining of deep cavities or with long overhangs is prone to vibration problems. One way to overcome this is to reduce the depth of cut, the speed or the feed. However, losing productivity in favor of keeping the process running is not beneficial. The use of a Silent Tool when going deeper into a bore, will retain, or in many cases improve productivity with a high-quality surface finish, closer tolerances and improved tool life even when working with boring bars with large overhangs. Silent Tools is a family of products for internal turning, milling, boring, and drilling. These products are tuned to work on overhangs beyond the limitation of solid steel and solid carbide shanks. They are easy to operate and are very flexible due to the wide variety of back-end and front-end couplings.[113]

From above it is evident that with effective control on error sources, HPM could achieve the level of desired geometrical accuracies. It can even surpass the grinding capabilities if executed carefully. Since machining with a severely worn tool affects the dimensional accuracy and surface finish and replacing the tool well before the end of its life affects the machining economy. Several attempts made by the researchers to model the cutting forces, flank wear progression and RSs during machining of hardened steel which will be discussed in next section.

1.3.4 Modeling of Hard Machining Processes

Nowadays, with the increasing trend toward maximizing productivity and higher material removal rates, the ability to predict the cutting performance is embedded in the road map for cutting technology. Manufacturing evolution, i.e., the design-to-manufacturing cycle is strongly driven by the database of information on process, tooling, materials and workpiece requirements as shown in Figure 36. Evidently, process data and appropriate models can drive design and manufacturing decisions to achieve goals with increasing levels of complexity.[115]

Predictive models which are capable of predicting quantitatively the influence of the magnitude of one or more input parameters on the magnitude of one or more output parameters are of special importance in the finish machining of hardened steel in view of to predict process results, such as, tool life, surface finish/integrity of the component being machined and forces on the tool and/or workpiece. Moreover, predictive models could be used to find ways of optimizing the processes, to obtain new knowledge of process steps and process design and to derive capabilities of process monitoring and control from this.[6] Considerable amount of modeling efforts have been undertaken to predict machining performance namely, tool wear, tool life, surface roughness, cutting forces/power, and part accuracy. Also, significant attempts have been made by the researchers in developing safer and secure operating conditions for machining, selection of appropriate tooling, and accessories such as jigs and fixtures to avoid machining chatter and vibrations.[67]

1.3.4.1 Modeling of Cutting Force

The understanding of the cutting forces considering the tool wear is important in addressing metal cutting issues such as

dimensional accuracy, surface finish, white layer effect, and RSs in finish machining of hardened steel. Several studies have concluded that in the machining of hardened steels higher workpiece hardness demands for higher cutting forces and hence generates higher temperature in the cutting zone that has a very strong influence on the tool wear, surface integrity, and workpiece quality.[8–11,38] Furthermore, determination of cutting forces, prior to machining is important because through these forces the power requirements of the machine tool and the cutting tool properties can be estimated.

However, it is imperative to estimate shear plane angle and friction parameters in order to calculate cutting forces. The single shear plane model has been criticized over the years. However, the infinite strain rate, assumption of the rigid, perfectly plastic workpiece material and the perfectly sharp cutting edge of the tool are the major inherent drawbacks of the single shear plane model.[116] Moreover, most of the analyses presented pertained only to orthogonal cutting.[117,118] A 3D analysis has been presented by Usui *et al.*[119–121] and Oxley[122] considering the secondary cutting edge and tool nose radius effects, which is of course the most usual in practice. However, both Oxley's and Usui's models require stress and strain data at the strain rate and temperature encountered in metal machining.

Mechanistic modeling, a combination of analytical and experimental modeling techniques, for cutting force is also presented by a group of researchers, a review of which can be found in Ehmann *et al.*[123] As this kind of modeling is not purely analytical and based on metal cutting mechanics, such an approach avoids the complications of incorporating parameters such as shear angle and friction angle, by using experimental force data and it is suitable for practical machining processes which are mostly oblique cutting in nature.[124] Attempts have been made to introduce the effect of the secondary cutting edge to predict the chip-flow direction for turning operations. A group of researchers.[125–127] predicted the cutting forces while using a sharp tool considering the effect of tool geometry complexity. They observed better prediction of cutting forces by replacing actual cutting edge of tools with nose radius with an equivalent cutting edge.

Although, several cutting force models have been developed, very few have considered the effect of tool wear on cutting forces.[33,118,128,129] Moreover, most of the models have used CBN/ceramic inserts as a tool material during machining of hardened steel. Chinchanikar and Choudhury[57] studied the interrelationship between the tool wear and cutting forces within the different phases of the tool life through mathematical modeling during turning of hardened AISI 4340 steel. They observed that the feed and radial components of cutting force are more influenced by tool wear and increase sharply when rapid deterioration of the cutting edge takes place. Huang and Liang[33] developed an analytical model for predicting the cutting forces due to flank wear under hard turning conditions by extending Waldorf's orthogonal force modeling approach. Model predictions showed better agreement with the experimental results. Worn tool cutting forces were obtained by summing up the predicted forces without any tool wear and the forces due to the flank wear alone. They observed that the predicted forces match better in the tangential cutting direction and the axial direction than in the radial direction with the progress of tool flank wear. In another study, Li and Liang[128] found that the cutting forces under near dry machining could reduce 10–20% cutting forces compared with the forces under dry machining conditions when cutting the AISI 1045 with uncoated carbides, suggesting that lubricating has a stronger effect on cutting forces than cooling under these conditions as shown in **Figure 37**.

Smithey *et al.*[129] developed a model for worn tool cutting forces in 3D cutting operations to show the growth of the plastic flow region at the tool flank during dry turning of AISI 4140 steel with TiN-coated carbide inserts. Sharp tool cutting forces were obtained by the authors using a mechanistic force model that showed an excellent agreement with the experimental results. However, the said model may not be applicable to other tool and work combinations. In another study, Huang and Liang[130] presented the ploughing effect in a mechanistic model to calculate the total 2D cutting forces in shallow cuts during hard turning. Chip formation forces were predicted by transforming the 3D cutting geometry into an equivalent 2D cutting geometry. Finally 3D cutting forces were estimated by geometric transformation. The proposed model was calibrated and validated using experimental machining data for finish turning of hardened 52100 steel. The Johnson–Cook equation was used by them to represent the workpiece material properties of hardened 52100 steel. The developed model showed prediction accuracy with experimental results within 15%.

From the available open literature, it has been observed that cutting forces could be better predicted by replacing actual cutting edge of tools with nose radius with an equivalent cutting edge.[125,127,131,132] Further, it has been observed that model prediction accuracy, especially when employed shallow cuts during finish machining of hardened steel, could be increased by summing up the ploughing forces and the chip formation forces. Several studies concluded that machining of hardened steels using coated carbide tools could become an economical alternative to costly CBN and ceramic tool materials.[31,32,56,71,133] Therefore, development of a reliable model which can predict the cutting forces considering tool wear effect in the finish machining of hardened steel using coated tools will be extremely valuable and needs to be taken.

1.3.4.2 Modeling of Tool Wear Progression

In finish machining of hardened steel, prediction of the tool wear progression will be extremely valuable since the machining with a severely worn tool, especially at the flank faces (flank wear), affects the dimensional accuracy, surface finish, and replacing the tool well before of its tool life affects the machining economy. Significant efforts have been made by several researchers in understanding and modeling the tool wear progression and wear mechanisms like abrasion, adhesion and diffusion in metal cutting as shown in **Table 4**.

Studies available in the literature,[38,41,152] confirming a strong influence of cutting force and temperature on the tool wear rate through different tool wear mechanisms like abrasion, adhesion, and diffusion. It is reported that during machining of hardened steels higher cutting temperatures in the range of 800–950 °C are generated in the cutting zone.

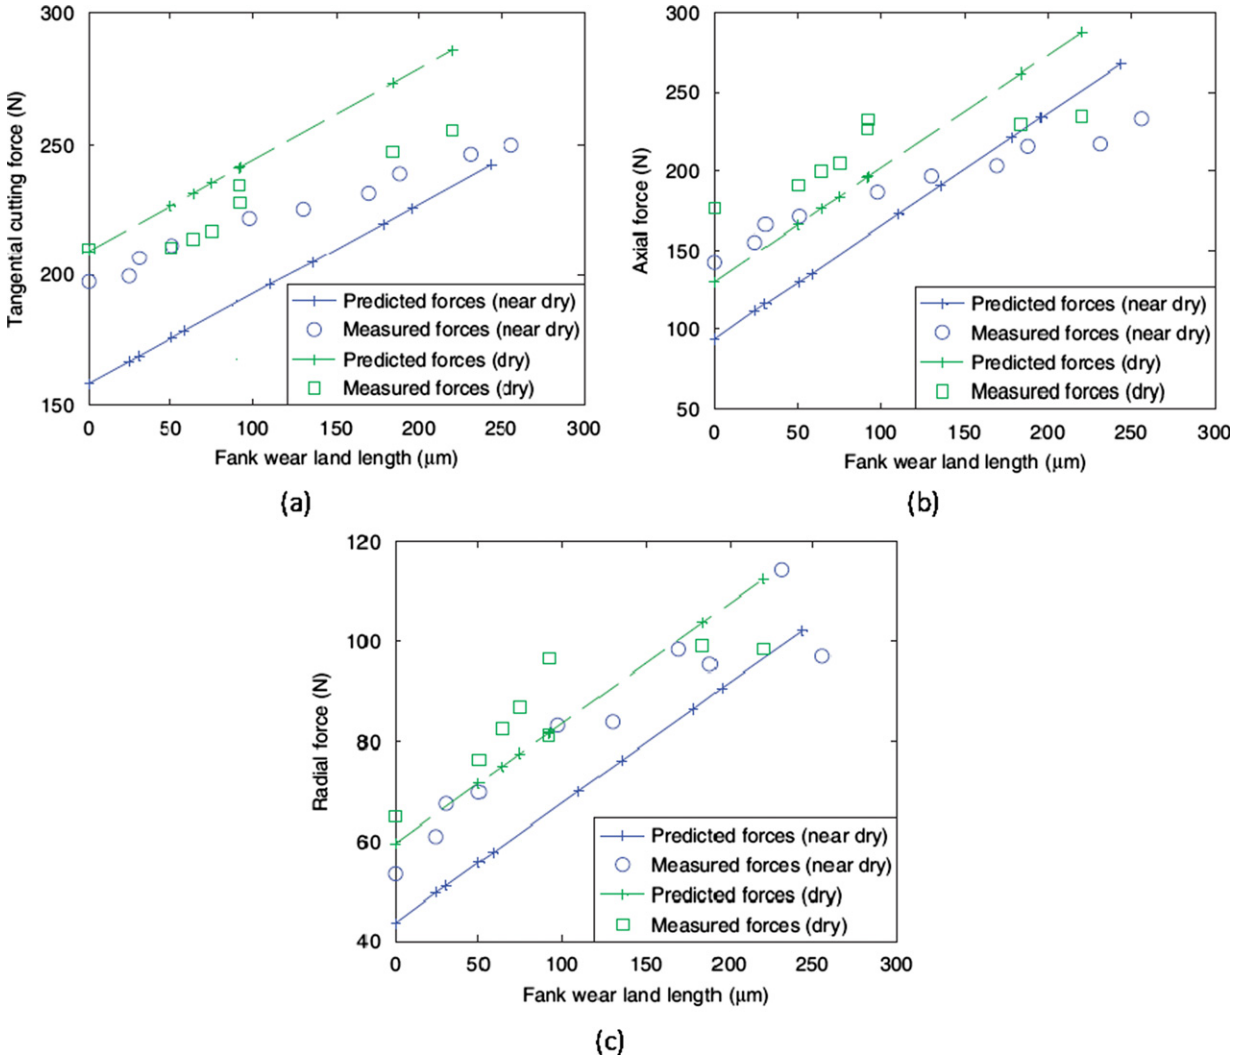

Figure 37 Model and experimental results of cutting forces under dry and near dry cutting (cutting speed of 91.5 m min^{-1} and feed and depth of cut values of 0.076 2 and 0.762, respectively.[128]

Tool wear, especially when using coated carbide tools during finish machining of hardened steel having hardness in the range of 50–65 HRC, is the main hurdle in the wide implementation of these tools in the industry.[3]

Abrasion and adhesion are usually predominant wear mechanisms when machining hardened steel. Abrasion wear is more prominent in case of turning harder workpiece. As against, adhesion wear is more prominent when turning softer workpiece. It has been observed that the contribution of abrasion wear increases and that of adhesion wear decreases with the machining time. However, the contribution of diffusion wear has been observed to increase at higher cutting speeds.[7] It is generally agreed that tool wear criteria in the range of 0.15–0.2 mm (flank wear length) is more realistic during finish machining of hardened steel as beyond this tool wear criteria tool failure occurred by chipping off of the cutting edges instead of progressive growth of tool wear.[7,60] Huang and Dawson[135] developed a model to predict crater wear depth of CBN tool incorporating abrasion, adhesion, and diffusion wear mechanisms. The proposed model was experimentally validated by them in finish turning of hardened 52100 bearing steel.

Singh and Rao[136] developed prediction model for flank wear of ceramic inserts in finish turning of hardened AISI 52100 steel. They found that abrasive and adhesive wear mechanisms as predominant mechanisms. However, abrasive wear was observed by them decreasing at higher cutting speeds and adhesive wear increasing as cutting speed increases. They also found that the contribution of diffusive wear mechanism increases at higher cutting speeds. However, when using CBN tool in finish hard turning of hardened AISI 52100 steel, Huang and Liang[147] observed adhesion as the main wear mechanism. On the other hand, they observed chemical diffusion as a dominant wear mechanism over extended periods of machining under aggressive cutting conditions as shown in **Figure 38**. Mechanical wear model which was modeled considering abrasion and adhesion as dominant wear mechanisms could be used to predict the flank wear progression and failure points of uncoated and ceramic-coated PCBN during finish turning of hardened steel.[134]

Table 4 Attempts made by various researchers in modeling of tool wear[3]

Researchers	*Tool wear model*
Chinchanikar and Choudhury[7]	Developed flank wear progression model considering abrasion, adhesion, and diffusion wear mechanisms in turning hardened AISI 4340 steel using multilayer-coated carbide tool
Chinchanikar and Choudhury[60]	Developed empirical models to predict flank wear of multilayer-coated carbide tool in turning AISI 4340 steel hardened at two different levels of hardness
Dawson and Kurfess[134]	Developed flank wear progression model considering abrasion and adhesion as dominant wear mechanisms
Huang and Dawson[135]	Developed model to predict crater wear depth of CBN tool incorporating abrasion, adhesion, and diffusion wear mechanisms
Singh and Rao[136]	Developed flank wear prediction model of ceramic inserts in hard turning considering abrasion, adhesion, and diffusion as dominant wear mechanisms
Kramer[137]	Developed wear rate model for coated tools considering abrasive wear and the chemical dissolution as dominant wear mechanisms
Singh and Vajpayee[138]	Developed flank wear model considering abrasion as dominant wear mechanism
Choudhury *et al.*[139]	Developed flank wear model in the machining of EN 24 steel using high speed steel (HSS) tools
Bhattacharya and Ham[140]	Developed flank wear model considering adhesion as a dominant wear mechanism
Molinari and Nouari[141]	Developed crater wear model considering diffusion wear as a dominant mechanism in high speed cutting processes
Wong *et al.*[142]	Suggested comprehensive equations for flank and crater wear
Haddag and Nouari[143]	Carried out tool wear and heat transfer analyses in dry machining based on multisteps numerical modeling
Halila *et al.*[144]	Developed wear model considering abrasive particles embedded at the interface between tool and chip
Luo *et al.*[145]	Developed flank wear rate model combining cutting mechanics simulation and an empirical model
Kannatey-Asibu[146]	Developed flank wear rate model considering adhesion and diffusion as dominant wear mechanisms while machining of AISI 1045 steel using tungsten carbide cutting tool
Huang and Liang[147]	Developed CBN tool flank wear rate model as a function of tool/workpiece material properties and cutting parameters in finish hard turning of hardened steel
Kwon[148]	Developed predictive models for flank wear that explicitly incorporate cutting temperature and physical properties of coatings and work materials
Kramer and Judd[149]	Presented quantitative models for the relative abrasive and chemical dissolution wear rates of potential tool coating materials
Palanisamy and Shanmugasundaram[150]	Developed regression and artificial neural network (ANN) models to predict tool wear in hard turning
Dureja[153]	Developed flank and crater wear models using response surface methodology (RSM)

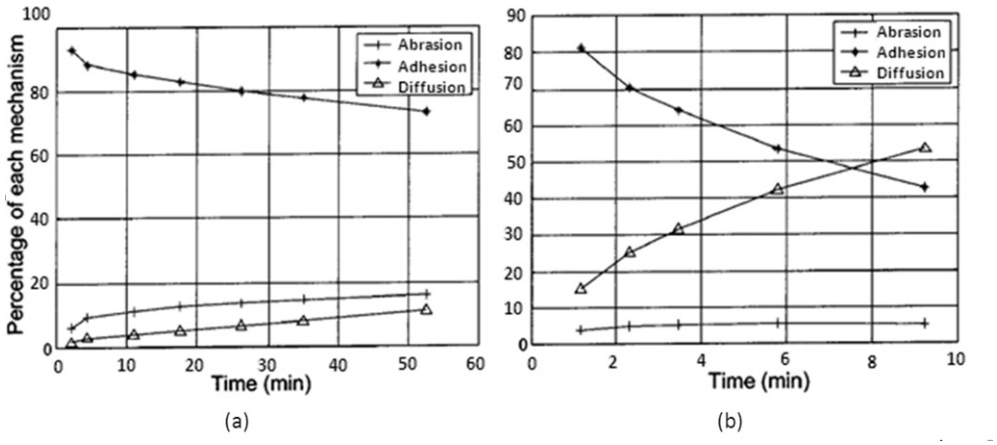

Figure 38 Contribution percentage of different wear mechanisms when using feed and depth of cut of 0.114 mm rev^{-1} and 0.203 mm and at cutting speed of (a) 1.21 m s^{-1} and (b) 2.29 m s^{-1}.[147]

Very few attempts have been made by the researchers to model the flank wear progression of coated carbide tool in machining of hardened steel as models developed are mostly applicable when using CBN or ceramic tools. The analysis of most of the studies concluded that tool wear increases with the increase in cutting speed, feed, and effective rake angle. However, cutting speed followed by feed was reported to be having most prominent effect on tool wear in comparison to depth of cut.[7,60,136,151,153] On the other hand, tool wear was reported to slightly decreasing with the increase in nose radius.[136]

1.3.4.3 Modeling of RSs

Considerable amount of modeling efforts have been undertaken to predict machining performance namely, tool wear,

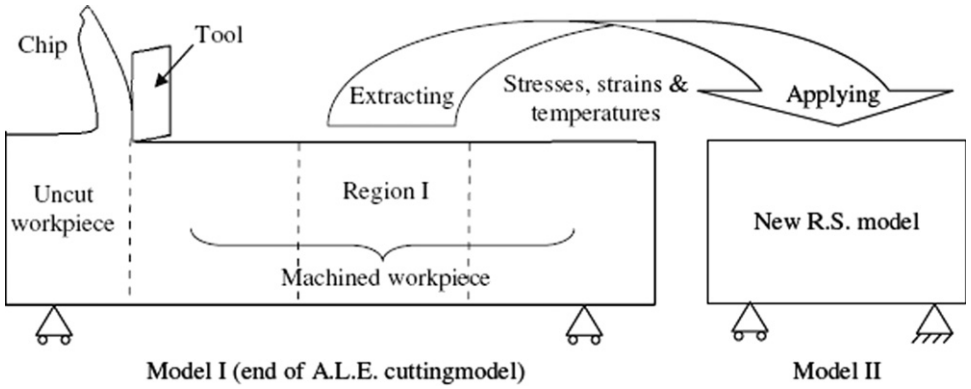

Figure 39 Schematic implementation of the modified RS approach.[162]

tool life, surface roughness, cutting forces/power, and part accuracy. Also, significant attempts have been made by the researchers in developing safer and secure operating conditions for machining, selection of appropriate tooling and accessories such as jigs and fixtures to avoid machining chatter and vibrations.[67] RS profile in a component is often considered as the critical characteristic as it directly affects the fatigue life of a machined component. Predictive models for RSs are among the fastest growing research topics in several research groups owing to its correlation with the fatigue life of the machined components.[154]

The desired RSs in the machined surfaces can be obtained by selecting correct cutting conditions, tool geometry and other process parameters. The service life of a machined product will heavily depend on the machining-induced RSs and would be of paramount importance in the overall enhancement of product sustainability. The computational methods such as numerical modeling using finite element methods have been widely used to predict machining-induced RSs, despite the questions surrounding the validity of the various assumptions made and the material constitutive relationships being incorporated in these models.[67] Moreover, its high computational cost has been always an issue. Hua *et al.*[155] investigated through numerical modeling the effects of cutting conditions, tool edge configuration, and the work material hardness on the axial and circumferential RSs in hard turning of bearing steels using commercial FEM software. The effect of cutting conditions, tool geometry parameters such as rake angle, tool nose radius and tool edge configurations with chamfer on RSs was investigated using a thermo-elastic–plastic finite element model.[156–159] Outeiro *et al.*[160] investigated using FEM the role of size effect on RSs and the microstructural transformation of the machined layer.

El-Axir[161] developed experimental-based model to predict turning-induced RSs in five different materials. The proposed model developed by them fitted the experimental data with a high degree of accuracy and determines both the location and depth of the maximum RS. In this study, tensile strength of material, cutting speed, and feed rate were considered as input parameters affecting RS distribution. Further, it was postulated that the RS profile along the depth beneath surface is a polynomial function of the depth beneath surface and the coefficients of this polynomial are, in turn, functions of the input parameters.

Nasr *et al.*[162] presented a modified FE approach to predict machining-induced RSs using commercial FE software (ABAQUS™). In order to cut down the computational time from days as in case of the traditional approach to just few minutes, a modified approach was developed. The flow chart for both the traditional and modified approaches can be referred from.[162] In the traditional approach, the same model is left to relax and cool down to predict RSs. However, in the modified approach, only the machined workpiece is modeled, while the chip, tool, and uncut workpiece are not considered. **Figure 39** shows a schematic for the implementation of the modified approach, where the workpiece parameters (stresses, strains, and temperature) are exported from the cutting model and imported to the new RS model. Four different workpiece materials (AISI H13, AISI 316L, AISI 52100, and AISI 4340) were used by them to validate the predicted results of their model with the experimental results which were obtained under similar cutting conditions. They observed predicted results in reasonable agreement with experimental results.

Agrawal and Joshi[163] developed an analytical model to predict the RSs in orthogonal machining of AISI 4340 steel. Predicted results of the RSs obtained by them are in good (86–88%) agreement with the experimental values in the *X*- and *Y*-directions. They found that the RS is greatly affected by the process parameters such as feed, cutting speed, machining temperature, and tool design parameters, such as edge radius as shown in **Figures 40–42**.

The analysis of their study concluded as follows:

- The tensile RSs on the machined surface decrease with an increase in the edge radius. However, the compressive RSs below the machined surface increase with an increase the edge radius.
- The tensile RSs on machined surface increase with an increase in the cutting speed and observed to decrease with increase in the depth of cut. However, below the surface, the compressive RSs increase with increase in the depth of cut.

The predictions of RSs are most critical on the machined aerospace components for the safety of the aircraft. With this view, Lazoglu *et al.*[164] presented an analytical model to predict the RSs which was validated with the measured experimental results obtained in machining of the high strength engineering

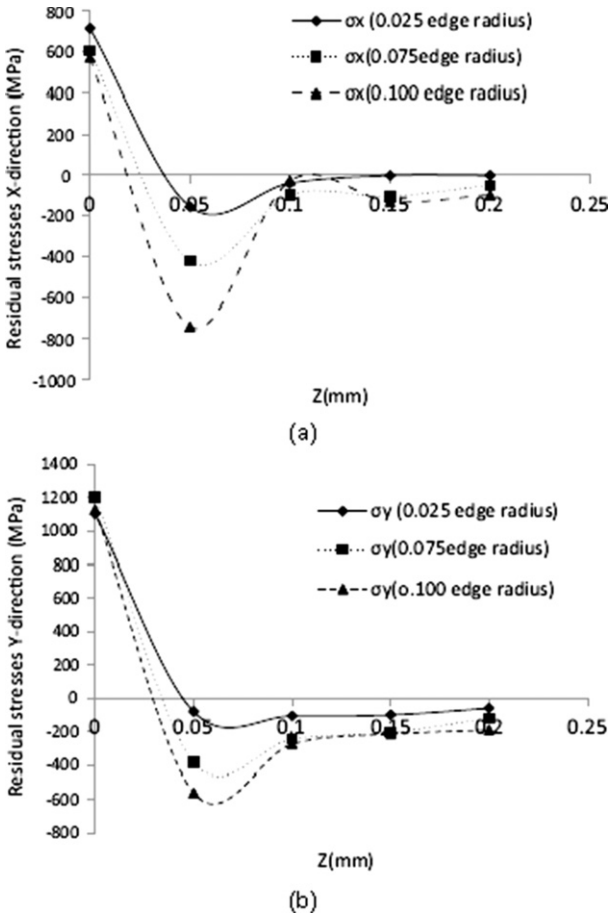

Figure 40 Effect of tool edge radius on residual stresses in (a) *X*-direction (σ_x) and (b) *Y*-direction (σ_y).[163]

material Waspaloy. They employed an enhanced analytical elasto-plastic model using the superposition of thermal and mechanical stresses on the workpiece, followed by a relaxation procedure. By changing the material properties and cutting conditions, the algorithm suggested by them could be easily applied to different materials.

The analytical model of RS in orthogonal cutting proposed by Jiann is an important tool for RS prediction in orthogonal cutting.[165] However, a significant error in the prediction accuracy has been observed for the surface RSs. With this view, Qi *et al.*[166] developed an improved analytical model to predict RSs in orthogonal cutting. The simulation results obtained for RSs by their model were compared with the Jiann's model and the simulation results of the two models are compared with the experimental results in cutting AISI 1045 steel. The authors observed better prediction accuracy in comparison to Jiann's model and claimed that the developed model could provide favorable conditions for the optimization of cutting parameters.

Ulutan *et al.*[167] developed an analytical model for prediction of RSs which is verified with experimental measurements of RSs on bearing steel 100Cr6 (JIS SUJ2) in the literature. Thermal field of workpiece which was determined using a finite-difference-based technique was used by them in the thermo-mechanical model of the RSs. Stresses resulting from thermal and mechanical loading were obtained by them using an analytical elasto-plastic model and a relaxation procedure. With the analytical model presented by them, the RSs could be predicted with acceptable accuracy and quite fast.

Predictive models for surface and subsurface, covering RSs, microstructural and metallurgical alteration, variations in mechanical properties, micro-crack development and growth, etc., are urged as significant owing to their correlation with the fatigue life of a product.[168] Nevertheless, the gaps in the experimental and predicted values point to the opportunity for the future work. The gap may be reduced by better definition of the physical phenomena at tool–chip, tool–work, and tool edge radius interfaces in a machining process.[166]

1.3.5 Hard Machining: Application of Different Cooling Techniques

Green cutting will become an important tendency of machining with environment consciousness enhanced laws and regulations consummated. At present, green cutting technology includes dry machining, semidry machining using minimum quantity lubrication (MQL), compressed air cooling, cryogenic machining, and solid lubrication. Dry cutting involves heat dissipation without coolants and for machining of harder materials, it demands high performance cutting tools. MQL technology is close to dry cutting technique, which is between dry and wet machining wherein a small quantity of cutting fluid mixed with compressed air access the contact zone between tool and chip as shown in **Figure 43**.[3]

1.3.5.1 Dry, Semidry, and Cryogenic Machining

Finish machining of hardened steel is almost cited in literature using dry cutting, because the increase of the temperature makes chip deformation and shearing of the hardened material, easier. Moreover, since the process is performed usually at high speed, most of the heat is carried away by the chip flowing at a high speed making the use of cutting fluid redundant. It is reported that HSM of hardened steels under flood coolant condition lowers the tool life due to formation of severe thermal cracks.[169] However, the complete absence of lubrication creates problems in chip transportation and causes an increase of tool–chip and tool–workpiece friction. On the other hand, the use of abundant cutting fluid has the advantages of providing chip transportation, reducing friction, and cooling the workpiece. In machining of hardened steel, the application of abundant cutting fluid does not allow the workpiece to soften, which is good for the process. Moreover, the use of cutting fluids increases the cost of cutting process and poses a serious problem to the preservation of the environment and human health. Therefore, MQL may represent a compromise between the dry cutting and wet cutting.[3]

Chinchanikar and Choudhury[48] during their investigation on finish turning of hardened AISI 4340 steel (54–57 HRC) using differently coated carbide tools observed that improvement in tool life of almost 20–25% under MQL in comparison to dry turning as shown in **Figure 44**. However, this effect was

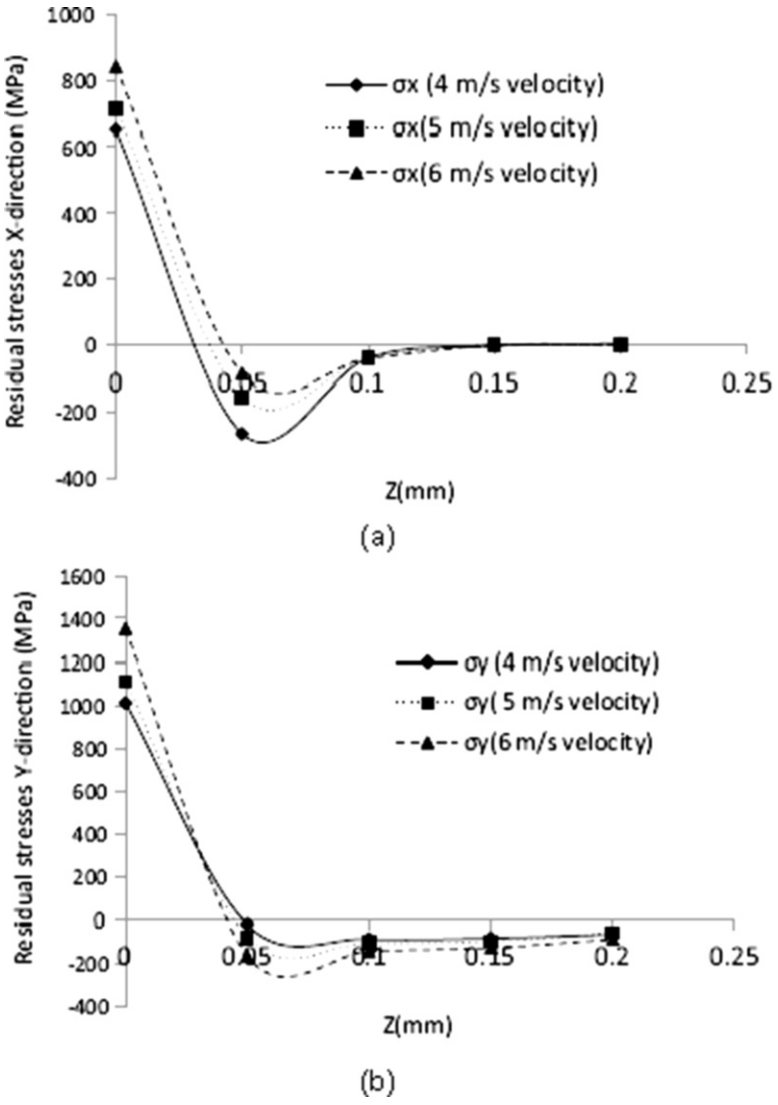

Figure 41 Effect of cutting speed on residual stresses in (a) *X*-direction (σ_x) and (b) *Y*-direction (σ_y).[163]

observed by them more prominent at higher cutting speed of 150 m min^{-1}. The tool nose wear width progression with machining time and the tool images indicating tool condition at the end of cutting under dry and MQL cutting conditions are shown in **Figure 45**. Nose wear, chipping off at the nose and clearance face was observed as a dominant wear forms under both dry and MQL cutting conditions.

The cooling and lubricating technique employed during machining significantly improves the surface properties. Avila and Abrao[171] observed that during turning of hardened AISI 4340 steel using mixed alumina inserts emulsion-based fluid without mineral oil and dry cutting provide better results in comparison to synthetic fluid and emulsion containing mineral oil. In general, machining under MQL improves tool life due to better cooling and lubricating effects in comparison to machining under dry and wet conditions. However, effectiveness of the cooling and lubricating technique to a large extent depends on the cutting parameters, namely the cutting speed and feed rate.[172]

Machining under MQL provides extra oxygen resulting in the formation of a protective oxide layer in between the chip–tool interface which acts as a diffusion barrier. However, there exists an optimal cutting speed at which a stable protective oxide layer can be formed. When cutting speed is lower than this speed, there is less oxide layer and the improvement of tool life is less apparent. As the cutting speed is far beyond the optimal value, the protective layer is absent and the thermal cracks are apt to occur at the cutting edge due to large fluctuation of temperature. Therefore, by properly selecting cutting parameters under MQL the tool life could be effectively improved.[173] It is reported that the tool flank wear and the cutting temperature were effectively reduced due to the lubricant percolating in mist and wet cutting. In dry cutting, the tool wear width was at its maximum near the boundary of the depth of cut, whereas for the mist and wet cutting methods the tool wear was almost flat.[174]

Khan *et al.*[175] observed a significant improvement in tool life under MQL as MQL-assisted in lowering the tool wear rate

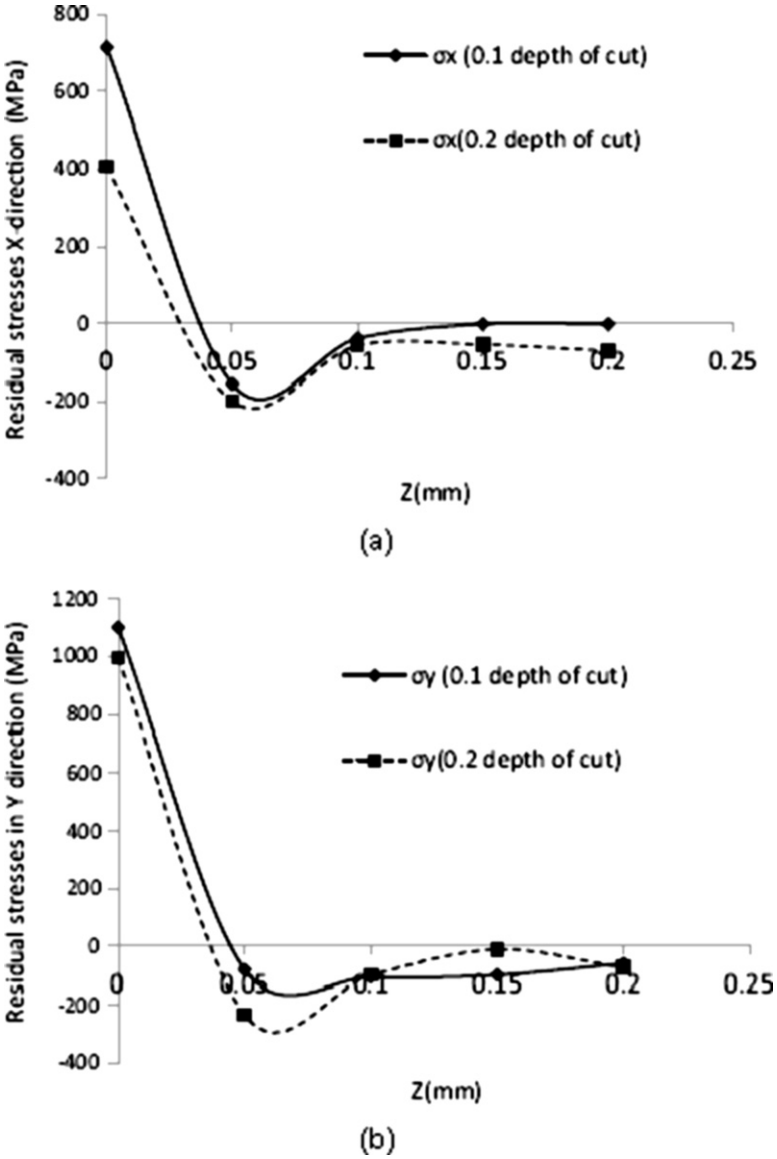

Figure 42 Effect of depth of cut on residual stresses in (a) *X*-direction (σ_x) and (b) *Y*-direction (σ_y).[163]

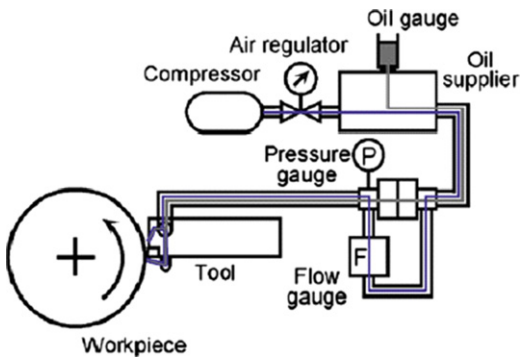

Figure 43 Schematic view of the components of a MQL system.[170]

due to abrasion, adhesion and diffusion type thermal sensitivity wear. Moreover, they found that MQL eliminates built-up edge formation and reduces deep grooving and hence, catastrophic failure of the cutting tools. Varadarajan *et al.*[176] during their investigation on hard turning developed a fluid application system by which a thin pulsed jet of cutting fluid at high velocity was applied at the immediate cutting zones. They observed superior performance in terms of cutting force, tool life, surface finish, cutting ratio, cutting temperature, and tool–chip contact length during MQL in comparison to that of dry and conventional wet turning.

Vikram Kumar and Ramamoorthy[177] also found better machining performance in terms of cutting force, temperature, and surface finish under MQL than that of dry and conventional wet turning. Dhar *et al.*[69] observed significant reduction in tool wear rate and surface roughness under MQL mainly through reduction in the cutting zone temperature and favorable change in the chip–tool and work–tool interaction as shown in **Figure 46**. In another study,[111] they found that MQL-assisted machining results in lower cutting temperature,

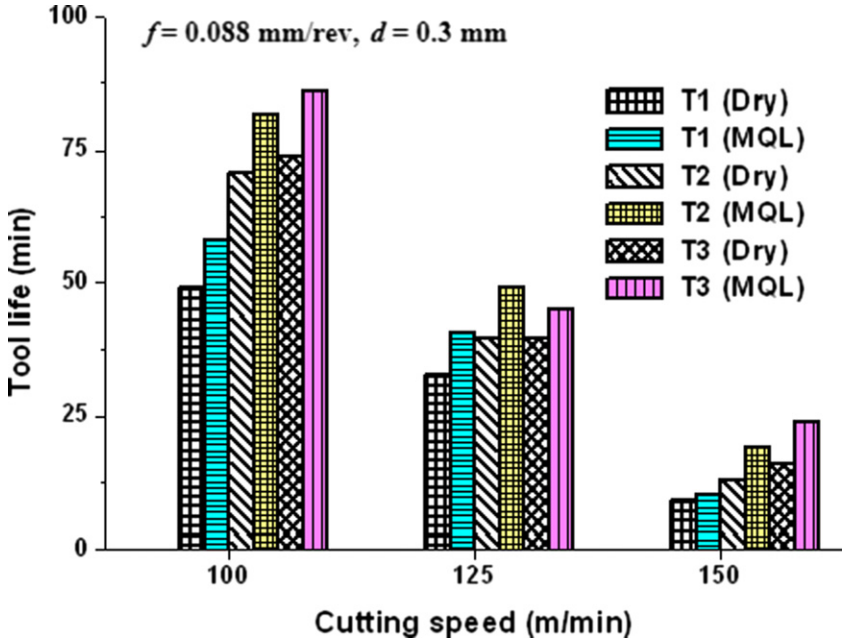

Figure 44 Histogram showing tool life for differently PVD-coated carbide tools, T1: AlTiN coated, T2: Multilayer TiAlN/TiSiN coated, and T3: AlTiCrN coated.[48]

lower cutting force and hence, resulting in lower dimensional deviation.

On the other hand, a group of researchers observed that dry machining leads to the lowest values of tool wear and surface roughness, while the minimal quantity of lubricant technique does not provide any advantage over dry hard turning.[20,62,74] Bruni *et al.*[20] investigation also showed that MQL technique did not significantly reduce the tool wear, whilst wet cutting produced the worst surface finish. Attanasio *et al.*[178] observed similar tool life under dry cutting conditions and under MQL applied on the rake. However, MQL applied on the flank surface resulted in reducing tool wear and hence, in increasing tool life. Finally, they concluded that although, MQL gives some advantage during turning operation, but it presents some difficulty in exactly reaching the lubricant at the cutting zone.

Although, dry and semidry machining are the most commonly used machining techniques which complement to reduce or eliminate the use of conventional cutting fluids, chilled air, and cryogenic machining techniques also have been found to be a complete alternative for cutting fluids due to the difficulties in machining difficult-to-machine materials. Cryogenic machining is a term referred to machining operations conducted at very low temperatures (lower than 120 K) using a super cold medium, usually liquefied gases.[179] Schwach *et al.*[180] investigated the effect of cryogenic cooling during hard turning of AISI 52100 steel and AISI D2 steel using CBN and ceramic tools. The effect of cryogenic liquid nitrogen cooling, tool and workpiece materials, and cutting speeds on white layer formation were investigated. It was found that with cryogenic cooling ceramic tools performed well and resulted in thinner white layer than conventional CBN dry hard turning. It was also observed that hard turning without coolant include surface softening and more fluctuation of RSs. Liquid nitrogen cooling resulted in retention of material hardness, flatter stress gradients, and elimination of tensile stresses in case of hard turning with alumina inserts.

1.3.5.2 Application of Vegetable Oils and Solid Lubricants

In the twenty-first century, with environment consciousness enhanced laws and regulations consummated, green cutting will become an important tendency of machining. Although, cutting fluids are beneficial in the industries, today their uses have become more and more prevalent around the world as they are contaminated with metal particles and degradation products which create health and environmental issues.

From last decade, vegetable oil-based cutting fluids are getting more and more attention in industry as they are renewable, biodegradable, nontoxic and have high viscosity and high flash point.[181] Among users, rapeseed,[182] canola,[183] and coconut oils[184–186] are mostly preferred as vegetable oil-based cutting fluids to alleviate problems faced by workers such as skin cancer and inhalation of toxic mists in the working environment when using mineral oil-based lubricants.[187] Ozcelik *et al.*[188] experimental study during turning using sunflower oil, canola oil, semisynthetic, and mineral-based oils also concluded that mineral and semisynthetic cutting fluids could be replaced by vegetable-based oils.

A group of researchers made great effort to compare machining performance under dry cutting, wet cutting, and cutting with vegetable-based oils. Chinchanikar *et al.*[189] performed hard turning of AISI 52100 steel (60–62 HRC) PVD-coated nanolaminated TiSiN–TiAlN carbide tool under dry, with water-based and coconut oil-based cutting fluids. Experimental observations of their study indicate that hard turning under dry condition produced lower values of surface roughness. However, at higher cutting speeds hard turning using coconut oil showed lower values of surface roughness.

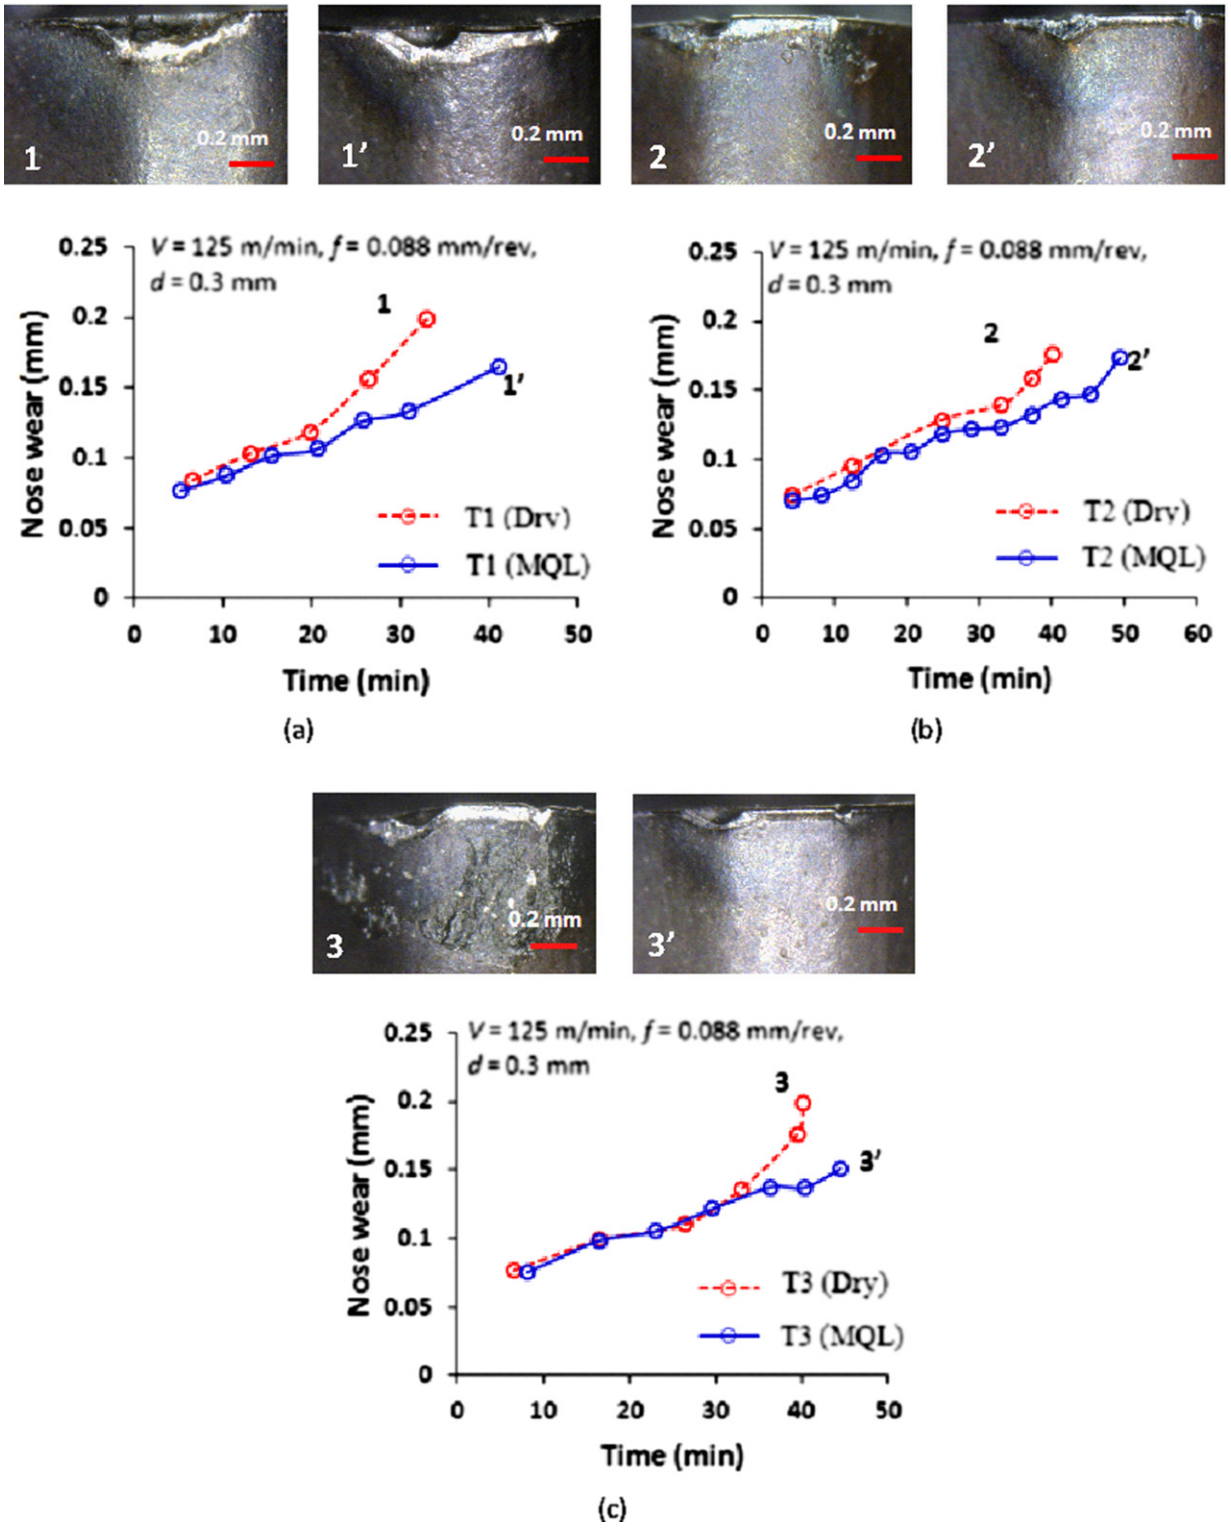

Figure 45 Nose wear with time of cutting under dry and MQL cutting condition at V=125 m min^{-1}, f=0.088 mm rev^{-1} and d=0.3 mm (a) AlTiN (T1), (b) multilayer TiAlN/TiSiN (T2), and (c) AlTiCrN (T3). Tool images indicate tool condition at the end of cutting shown by numbers.[48]

The coconut oil also found to be more effective in lowering surface roughness at higher values of feed and depth of cut. They observed that surface roughness gets affected mostly by feed and increased when cutting speed exceeds 150–160 m min^{-1} irrespective of the cooling mediums used. However, this effect can be seen as more prominent when turning under dry cutting conditions as shown in Figure 47.

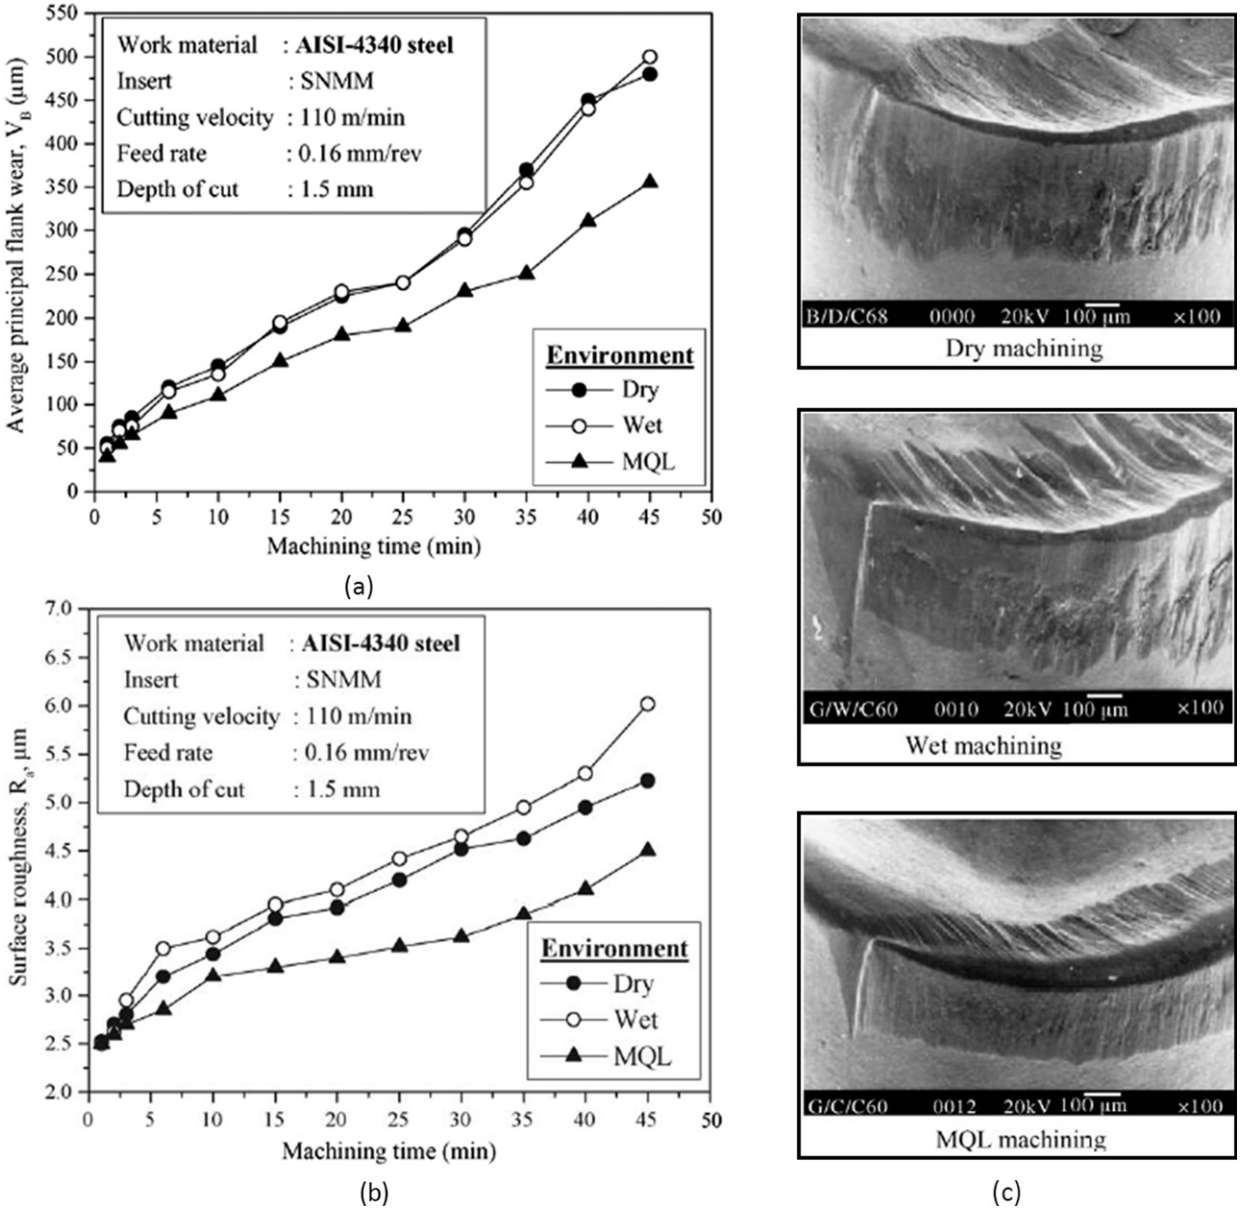

Figure 46 (a) Growth of average principal flank wear, V_B, (b) surface roughness with progress of machining, (c) SEM views of the worn out insert after machining 45 min.[69]

Xavior and Adithan[184] observed better performance in terms of lower tool wear and improved surface finish when using coconut oil in comparison to emulsion and neat cutting oils during turning of AISI 304 stainless steel. Ojolo *et al.*[190] observed better performance during turning with groundnut oil in comparison to coconut oil, palm kernel oil, and shear butter oil. Further, they found that the performance of vegetable-based cutting fluids depend on the workpiece material and cutting parameters employed during machining.

With a view to have eco-friendly and user-friendly alternatives to conventional cutting fluids, a group of researchers performed machining using solid lubricants as a cooling medium. It is reported that, solid lubricants, if employed properly, limits the cutting temperature by effectively removing the heat from the machining zone. Rao and Krishna[191] investigated and compared the machining performance in terms of cutting forces, tool wear, tool temperature, and surface roughness under the lubricating action of boric acid and compared with dry and wet machining. They reported that the use of boric acid as solid lubricant is advantageous over dry and wet machining.

Singh and Rao[192] investigated the effect of molybdenum disulfide solid lubricant on surface roughness while hard turning of bearing steel. Experimental results of their study indicate that a considerable improvement in the machining performance when using solid lubricant as compared to dry hard turning. In another study, Singh and Rao[193] explored the use of solid lubricants during hard turning while machining

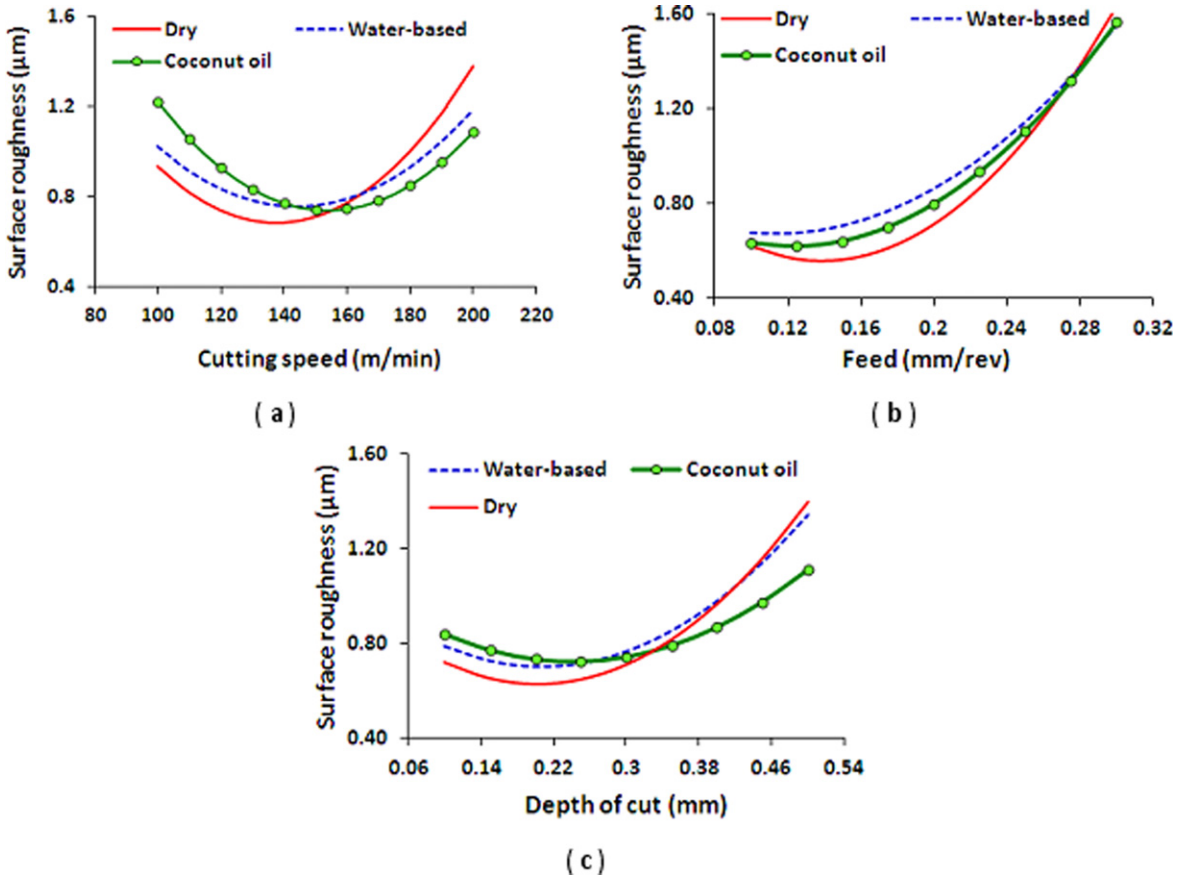

Figure 47 Effect on surface roughness under dry cutting, wet cutting, and cutting with vegetable-based oils by (a) cutting sped, (b) feed, and (c) depth of cut.[189]

bearing steel with mixed ceramic inserts at different cutting conditions and tool geometry. Results show considerable improvement from 8 to 15% in the surface finish with the use of solid lubricants as compared to dry hard turning. Experimental results of their study showed the superiority of the molybdenum disulfide hard turning over the graphite-assisted hard turning. Surface roughness value went down initially with increase in speed and then started increasing with the further increase in cutting speed. This might be due to increase in tool wear rate at higher speeds. Surface roughness was found to be increasing with increase in feed. Surface finish first improved with increase in effective rake angle, but, on further increasing rake angle, it deteriorated due to increase in forces. Increase in nose radius also improved surface finish. Their work emphasizes that the proper selection of the solid lubricants along with cutting conditions and tool geometry is essential for achieving the overall improvement in hard turning process. The solid lubricant-assisted hard turning may become a viable alternative to the dry and wet hard turning process.

Hard turning is mostly performed without coolant, but if lubrication and some cooling methods are used, it may prove beneficial for the process. It reduces abrasion and adhesion, thereby reducing rate of flank wear propagation which is the major cause of increase in workpiece temperature and formation of white layer at machined surface.[37] From the literature review, it has been observed that researchers have made a great effort to obtain eco-friendly and user-friendly alternatives to conventional cutting fluids using vegetable-based oils, solid lubricants, compressed air, and MQL technique. However, very few studies are reported on using coolants in hard turning while most works do without it. Moreover, there is disagreement between researchers about the use of coolants in hard turning so the area is still open for further investigations. New developments in the cutting tool materials and coating technology has brought some advantageous conditions for application of MQL in the machining of hardened steels. However, the major factor in this technology is to ensure cutting fluid accessing cutting zone and confirm minimal quantity of lubricant.

1.3.6 Optimization Studies in Machining of Hardened Steel

Finish machining of hardened steels by turning is receiving increasing attention especially in automotive and bearing industries. HPT offers a number of potential benefits over traditional grinding and has, nonetheless, several unique characteristics, as segmented chip formation and microstructural alterations at the machined surfaces, fundamentally different from conventional turning.[194] Moreover, HPT reduces processing time, the production cost, and setup time,

besides an adequate surface roughness. Furthermore, many of its process responses are predictable such as tool wear, tool life, quality of machined surface, and amount of material removed.[195]

One of the major problems in industries is to cut down the manufacturing cost without sacrificing the quality of the components as economy of machining operation plays a key role in competitiveness in the market. As a consequence of this, in any process planning of metal parts, modern sophisticated machine tools need optimization procedure for the selection of process parameters. Optimization in turning means determination of the optimal set of machining parameters such as cutting speed, feed rate, and depth of cut to satisfy the objectives within the operational constraints. These objectives may be desired roughness of the machined surface and RSs, minimum white layer thickness and dimensional deviation, minimum tool wear and maximum metal removal rate or any weighted combination of both.[196] However, in practice, parameter settings that are optimal for one defined objective function may not be particularly suited for another objective function. This results in an important optimization problem to define parameter settings given multiple. Therefore, the simultaneous consideration of multiple objectives, especially conflicting objectives with their different relative priorities need to be considered for efficient hard turning operation.[197]

Optimal selection of process parameters by formulating and solving as a multi-objective optimization problem has been analyzed with varying degree of generality by many researchers. A group of researchers analyzed multi-objective optimization problem in hard turning by combining neural network modeling with optimization methods. Effect of process parameters on the machining responses such as tool wear, surface integrity in terms of surface roughness, RSs, and microstructure alterations can be better understood by neural network modeling. Usually, evolutionary algorithms (EAs) such genetic algorithms (GAs) and particle swarm optimization (PSO) are preferred for optimization of neural network based models.[197,198] These days, with the availability and affordability of high-speed computers, optimization techniques based on EAs are becoming more popular in engineering design and manufacturing activities.[196]

Karpat and Ozel[197] presented multi-objective optimization of hard turning process using CBN tool. Objective of their study was to obtain optimum process parameters to limit tool wear and surface roughness and maximize the productivity while hard turning. A neural network model was developed by them to predict the surface roughness and tool wear. PSO algorithm was used to obtain optimum cutting speed, feed rate, and tool edge geometry. Results of their analysis concluded that the combined neural network and PSO system was capable of generating optimal process parameters and could be used successfully in the multi-objective optimization of hard turning. Tandon *et al.*[198] optimized machining parameters in end milling to minimize machining time by combining a feed forward neural network force model with PSO.

Pytlak[199] attempted multi-objective optimization of hard finish turning of 18HGT steel using CBN tool with wiper geometry. The cutting parameters such as cutting speed, feed and depth of cut were optimized to obtain minimum unit production cost, production time per unit and resultant cutting force. The multi-objective optimization was carried out by them with the application of traditional method of weights, as well as the modified distance method (MDM) based on evolutionary computations (EC). The authors claimed that the multi-objective optimization based on EC (the MDM method) quickly and effectively finds Pareto set of solutions. However, they pointed out that the large numbers of solutions obtained in the Pareto set seem to be one of the greatest disadvantages and the selection of a single solution from the set requires additional information about the decision maker's preferences. Finally, from the optimal sets obtained of Pareto solutions, the best solution was selected with the aid of the hierarchical optimization method. The results of their multi-objective optimization study show that in order to assure low unit production cost, low values of cutting force and to comply with constraints related to the surface roughness, the cutting speed of 119 m min^{-1} and the values of feed and depth of the cut of 0.3 mm rev^{-1} and 0.1 mm, respectively, to be adopted during hard finish turning of 18HGT steel using CBN tool with wiper geometry.

Ganesan *et al.*[200] during their investigation on continuous profile multi-pass machining obtained optimal machining parameters for minimum production time subject to a set of practical constraints such as cutting force, power and dimensional accuracy, and surface finish. They formulated process model using nontraditional algorithms such as GA and PSO. Their study shows that PSO produced better results in comparison to GA. Attempts also have been made to solve multi-objective optimization problem in turning by using multi-objective differential evolution (MODE) algorithm and nondominated sorting genetic algorithm (NSGA-II).[196] MODE and NSGA-II are the improved population-based search and optimization techniques which are widely used by the researchers in engineering design application.[201]

Yang and Natarajan[196] presented the optimum set of input parameters namely cutting speed, feed rate, and depth of cut during a single-pass turning of EN24 steel with tungsten carbide tool. Objective of their study was to minimize the tool wear and maximize the metal removal rate subjected to the temperature and surface roughness constraints. The regression models, developed for tool wear, temperature, and surface roughness were used for the problem formulation. In their study, the nondominated solution set which was obtained from MODE was compared with NSGA-II using the performance metrics and reported. They found 100 wider solutions with the NSGA-II algorithm. As against, the MODE algorithm was observed to be having lack of solution diversion. However, they observed that the MODE algorithm performed better than NSGA-II with fewer values of algorithm effort (AE) and optimizer overhead (OO).

Paiva *et al.*[202] presented a novel multi-objective optimization method based on the concept of multivariate mean square error (MMSE) approach in turning of hardened AISI 52100 steel. This novel approach combines principal component analysis (PCA) with RSM focusing a multidimensional nominal-the-best (NBT) problem. The results and confirmation runs of their study show that the MMSE approach outperforms the desirability method applied in the optimization of the 52100 hard turning. However, the solutions obtained

from MMSE and RSM-desirability function approach were not very different in practical terms.

Over the years, many researchers have developed algorithms based on classical techniques such as least-squares (LS) and many others for the domain engineering applications.[11] A desirability function approach presented by Derringer and Suich[203] is one of them, which is employed for simultaneous optimization of response variables. When using this approach, each response variable is transformed into desirability function (D_i), which is a dimensionless number ($0 \leq D_i \geq 1$). '0' indicates the completely undesirable level of response. '1' indicates the completely acceptable level of response. With this approach, optimization of several response variables (R_i) are converted into optimization of single desirability function, 'D_m' which is the geometric mean of the desirability of several responses and has to be optimized with respect to process variables.[11,40]

Chinchanikar and Choudhury[11] obtained the optimum values of process variables (cutting speed, feed, and depth of cut) in order to get the better tool life, minimum cutting forces and minimum surface roughness during turning of hardened AISI 4340 steel at two different levels of hardness, namely, 35 and 45 HRC, when using multilayer CVD-coated TiCN/Al_2O_3/TiN carbide tool. Optimization study was carried out by them in two different modules; the first module generates a set of solutions which ensures minimum surface roughness and cutting forces. The second module selects a most optimum cutting condition among the solutions generated in module 1, which gives better tool life. They found that lower feed and depth of cut values of 0.15 mm rev^{-1} and 1 mm and cutting speed of 235 and 144 m min^{-1}, while turning, namely, 35 and 45 HRC workpiece using CVD-applied multilayer-coated carbide tool, are the optimum cutting parameters which ensures minimum cutting forces, minimum surface roughness and better tool life. In another study, Chinchanikar and Choudhury[40] obtained a cutting speed of 176 m min^{-1} and lower values of feed and depth of cut of 0.15 mm rev^{-1} and 1 mm is the optimum cutting condition which ensures minimum cutting forces, minimum surface roughness and better tool life when using PVD-coated single-layer TiAlN carbide tool during turning of AISI 4340 steel (35 HRC).

Aouici *et al.*[41] presented the optimal manufacturing conditions subjected to minimum values of the cutting forces and surface roughness during the hard turning of hot work steel (AISI H11) using CBN 7020 tool. They obtained optimized surface roughness in the range of 0.327–0.34 μm and cutting force components in the axial direction of 33.91–38.78 N, radial direction in the range of 90.12–102.38 N and tangential direction of 63.85–77.57 N for the cutting speed in the range of 189–197 m min^{-1} and at lower values of feed and depth of cut of 0.08 mm rev^{-1} and 0.15 mm, respectively. In another study, tool geometry combination in terms of nose radius, rake and approach angles was optimized to obtain minimum surface roughness.[204] In this study, optimum cutting insert geometries obtained are found to be tool nose radius of 0.4 mm, approach angle of 60° and rake angle of −3° and the optimized surface roughness parameter obtained of 1.829 4 μm.

Sufficient efforts have been made by the researchers to obtain optimal cutting parameters for optimizing the various responses during machining of hardened steels. However, in most of the studies cutting parameters were optimized considering surface roughness or cutting forces or both. The tool life, being an important aspect was not considered while optimizing the cutting conditions. Moreover, most of the studies available are applicable for CBN/ceramic tools. Very few attempts have been made by the researchers by using coated carbide tools in the machining of hardened steel. On the other hand, process responses which are very important in finish machining of hardened steel such as RSs, white layer effect, and dimensional variation are rarely considered while optimizing the cutting conditions and further studies are required in this domain using coated carbide tools.

1.4.1 Introduction

Gear is a modified form of a wheel. It is the second most important machinery element after the wheel. Gears can be classified according to following three criteria: (1) according to configuration: external and internal gears; (2) according to axes of transmission; (a) for transmission of power and/or motion between two parallel shafts: straight toothed spur gear, single helical, and double helical or herringbone gears, (b) for transmission of power and/or motion between two intersecting shafts: bevel gears (straight-tooth, spiral-tooth, zero-bevel, crown, and miter type), (c) for transmission of power and/or motion between nonparallel and nonintersecting shafts: spiral gears, hypoid gears, worm and worm wheel; and (3) according to pattern of rotation; (a) rotation to rotation, (b) rotation to translation and vice-versa. Gear drives are preferred for various power and motion transmission purposes due to their compactness and higher reliability. Annually more than 10 billion gears are manufactured and consumed in various applications in almost all the industries.[1] Some worth mentioning are:

- automobile (i.e., cars, trucks, tractor, motor-cycles, scooter, etc.),
- transportation (i.e., buses, train, subways, mine cars, etc.),
- aerospace (i.e., high speed aircraft engine),
- marine (i.e., high power high speed marine engine, navy fighting ships),
- control systems (i.e., gun, helicopter, tanks, radars application),
- earth moving vehicles,
- different types of machine tools,
- oil and gas industry (i.e., oil platforms, pumping station, drilling sites, refineries and power stations),
- industrial application (i.e., power transmission; construction equipment, agriculture machinery, equipment and machines used in mining, cement manufacturing, steel manufacturing, food processing, sugar manufacturing and other industries),
- home appliances (i.e., washing machine, food mixtures, fans, etc.), and
- mechanisms, toys and gadgets.

Despite of excellent market position there are some increasing requirements for further improvement in gear drives, namely: (1) improvement of power density and transmitted power; (2) reduction in running noise, toxic emission, and price; (3) increase in reliability and service life time; (4) easy disposal and material recycling of the used gears; and (5) integration of electronic systems such as data acquisition, logical control, integrated safety system.[2] Gear failure is an unpredictable and catastrophic phenomenon and there are various reasons responsible for different types of gear failures. Gear failure can be categorized into two types, i.e., failure related to lubrication and failure related to non-lubrication. **Table 1** presents different modes of the gear failures.

Table 1 Different modes of gear failures[3]

Failures related to lubrication		*Failures related to non-lubrication*		
Overload	*Bending fatigue*	*Hertzian fatigue*	*Wear*	*Scuffing*
1. Brittle fracture 2. Ductile fracture 3. Plastics deformation ● Cold flow ● Hot flow ● Indentation ● Rippling ● Ridging ● Bending	1. Low cycle fatigue (<1000 cycles to failure) 2. High cycle fatigue (>1000 cycles to failure)	1. Pitting ● Initial ● Superficial ● Destructive ● Spalling 2. Micro-pitting ● Frosting ● Gray stanning ● Peeling 3. Sub-case fatigue	1. Adhesion 2. Abrasion 3. Corrosion 4. Fretting	1. Scoring 2. Galling 3. Seizing 4. Welding

Table 2 Surface quality related parameters of a gear which affect its various performance aspects

To improve service life and operating performance	*To reduce noise and transmission error*
Reduce parameters of surface roughness (i.e., R_a, R_{max} and R_z) on the tooth flank	
Improve wear characteristics by reducing sliding coefficient of friction and friction forces	Eliminate microgeometry errors
Improve the microstructure	Remove sharp corners from gear tooth
Increase the fatigue life	Increase the wear resistance

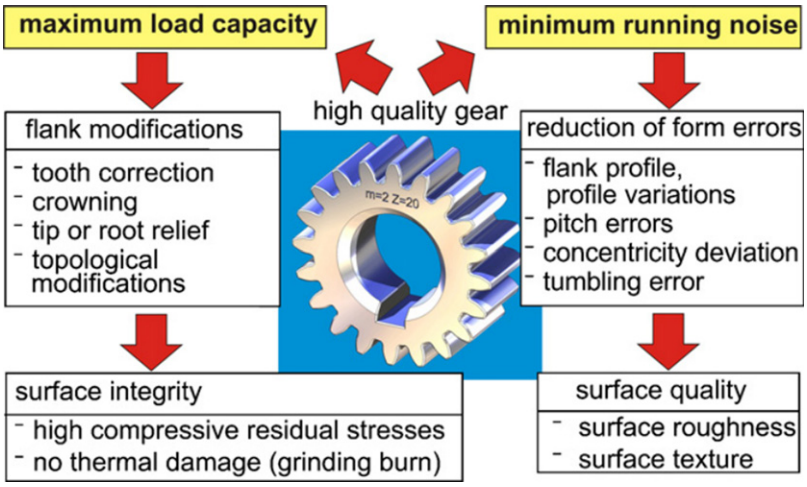

Figure 1 Different goals of a gear finishing process. Reprinted with permission from Ref. [2]. Elsevier © 2008.

Prevention of premature failures of the gears requires careful consideration of interrelationship between following factors: (1) gear tooth geometry; (2) gear tooth motion; (3) gear tooth forces (static and dynamic); (4) gear material; (5) lubricant characteristics (physical and chemical); (6) operating environment; and (7) tooth surface quality. Among these, first six factors are related to the design and use environment of the gears, whereas the last factor depends on the surface quality of the gears. Surface quality of gears is evaluated in terms of surface finish, microgeometry, i.e., form errors, and wear characteristics. Poor surface quality, i.e., errors in microgeometry and poor surface finish of gear tooth are the major source of noise generation particularly at higher running speed, errors in motion transfer, excessive wear, backlash between the meshing gear pairs and large dynamic forces during power transmission.[3] All these factors reduce the power to be transmitted and incorrect velocity ratios. Microgeometry of gear teeth is the most dominant factor among the causes of gear noise generation, contributing approximately 20% to it. Other contributing factors include: gear teeth surface finish (10%), accuracy of assembly (15%), gear material, gear design, lubrication of gears, bearing, motor and variation of load, driving condition, shaft alignment, wear, surface damage and gearbox configuration.[4] **Table 2** presents the surface quality related parameters of a gear that affect its service life, operating performance, transmission errors, and noise reduction.[5] It can be concluded from this table that gear tooth surface should have very good surface quality for smooth, noiseless power and/or motion transmission and to improve the load carrying capacity.

Increasing demands for different types of gears have motivated researcher to investigate and improve their surface quality using different conventional and advanced gear finishing processes. Surface quality of the gear tooth can be significantly enhanced by using a proper gear finishing process. **Figure 1** presents the different goals of a gear finishing process. These goals can be classified in two major categories namely: (1) improvement in surface quality and reduction in errors in microgeometry (i.e., form errors) to minimize the running noise; and (2) flank medications and improving surface integrity to maximize load capacity.[4,6]

1.4.2 Microgeometry of Gears

Microgeometry of gears is very important due to its effect on service life, low noise emission, high load carrying capability and transmission efficiency of the gears. Errors in microgeometry has two components form errors and location errors. **Figure 2** illustrates different components of errors in microgeometry of a gear and their effects on various performance aspects of a gear.

Form errors has two components, which are namely error in profile and lead of a gear. Total profile error or deviation (F_a) defines the form and location of the involute profile and it is evaluated perpendicular to the involute profile from root

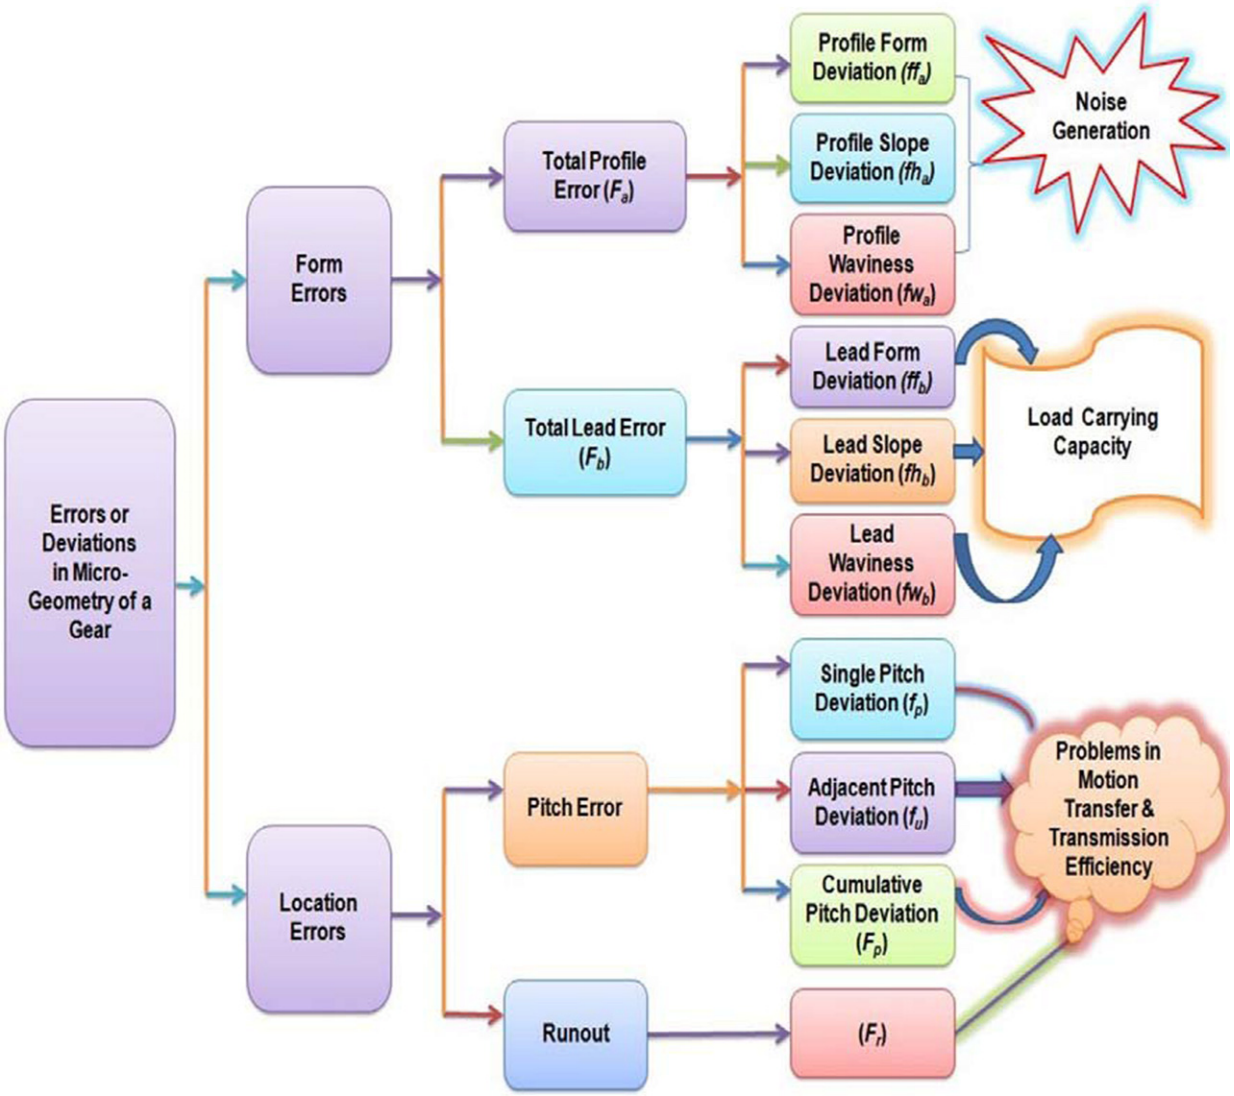

Figure 2 Different components of errors or deviations in microgeometry of a gear and their effects.

to tip. It determines noise generation characteristics of a gear. Total profile error is sum of two components: (1) profile form deviation (ff_a): it is a difference between nominal involute form to actual involute form; and (2) profile angle deviation (fh_a): it is a difference between nominal involute angle to actual involute angle. Total lead error or deviation (F_b) defines the form and location of the tooth flank and it is evaluated at the middle of the tooth height along the tooth width. It determines load carrying capacity of gear. Total lead error is sum of two components: (1) lead form deviation (ff_b): it is a difference between nominal lead form line to actual lead form line; and (2) lead angle deviation (fh_b): it is a difference between nominal helix angle to actual helix angle. Location errors are associated with pitch and runout of gear. These errors affect motion transfer characteristics and transmission efficiency of a gear. The characteristics of pitch error or deviation are evaluated at the middle of the tooth height along the pitch circle and describe the middle location of all right and left flanks with respect to each other. It has three components: (1) single pitch deviation (f_p) is the difference between the actual and nominal angular positions of two respective flanks on the two consecutive gear teeth; (2) adjacent pitch deviation or pitch-to-pitch deviation (f_u) is the maximum difference between the angular deviations of any two adjacent right flanks or left flanks; and (3) cumulative pitch deviation or index error (F_p) is the difference between the summation of the theoretical values of pitches and summation of the actual values of the pitches over all the teeth of a gear. Runout error (F_r) is the maximum difference between the actual radial positions of all teeth measured with respect to their nominal radial position. It describes the radial location of all teeth with respect to the pitch circle and is evaluated at the middle of the tooth height along the pitch circle.

1.4.3 Materials, Manufacturing and Quality of Gears

Materials used for manufacturing the gears depend on various types of selection criteria such as application, shape, size, service, peripheral speed, required accuracy, type of manufacturing process, load carrying capacity, wear resistance, allowable stress, etc. Following are some guidelines which can be used for selecting a gear material[6]:

- Cast iron is a popular gear material due to its good wear resistance, good lubrication, relatively good machinability, and ease of producing complicated shapes by casting it. It is used for manufacturing large gears of complicated shapes.
- Steel is sufficiently strong and possess good resistance to abrasive wear of the gears.
- Cast steel is used where stress on gear is higher and gear geometry is difficult to fabricate.
- Plain carbon steels are used for manufacturing the gears for industrial applications due to combination of their high toughness and high strength.
- Alloy steels are used where higher gear tooth strength and lower wear of gear flank surface are desired.
- Aluminum is used for manufacturing light-weight gears.
- Nonmetallic materials are used for manufacturing gears for noiseless operation at higher peripheral speeds.

Conventional gear manufacturing processes are classified in two major categories, i.e., generative type and non-generative type gear manufacturing. Table 3 presents different gear manufacturing processes of each category. Conventional manufacturing processes of gears do not yield acceptable surface quality thus failing to meet the requirements of the end users. For example, gears manufactured by hobbing and shaping have tool marks and scallops on the gear tooth surface. Post-manufacturing heat treatment to improve gear hardness also adversely affects the surface quality of the gears. Therefore, a proper gear finishing process becomes necessary to ensure better surface quality of the gear teeth to eliminate the imperfections/discontinuities occurred during gear manufacturing and heat treatment processes such as small pits, burrs, scratches, cut marks, etc. and to attain the required surface quality.

There are different international standards for expressing gear quality. Some worth mentioning standards are Deutsches Institut fur Normung (DIN) of Germany, American Gear Manufacturing Association (AGMA) of USA, Japanese International Standard (JIS) of Japan, Korean Standard (KS) of South Korea, Italian Organization of Standardization (UNI) of Italy and British Standards Society (BSS) of UK. Two most commonly used standards in the industries to define the gear quality are AGMA 3900 and DIN 3963.[1,6] Table 4 presents typical applications of the gears of different quality expressed on both AGMA 3900 and DIN 3963 standards.

Table 3 Different types of gear manufacturing processes

Gear manufacturing processes		
Conventional gear manufacturing processes		*Special and advanced gear manufacturing processes*
Generative type	*Non-generative type*	
1. Hobbing 2. Shaping 3. Milling 4. Broaching 5. Bevel gear generating	1. Casting 2. Powder metallurgy 3. Forming ● Stamping ● Extrusion ● Forging ● Hot Embossing	1. Gleason method 2. Template gear cutting 3. EDM and micro-EDM (μ-EDM) 4. WEDM and micro-WEDM (μ-WEDM)

Table 4 Typical applications of gears according to their quality[1]

Designation	*Gear quality*		*Typical applications*
	AGMA 3900	*DIN 3963*	
AA: Ultra-high accuracy	14 or 15	2 or 3	Military navigation, precision, instruments, computer, and equipment
A: High accuracy	12 or 13	4 or 5	Instruments, aircraft engines, turbines, professional cameras,
B: Medium-high accuracy	10–11	6–7	Precision machine-tool speed drives, automotive transmissions, and high-speed machinery
C: Medium accuracy	8–9	8–9	
D: Low accuracy	6 or 7	10 or 11	Appliances, hand tools, pumps, Commercial clocks, farm machines,
E: Very low accuracy	4 or 5	12	fishing reels, hoists, and slow–speed machinery

1.4.4 Gear Finishing Processes

Different gear finishing processes can be grouped into following two categories (1) conventional gear finishing processes such as gear grinding, gear lapping, gear honing, gear shaving, and gear burnishing; and (2) unconventional or advanced gear finishing processes such as abrasive flow machining (AFM), electrochemical finishing (ECF), electrochemical honing (ECH), electrochemical grinding (ECG), hybrid finishing processes, etc. The selection of an appropriate gear finishing process depends on various factors such as gear material hardness, productivity, need, and type of finishing. **Table 5** summarizes applicability of four conventional finishing processes for gears.

1.4.4.1 Gear Grinding

Gear grinding process uses a properly formed and dressed grinding wheel, which finishes the gear teeth flanks by abrading action of the fine abrasives. It is performed during the manufacturing cycle of gears to achieve certain desired characteristics in the finished gears. Heat treatment processes have tendency to thermally distort the gears thus deteriorating their tooth accuracy. This necessitates hard finishing of the gear teeth. Grinding is an effective means of finishing the heat-treated high-hardness steels (having hardness 40 HRC and above). Therefore, grinding is used to correct the thermal distortions and to improve the surface finish and microgeometry of the gears. Generally, it removes very small of material from precut gears to make gear teeth more accurate for various engineering applications.[8]

Wear of the grinding wheel is an important aspect. As the sharp cutting edges of the abrasives wear out, the cutting forces on these abrasive grains increase until either the abrasive grains fracture thus revealing new sharp cutting edges or the abrasive grains are pulled out from the grinding wheel thus exposing new abrasive grains. Essentially, if the process were perfect then the grinding wheel would be self-sharpening. Even though grinding wheel wear is an accepted phenomenon, but very high grinding wheel wear rate will not only result in wheel replacement but also in other nonproductive preparatory operations for a grinding wheel such as trueing, dressing, and profiling. Grinding or G-ratio (ratio of volume of the work material removed to volume of the grinding wheel wear) is a measure of grinding efficiency. Values of G-ratio can range from less than one to several hundred, depending on these variables.[8]

Another distinguishing feature of the grinding process is the fractional amount of time the abrasive grain is actually generating the chips in comparison with the total time this grain is in contact with the workpiece material. Three distinct phenomena have been recognized to occur as the abrasive grain comes in contact with and leaves contact with the work surface. They are rubbing, plowing, and cutting. The actual cutting or chip formation may be occurring for only about 30% of the time the abrasive grains and the workpiece are in contact. The force at which the transition from rubbing and plowing to cutting occurs is called the *threshold force*. When the machine holding the grinding wheel and the workpiece, exert a force in excess of this threshold force, grinding process will happen. There are essentially two techniques for grinding the gears: form grinding and generating type grinding.[8,9] The parameters affecting the grinding process and their types with advantages and limitations are presented in the following sections.

1.4.4.1.1 Types of gear grinding

Gear grinding can be classified as form or non-generative grinding or generative grinding according to shape of the grinding wheel used. **Table 6** presents different versions of the gear grinding process. **Figure 3** depicts working principle of form and generative grinding of a gear.

1.4.4.1.2 Form or non-generative grinding

Form grinding of gears uses a specially manufactured abrasive grinding wheel whose circumference is profiled to have involute form by a diamond dressing tool as shown in **Figure 3**. This special form of the wheel fits in the space between two consecutive teeth of a gear. When this wheel is given rotary motion then flank surfaces and root of two adjacent gear teeth are ground. Indexing motion given the workpiece gear ensures grinding of the all the teeth of the workpiece gear. According to abrasive material of the grinding wheel, it can be further classified in two categories, i.e.,

Table 5 Applicability of different conventional finishing processes for gears[7]

Gear grinding can be used when	*Gear shaving can be used when*	*Gear lapping can be used when*	*Gear honing can be used when*
• More material is to be removed • For gears having more pressure angle • For gears having large face width and module • For gears requiring higher accuracy in profile and lead • Presence of thermal distortions • For mixed volume and frequent changeovers	• For finishing high volume of small gears • For heat treated gears having poor accuracy in profile and lead • Minor thermal distortions are present • For mixed volume and frequent changeovers	• For finishing the mating gears in a pair using suitable lapping medium • Minute corrections in involute profile, helix angle, runout or index error are desired • Dimensionally accurate gear with high tolerance is required • Excellent surface quality is required	• Less material is to be removed • For gears having high contact ratio, low pressure angle, and long addendum • Removing nicks and burrs • Minor corrections in gear microgeometry are required • Resistance to wear and pitting is to be improved • High surface finish

ceramic form grinding which uses ceramic as abrasive. Most commonly used ceramics are aluminum oxide (Al_2O_3) and silicon carbide (SiC). It is used to grind the harder material normally (60 HRC or above), and borazon form grinding which uses cubic boron nitride (CBN) as abrasives. Figure 4 depicts different versions of form grinding of a spur gear using single form grinding wheel (Figure 4(a)), multiple form grinding wheels (Figure 4(b)), and straddle grinding wheel (Figure 4(c)).One of the primary advantages of form grinding of gears is that various simple and compound forms of the gear teeth can be ground using manufacturing the specially designed grinding wheel whose form has to be changed with change in module, pressure angle, and even number of gear teeth. Form grinding can be used for finishing spur gears, single helical gears, straight bevel gears, worm and worm wheel, and internal gears.[4,8–9]

Table 6 Different versions of the gear grinding process[1]

Gear grinding	
Form grinding	*Generative grinding*
1. Ceramic form grinding 2. Borazon form grinding	1. Threaded wheel 2. Cup-shaped wheel 3. Dish-shaped wheel (Saucer process) 4. Rack-tooth worm wheel 5. Generative grinding of bevel gears

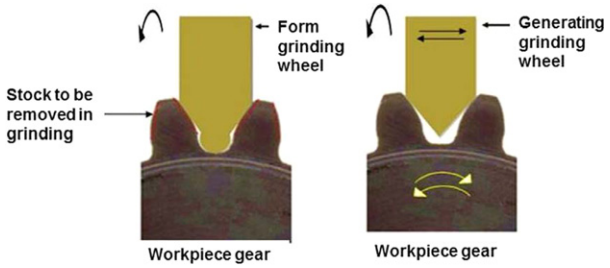

Figure 3 Comparison of form grinding and generative grinding of a gear.[1]

Estimation of grinding time in form grinding: the time required to grind a gear depends on three major factors: (1) time for rough grinding, (2) time for finish grinding, and (3) time to dress the grinding wheel. In addition, there are some handling times. The time required for rough or finish grinding may be calculated by following equation.

$$\text{Grinding time (minutes)} = \frac{\text{No. of gear teeth} \times \text{Number of cuts}}{\text{cycles per minute}}$$

Number of cuts is the ratio of amount of the gear material available for grinding and amount of material ground per cut.

1.4.4.1.3 Generative grinding

Generating grinding of gear is performed using a grinding wheel (or wheels) whose flanks imitate a toothed rack which rolls over the reference circle of the gear forming the involute flank. The grinding wheel performs three motion rotation about its own axis, tangential to gear pitch circle which shifts and turns and axial along the tooth width. It is commonly used for gear with module 0.5–10 mm. Generative grinding

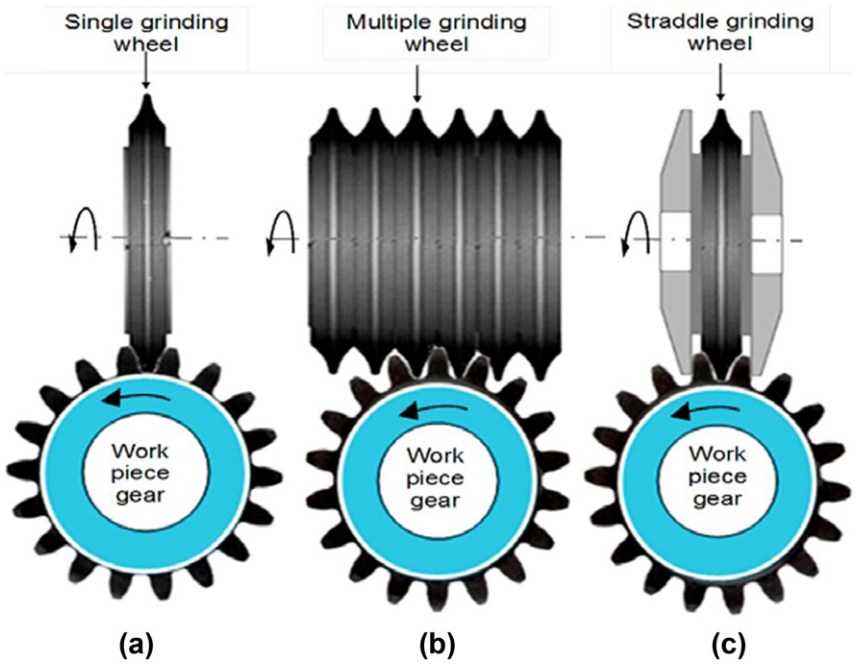

Figure 4 Different versions of form grinding of a spur gear using (a) single form grinding wheel; (b) multiple form grinding wheels; and (c) straddle grinding wheel.[3]

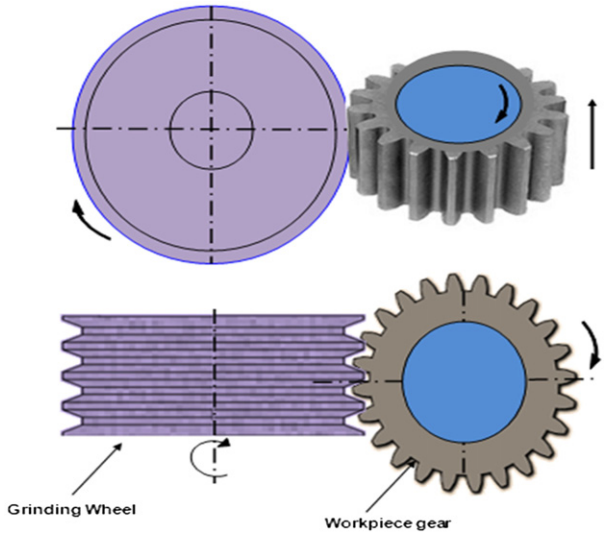

Figure 5 Schematic of generative grinding of a gear using threaded grinding wheel.[4]

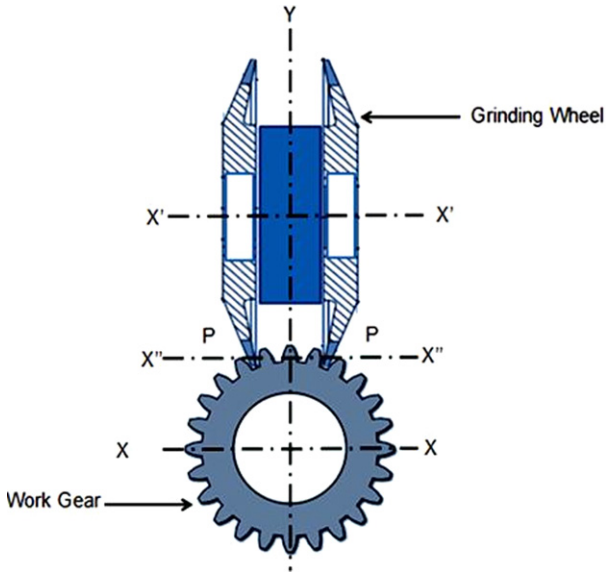

Figure 6 Schematic of generative grinding of a gear using cup-shaped grinding wheel.

has following four versions according to type of the grinding wheel used: threaded wheel, cup-shaped wheel, dish-shaped (saucer) wheel, and rack-tooth worm wheel.[8–10] These are described in following sections.

1.4.4.1.3.1 Generative grinding using threaded wheel

Figure 5 depicts schematic of generative grinding using a threaded grinding wheel. The finishing mechanism of this process is similar to gear hobbing with only difference that a threaded grinding wheel is used in place of the hob cutter. The workpiece gear mounted is on an arbor. Ratio of speed of workpiece gear and grinding wheel is equal to ratio of number of teeth on the workpiece gear and number of thread start on the wheel. Generally, operating speed of the threaded grinding wheel is chosen as 25 m s^{-1}. Gear quality produced by this process depends on the indexing mechanism. This process can be used for generative grinding of external spur or helical gears.

1.4.4.1.3.2 Generative grinding using cup-shaped wheel

In this process the gear is rolled against a cup-shaped grinding wheel, the sides of which are beveled at an angle equal to the pressure angle of the gear teeth. The grinding wheel moves in a straight line along the gear tooth width grinding the flank surfaces of two teeth as depicted in **Figure 6**. Soft grinding wheel without coolant is used to minimize grinding wheel wear. Spur and helical gears up to 457 mm (or 18″) pitch diameter can be ground by this process.

1.4.4.1.3.3 Generative grinding using dish-shaped wheel

This process uses two dish-shaped grinding wheels which are either inclined at 15°–20° with each other or parallel to each other and are mounted on a simulated rack as shown in **Figure 7**. This process is used when higher productivity, exact profile and longitudinal modification are required. Lack of uniform transition between gear tooth flank and root is the main limitation of this process.

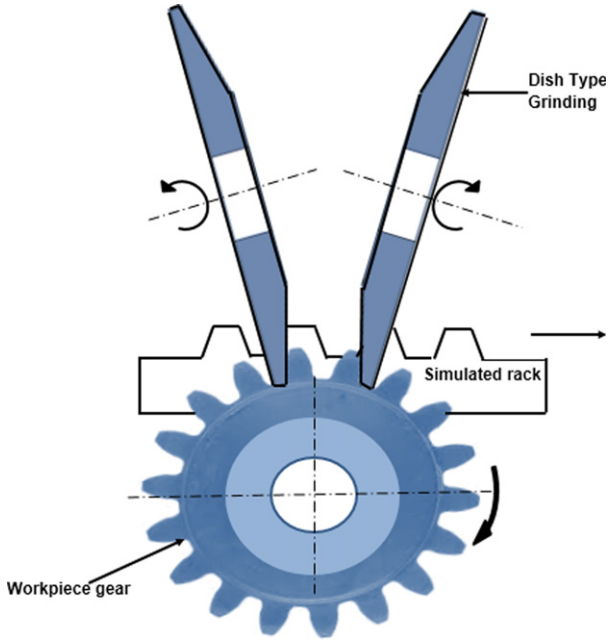

Figure 7 Schematic of generative grinding of a gear using dish-shaped grinding wheel.[3]

1.4.4.1.3.4 Generative grinding using rack-tooth worm wheel

Figure 8 shows schematic of working of this process in which workpiece is mounted on a vertical arbor or in a fixture that fits between the centers of the machine. The grinding wheel is dressed to have shape of a conventional or CBN-plated rack-tooth worm. For grinding the helical gears, the workpiece holding slide of the machine is set at an angle equal to the helix angle of the gear. The workpiece gear is rotated by a motor that is synchronized with motor of the grinding wheel. Al_2O_3 or SiC as abrasive can be used to prevent burning of

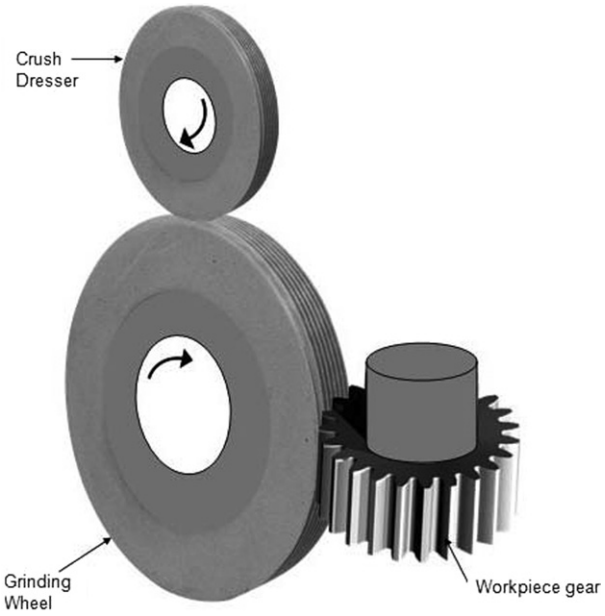

Figure 8 Schematic of generative grinding of a gear using a rack-tooth worm wheel.[3]

the hardened gear teeth. But, this result in more breakdowns of the grinding wheel and loss of correct tooth profile. Grinding accuracy mainly depends on careful dressing of the wheel. Generally, special diamond wheel are used for dressing the grinding wheel. Gear quality mainly depends on profile of the rack-tooth on the grinding wheel, accuracy of dressing operation, and accuracy of diamond wheel used for dressing.

1.4.4.1.4 Selection of parameters

A grinding wheel is basically a precision tool composed of abrasive grains held together by a bonding material. The abrasive grains provide the wheel with its cutting ability which helps in finishing the material to the required dimensional accuracy and surface finish. Material of grinding wheels becomes more important in case of gear grinding due to need of high precision in terms of surface finish and material removal rate (MRR). Al_2O_3, SiC, and CBN are the most commonly used abrasives. Synthesis of these abrasives allows accurate control of their form and physical characteristics.[10] Grinding wheel speed is an important parameter during gear grinding. Increase in grinding wheel speed keeping other parameters constant, reduces grinding forces and roughness, and increases life of redressed grinding wheel and specific energy consumption. **Table 7** presents the details of abrasives, grinding wheel speed, and depth of cut for different gear materials.

Grinding fluid is also considered as one of the important parameter of the process. It removes heat and chips and helps in improving grinding wheel life and enhancing the gear tooth finish. It minimizes possibilities of burning of gear surfaces. Generally, mineral base sulfochlorinated or sulfurized oils are used. Plain soluble-oil emulsions and chemical solutions have also been reported to give satisfactory performance for many gear grinding applications.[4,8,9]

1.4.4.1.5 Advantages

- Gear grinding is fast and is able to provide micro-finish.
- Microgeometry errors can be correct by using a properly shaped grinding wheel.
- It is the only finishing process other than gear honing which can finish hardened gears having hardness value more than 40 HRC.[4]
- It is only productive process for finishing the conical gears.

1.4.4.1.6 Limitations

- Grinding results in two major undesirable effects namely: grinding burns caused by high temperature damage surface integrity of the ground gears and can even sometime lead to gear failure through tooth breakage and transverse grind lines on the finished surface which cause noise and vibration of the gears.
- Additionally, ground gear teeth have detects such as fine cracks, thermal distortion, and uneven stress distribution over the gear tooth surface. To detect these defects magnetic particle inspection and macro-etching with dilute nitric acid inspection is required which is costly.[4,8–11]
- Gear grinding is unable to finish some special gears such as inner gears, multi-joint gears and large-size gears.[8–10]
- Abrasive grains lose their cutting ability due to wear necessitating redressing of grinding wheel.
- Control of rate of heat generation is required to eliminate cracking and burning of gear surface. This requires use of cutting fluid and frequent dressing of grinding wheel which increases cost of finishing.[8]
- Gear grinding is an expensive, complex process, and comparatively low productivity process due to smaller MRR.[4,8–11]

1.4.4.1.7 Applications

- Frequently used to finish tooth profile of different type of gears of hard material which have been heat treated to a high hardness level after gear cutting.
- Gear grinding can finish spur, helical and conical gears.

1.4.4.2 Gear Lapping

Lapping is a fine finishing process which uses a lapping medium between the workpiece and a lapping tool rotating at a very low speed (<80 rpm). Lapping medium is chalky paste consists of abrasive particles having mesh size from 300 to 900 (i.e., abrasive particle size ranging from 17 to 51 μm) and a carrier fluid. Al_2O_3, SiC, boron carbide, and diamond powder are the most commonly used abrasives. Oil, grease, water, and kerosene are the mostly commonly used carrier fluid. Lapping tool should be made of a material softer than the workpiece material. Fine grain cast iron is the most commonly used material for making the lapping tool. However, cloth (for lapping of hardened materials for metallographic examination), copper (for lapping of diamond), leather, wood, brass, steel, and glass can also be used.[12] Shape of the lapping tool should be complementary of the desired shape of workpiece. There are two versions of lapping process: free-abrasive

Table 7 Details of abrasives, grinding wheel speed, and depth of cut for different gear materials[3]

Gear material	*Abrasive*	*Grinding wheel speed (m min^{-1})*	*Depth of cut (mm/pass)*
Hardened and case hardened steel	Aluminum oxide (Al_2O_3)	1700–2000	0.038
Nitrided gears	Silicon carbide (SiC)	1700–2000	0.13–0.25
High speed steel	Cubic boron nitride (CBN)	3000	0.13–0.25

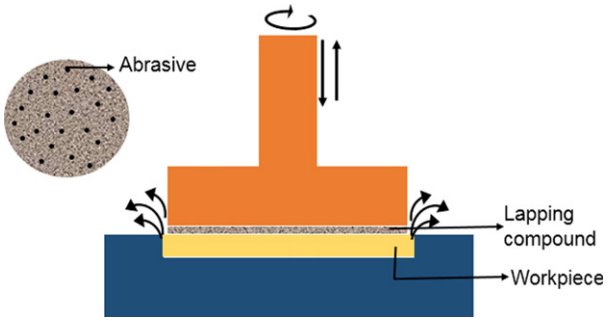

Figure 9 Schematic of a typical lapping process.

lapping and fixed-abrasive lapping.[1,4] In the **free-abrasive** lapping process, lapping medium is supplied between the lapping tool and workpiece. This is one of the most accurate finishing processes causing the least amount of damage to the workpiece due to use of a rigid lapping tool which can be tailored to suit a particular material. In the **fixed-abrasive** lapping process, abrasive particles are bonded to either to a film or to a paper. An abrasive lapping film has various abrasive particles bonded to a thin, uniform polyester film and is capable of producing a highly finished surface. SiC papers are much thicker than the films and can create rounded edges on the workpiece.[4]

Figure 9 depicts working of a typical lapping process in which a lapping tool is pressed against the workpiece and moved back and forth in a figure of eight or in other motion pattern over the workpiece surface. Abrasive particles remove the workpiece material and soft lapping tool is not worn away because abrasives get embedded in its surface instead of moving across it. Sometimes lapping can be performed by hand also but, for greater accuracy and consistency machines are preferred. Lapping of soft materials is difficult as abrasives may get embedded. Centerless lapping machine is used for lapping small cylindrical parts such as piston pins, ball-bearing races, etc. Two alternative cutting mechanisms have been suggested for material removal by lapping: (1) for a hard lapping tool, abrasive particles roll, knead, and slide between the lapping tool and workpiece removing material from both the surfaces; and (2) for a soft lapping tool, abrasive particles are embedded to the lapping tool surface and material removal action is similar to the grinding process.

Gear lapping finishes the mating gears simultaneously by running them together in the presence of the lapping medium which is supplied continuously under pressure. Smaller gear is used as the driver and the larger gear is as the driven member. The necessary tooth contact load is applied by driven gear for a very short duration. Since, gear lapping finishes the mating gears simultaneously therefore no stock allowance is provided on the mating gears for their finishing by lapping. Before starting lapping process both gears are ground by hand grinder to remove nicks and burrs. Lapping removes very small amount of material when the matting gears are rotated and their direction of rotation is changed thus imparting them a very fine finish, very high accuracy and achieving the desired contact pattern.[4,13] There are four important parameters namely lapping pressure, size of abrasive particles, concentration of abrasive in the lapping medium, and lapping speed that affect performance of the lapping process. Coarser abrasives are used for gears having a coarse pitch and finer grits are used for gears having a fine pitch. Generally, abrasives having 280 mesh size are used for lapping of the spiral bevel gears and 400 mesh size for lapping the hypoid gears. Reduction in noise level between the mating gears is criteria for successfully lapping.

1.4.4.2.1 Advantages

- Gear lapping improves wear properties of gear teeth.
- It is less damaging than grinding. It can even remove subsurface damage caused by sawing or grinding.
- Lapping improves flatness, parallelism and gives very surface finish.
- Lapping finishes products to a very high value of dimensional accuracy imparting tolerance values generally less than 2.5 μm over all the lapped surfaces.
- Lapping machines can be adjusted to lap gears with shaft angles of 0°–180°.
- Minor corrections in tooth bearing shape and position can be obtained through lapping.

1.4.4.2.2 Limitations

- Gear lapping corrects only minute errors in the involute profile, helix angle, tooth spacing, and concentricity produced during either manufacturing or heat treatment of the gears.
- It finishes the mating gears is a pair which cannot be interchanged with the members of any other similar pair.
- It is a very slow process and is costly as compared to other finishing methods. Material removal in lapping usually ranges from 0.003 to 0.03 mm but many reach up to 0.08–0.1 mm in certain cases.
- Low MRR and nonuniform lapping over tooth surface result poor correction in profile error.[14]

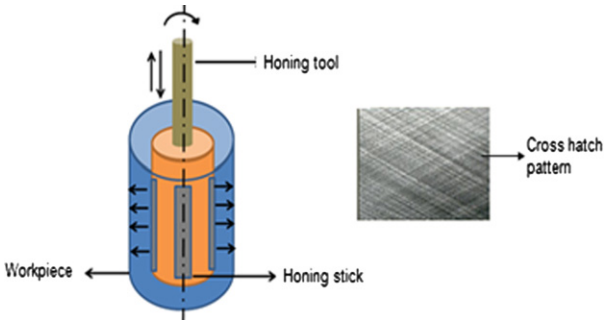

Figure 10 Working principle of finishing of internal cylinders by honing process.

1.4.4.2.3 Applications

- Gear lapping can finish spur, helical and conical gears but it is mainly used for finishing spiral bevel gears and hypoid gears.[15]
- Lapping is used to produce optical lenses, metallic bearing surfaces, gauges, and other parts requiring very good finishes and extreme accuracy.
- Lapping process is used to produce dimensionally accurate specimens to high tolerances (generally less than 2.5 μm uniformity).
- Lapping can also be used to finish bearings, guideways of lathe and planer, poppet and plug valves, silphon type seals, piston and cylinder walls, and relieving of the hot bearings.

1.4.4.3 Gear Honing

Finishing of internal cylinders by conventional honing process uses a honing tool having equally spaced bonded abrasive sticks protruding on its periphery as shown in **Figure 10**. They are held against the workpiece with a controlled light pressure usually exercised by small springs. The honing tool is provided a combination of rotatory and reciprocating motion and is regulated in such a way that a given point on the honing stick does not trace the same path repeatedly. This produces a fine surface finish having cross-hatched lay pattern.[16] Angle of this cross-hatch lay pattern depends on the ratio of rotary to reciprocating motion. This lay pattern helps in retaining the lubricating oil in the lengthwise and circumferential direction of the workpiece, in improving frictional resistance and uniformly distributing the load. Surface finish depends on (1) type and size of abrasives used; (2) honing pressure applied; (3) rotational speed; (4) speed of reciprocation; and (5) length and position of stroke. A cutting fluid is used to remove chips and keep temperature low. There are different versions of honing process for finishing different type of product as mentioned in **Table 8**.

Gear honing is hardened gear finishing process which also improves their noise characteristics. It was used for the first time in 1970s to remove transportation damages on hardened tooth flanks. It uses an abrasive-impregnated helical gear-shaped tool which is run in tight mesh with the hardened gear in a cross-axes relationship. The workpiece gear is driven by the honing tool at high speeds (up to 1000 sfpm) while being traversed back and forth across the honing tool in a path parallel to the axis of the workpiece gear to ensure finishing of its entire face width. The workpiece gear is driven in both directions during the honing cycle. Conventional honing oil used as a coolant, lubricant, and a medium to flush away the wear debris. Amount of material removed from the workpiece gear ranges from 0.013 to 0.05 mm. Honing gives higher dimensional accuracy, fine finish of gear flank surfaces with cross-hatch lay pattern, minor corrections in tooth irregularities, and improved noise and wear characteristics of the hardened gears.[18–21]

The honing gear material must have the capability to yield the gear profile as well as hold its shape under pressure. Generally, it is a mixture of plastic resins (polyurethane and epoxy matrix) and abrasive grains and is formed in a precision mold. **Table 9** presents commonly used abrasives for different gear materials. The abrasives are bonded together by vitrified, resinoid, or metallic type bonds. The bond must be strong enough to hold the abrasive grains but should not be so hard that it rubs workpiece gear deteriorates its quality rather than improving it. Abrasive grain size generally depends on the

Table 8 Different versions of the honing process and their applications[17]

Version of honing process	*Applications*
Longitudinal honing	Connecting rod holes, brake drum, cylinder liners, correct out-of-roundness or circularity, taper, boring tool marks, bell mouth, and barrel and axial distortion in workpiece
Short-stroke honing (fine honing)	Crank shaft, rotor shaft
Surface honing	Rollers, guideways, and guide rails
Profile honing	Tracks of inner and outer ball-bearing rings

Table 9 Commonly used abrasives for different gear materials[1,2,4]

Gear material	*Abrasive*
Steels	Al_2O_3
CI and nonferrous materials	SiC
steels (soft and hard), Ni- and Co-base super alloys, stainless steels, Br–Cu-alloy and Zr	CBN
chromium plating, carbides, ceramics, glass, CI, brass, bronze, and surfaces nitrided to depths greater than 30 μm	Diamond

Type	*Composition of honing tool and use*	*Surface roughness*
Standard type honing tool	Mixture of variety of resin and abrasives used for shaved and heat treated gears. Improves tooth spacing and runout	0.2–0.35 μm
AA ground honing tool	Mixture of variety of resin and abrasives with precise tooth form. Improves tooth spacing and runout	0.2–0.25 μm
Polishing type honing tool	Consist of a flexible, porous polyurethane material. Polishing achieved by use of abrasive liquid compound	0.1–0.15 μm

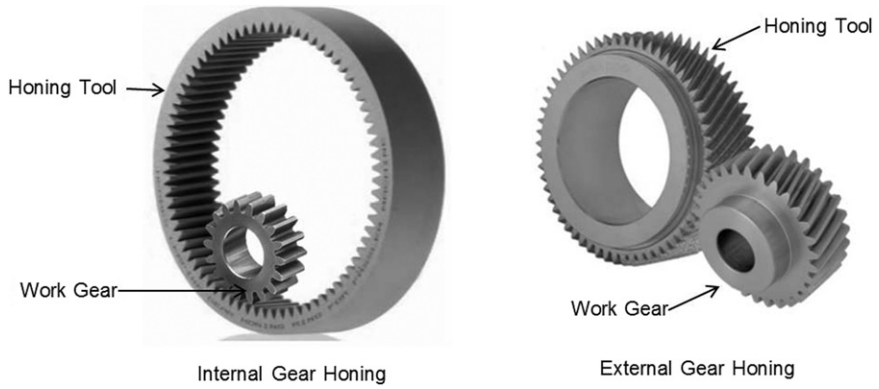

Figure 11 Concept of internal and external honing for finishing a gear.

desired value of MRR and surface finish.[1,2,4] Generally, it varies from 60 to 500 mesh number. **Table 10** presents size of abrasives for different combinations of circular pitch of gears and surface roughness. Type of honing gear depends on the workpiece gear material, finishing method, application requirement, and available machine capacities. Size of honing gear ranges from 3.5″ (for internal gears) to 14″ while face width ranging from 0.5 to 2 in. **Table 11** presents the various tools used in honing of gear teeth.[4,21]

Two basic methods are used to hone the gear teeth. One is the zero-backlash method and the other is called the constant-pressure method. The zero-backlash method is used for hardened gears made within commercial tolerance specifications. The constant-pressure method is used to hone the gear teeth on hardened gears produced to dimensions outside commercial tolerance ranges. Depending on relative position of the honing and workpiece gears, gear honing can be performed either as (1) external honing; or (2) internal honing. **Figure 11** illustrates their concept.

1.4.4.3.1 External Honing

In this process, honing and workpiece gears mesh with each other in a cross-axis arrangement with constant center distance. Gear tooth are finished from root to the tip and direction of rotation of the honing gear is reversed for finishing the second flank as shown in **Figure 12**.

1.4.4.3.2 Internal honing

Figure 13 shows schematic of internal honing process for finishing an external spur gear. In this process, a large-size

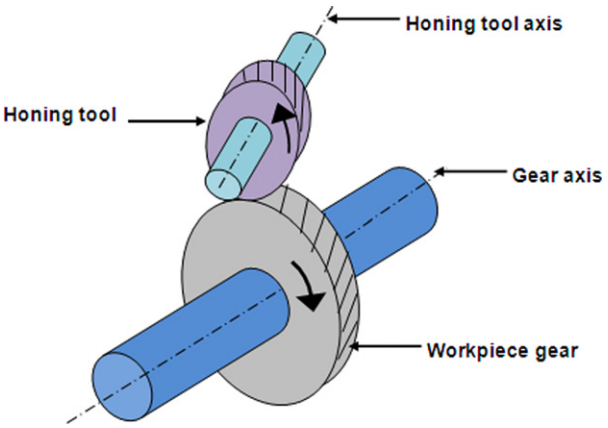

Figure 12 External honing of a single helical gear.

internal helical gear made of a ceramic material is used as honing tool which has cross-axis meshing with the workpiece gear held between the centers of the honing machine. Axis of the honing gear can be varied to match the required crossed-axis angle meshing arrangement with workpiece gear. The gear honing machine has provision of back and forth traverse along the workpiece gear axis finishing a gear having large face width.

1.4.4.3.3 Advantages of internal honing over external honing

- Internal honing has higher traverse contact ratio as compared to external honing. It results in balanced contact pressure,

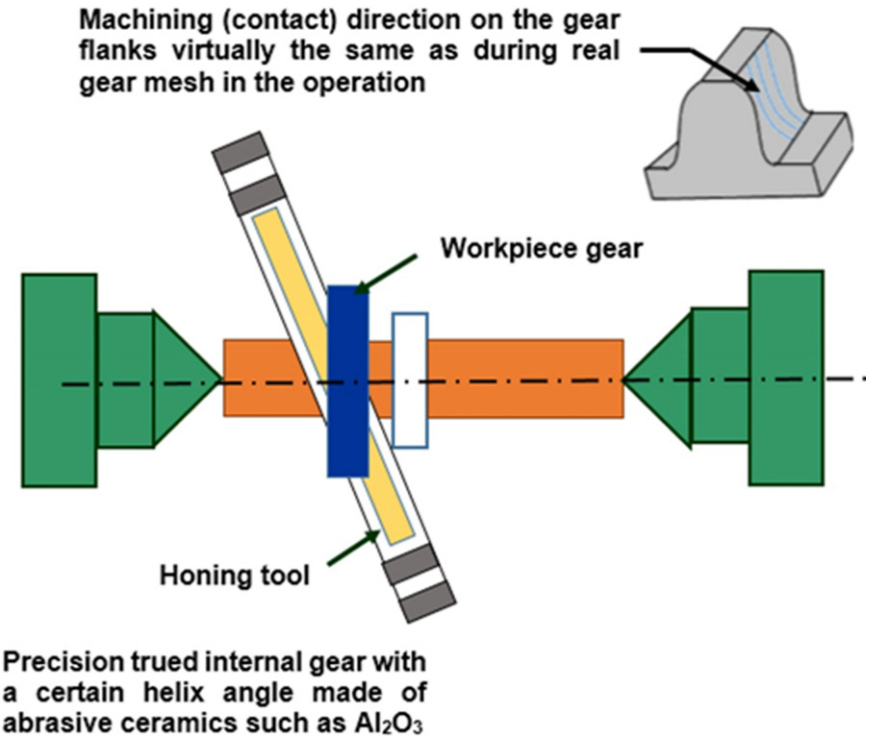

Figure 13 Internal honing of an external spur gear.[19]

good tooth form, large honing stroke, reduced adjacent and accumulated pitch error, and reduced radial runout.
- Internal honing gives higher accuracy.
- Internal honing tool has higher stability as compared to external honing tool. It offers more resistance against breaking.

1.4.4.3.4 Advantages

- Honing generates a tribologically superior surface which retains lubricating oil on contact surface thus reducing friction and minimizing wear of the contact surfaces under load.[22]
- Functional characteristics of the gears such as geometric accuracy, dimensional accuracy, roughness, lay pattern and integrity can be improved by gear honing.
- It reduces or corrects geometric errors induced by previous manufacturing or finishing processes.
- It does not increase tooth surface temperature, nor does it produce heat cracks and burned spots nor it reduce skin hardness.
- It does not generate internal stresses.
- It does not cold work or alters the microstructure of the gear materials.
- Low cost and economical process of gear finishing.

1.4.4.3.5 Limitations

- Limited life of honing gear tool.
- Honing time increases as error in tool shape increases.

1.4.4.3.6 Applications

- Can be used for finishing hardened external and internal gears.
- For improving geometric accuracy and surface conditions and to remove nicks and burrs.[22]
- For minor corrections in tooth shape which increases wear resistance and reduces noise generation.
- Honing can do crowning of gears also.

1.4.4.4 Gear Shaving

Gear shaving removes a small amount of material from the workpiece gear to correct errors in its profile, pitch, helix angle, eccentricity, and improves surface finish of the gear.[4,23] by using a specially shaped shaving cutter which is similar to a helical gear having serrated cutting edges as shown in Figure 14.

The shaving cutter and workpiece gear are pressed to make proper meshing contact and center distance between cutter and workpiece gear is reduced incrementally. The shaving cutter rotates in a tight mesh with the workpiece gear either in parallel or crossed-axes arrangement. The meshing between cutter and workpiece gear is flexible to obtain any desired value of cross-axes angle.[23] The rotary motion between the workpiece gear and shaving cutter is performed in both directions (i.e., clockwise and anticlockwise) during the finishing cycle and material removal takes place in the form of hair-like chip.[24–25] The workpiece gear is reciprocated parallel to its axes across the face of the cutter and fed up into the cutter with each stroke of the table. Cutting action in gear shaving includes fine cutting and finishing caused by a land of

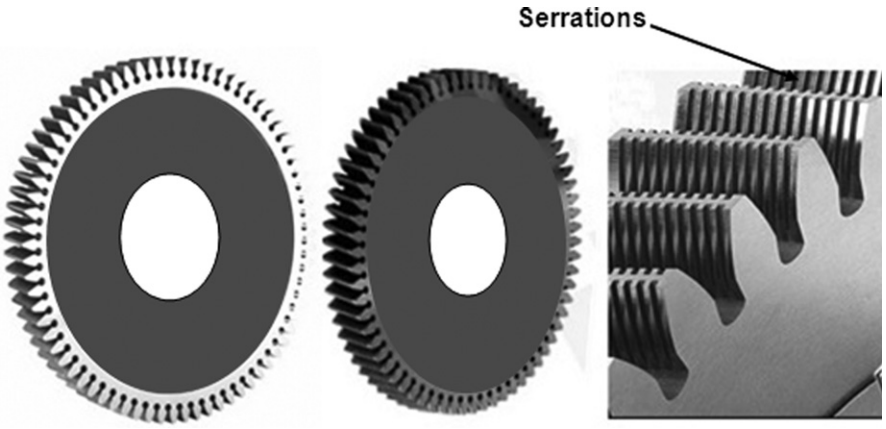

Figure 14 Photographs showing (a) gear shaving cutters (b) serration of shaving cutter.

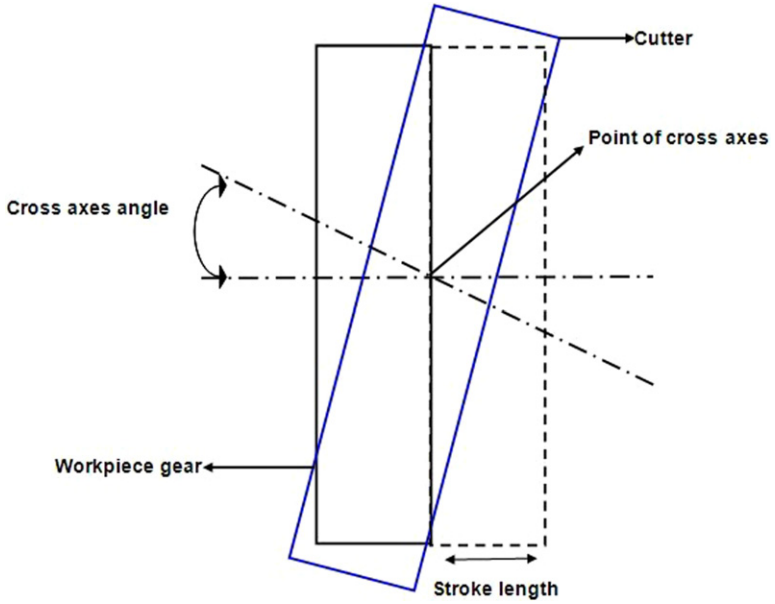

Figure 15 Schematic of cross-axes arrangement in the gear shaving process.[4]

the shaving cutter. Gear shaving process differs from other finishing processes in many aspects. Main difference is the use of geometrically defined cutting edges in gear shaving. Other differences include negative clearance angles, very small chips (height: 50–150 μm, length: 100–400 μm), low thermal load on the cutting edge due to low cutting speeds and chip thicknesses, and strongly varying load on cutting edge and clearance face.[26]

1.4.4.4.1 Mechanism of gear shaving

There is a difference between the helix angle of the gear shaving cutter and that of the workpiece gear which causes them to rotate in different planes. This difference between their axes is called cross-axes angle and is approximately equal to the difference in their helix angles. Figure 15 depicts cross-axes arrangement in the gear shaving process. Value of cross-axes angle in the range from 10° to 15° usually yields better accuracy and surface finish of the gear tooth.[27] Higher value of cross-axes angle may result in large amount of material removal by cutting action but it lowers down the width of contact zone which reduces the cutting action itself. An axial motion is provided to the workpiece gear to enable penetration of the cutting edges of the shaving cutter. Extra care should be taken care to avoid the direct contact between shaving cutter and the gear root fillet because it may adversely affect the accuracy of the involute.

Selection of material for the gear shaving cutter is one of the most important parameters in gear shaving. It depends on the hardness of the workpiece gear. Generally, hardened high speed steel (HSS) of M2 or M7 grades is used in many gear finishing applications while, T15 or M30 grades of HSS is used for conditions where higher red hardness is required. Carbide shaving cutters are used to achieve the high quality finishing of workpiece gear made of difficult to machine

materials. A fresh shaving cutter can finish around 80 000 gears. It can be redressed around four to ten times and the cutter life has been estimated to finish approximately 1500 gears per sharpening cycle.[4] Shaving stock or allowance is another important aspect of the gear shaving process. Sufficient shaving allowance should be provided on the gear to achieve good finish and accuracy by gear shaving. **Table 12** presents the standard shaving allowances for different size of gears.

1.4.4.4.2 Types of gear shaving

Gear shaving is classified according to type of the shaving cutter and type of relative motion between shaving cutter and workpiece gear. According to type of the shaving cutter, gear shaving can be classified as rotary shaving or rack shaving as depicted in **Figure 16**. Rotary shaving method uses a pinion shaped shaving cutter with serrated teeth, while rack shaving uses rack type shaving cutter having serrated teeth.

In the rack shaving process, the rack type shaving cutter is reciprocated under the workpiece gear and infeed takes place at the end of each stroke. Since, is impractical to have rack longer than 20 in (508 mm) therefore 6 in (or 152 mm) is the maximum diameter of gear that can be shaved by this process.

In the rotary shaving process, the cutter has serrated gear teeth ground in such a way that teeth profile will conjugate with that of the gear to be shaved. The shaving cutter rotates while meshing with the workpiece gear thus scraping off or shavings little amount of material from the workpiece gear.[28] There is no indexing mechanism involved in this process. Shaving cutter is the driver and the workpiece gear is the driven member. Rotary gear shaving is done in the green or soft state of the gear, i.e., prior to heat treatment. This process has the ability to modify the pinion geometry to compensate for the distortions that occur during heat treatment. The rotary gear shaving is further classified in four categories namely axial or conventional, diagonal, tangential or under pass and plunge. The basic difference between these versions of rotary shaving is type of relative motion between workpiece gear and shaving cutter.[26] Following paragraphs briefly describe these different versions of rotary shaving.

Table 12 Recommended shaving allowance for pre-shaved gears[1]

Gear size		*Shaving allowance on tooth thickness (mm)*	
Module	*Pitch*	*Minimum*	*Maximum*
1.6	16	0.025	0.050
2.5	10	0.038	0.075
4	6	0.050	0.100
12	2	0.075	0.150

1.4.4.4.2.1 Axial or conventional gear shaving

There are two independent motions in the axial or conventional type of rotary gear shaving: first is tight rotational meshing between the workpiece gear and shaving cutter and second one is the traverse motion of the shaving cutter along the axis of the workpiece gear as shown in **Figures 17**.[28,29] Length of traverse is generally 1.6 mm greater than the face width of the workpiece gear and it is adjusted to ensure finishing of entire face width of the gear.[27] Crowning of the gear teeth can be done using the built-in crowning mechanism in the gear shaving machine.

This process is suitable for gears having wider face width. It can improve the roughness of tooth flanks and can decrease the individual pitch error by 30% but, it cannot correct cumulative pitch error or index error in fact in some cases a shaved gear may have cumulative pitch error increased because it creates flank grooves in the middle of tooth profiles.[31]

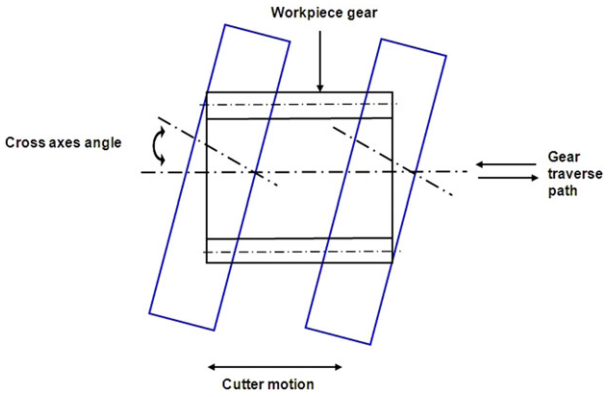

Figure 17 Schematic of axial or conventional type of rotary gear shaving.[30]

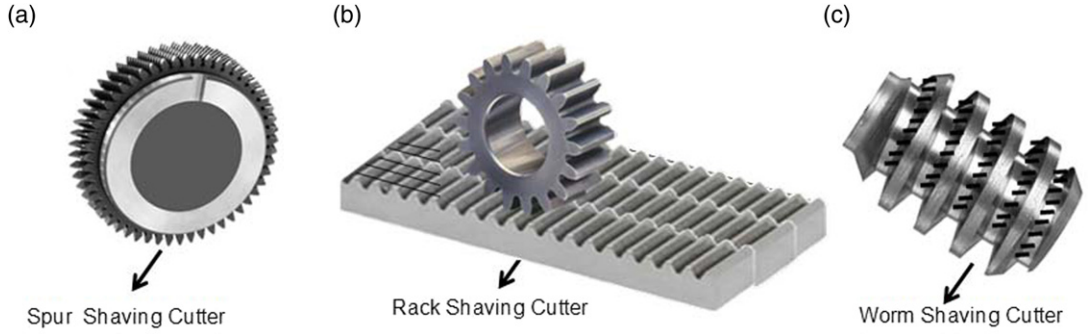

Figure 16 Types of gear shaving cutters (a) spur gear type; (b) rack type; and (c) worm type.

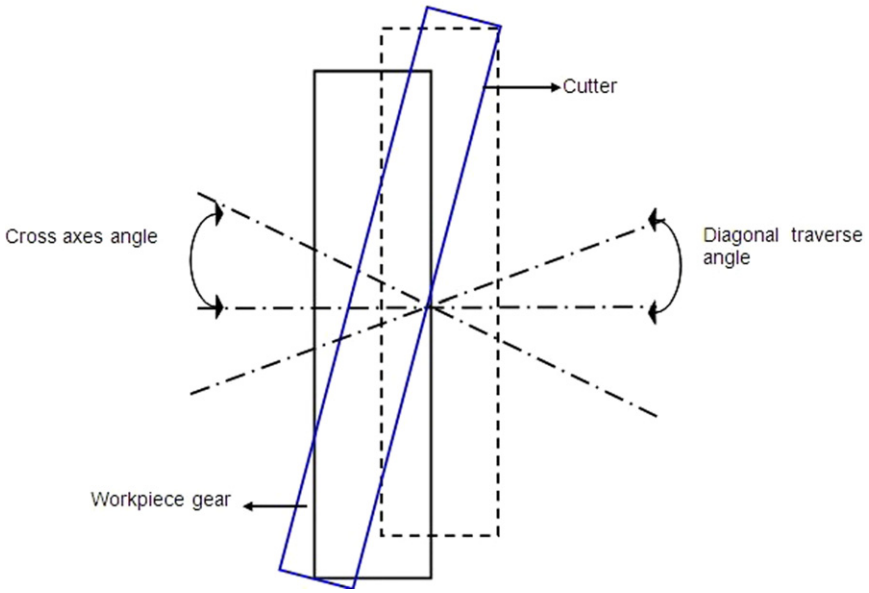

Figure 18 Schematic of diagonal type of rotary gear shaving.[4]

1.4.4.4.2.2 Diagonal gear shaving

In diagonal type rotary gear shaving, face width of gear and shaving cutter has a special relationship with diagonal traverse angle and there is a relative motion between the shaving cutter and workpiece gear as shown in **Figure 18**. Width of shaving cutter depends upon face width of the workpiece gear and diagonal traverse angle. Diagonal traverse angle varies from 30° to 60° to obtain optimum conditions of cutting speed and quality of workpiece gear.[32] Wide face width of workpiece gear and narrow shaving cutter restrict the diagonal traverse to a small angle. Increasing the cutter face width permits increase in the diagonal angle. Crowning of the gear teeth is accomplished by rocking the machine table by providing the sum of traverse angle and crossed-axes angle. As the traverse angle approaches to 90°, machine controlled crowning is no longer possible then it is obtained by modifying shaving cutter only. A special cutter with differentially staggered gashes becomes essential when the traverse angle is above 60° to have effective shaving of the entire tooth surface.

In this process, wear of shaving cutter is uniform hence increasing its life.[27] This process can reduce shaving time up to 50%. It is mainly used for medium and high-production rate. It can be used for finishing shoulder gears also.[27]

1.4.4.4.2.3 Tangential or underpass gear shaving

In this process, workpiece gear is rolled into the shaving cutter teeth and moved in radial direction at right angle to its axis in forward and return stroke from an initial center distance to the desired final center distance as shown in **Figure 19**. For this, width of the shaving cutter should be more than face width of the workpiece gear. Pitch surface of the cutter is given a hyperboloid form (concave curvature) to ensure proper contact across the full face width of workpiece gear. Concave pitch surface on the shaving cutter is obtained by negative longitudinal crowning of its teeth. A special shaving cutter with mutually staggered gashes is required to clean the shaved gear teeth.

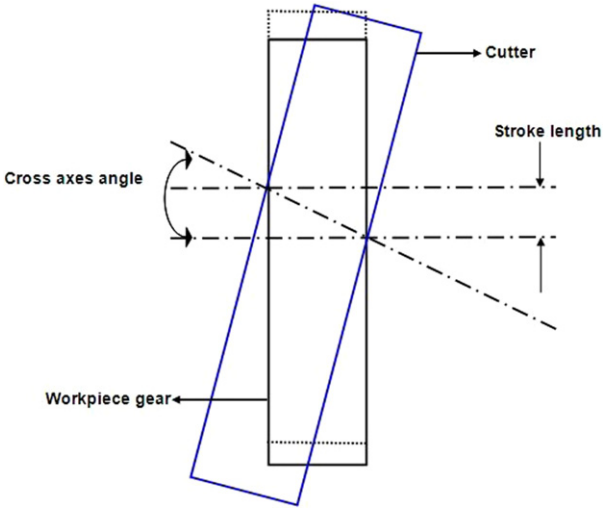

Figure 19 Schematic of tangential or underpass type of rotary gear shaving.[4]

Stroke length in this process is smaller than that for axial and diagonal type gear shaving processes consequently shaving time is less as compared to these versions of rotary gear shaving process. Since, the pivot point of the shaving cutter moves along the entire face width of the workpiece gear resulting in its uniform wear which increases shaving cutter life. This process is most suitable for shoulder gears with critical clearance between the gear and the shoulder.[27]

1.4.4.4.2.4 Plunge gear shaving

This process does not require any translational motion of shaving cutter or workpiece gear because workpiece gear is plunged into the shaving cutter. Chip thickness value in this process is in the range of 2–10 μm depending on the feed rate and the gear data.[32] Theoretical pitch surface of the shaving cutter used in this process

is a hyperboloid with a hollow tooth form.[33] There is line contact between shaving cutter tooth surface and workpiece gear tooth surface whereas other versions of rotary gear shaving have point contact between them. Consequently, this process requires wider shaving cutters with special tooth flank geometry. This restricts value of crossed-axes angle in the range from 10° to 20°. Advantages of this process are simple machine structure, increased productivity, good accuracy, and longer cutting life. Since, stroke length of shaving cutter is very short therefore shaving time in process is the least.[34] The time required to shave a gear of a car gearbox with diagonal shaving is approximately 1 min, while with plunge shaving typically it only takes 10 s.[22] Therefore, this process is generally used for finishing gear in mass production due to low finishing cost and short machining time.[34–36]

1.4.4.4.3 Advantages

- Gear shaving improves gear tooth surface finish and concentricity of the tooth profile, modifies tooth form and eliminates danger of tooth end load concentration in service.
- It can give same surface finish as given by gear grinding (R_a from 0.4 to 0.6 μm).[36]
- It can reduce errors in microgeometry of the hobbed and shaped gear by 65–80%. Gear quality of DIN class 6 or 7 can be achieved routinely with low finishing cost and high process reliability. While, gear quality up to DIN standard 4 can be achieved with extra care during pre-shaving and shaving processes and maintaining workpiece characteristics favorable to shaving process.[37]
- It provides profile modifications that improve noise and load carrying capacity of gear. Profile modifications can be incorporated in either axial or transverse plane and small errors of lead can be corrected readily.[32]
- It can minimize thermal distortions caused by heat treatment.
- It is faster and economical gear finishing process.[38]

1.4.4.4.4 Limitations

- Gear shaving can finish either unhardened gears or gears having hardness value up to 40 HRC only.
- Shaved gears have a step mark left on gear teeth the end of the involute profile which causes excessive noise, wear, and vibration.[39]
- Shaving causes more material removal from the gear tooth surface around pitch points of a gear. This adversely affects gear tooth surface finish and their transmission quality specially when they have true involute profile.[40–41]

1.4.4.4.5 Applications

- Gear shaving is generally used for finishing of soft gears while shaving followed by some surface hardening and then lapping for soft but precision gears.[26]
- It is widely used for finishing spur, helical and worm wheels of moderate size.
- It can be used to remove hobbing scallops and other irregularities produced by gear hobbing process.[36]
- It can be used to provide crowned tooth or a tapered tooth which are required to avoid end bearing condition.

Outcome of gear shaving process depends upon various factors such as workpiece gear material, its geometry, shaving allowance, shaving cutter and its material, shaving process parameters, and shaving machine related parameters. **Table 13** presents summary of Influence of different workpiece gear related parameters on different aspects of gear shaving process.

1.4.4.5 Gear Burnishing

Gear burnishing finishes a gear by plastic deformation rather than material removal. In this process, workpiece gear is rolled under pressure while meshing accurately with ground, polished and hardened master gears (known as burnishing die) of high accuracy and surface finish. As the burnishing die (driver) start engaging with the workpiece gear (driven), the sliding action occur along the line of action from top of burnishing die tooth toward its pitch point on approach side as shown in **Figure 20(a)** and from pitch point toward root of

Table 13 Influence of workpiece gear related parameters on different aspects of gear shaving process[36]

Workpiece gear related parameter	*How it affects*		
	Shaving cutter	*Shaving parameters*	*Shaving machine*
Gear material	Type of steel used	Type of shaving process	Type of machine
Gear geometry parameters (i.e., module, pressure angle, number of teeth, helix angle, faces width)	Hardness and structure of the steel (heat treatment quality)	Feed and cutting speed	Machine in good conditions and of medium life
Shaving allowance	Serrations characteristics (dimension and finish, especially of side walls)	Cross-axes angle	Type of the clamping fixtures for gear and cutter
Pre-shaving condition (type of manufacturing process, microgeometry, etc.)	Manufacturing accuracy and precision in re-sharpening	Number of passes	Old machine in bad condition
Post-shaving gear accuracy, profile and helix corrections	Geometry characteristics (i.e., bore, faces, etc.)	Type of lubrication	–
Single open gear or cluster gear with shank (and danger of flexion)	Accurate design (even contacts, number of teeth, outside diameter)	–	–

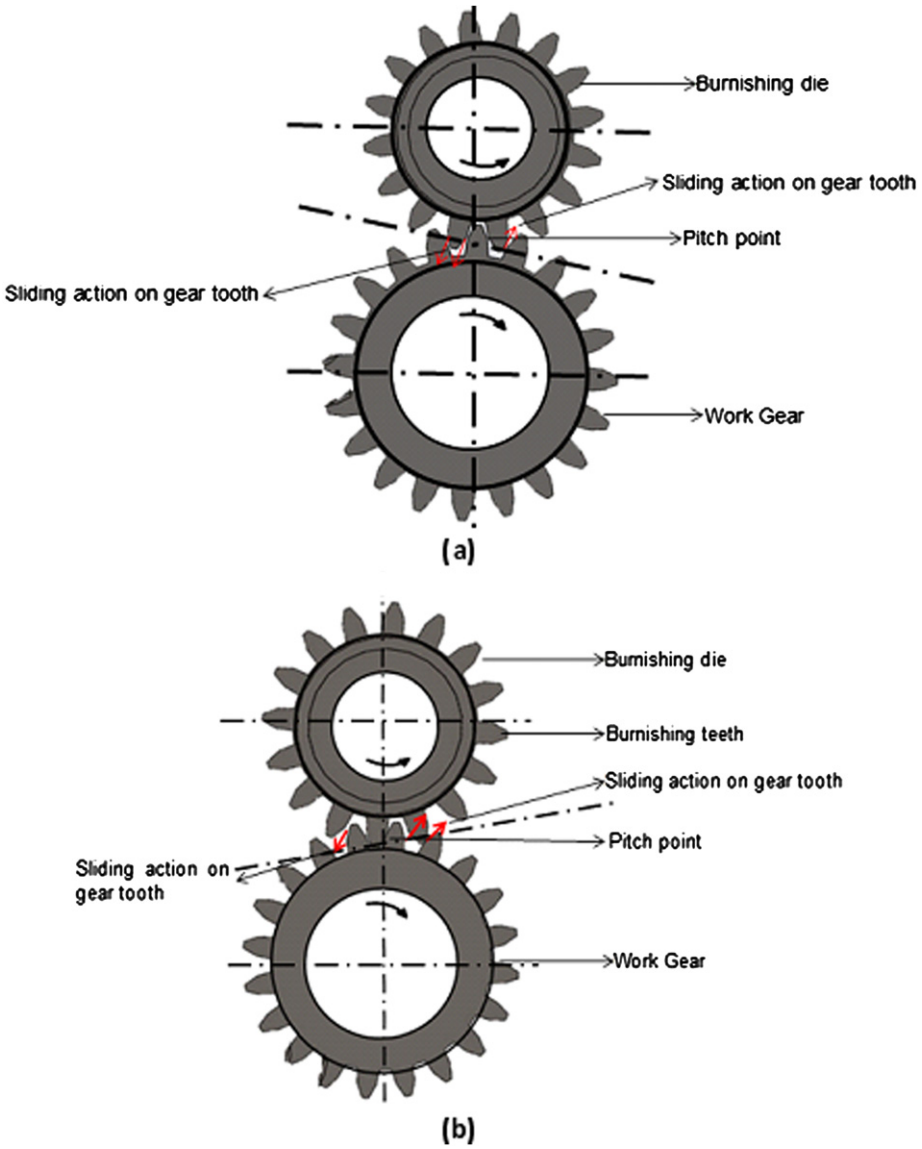

Figure 20 Sliding action in gear burnishing process: (a) approach side; and (b) recession side, of the burnishing die teeth.[4]

tooth on recession side as shown in **Figure 20(b)**. These changes in sliding action compresses the workpiece gear from root toward pitch point on approach side and from pitch point toward top on recession side. Changes in direction of sliding causes more material to be displaced on the recession side as compared to approach side approximately in the ratio of 3:1.[4,42] The workpiece gear is finished by smearing off the minute irregularities from its teeth surfaces by cold plastic deformation along line of contact which also helps in improving the surface integrity of the workpiece gear by inducing compressive residual stresses in it.[42] Accuracy and quality of gear burnishing is affected by amount of material flow and hardness of the workpiece gear material. Stock allowances given on workpiece gear also affect its accuracy and quality. Gear burnishing dies are generally made of special fatigue and impact resistant high speed steel. **Figure 21** depicts photographs some gear burnishing dies.

Gear burnishing machines are generally either single-die or double-die type. Selection criteria include rigidity, strength, high speed loading, die-phasing, independent adjustment for die axis and die positioning. Arrangement of workpiece gear and burnishing dies for single-die and double-die gear burnishing machine are shown in **Figures 22(a)** and **22(b)**, respectively.

In a single-die gear burnishing machine the workpiece gear is mounted on the roller steady rest in between head stock and tail stock while burnishing die is mounted on a heavy duty gearhead above the workpiece gear. The die is driven by an electric motor which in turn rotates workpiece gear due to tight meshing with it. Direction of rotation of the burnishing die is reversed during the burnishing process to provide balanced

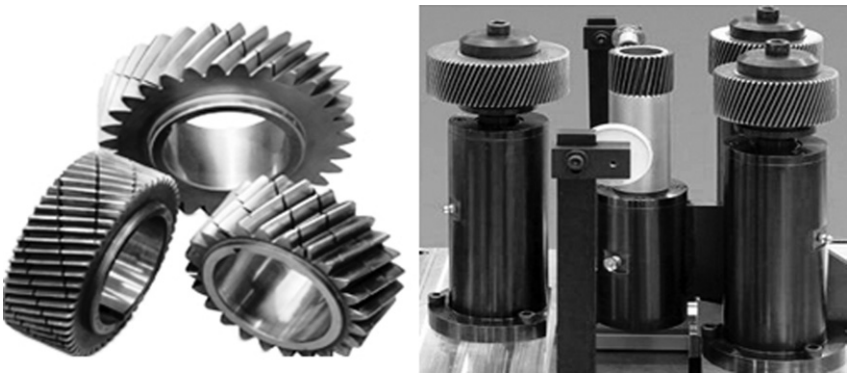

Figure 21 Photographs of some gear burnishing dies.[43]

material flow on the leading and trailing side of a gear tooth. Lubrication is provided to get the desired surface quality and to prevent abrasion of the workpiece gear.[4,32] In a double-die gear burnishing machine, the workpiece gear is sandwiched between fixed upper burnishing die and hydraulically fed lower burnishing die. Arbor of the workpiece gear is rotated by a hydraulic motor slightly slower or faster than the speed of die to ensure clash-free engagement. Amount of upward movement of the lower die controls gear finishing.

1.4.4.5.1 Advantages

- Burnishing is very fast finishing process for producing smooth surface compared to shaving and honing for finishing same dimension gear due to very short finishing times (i.e., 5–10 s) for the gear.[44]
- It can finish both external and internal gears.
- It removes or reduces nicks and burrs from the gear teeth.
- It improves surface integrity and fatigue life of the gears.
- Longer life of burnishing dies (typically 500 000–750 000 cycles) and their lower maintenance cost makes it very suitable for mass production.[44]

1.4.4.5.2 Limitations

- Burnishing can finish only unhardened gears.
- It cannot improve tooth position, tooth profile, lead, spacing, or concentricity.
- Since, it is a localized cold-working operation therefore it may result in some undesirable effects such as localized surface stresses and nonuniform surface characteristics.
- Cost of burnishing dies is higher as compared to the cutter used shaving and grinding.
- Causes damage when a large portion of workpiece gear tooth is rolled over.

1.4.4.5.3 Applications

- For finishing the helical gears.
- For improving fatigue strength of gears teeth.
- For improving gear tooth profile and gear noise.
- For improving gear quality and surface finish.

1.4.4.6 Conventional Finishing Processes for Conical Gears

Due to complex geometry of conical gears, only two conventional gear finishing processes namely gear grinding and gear lapping can be used for finishing them. There is minor difference in working principle of these two gear finishing processes when they used for conical gears as mentioned below. Other details of these two processes are same as described earlier.

1.4.4.6.1 Finishing of conical gears by grinding

Grinding is very accurate and precise process for finishing the conical gears and can finish gear having hardness value up to 92 HRC. It can attain surface roughness values in the range of 0.25–0.76 μm; gear quality of DIN standard 6–7 normally and DIN standard 2–3 with extra care. But, it is very complex and costly process. Moreover, it causes two major undesirable effects namely: grinding burns caused by high temperature damage surface integrity of the ground gears and can even sometime lead to gear failure through tooth breakage and transverse grind lines on the finished surface which cause noise and vibrations of the gears. There are two versions of gear grinding which can be used for finishing conical gears. They are generative grinding and form grinding.[4]

1.4.4.6.1.1 Generative gear grinding

In this process, the workpiece gear is run in mesh with a cup-shaped grinding wheel and relative motion between the workpiece gear and the grinding wheel finishes flank surfaces and root of the gear teeth. Al_2O_3 or CBN as abrasives and vitrified or resinoid as bond are most commonly used for manufacturing cup-shaped grinding wheel. It is used for finishing hypoid and spiral gears. It provides accurate tooth spacing, concentricity, and profile.

1.4.4.6.1.2 Form or non-generative gear grinding

Figure 23 shows schematic of 'Waguri method' for finishing the bevel gears which uses a circular grinding wheel with an average point width equal to 0.25–0.50 mm which is less than the slot width of workpiece gear. Grinding wheel rotates about its axis and gears are ground along the line contact between grinding wheel and workpiece gear tooth.

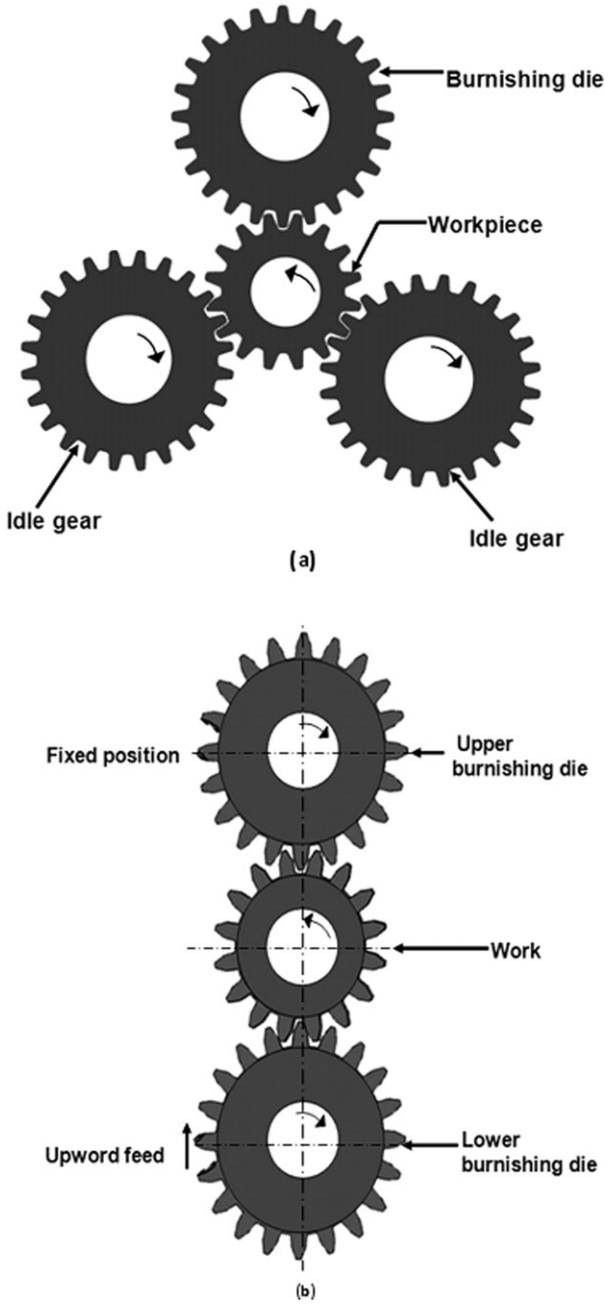

Figure 22 Arrangement of workpiece gear and burnishing dies in (a) single-die gear burnishing machine; and (b) double-die gear burnishing machine.

1.4.4.6.2 Finishing of conical gears by lapping

In this process, small gear (driver) run in mesh with workpiece gear (driven) under tooth contact load and lapping compound is supplied in between them for finishing operation. Lapping is usually used to finish hypoid and spiral bevel gears.[15] **Figure 24** shows the schematic of finishing a spiral bevel gear by the lapping process.

1.4.4.7 Gear Finishing by AFM

In the recent years, developments in materials and manufacturing technology grew up very rapidly so as the demand for better quality product at minimum cost. Major focus of these developments has been on reduction of manufacturing lead time, manufacturing and finishing costs, improving product quality, operating performance, service life, and product reliability. Finishing cost of a product contributes 15–20% toward its total manufacturing cost.[45] As the requirements for surface roughness go below 1 μm value, finishing cost increases very rapidly. AFM process was developed by Extrude Hone Corporation, USA in 1960s with an objective to achieve high surface finish with minimum cost. Initially, it was used for deburring hydraulic control block radar guided acquisition system.[45]

1.4.4.7.1 Working principle of AFM process

AFM is an advanced fine finishing process which is used to polish, deburr, and radius the inaccessible or difficult-to-reach surfaces, complex intricate geometries and edges by flowing abrasive laden viscoelastic self-deformable putty through them. **Figure 25** depicts working principle of AFM process in which abrasive laden viscoelastic self-deformable putty is filled in two vertically opposite cylinders and is extruded back and forth through the passage formed by the workpiece and the tooling or by workpiece alone.[46,47] This causes shearing off surface peaks from the workpiece surface imparting very fine finish to it. More aggressive finishing is done where restriction to flow of the putty is more. Extrusion pressure to medium-containing cylinder is applied by a hydraulic unit or by mechanical means.

1.4.4.7.2 Types of AFM process

Three types of AFM process namely one-way, two-way and orbital have been reported in the literature.[46] The most frequently used version is two-way AFM process.

1.4.4.7.2.1 One-way AFM

This system consists of one hydraulically operated piston-cylinder arrangement, one specially designed medium-containing cylinder and tooling for holding the workpiece as depicted in **Figure 26**. Piston of the hydraulic cylinder pushes the AFM medium causing it to flow through the medium-containing cylinder and through those surfaces of the workpiece which are to be finished, in a closed loop manner. AFM medium is extruded from one side of workpiece in one cycle and then it is collected and reinserted for circulation in the next cycle and this sequence continues till the desired results are obtained. This process causes wastage of AFM medium and finishing time is long.

1.4.4.7.2.2 Two-way AFM

It consists of two oppositely positioned hydraulic cylinders and two cylinders containing AFM medium for extruding the viscoelastic putty through the passage formed by workpiece fixture and tooling (See **Figure 27**). Pistons of the medium-containing cylinders can be moved back and forth either hydraulically or mechanically. Initially, the AFM medium is filled in the lower medium-containing cylinder. Workpiece is clamped in the specially designed fixture positioned between both medium-containing cylinders. The AFM medium is moved back and forth by the pistons of the medium-containing cylinders. Fixture and clamp not only hold the workpiece in position during its finishing by the AFM process but

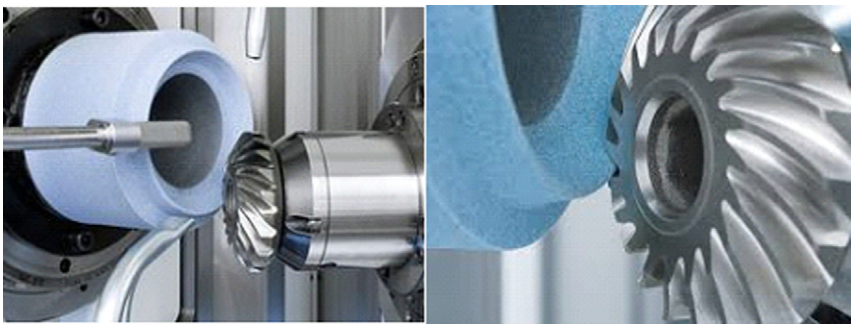

Figure 23 Photographs of Schematic of Waguri method for finishing the bevel and hypoid gear.

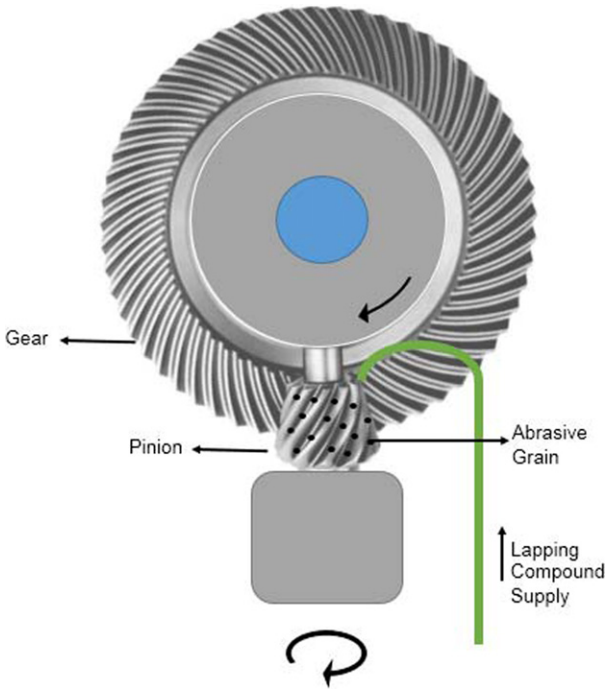

Figure 24 Schematic of finishing a spiral bevel gear by the lapping process.

also direct the AFM medium on those areas of the workpiece which are to be finished. Abrasive particles contained the AFM medium shears off the surface peaks from the workpiece surfaces thus imparting fine finish to them. One complete cycle consist of an upward and downward stroke. The process can either be operated for a fixed number of cycles or till the desired surface finish is achieved.

1.4.4.7.2.3 Orbital AFM process

In this version of AFM, workpiece surface is finished by providing high frequency and low amplitude vibrations to the workpiece as shown in **Figure 28**. The AFM medium is filled in two medium-containing cylinders, workpiece is placed in a fixture positioned between cylinder and orbital vibrations are given to the workpiece in a direction normal to the movement of the AFM medium. Surface finishing takes place due to restrictions created between the workpiece and fixture by orbital vibrations.

1.4.4.7.3 AFM machines

Standard AFM machines have extrusion pressure from 0.69 to 220 bar and flow rate up to 400 l min^{-1}. Modern AFM machines have CNC control and flexibility to hold any complicated internal or external parts with a facility to vary extrusion pressure, number of cycles or strokes, finishing time, flow rate of AFM medium, volume per stroke, etc.[47]

1.4.4.7.4 Components of an AFM machine

Major components of a complete AFM system are machine structure, tooling and abrasive medium.[46–47]

- **Machine structure:** generally, AFM machine has two hydraulic cylinders, two medium-containing cylinders, workpiece fixture, limit switches, supporting structure, pressure control valve, stroke counter, and hydraulic power unit. CNC control system is also provided in modern machines to run machine for mass production as shown in **Figure 29**. AFM medium is moved back and forth from one medium-containing cylinder to other medium-containing cylinder by the pistons of hydraulic cylinders operated by hydraulic power unit. Workpiece is clamped between the medium-containing cylinders through fixture unit.
- **Tooling:** it is very significant part of AFM system because it holds and supports the workpiece during the finishing process. It confines and directs the flow of AFM medium to the appropriate areas of workpiece for deburring, radiusing, and surface improvements and same time it blocks flow of AFM medium into or out of workpiece passages where no finishing is desired. Tooling can be designed to provide more restriction to flow of AFM medium to remove the more material and impart better finishing. Replaceable inserts made of nylon, teflon or hardened steel are used to restrict tooling area. The tooling can be designed to hold single or multiple workpieces for their simultaneous finishing.
- **Medium:** AFM medium is in the form of semi-solid putty having self-deforming ability which is forced through a passageway or restrictions either in one direction or in both directions. It is a mixture of pliable polymer carrier, abrasive grains and lubricating oil. It is resilient enough to act as a self-deforming grinding stone when forced through the workpiece. Commonly used abrasives are alumina, SiC, CBN, and diamond. Size of abrasive

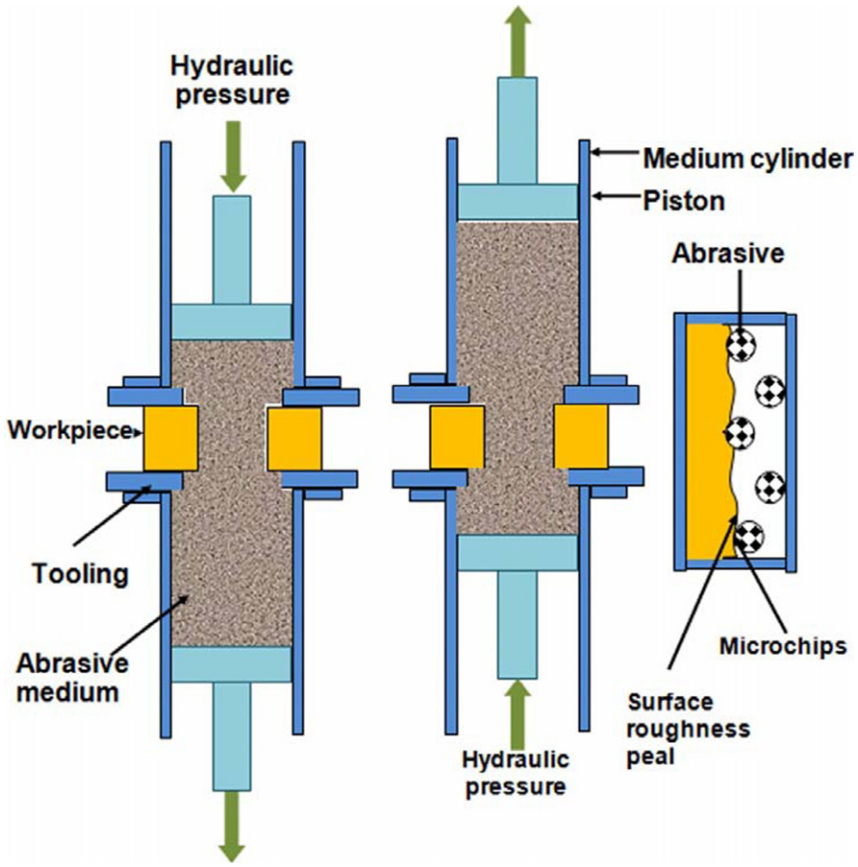

Figure 25 Schematic of working principle of AFM.[47]

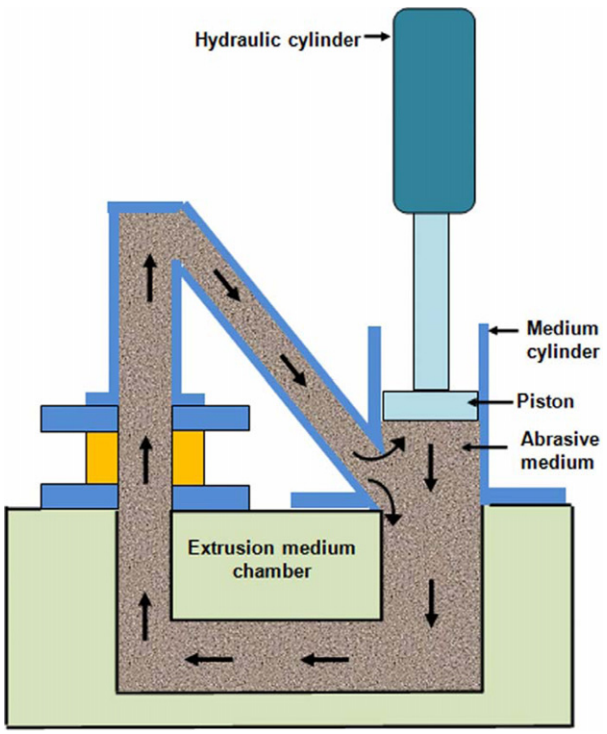

Figure 26 Working principle of one-way AFM process.[46]

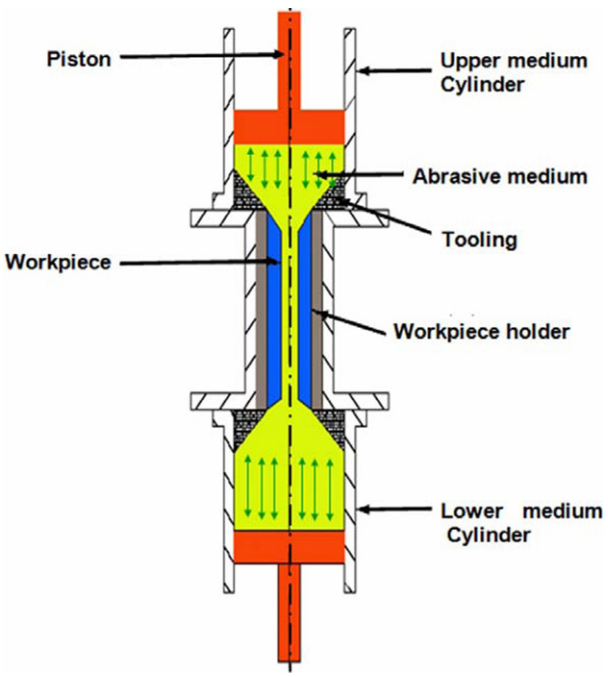

Figure 27 Working principle of two-way AFM process.[48]

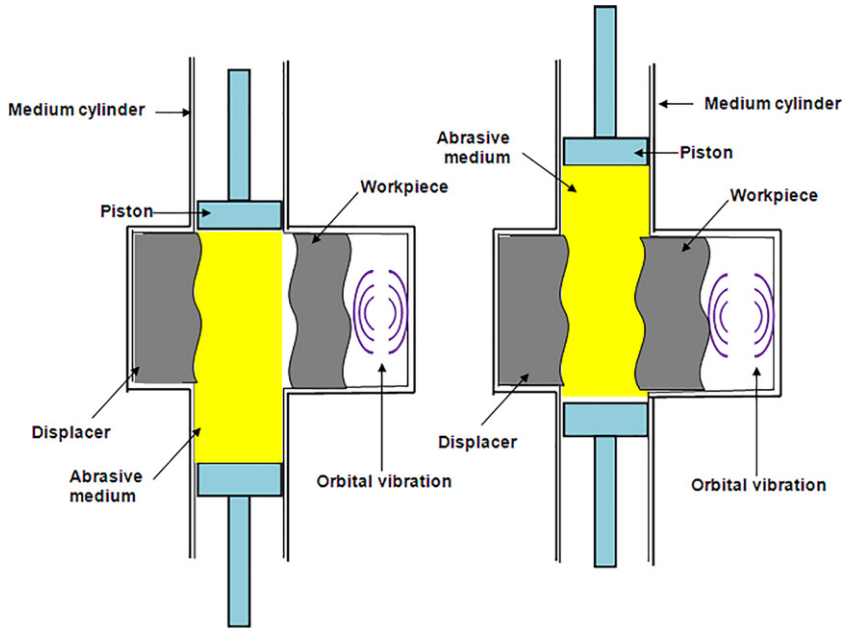

Figure 28 Working principle of orbital AFM process.[47]

particles ranges from 0.005 to 1.5 μm. Different values of viscosity can be obtained by changing ratio of polymer and lubricating oil. Higher viscosity medium is generally used for uniform abrasion and lower viscosity medium is suitable for radiusing the edges. The viscosity and flow rate of medium significantly affect MRR and edge radius size. Low viscosity medium with higher flow rate is applicable for deburring whereas low and steady flow rate is used for uniform material removal in finishing and polishing applications.

1.4.4.7.5 AFM parameters

AFM is a controllable finishing process in which, parameters related to AFM medium, abrasive particles, AFM process, and workpiece can be changed to meet the desired finishing and shaping requirements and MRR. MRR in AFM process depends on the following parameters:[47–49]

- extrusion pressure,
- number of cycles/strokes,
- flow rate of medium,
- viscosity of medium,
- size of abrasive particles,
- concentration of abrasive particles,
- hardness of abrasive particles, and
- geometry and Hardness of workpiece.

1.4.4.7.6 Gear finishing by AFM

AFM has all potential and capabilities to be developed as economical and productive alternative to conventional finishing processes of gears. Recent investigations[50–52] have reported AFM being capable of improving surface finish within a very less time and simultaneously improving microgeometry, service life, and stability of gear. Figure 30 depicts geometry of an unfinished gear manufactured by WEDM and same gear finished by AFM process[50] showing that AFM helped in achieving the required cambered shape of gear tooth. Helical gears finished by Xu *et al.*[51] using AFM have been found to have increased tooth stiffness and load carrying capacity and reduction in contact area, friction and wear of the tooth surface. Venkatesh *et al.*[52] used ultrasonic assisted AFM (UAAFM) for finishing the straight bevel gears and reported improvement in surface finish. Further research is under progress at IIT Indore investigating on finishing of cylindrical and conical gears by AFM.

1.4.4.7.7 Advantages

- AFM is excellent process for finishing inaccessible or difficulty-to-reach areas completing roughing and finishing in one pass.
- It gives average surface roughness values as small as 50 nm with dimensional tolerance as good as ± 5 μm. Thickness of material removed is in the range of 1–10 μm.
- It can produce consistent surface quality with tight tolerances repeatedly.
- Multiple-holes can be finished simultaneously in single setup of AFM process in minimum time. Similar finishing by manual polishing takes very long time and is very costly. A minimum limit on the hole size that can be finished/deburred properly is 0.22 mm and the largest size (or diameter) that has been finished is around 1000 mm.
- Results of finishing multiple parts simultaneously are uniform, repeatable, and predictable. Automated AFM system can finish thousands of parts per day and labor cost reduces to great extent by reducing manual hand work.

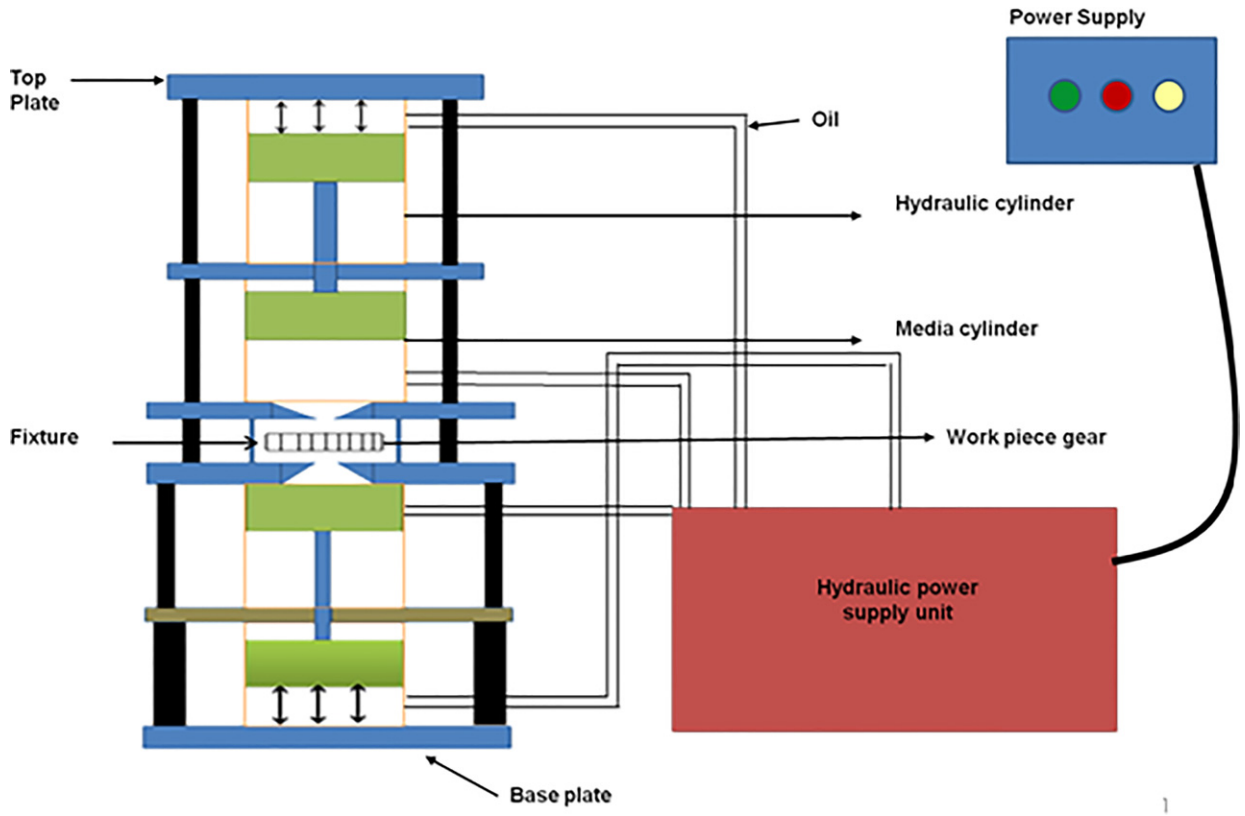

Figure 29 Schematic of a complete AFM system.

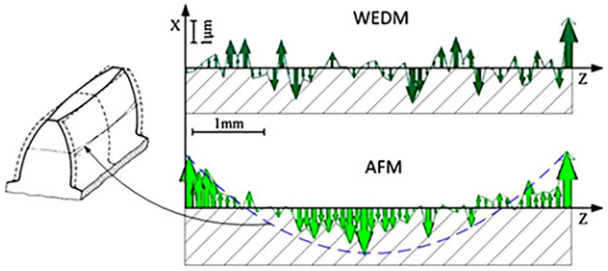

Figure 30 Tooth profile of a gear manufacturing by WEDM and then finished by AFM. Reprinted with permission from Ref. [50]. Springer. © 2014.

- It offers flexibility for change in material, geometry, and dimension of the workpiece, type of AFM medium and abrasives and AFM process parameters thus enabling finishing of variety of parts on same setup by just changing the fixtures for holding workpiece.
- Suitable medium can be used as per finishing requirements.

1.4.4.7.8 Limitations

- Unable to improve surface irregularities like deep scratches, large bumps, out-of-roundness, and taper, etc.
- MRR in AFM is slow hence process is not applicable for mass material removal.

1.4.4.7.9 Applications

AFM finds many finishing applications in different fields. Figure 31 illustrates photographs of some typical components before and after finishing by AFM demonstrating improvement in surface quality the AFM process. Some major applications of AFM process are:

- Finishing of different components used in aerospace, automotive, diesel and turbine engines, i.e., deburring of aircraft valve bodies and spools, fuel spray nozzles, fuel control bodies, airfoil surfaces of impellers, etc.
- Finishing of fluid handling components of the food processing systems.
- Finishing of the components manufactured by additive layer manufacturing processes.
- Finishing common rail pipe fuel system of a diesel engine.[53]
- Finishing of outer rotor surface of the cycloidal pump.[54]
- Modification of surface texture and removal of surface layer which is subjected to mechanical and thermal damage.[46]
- Aerospace applications include removal of the thermal recast layer in the cooling holes of blades and disks, deburring fuel spray nozzles, and polishing cast surfaces of blades, compressor wheels, and impellers.[54]

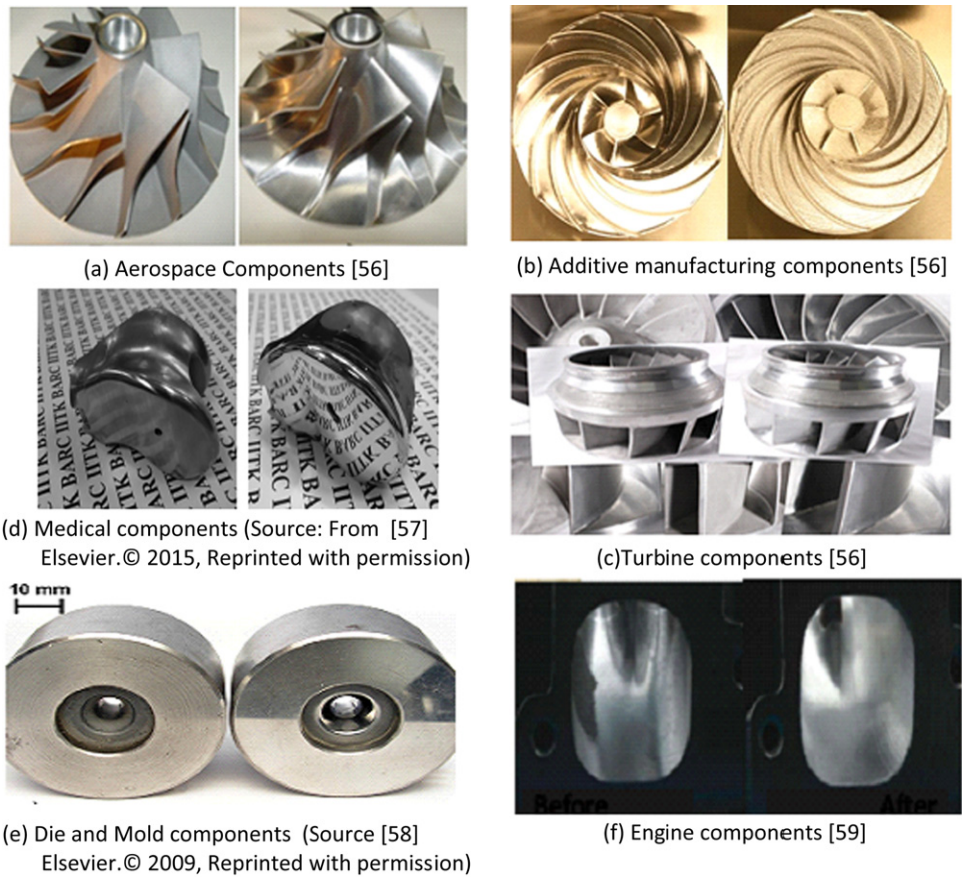

Figure 31 Components before finishing and after finishing by AFM.[56–59]

- Radiusing and deburring of air cooling holes of turbine disk and holes of combustion liner.[55]
- Reworking components to remove coke and carbon deposits, improve surface integrity and enhance eddy current readings.
- Materials ranging from soft aluminum to hard nickel alloys, ceramics, and carbides can be successfully finished with this process. Surface integrity problems such as residual stresses, metallurgical transformations, plastic deformation, tearing and cracking can be reduced or avoided.[46]

1.4.5 Comparative Evaluation

Gears are manufactured according to the given design, drawing, and service requirements. Successful production of gears depends on availability of manufacturing machines, cutting tools, finishing, and heat treatment processes and machines for them. Gear finishing is very critical aspect which affects overall performance of gear after its manufacturing. Various conventional finishing processes such as grinding, lapping, shaving, honing, burnishing, and unconventional or advanced processes such as AFM and ECH can be used to perform finishing of gears. This chapter described these processes in details. Table A1 in Appendix A presents comparative summary of these processes which should help the reader to select a suitable gear finishing process.

Grinding is the oldest process of gear finishing which is used widely in gear industry. This process is capable of giving DIN quality 2–3 with extra care but has certain limitations such as grinding burn, traverse grid line generation which affect surface integrity of the gears adversely. Lapping can produce DIN quality of 6 and the mating gears after lapping cannot be interchanged. Shaving can produce DIN quality 3–4 with extra care but this process is applicable for soft and unhardened gears only. Honing can produce DIN quality 6 with extra care but life of honing tool is limited. AFM is recently developed advanced finishing processes which can finish hard and hardened gears made of both metallic and nonmetallic materials. Some hybrid processes based on AFM for gear finishing are also under development stage.

Acknowledgments

Authors express their sincere gratitude toward all those researchers and authors whose figures have been used in this manuscript and their publishers for permitting to use these figures.

Appendix A

Table A1 Comparison of different processes for finishing the gears

Process	Capabilities	Applications	Limitations
Gear Grinding	• It is very accurate and frequently used gear finishing process • It can finishes gears having hardness value up to 92 HRC • It can do profile modification • It improves accuracy of gears • **Gear quality:** DIN standard 6–7 in normal condition and 2–3 with extra care • **Average surface value:** 0.25–0.80 μm.	• Generally used to finish tooth profile of different types of gears made of hard materials and gears which have been hardened after their manufacturing • For finishing of spur, helical, and bevel gears	• The thermal damage may lead to grinding burn on the gear surface • Generates transverse grind lines on the gear face which increases noise and vibrations of a gear • Redressing of grinding wheels affect form accuracy of a gear • Cost of grinding machine is very high and operation is complicated as it requires skilled machine operator • Take long time in form grinding • Grinding cannot modify some special gears such as an inner gear, multi-joint gears, and very large-size gear
Gear Lapping	• It corrects minute distortion caused due to heat treatment, errors in involute profile, helix angle, spacing, and eccentricity in the hardened gears • Gear tooth contact improves by lapping • **Gear quality:** DIN standard 7 in normal condition, 6 with extra care • **Average surface value:** 0.08–0.25 μm	• For finishing of spur, helical, bevel gear, spiral bevel, and hypoid gears • Usually employed on those gears that has been shaved and hardened	• Longer lapping cycles affects the form accuracy adversely • Only mating gears are lapped in a pair and they cannot be interchanged
Gear Honing	• It improves noise characteristics of the gears • It produces cross-hatch lay pattern on finished gear teeth surface which improves lubricating oil retention • No increase in backlash • High gear quality and improved gear efficiency • Correct the distortion after heat treatment • Improves concentricity • No machining marks in transverse direction • **Gear quality:** DIN standard 7 in normal condition and 6 with extra care • **Average surface roughness:** 0.13–1.25 μm	• For finishing of spur, helical, and bevel gear	• Can be used only for unhardened gears only • Limited life of honing tool • Slow process

Gear Shaving	• It corrects error in index, helical angle, tooth profile, and eccentricity • It increase load carrying capacity of gears • Improve tooth surface smoothness • Reduces gear noise • Eliminates the danger of tooth end load concentration in service • Effectively correct spacing error • Shaving can remove 80% of errors of manufactured gear • **Gear quality:** DIN standard 7 in normal condition and up to 3 with extra care • **Average surface value:** 0.4–0.6 μm	• Widely used for teeth of straight or helical toothed external spur gears and worm wheels of moderate size	• Can be used only for those gears which have hardness up to 40 HRC • High investment cost • Cost of shaving cutter very high • High tool wear
Gear Burnishing	• Improves surface integrity and fatigue life of the gears • Faster than other conventional gear finishing methods • **Gear quality:** DIN standard 7 in normal condition • **Average surface value:** Not available	• For finishing helical gears	• Some undesirable effects such as localized surface stresses and nonuniform surface characteristics are produced due to cold working • Can be used only for soft and unhardened gears only
Gear Finishing by Abrasive Flow Machining (AFM)	• Improves surface roughness and fatigue life • Take less time to finish gear than conventional gear finishing methods • **Gear quality:** not reported • **Average surface value:** not reported	• For finishing of spur, helical, and bevel gears • Both external and internal gears can be finished	• Selection of abrasive and media is major issue • High cost of medium • Specially designed fixture is required to hold gear and direct abrasive putty. This increases cost

1.5.1 Contact Area-Based Path Planning

1.5.1.1 Contact Mechanics

Over the last 30 years or so, a great deal of research has been carried out to develop automated polishing/deburring systems.[1] During polishing, an abrasive tool, such as disk, wheel, stone, belt, and brush, is pressed under a force/pressure against the surface of a part while undergoing a linear or circular reciprocal motion. The pressing interaction between the tool and the part can be modeled using the Hertzian contact theory.[2] The purpose of this modeling is to determine their contact area which represents an effective polishing region.

Contact area is the area generated between two separate nonconforming bodies made of elastic materials under an applied compressive force F, as shown in **Figure 1**. Nonconforming refers to bodies with different profiles and a small contact area relative to the dimensions of the bodies themselves. The upper body is labeled by B_1 and the lower body

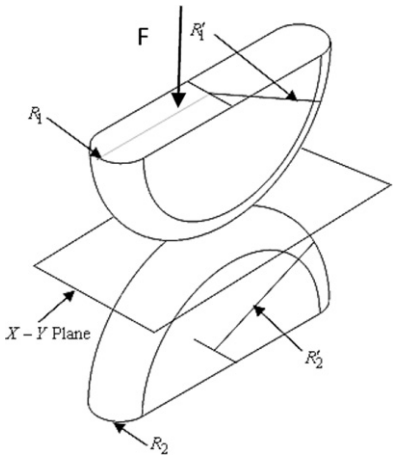

Figure 1 Two contact bodies. Roswell, A. *Modelling for Contact Stress Control in Automated Polishing* (MSc Thesis); Toronto, ON: Ryerson University, 2004.

by B_2. The first point where B_1 and B_2 interact is referred to the initial contact point. If the bodies are assumed to be disks, then each disk has maximum and minimum radii of curvature R_1 and R_1' for the upper disk at the point of contact and R_2 and R_2' for the lower disk. The line of action of the compressive force F is normal to the xy plane, i.e., a tangential plane passing through the point of contact.

Before the compressive force is applied, the separation distance between two points on the surfaces of the bodies and along the line normal to the $x-y$ plane near the point of contact is approximated by.[2]

$$d = Ax^2 + By^2 \quad [1]$$

where x and y are coordinates with the origin at the point of contact, and the constants A and B depend on the principal radii of curvature of both disks at the point of contact as given below

$$A = \frac{1}{4}\left(\frac{1}{R_1}+\frac{1}{R_2}+\frac{1}{R_1'}+\frac{1}{R_2'}\right) - \frac{1}{4}\sqrt{\left[\left(\frac{1}{R_1}-\frac{1}{R_1'}\right)+\left(\frac{1}{R_2}-\frac{1}{R_2'}\right)\right]^2 - 4\left(\frac{1}{R_1}-\frac{1}{R_1'}\right)\left(\frac{1}{R_2}-\frac{1}{R_2'}\right)\sin^2\varnothing} \quad [2]$$

$$B = \frac{1}{4}\left(\frac{1}{R_1}+\frac{1}{R_2}+\frac{1}{R_1'}+\frac{1}{R_2'}\right) + \frac{1}{4}\sqrt{\left[\left(\frac{1}{R_1}-\frac{1}{R_1'}\right)+\left(\frac{1}{R_2}-\frac{1}{R_2'}\right)\right]^2 - 4\left(\frac{1}{R_1}-\frac{1}{R_1'}\right)\left(\frac{1}{R_2}-\frac{1}{R_2'}\right)\sin^2\varnothing} \quad [3]$$

where the angle $\varnothing$ is the intersection angle between planes generated between R_1 and R_2 Note that A and B are related to the geometric shape and configuration of the bodies.

The force F causes elastic deformation of the bodies over the region surrounding the initial point of contact. When the force is applied, the point of contact becomes surface contact and increases with increasing force. The boundary line of the contact surface forms an elliptic area given by

$$\frac{x^2}{a^2}+\frac{y^2}{b^2} = 1 \quad [4]$$

where a and b are the semimajor and semiminor axes of the elliptic contact area. The positive constants a and b determine the shape of the contact area between the disks. a and b are related by $k = b/a$, where b is determined by[2]

$$b = \sqrt[3]{\frac{3kE(k')}{2\pi}(F\Delta)} \quad [5]$$

and

$$\Delta = \frac{1}{A+B}\left(\frac{1-U_1^2}{E_1}+\frac{1-U_2^2}{E_2}\right) \quad [6]$$

where U_1 and U_2 are the Poisson's ratios of the disks, E_1 and E_2 are the modulus of elasticity of body B_1 and B_2, and $k' = \sqrt{1-k^2}$. Note that k is not an exact solution but an approximation given by the following equation:

$$\frac{B}{A} = \frac{\left(\frac{1}{k^2}\right)E(k') - K(k')}{K(k') - E(k')} \quad [7]$$

where $K(k')$ is the complete elliptic integral of first kind

$$K(k') = \int_0^{\frac{\pi}{2}} \frac{d\theta}{\sqrt{1-k'^2\sin^2\theta}} \quad [8]$$

and $E(k')$ is the complete elliptic integral of second kind

$$E(k') = \int_0^{\frac{\pi}{2}} \sqrt{1-k'^2\sin^2\theta}\, d\theta \quad [9]$$

If all model parameters are held fixed (i.e., compressive force, modulus of elasticity, Poisson's ratio), the contact area is a function of one variable, i.e., radius of curvature of the bodies.

1.5.1.2 Contact Area

With the introduction of Hertzian contact theory, the polishing tool is substituted with B_1 and the part surface with B_2. Figure 2 shows a simple yet practical case, where the part has a semi-elliptic cross section area with a semimajor axis $u = 20$ cm and a semiminor axis $v = 10$ cm. The radii of curvatures of the part surface changes in one direction while kept constant in

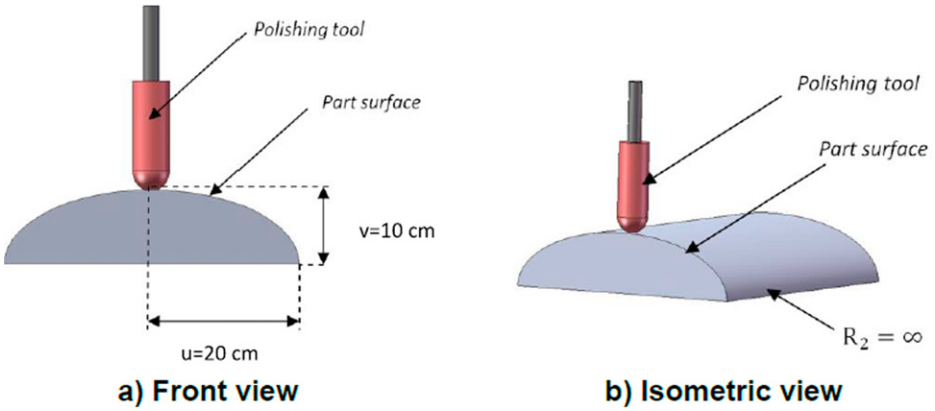

Figure 2 Polishing tool and part. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

the other, i.e., the maximum radius of curvature of the part surface approaches infinity (i.e., $R_2=\infty$).

The polishing tool under study is assumed to carry a semi-spherical polishing head where the tool tip is tangent to the part surface and its centerline is normal to the part surface. This implies that: (1) equal minimum and maximum radii of the polishing tool (i.e., $R_1=R_1'$); and (2) the angle between planes of principal curvature equals to zero (i.e., $\varnothing=0$).

Substituting the assumption into eqn [2] results in[3]

$$A=\frac{1}{2R_1} \qquad [10]$$

which indicates that A is a function of the principal radius of the polishing tool only and a constant principal radius of the polishing tool implies of a constant A. Following the same procedure for eqn [3] results in[3]

$$B=\left(\frac{1}{2}\right)\left(\frac{1}{R_1}+\frac{1}{R_2'}\right) \qquad [11]$$

which indicates that B is a function of the radii of curvatures of the polishing tool and the part surface. If R_1 is constant then B is a function of R_2' only. Changes in A and B results in changes to the semimajor a and semiminor b of the contact area. Therefore, the contact area changes along the part surface.

The radius of curvature of the part can be calculated as follows

$$R=\frac{|x'y''-y'x''|}{(x'^2+y'^2)^{\frac{3}{2}}} \qquad [12]$$

where x', x'', y', and y'' are the first and second derivatives of x and y, respectively. For an ellipse, it can express $x=u\cos\theta$ and $y=v\sin\theta$. Then, the equation for the radius of curvature of an ellipse is given by

$$R=\frac{uv}{\left(v^2\cos^2\theta+u^2\sin^2\theta\right)^{\frac{3}{2}}} \qquad [13]$$

Figure 3 shows the change in radius versus the location of the polishing tool. This part has a semi-elliptic surface with symmetry along its main axis. The radius of the profile increases from both ends toward the center of the part. The maximum radius occurs at the center where $x=0$ and the minimum radius at both ends where $x=\pm 20$(cm), corresponding to the major axis of elliptic cross section.

In this case, the ratio B/A is a function of R_1 and R_2'. Since R_1 is constant, B/A is a function of R_2' only. As R_2' increases, B/A decreases and vice versa, as R_2' decreases B/A increases. The change in radius affects the semimajor and semiminor axes of the contact area between the polishing tool and the part surface. Therefore, increase in the radius of curvature of the part results in a large contact area. **Figure 4** shows a graph of k vs. tool location along the part surface. The following observations are made:

1. At $x=0$(cm) (Maximum R_2'): k ratio approaches unity implying a circular contact area. Note that $k=1$ implies equal semimajor and semiminor axes which indicate that the equation of an ellipse reduces to the equation of a circle and the contact area is circular.
2. At $x=\pm 20$(cm) (Minimum R_2'): small k ratio implying an elliptic contact area at these points.

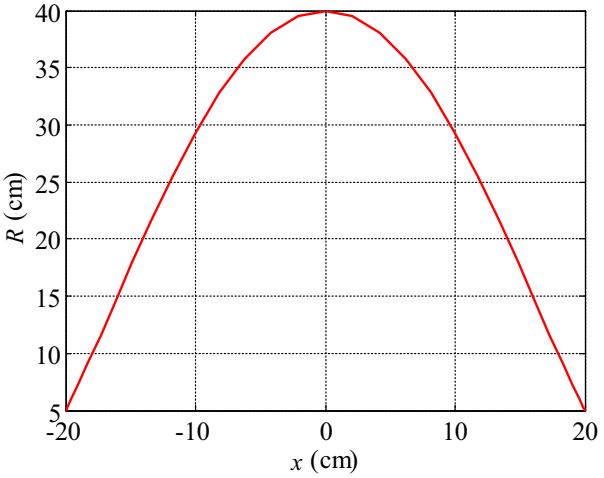

Figure 3 Part surface radius vs. tool location.[3]

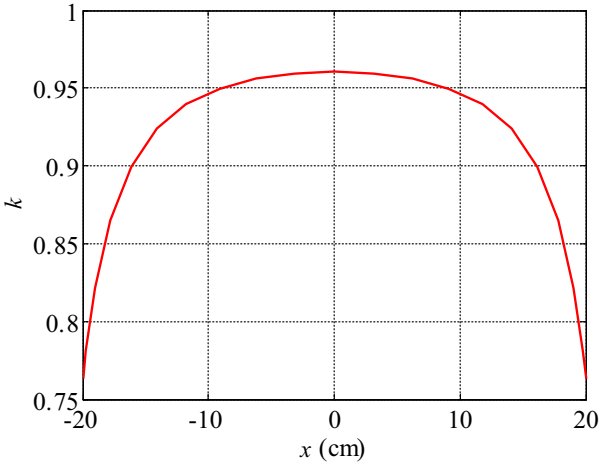

Figure 4 k vs. tool location.[3]

Figure 5 shows a plot of the semimajor axis a and semiminor axis b of the elliptic contact area versus tool locations. The following observations are made:

1. At $x=0$: Small difference between a and b indicating $k\approx 1$. Thus, the contact area resembles a circle.
2. At $x=\pm 20$(cm): Large difference between a and b indicating a small k ratio which implies that the contact area is elliptic.

This figure indicates that for a part with curved profiles the contact area between the polishing tool and the part surface changes with the change in radius of curvature of the part.

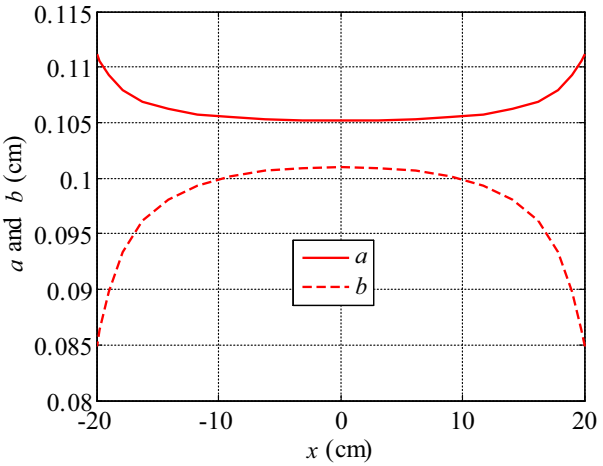

Figure 5 Major axis and minor axis of contact area vs. tool location.[3]

Two conclusions with respect to the contact area between the polishing tool and the part surface are derived from the above discussion:

1. Increase in the radius of curvature of the part results in increase of the contact area between the polishing tool and the part profile.
2. Decrease in the radius of curvature of the part results in decrease of the contact area between the polishing tool and the part profile.

1.5.1.3 Coverage Area Map

Based on the above discussion, a coverage area map (CAM) can be generated along a prescribed polishing path. Here CAM is defined as a two dimensional evidence describing the interaction between the polishing tool and the part surface. For generating the CAM, let N represent a single contact point and CA the corresponding contact area. Any contact point N implies of a contact area CA which is a function of the radius of curvature (i.e., $\forall N \exists \mathrm{CA}(R_1, R'_1, R_2, R'_2)$) as seen in Figure 6.

The polishing path P is a collection of distinct contact points N_i generated by interpolating discretized control points along the part surface. The polishing path for a single raster path is given by

$$P = \{N_1, N_2, \cdots, N_i, \cdots, N_k\} \quad [14]$$

where N_i is the i^{th} contact point along the part surface and N_k is the last contact point. Since, the contact point N_i implies of a corresponding contact area CA_i (i.e., $\forall N_i \Rightarrow \exists \mathrm{CA}_i$), the CAM for a single raster path is given by

$$\mathrm{CAM} = \{\, \mathrm{CA}_1 \quad \mathrm{CA}_2 \quad \cdots \quad \mathrm{CA}_i \quad \cdots \quad \mathrm{CA}_k \,\} \quad [15]$$

where

$$\mathrm{CA}_i = \left\{ (x,y) \middle| \left(\frac{x^2}{a_i^2} + \frac{y^2}{b_i^2} = 1 \right) \right\} \quad [16]$$

Therefore, the Contact Area Map is a set of contact areas where each CA_i is the elliptic contact area generated between the polishing tool and the part surface along the polishing path. The coordinates x and y are defined in the local frame of reference and a_i and b_i are the semimajor and semiminor axes of the contact area.

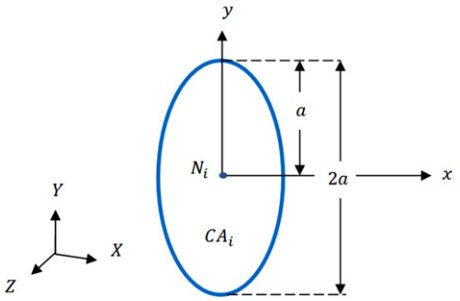

Figure 6 Elliptical contact area at contact point *N*. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

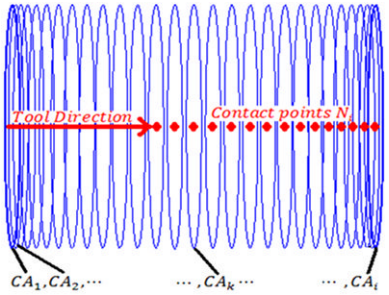

Figure 7 Coverage area for a single raster path. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

Figure 7 shows the CAM for a single raster path. This is a special case of CAM since all the contact points along the path are in a straight line and the contact area has the same length throughout the path indicating a constant semimajor axis. Generating the CAM only requires the semimajor axis a_i since the semiminor axis b_i has little effect in path definition as long as the polishing tool moves slowly and continuously to provide sufficient overlapping. Therefore, the CAM for a polishing path is given by

$$\mathrm{CAM} = f\begin{pmatrix} a_1 & a_2 & \cdots & a_i & \cdots & a_k \end{pmatrix} \quad [17]$$

The two envelop lines represent the semimajor axis a. The area generated by the boundary lines is the coverage area during polishing. Figure 8 shows the coverage area for a single raster path along the part surface. Note that the boundary lines of the coverage area are straight lines.

1.5.1.4 Continuous Polishing Path

Generating continuous raster path based on CAM is a complicated task but the main idea is that it is a set of all

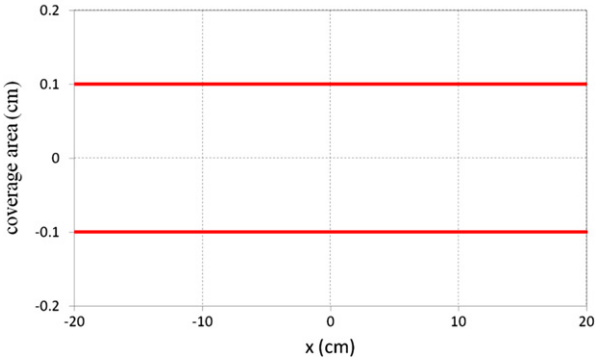

Figure 8 Coverage area for a single raster path. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

individual raster paths along the part surface as described by

$$\mathrm{CRP} = \{P_1, P_2, \cdots, P_l, \cdots P_j\}^T \quad [18]$$

where CRP stands for continuous raster path. P_1 represents the l^{th} polishing path along the part surface and P_j represents the last polishing path. Using eqn [15] and recalling that every contact point N_{i1} implies of a contact area CA_{i1} results in[3]

$$\mathrm{CAM} = \begin{Bmatrix} \mathrm{CA}_{11} & \mathrm{CA}_{21} & \cdots & \mathrm{CA}_{i1} \\ \mathrm{CA}_{12} & \mathrm{CA}_{22} & \cdots & \mathrm{CA}_{i2} \\ \vdots & \vdots & \cdots & \vdots \\ \mathrm{CA}_{1l} & \mathrm{CA}_{2l} & \cdots & \mathrm{CA}_{il} \\ \vdots & \vdots & \ddots & \vdots \\ \mathrm{CA}_{1j} & \mathrm{CA}_{2j} & \cdots & \mathrm{CA}_{ij} \end{Bmatrix} \quad [19]$$

where l represents the l^{th} polishing path and i represents the i^{th} point along the part surface. Because of $\mathrm{CA}(R_1, R_1', R_2, R_2')$, changes in radii of curvatures result in changes to the contact area.

Figure 9 shows the CAM for a flat surface with constant radii of curvature. This is a special case of CAM since: (1) the contact area is circular indicating that $a_{i1} = b_{i1}$, (2) the contact area remains constant throughout the part surface, i.e., $\mathrm{CA}_{il} = \mathrm{CA}_{il+1}$, and (3) minimum and maximum radii of curvatures approaching infinity $(R_2 = R_2' = \infty)$. Therefore, the vertical distance between consecutive path centers CA_{ik} and CA_{ik+1} remains constant. Note that the contact points were placed farther away from each other so that the contact area will be more visible. In practice, however, the CAM is much denser between contact points.

The step-over size between paths P_1 and P_{i+1} depends on the vertical distance of the boundary between CA_l and CA_{l+1}. The vertical distance of the contact area is twice the semimajor axis (i.e., $2a_{il}$). Thus, the step-over size between P_l and P_{l+1} have a maximum vertical distance of $2a_{il}$ and the Contact Area Map (eqn [19]) can be rewritten

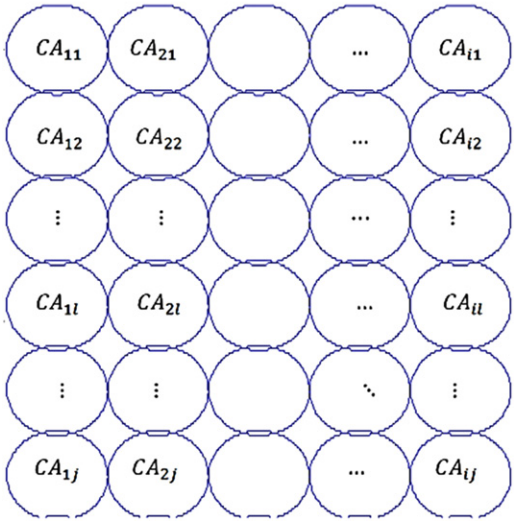

Figure 9 Coverage area map for a flat surface. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

in terms of the semimajor axis a:

$$\mathrm{CAM} = \begin{Bmatrix} 2\mathrm{a}_{11} & 2\mathrm{a}_{21} & \cdots & 2\mathrm{a}_{i1} \\ 2\mathrm{a}_{12} & 2\mathrm{a}_{22} & \cdots & 2\mathrm{a}_{i2} \\ \vdots & \vdots & \cdots & \vdots \\ 2\mathrm{a}_{1l} & 2\mathrm{a}_{2l} & \cdots & 2\mathrm{a}_{il} \\ \vdots & \vdots & \ddots & \vdots \\ 2\mathrm{a}_{1j} & 2\mathrm{a}_{2j} & \cdots & 2\mathrm{a}_{ij} \end{Bmatrix} \quad [20]$$

Achieving a complete coverage area between two adjacent paths P_l and P_{l+1} the step-over size must have a maximum vertical distance of $2a_{il}$ between centers of contact area to adjacent one. Letting $2a_{ij} = \begin{bmatrix} a_{ij} & a_{ij} \end{bmatrix}^T$ and substituting into [20] results in

$$\mathrm{CAM} = \begin{Bmatrix} \begin{bmatrix} \mathrm{a}_{10} \\ \mathrm{a}_{10} \end{bmatrix} & \begin{bmatrix} \mathrm{a}_{20} \\ \mathrm{a}_{20} \end{bmatrix} & \cdots & \begin{bmatrix} \mathrm{a}_{i0} \\ \mathrm{a}_{i0} \end{bmatrix} \\ \begin{bmatrix} \mathrm{a}_{11} \\ \mathrm{a}_{11} \end{bmatrix} & \begin{bmatrix} \mathrm{a}_{21} \\ \mathrm{a}_{21} \end{bmatrix} & & \begin{bmatrix} \mathrm{a}_{i1} \\ \mathrm{a}_{i1} \end{bmatrix} \\ \begin{bmatrix} \mathrm{a}_{12} \\ \mathrm{a}_{12} \end{bmatrix} & \begin{bmatrix} \mathrm{a}_{22} \\ \mathrm{a}_{22} \end{bmatrix} & \cdots & \begin{bmatrix} \mathrm{a}_{i2} \\ \mathrm{a}_{i2} \end{bmatrix} \\ \vdots & \vdots & & \vdots \\ \begin{bmatrix} \mathrm{a}_{1l} \\ \mathrm{a}_{1l} \end{bmatrix} & \begin{bmatrix} \mathrm{a}_{2l} \\ \mathrm{a}_{2l} \end{bmatrix} & \vdots & \begin{bmatrix} \mathrm{a}_{il} \\ \mathrm{a}_{il} \end{bmatrix} \\ \vdots & \vdots & \ddots & \vdots \\ \begin{bmatrix} \mathrm{a}_{1j} \\ \mathrm{a}_{1j} \end{bmatrix} & \begin{bmatrix} \mathrm{a}_{2j} \\ \mathrm{a}_{2j} \end{bmatrix} & \cdots & \begin{bmatrix} \mathrm{a}_{ij} \\ \mathrm{a}_{ij} \end{bmatrix} \end{Bmatrix} \quad [21]$$

Note that $\begin{bmatrix} \mathrm{a}_{ij} & \mathrm{a}_{ij} \end{bmatrix}^T$ represents the total length of the contact area at the i^{th} discretized point along the j^{th}

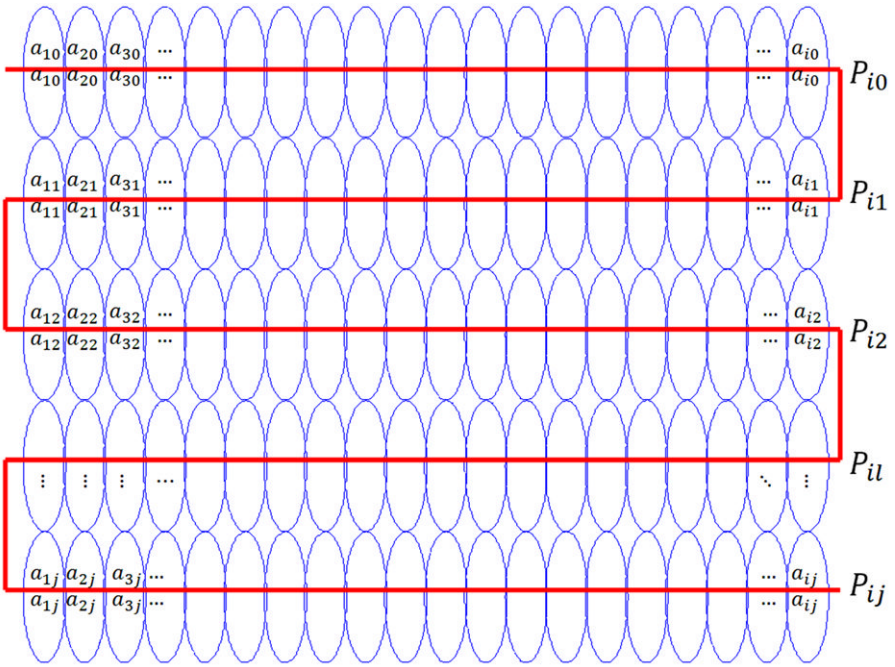

Figure 10 Coverage area map for a continuous polishing path. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

polishing path. Figure 10 shows a CAM for a continuous polishing path.

1.5.1.5 Step-Over Size

Step-over defines a gap between two adjacent polishing polish paths. A constant step-over size is commonly used in conventional machining including polishing. However, this would result in undesired effects during polishing. If a large step-over size is used, an unpolished region is generated between two paths as shown in Figure 11. This region indicates that the polishing tool did not come in contact with the part surface resulting in a rough surface. Additional pass is required to remove the roughness and guarantee full coverage during polishing. If a small step-over size is used, it results in overlapping between adjacent paths as shown in Figure 12. Overlapping, also called crowding, may degrade the part surface and decrease polishing tool life as the same area is covered more than once. This results in increased production time and manufacturing costs.

To explain more on this effect, an ellipsoid shown Figure 13 is considered for a 3D case, which can be expressed as

$$\frac{x^2}{u^2}+\frac{y^2}{v^2}+\frac{z^2}{w^2}=1 \qquad [22]$$

where, in the simulation, $u=1$(cm), $v=0.6$(cm), and $w=0.8$ (cm) are fixed positive real numbers that determine the shape of the ellipsoid.

The radius of curvature in the xz plane is given by the following eqn [3]

$$K_{xz}=\frac{\overline{A}C_{xz}}{\left(\overline{A}^2\left(\frac{z^2}{c^2}\right)+C_{xz}^2\left(\frac{x^2}{a^2}\right)\right)^{\frac{3}{2}}} \qquad [23]$$

where $\overline{A}=\left[\frac{a^2(b^2-\gamma^2)}{b^2}\right]$ and $C_{xz}=\left[\frac{c^2(b^2-\gamma^2)}{b^2}\right]$ and the radius of curvature in the γz plane is given by the following equation:

$$K_{\gamma z}=\frac{\overline{B}C_{\gamma z}}{\left(\overline{B}^2\left(\frac{z^2}{c^2}\right)+C_{\gamma z}^2\left(\frac{x^2}{b^2}\right)\right)^{\frac{3}{2}}} \qquad [24]$$

where $\overline{B}=\left[\frac{b^2(a^2-x^2)}{a^2}\right]$ and $C_{\gamma z}=\left[\frac{c^2(a^2-x^2)}{a^2}\right]$

Figure 14 shows the CAM for the ellipsoid with both the crowding effect, highlighted in green, and the unpolished area, highlighted in red. For an ellipsoid, the unpolished area and the crowding effect are both present when the step-over size is maintained constant throughout the part surface.

1.5.1.6 Polishing Path Planning

To overcome the problems outlined with constant step-over size, a method based on the CAM is described for the generation of a tool path that guarantees a full coverage area at the contact between the polishing tool and the part surface during robotic polishing. Assume that the γ position of each contact point is given by the recursive equation:

$$P_{ij}=P_{ij-1}+a_{ij-1}+a_{ij} \qquad [25]$$

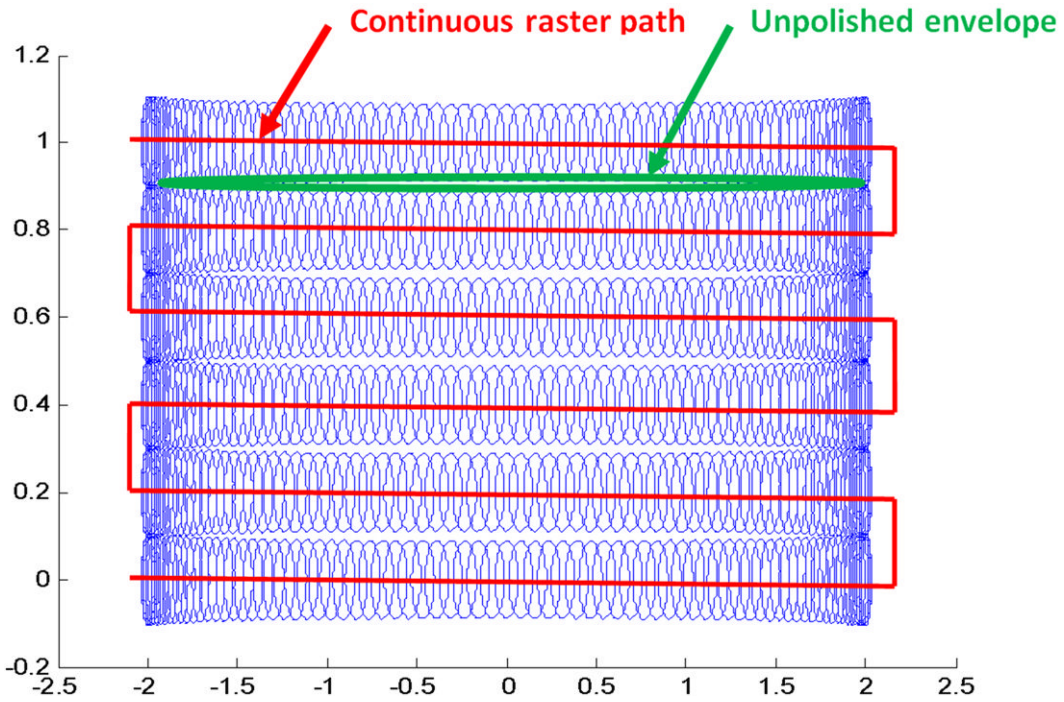

Figure 11 Large step-over size (elliptical cross section, major 2 cm). Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

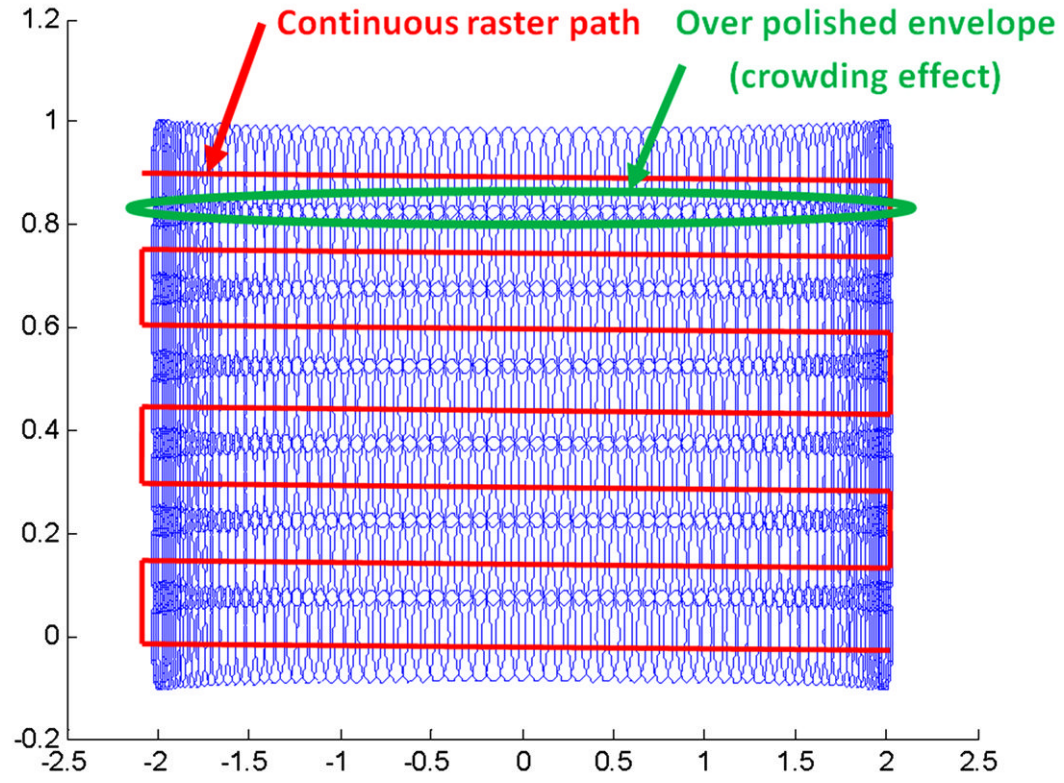

Figure 12 Small step-over size. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

where P_{ij-1}, P_{ij} are the $j-1^{th}$, j^{th} polishing path respectively, a_{ij-1}, a_{ij} are the semimajor axis of the contact area at the i^{th} element of the $j-1^{th}$, j^{th} polishing path, respectively.

Next, define the base path as the first polishing path generated along the part surface (i.e., $j=0$). The base pass P_{i0} is arbitrarily chosen along the part surface. Adjacent polishing path P_{i1} is generated relative to the base path. The γ position of any polishing path is a function of the boundary of the semimajor axis a. Therefore, the base path is also a function of γ and is defined by:

$$P_{i0}(a_{i0}) = 0 \tag{26}$$

indicating that P_{i0} is a function of a_{i0} defined for the polishing path $j=0$, and is assumed to be a straight line since its γ position is 0; thus, it is ignored. The base path P_{i0} passes through the contact point N_{i0} at the center of the contact area CA_{i0} (i.e., along a_{i0} and not $2a_{i0}$). The γ position of the next polishing path P_{i1} follows eqn [25] as described by $P_{i1}=P_{i0}+a_{i0}+a_{i1}$, where a_{i0} and a_{i1} are the semimajor axes of the first and second contact areas for the i^{th} element. Since, $P_{i0}=0$ the equation reduces to:

$$P_{i1} = a_{i0} + a_{i1} \tag{27}$$

All adjacent polishing tool-paths along the part surface are described by the recursive method as follows:

$$\begin{aligned} P_{i2} &= P_{i1} + a_{i1} + a_{i2} \\ P_{i3} &= P_{i2} + a_{i2} + a_{i3} \\ &\vdots \\ P_{ij} &= P_{ij-1} + a_{ij-1} + a_{ij} \end{aligned} \tag{28}$$

This is a recursive method where determination of a polishing path requires the knowledge of the previous path. Alternatively, eqn [28] is written in the following form:

$$\begin{Bmatrix} P_{i2} \\ P_{i3} \\ \vdots \\ P_{ij} \end{Bmatrix} = \begin{Bmatrix} a_{i0} + 2a_{i1} + a_{i2} \\ a_{i0} + \sum_{j=1}^{j=2} 2a_{ij} + a_{ij} \\ \vdots \\ a_{i0} + \sum_{j=1}^{j=j-1} 2a_{ij} + a_{ij} \end{Bmatrix} \tag{29}$$

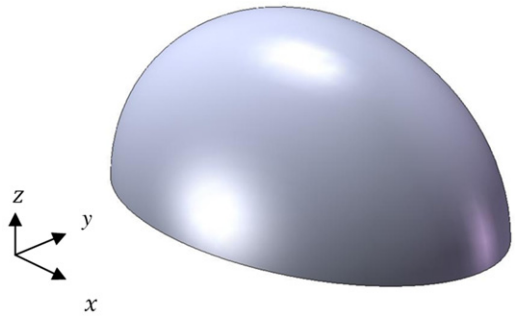

Figure 13 Semi-ellipsoid part surface. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

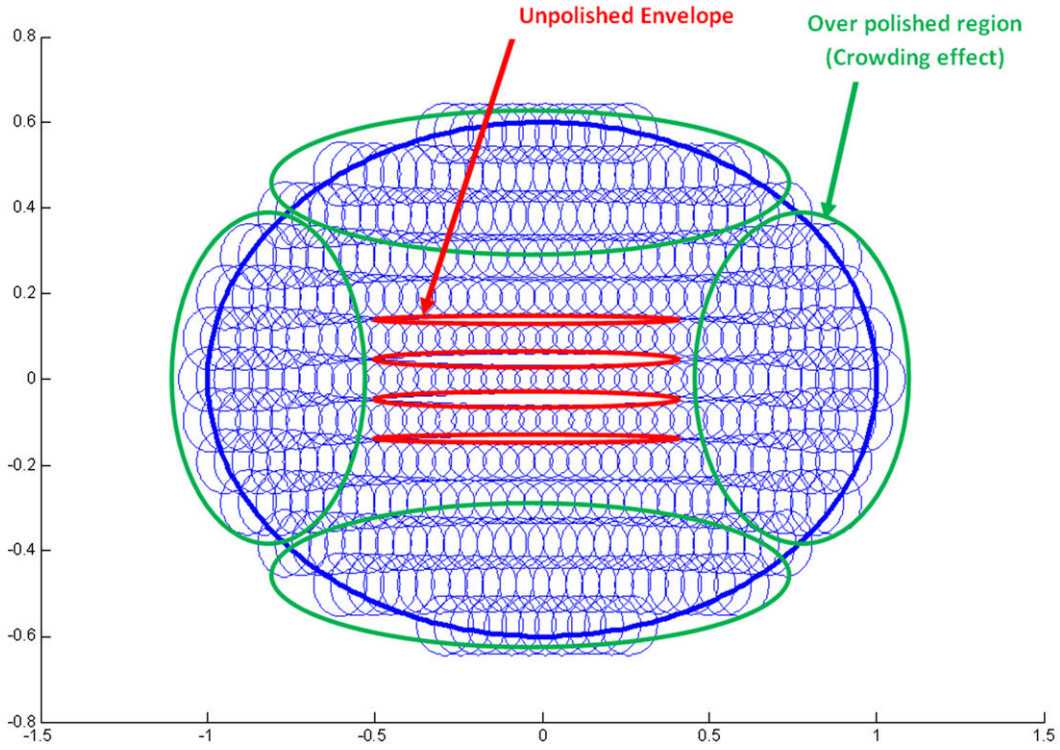

Figure 14 Crowding and unpolished areas for an ellipsoid. Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

In conclusion, the contact points for the polishing path P_{ik} are placed at the γ position as defined by the following equation

$$P_{ij} = \begin{cases} 0 & j = 0 \\ a_{i0} + a_{ij} & j = 1 \\ a_{i0} + \sum_{j=1}^{j=j-1} 2a_{ij} + a_{ij} & j \geq 2 \end{cases} \quad [30]$$

This algorithm guarantees a full coverage area during robotic polishing. The algorithm eliminates the crowding effects and the unpolished envelope identified in the previous section.

Now this algorithm is applied to the parts from the previous section. **Figure 15** shows the modified polishing path of **Figure 11**. In this case the modified CAM shows a full coverage of the part surface. The step-over size between each polishing path is determined by summing up the γ positions of the semimajor axis a. Notice that a small overlap is generated between two adjacent paths. This slight overlap is desired to compensate for imperfections in the polishing tool. Note that the base polishing path is a straight line since the γ position of this path is defined to be at $P_0(a_{ij})=0$. Adjacent paths are summation of the semimajor axis generated at the contact points between the polishing tool and the part surface. Notice that the path becomes more curved for each consecutive polishing path.

Figure 16 shows the modified polishing path for the ellipsoid of **Figure 14**. In this case the modified *CAM* shows a full coverage along the part surface. The step-over size between each polishing path is determined by summing up the γ positions of the semimajor axis a. The base path was defined to be at $\gamma=0$ therefore it is a straight line. Symmetry exists along the x axis since that the part surface was divided into two separate sections. **Figure 16** shows the modified polishing path for the ellipsoid where the radii of curvatures changes in both xz and yz planes for every contact point.

To this end, one may notice that on flat surfaces the radii of curvatures of the part surface approaches infinity and the contact area is circular throughout the polishing path. Therefore, the semimajor axis a_{ik} of any contact point always equals the semimajor axis of adjacent contact point a_{ik+1}. The radii of curvatures of the part surface are constants along the pat surface. Therefore, changing the γ position of any contact point does not affect the contact area.

On part surface where the radius of curvature changes along the x axis but maintained constant along the y axis, the radius of curvature is constant along the γ axis. Therefore, changing the γ position of any contact point does not affect the contact area. However, part surfaces where both radii of curvatures change along the part surface the modified polishing path is complicated to generate. In this case the proposed recursive method still applies, but small modification is required. The complication arises since the radius of curvature constantly changes in both the xz and yz planes. Both planes are functions of x, y, and z axes. Changing the x or y positions of a contact point changes the z position of the contact point. Therefore, the radius of curvature changes which results in different contact areas. **Figure 17** shows a wire frame design of the part surface. Note that changing the position of the contact point from point 1 to point 2 changes the z position of the part surface which results in different radius of curvature. Thus, changing the position of the contact point results in different coverage area.

To generate the modified polishing path that guarantees full coverage area an iterative search method has to be implemented for the recursive method. The search method calculates the semimajor axis a_{ij+1} at a given contact point and adopts itself to the previous semimajor axis a_{ij} until there is no crowding effect or unpolished regions along the part surface.[3]

1.5.2 Surface Roughness Modeling

1.5.2.1 Generation of a Polishing Stone Topography

Within the contact area, surface roughness after polishing can be predicated through modeling. The first step is to generate the topography of a polishing tool. The surface roughness of the polished part can be considered as an imprint created by the polishing tool rubbed against the part. Previous experimental research has revealed that the distribution of the grain protrusion heights of an abrasive tool is of a Gaussian distribution.[5] To generate a random distribution for the grain protrusion heights of a polishing stone, the mean value and standard deviation are required. The grid numbers (M) of commonly used polishing stones are $M=320$ for the first stage stoning, $M=400$ for the second stage stoning, and $M=600$ for the final stage stoning. The grain dimension d_g is expressed equal to the aperture opening of the screen according to the following relationship[5]

$$d_{g\max}(mm) = 15.2M^{-1} \quad [31]$$

This grain size is considered as the maximum grain size, denoted by $d_{g\max}$, for a given grit number M. Furthermore, the average grain dimension denoted by $d_{g\text{avg}}$ is related to grit number M (for $M > 40$) as

$$d_{g\text{avg}}(mm) = 68M^{-1.4} \quad [32]$$

From eqns [31] and [32], it can be calculated that for $M=320$, 400, and 600, $d_{g\max}=47.5$, 38, and 25.3 μm, respectively, and $d_{g\ \text{avg}}=21.1$, 15.5, and 8.8 μm, respectively.

Extensive experiments using 3-D stylus instruments and SEM micrographs show that $d_{g\max}$ and $d_{g\text{avg}}$ are very close to the maximum grain protrusion height $h_{\max}$ and the mean grain protrusion height h_{avg}, respectively. Therefore, the mean value and standard deviation for generating the topography of a polishing stone are given as

$$\mu = d_{g\text{avg}} \quad [33a]$$

$$\sigma = \left(d_{g\max} - d_{g\text{avg}}\right)/3 \quad [33b]$$

where μ and σ are the mean value and standard deviation, respectively. From eqns [33a] and [33b], it can be calculated

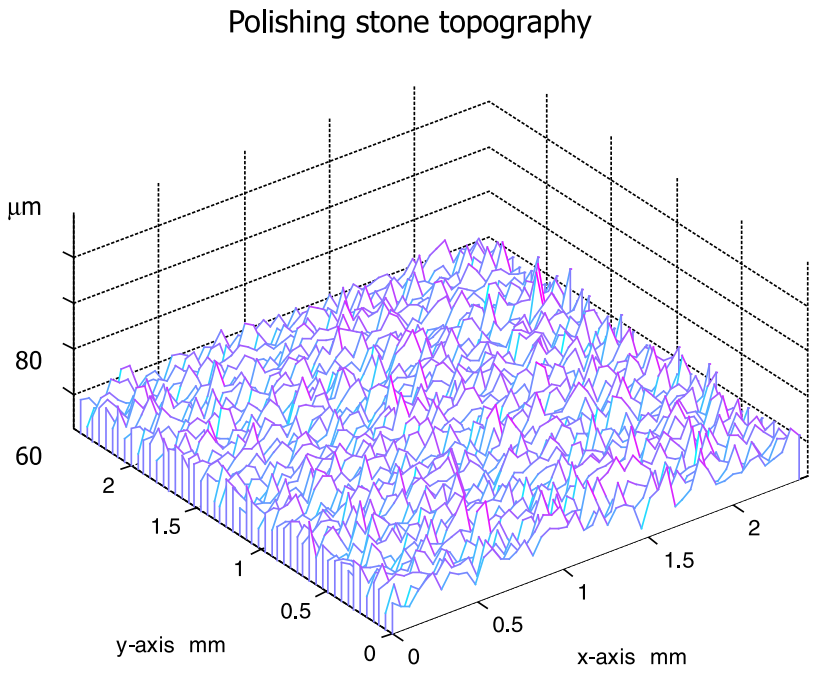

Figure 18 Polishing stone topography. Xi, F.; Zhou, X. Modeling Surface Roughness in the Stone Polishing Process. *Int. J. Mach. Tool. Manu.* **2005**, *45*, 365–372.

that $\mu = 21.1$, 15.5, and 8.8 µm, respectively, and $\sigma = 8.8$, 7.5, and 5.5 µm, respectively, for $M = 320$, 400, and 600.

To generate the topography, the polishing stone is meshed by a grain interval. The grain interval is the distance between two adjacent grains and it is related to the structure number S of the polishing stone. The structure number indicates the volumetric concentration of abrasive grains in the stone. For a given number of S, the density of the stone, V_g (%), may be approximated as[5]

$$V_g = 2(32 - S) \quad [34]$$

In general the distribution of the grain intervals is assumed uniform. The interval Δ can be derived from the following relation

$$\frac{\pi}{6} d_{g\,\mathrm{avg}}^3 = V_g \Delta^3 \quad [35]$$

The left-hand side of eqn [35] indicates the volume of the grains in the polishing stone in terms of the average grain size, and the right-hand side in terms of the density. The two sides should be equal. Therefore, from eqn [35], the grain interval Δ (mm) can be determined as

$$D = 137.9 M^{-1.4} \sqrt[3]{\frac{\pi}{32 - S}} \quad [36]$$

To generate a polishing stone topography, the stone is meshed using the interval determined by eqn [36]. The distribution of the grain protrusion heights is described by a Gaussian distribution with the mean value and standard deviation determined by eqns [33a] and [33b]. **Figure 18** is a simulated polishing stone topography with grit number $M = 400$, showing that the surface of a polishing tool is made of randomly distributed protrusion heights.

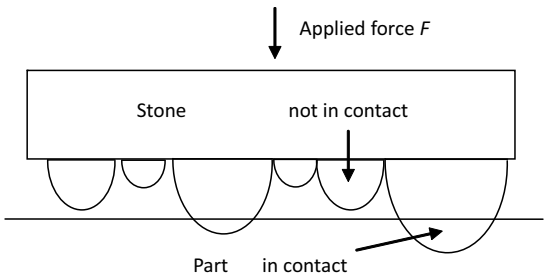

Figure 19 Micro-grain contact model. Xi, F.; Zhou, X. Modeling Surface Roughness in the Stone Polishing Process. *Int. J. Mach. Tool. Manu.* **2005**, *45*, 365–372.

1.5.2.2 Micro Depth of Cut of a Single Grain

Prior to studying the surface roughness of the polished part, the problem of determining the micro depth of cut of a single grain is addressed. Among three types of gain shape: semi-sphere, cone, and prism shape, the semi-sphere shape is adopted because of its commonality for grain modeling.

In the polishing process, the polishing stone is pressed under certain pressure against the part. Though the pressure is applied to the entire polishing stone, it is only concentrated on the grains that are in contact with the part. As shown in **Figure 19**, the contact grains are more protruded than the grains that are not in contact with the part. Due to the highly concentrated pressure on the contact grains, plastic deformation occurs in the contact area, thereby creating micro cuts. Therefore, the polishing cutting mechanism may be modeled based on the plasticity theory, similar to indentation.

Among three methods, Brinell, Vickers, and Rockwell, the Brinell test model is used to determine the micro depth of cut of a single grain. In other words, the grain is modeled as an

indenter inserted in the part. It is assumed that the grain is much harder than the part. For example, the common polishing grain material is aluminum oxide with HB over 1000, while steel is with HB around 300. In the Brinell test model, a hardened ball is pressed into the surface of the material by a standard force. In our polishing model, the hardened ball is replaced by the semi-sphere polishing grain. After the load and the ball have been removed, the diameter of the indentation is measured. The Brinell hardness number (HB) is obtained by dividing the size of the applied force f by the spherical surface area of the indentation A:

$$\mathrm{HB} = \frac{f(kgf)}{A(\mathrm{mm}^2)} \quad [37]$$

where f is the force applied on the grain, and its determination will be discussed later.

The contact area can be obtained by calculation from the values of the radius r_g of the ball and the radius r_c of the indentation, that is

$$A = 2\pi r_g(r_g - \sqrt{r_g{}^2 - r_c^2}) \quad [38]$$

Note that for the grain model, $r_g = d_g/2$, where as mentioned before, d_g is the grain diameter. The following relation holds among r_g, r_c, and h

$$r_g^2 = r_c^2 + (r_g^2 - h)^2 \quad [39]$$

From eqn [39], the micro depth of cut for a single grain can be derived as

$$h = r_g^2 - \sqrt{r_g^2 - r_c^2} \quad [40a]$$

Substituting eqns [37] and [38] into eqn [40a] yields

$$h = \frac{f}{2\pi r_g \mathrm{HB}} \quad [40b]$$

Using eqn [40b], the micro depth of cut of a single grain can be determined given the contact force on the grain and the hardness of the part.

1.5.2.3 Micro Depth of Cut of a Polishing Tool

Knowing how to determine the micro depth of cut of a single grain, two methods can be used to determine the micro depth of cut for a polishing tool. The first one is an average method, simply to estimate the micro depth of cut of multiple grains. This method assumes that all the grains are in contact with the part. In this case, eqn [40b] is used to calculate the average micro depth of cut of the multiple grains. For computing eqn [40b], HB is known if the part material is given, and the average diameter of the grains is equal to μ if the grit number M is given. However, the average force f on each grain is not given and needs to be determined as follows.

$$f = \frac{F}{N} \quad [41]$$

where F is the force exerted on the polishing stone, and N is the total of number of grains.

Table 1 shows the computed average micro depth for $M = 320$, 400, and 600. The grain diameter is determined by eqn [32], the grain interval is determined by eqn [36], the grain force is determined by eqn [41], and the micro depth of cut is determined by eqn [40b]. As shown in Table 2, the results obtained by the average method in fact are the lower bound.[6]

The second method is a search method. Compared to the experimental data, the micro depth of cut determined based on the average method is very small. This discrepancy results from the assumption that all the grains in the contact area are in contact with the workpiece. In reality, however only those protruded grains that are in contact with the workpiece will contribute to the micro depth of cut. Hence, in order to give a more realistic prediction of the surface roughness, it becomes clear that the grain protrusion heights must be considered with different heights obtained from its random distribution.

The basic idea of the search method is to find a solution that the force exerted on the stone is balanced by a number of more protrusion grains in the contact area. Then, these grains are taken as the contact grains to determine the micro depth of cut, while excluding the rest of the grains. Since the grain with the maximum protrusion height cuts off the surface polished by all the other contact grains, it generates the most dominant scallops and its micro depth of cut should be considered first. Then, if the second highest grain does not cut into the scallops generated by the first highest grain, the first scallops will be the final marks. If the second grain does cut, it will change the profile of the first scallops. The process of modifying the surface profile continues with more grains involved in a descending order, and it terminates when no grain cuts into the scallops anymore. Mathematically, the search method is described as follows.

Table 1 Micro depth of cut based on average method

Grit number M	*Grain diameter (μm)*	*Grain interval (μm)*	*Part hardness (HB)*	*Micro depth of cut (μm)*
320	21.1	21.8	300	0.02–0.03
400	15.5	15.9	300	0.01–0.02
600	8.8	9.0	300	0.009–0.01

Source: Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

Table 2 Micro depth of cut – upper bound, lower bound, and search method

Grit number M	*Upper bound (μm)*	*Lower bound (μm)*	*Search method (μm)*
320	47.5	0.02–0.03	0.4–0.8
400	38	0.01–0.02	0.25–0.6
600	25.3	0.009–0.01	0.2–0.5

Source: Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

First, the micro depth of cut of the most protruded gain is determined as

$$h_1 = \frac{F}{\pi d_{g1} \mathrm{HB}} \quad [42]$$

where h_1 is the micro depth of cut of the most protruded grain. Note that in eqn [42], the total stone force is initially applied to the most protruded grain with d_{g1} being its diameter.

After h_1 is obtained, the difference of $(r_{g1}–h_1)$ is compared to r_{g2}. If larger, it means that the first grain will balance the entire stone force. Then search terminates and h_1 is taken as the final micro depth of cut. If smaller, the second most protruded grain will contribute to the force balance. Since the force is distributed proportionally to the area, the stone force will be divided between the two grains as follows:

$$f_i = \frac{F r_{gi}}{\sqrt{\sum_{i=1}^{2} r_{gi}^2}} \quad [43]$$

where $i = 1, 2$. Under the force re-distribution determined from eqn [43], the micro depth of cut of the second most protruded grain will be calculated as

$$h_2 = \frac{f_2}{\pi d_{g2} \mathrm{HB}} \quad [44]$$

Similarly, the difference of $(r_{g2}–h_2)$ is compared to r_{g3}. If larger, it means that the first and second gain will balance the entire stone force. Then search terminates and h_2 is taken as the final micro depth of cut. If smaller, the third most protruded grain will contribute to the force balance.

To this end, the search algorithm can be expressed, first for the force distribution as

$$f_i = \frac{F r_{gi}}{\sqrt{\sum_{i=1}^{k} r_{gi}^2}} \quad [45]$$

where $i = 1, \ldots, k$, and then for the micro depth of cut as

$$h_k = \frac{f_k}{\pi d_{gk} HB} \quad [46]$$

where index k indicates a number of k contact grains. The search terminates when $r_{gk} - h_k > r_{g(k+1)}$.

For the simulation results of the search method provided in **Table 2**, the number of the contact grains is in the range of 100–120 for $M = 320$, 150–180 for $M = 400$, and 220–280 for $M = 600$. The depth of cut determined based on eqn [42] is usually very big because it is based on a single grain contact. If this value is greater than the diameter of the biggest grain, it is considered unrealistic; the reason being that the depth of cut cannot be greater than the size of grains. Therefore, the maximum size of the grain is taken as the upper bound.

The average method, on the other hand, represents the lower bound, which is too small because it is based on all grains contact. The search method provides a realistic prediction that lies in between the two bounds, since it is based on the actual number of contact grains. **Table 2** shows the results of the upper and lower bounds as well as the search method. The force range considered is ~ 10 N.

1.5.2.4 Prediction of Surface Roughness

A realistic way of predicting the surface roughness should be based on the surface roughness of the previous process. In this study, the ball-end milling process is considered as the previous process and the surface roughness of the milled surface can be approximated as[7]

$$R_a = \frac{0.0321 s^2}{r_m} \quad [47]$$

where s is the feed (mm) and r_m (mm) is the radius of the milling tool. The surface roughness of the milling process is in the range of 0.8–5 μm.[7]

In the actual polishing process, the part is first polished by a fine stone ($M = 320$) with a number of strokes till the coarse milling marks are removed and covered by the fine marks left by the stone. This is followed by the second polishing using a finer stone ($M = 400$), and then again followed by the third polishing using an even finer stone ($M = 600$).

Since polishing marks are created by the stone, it would be reasonable to assume that the surface roughness is very close to the micro depth of cut of the contact grains. Based on this assumption, the number of strokes needed to reduce the previous surface roughness to the current one may be calculated as

$$N_s = \left(\frac{G}{2G_k}\right)\left(\frac{R_a^{(j)}}{h^{(j+1)}}\right) \quad [48]$$

where N_s is the number of strokes, G is the number of grains in the contact area, G_k is the number of the contact grains determined from the search method, R_a is the surface roughness value of the previous process, h is the micro depth of cut of the current process, and index j indicates the jth time of polishing.

For example, assume that the surface roughness after milling is around 3 μm. From **Table 2**, the micro depth of cut of the first polishing using the stone of $M = 320$ is around 0.8 μm, which is considered as R_a after the first polishing. The number of strokes is estimated based on eqn [48]. The number of cutting layers is calculated around four, for the reduction from 3 to 0.8 μm. In addition, the grain ratio is needed. As mentioned before, the number of contact grains is around 100 for $M = 320$. The simulation shows that there are around 20 K grains within the contact area. Substituting these values into eqn [48], the number of strokes for the first polishing would be around 400. The similar approach can be used to determine the number of strokes for the second and third polishing. As shown in **Table 3**, the predicted surface roughness is in the same magnitude of the experiment data obtained from the SPI finishing guide.[8]

1.5.3 Contact Stress-Based Control

1.5.3.1 Robotic Polishing/Deburring System

Figure 20 shows a robotic polishing/deburring system developed at Ryerson University that consists of a hybrid robot with an active compliant toolhead. This is a decoupled system because the robot is used solely for motion control and the active compliance toolhead solely for force control. The robot has five axes, composed of a three-axis parallel robot (tripod) and a two-axis gantry. The active compliance toolhead is attached to the moving platform of the robot.

Figure 21 is a control block diagram for the toolhead. There are two control inputs, one for a pressure valve and another for a flow valve. There are two outputs, one being the contact stress and another being the tool spindle speed. The input voltage V_p is supplied to actuate the pressure valve to provide the tool pressure. Simultaneously, the input voltage V_q is supplied to actuate the flow valve to provide a flow rate. The volumetric flow entering the polishing spindle provides a polishing torque. The control method requires the following set of modeling.

Table 3 Comparison with the experiment data

Grit number M	*Predicted* (μm)	*Experiment range*[8] (μm)
320	0.4–0.8	0.7–0.8
400	0.25–0.6	0.5–0.6
600	0.2–0.5	0.25–0.3

Source: Rososhansky, M. *Coverage Based Tool-Path Planning for Automated Polishing Using Contact Mechanics Theory* (MSc thesis); Toronto, ON: Ryerson University, 2010.

1.5.3.2 Contact Stress Modeling

The first one is contact stress modeling, which refers to the pressure (contact stress) arising from two bodies subjected to compressive loading by forcing them together. It is modeled to obtain a relationship between the applied force (the compressive load) and the maximum pressure (maximum compressive stress). The principal stress on the contact surface is given as follows[10]

$$\sigma_{zz} = -\left[\frac{M}{2}\left(\frac{1}{n} - n\right)\right]\frac{b}{\Delta} \qquad [49]$$

where σ_{zz} is the compressive principal stress indicated by the negative sign, and

$$M = \frac{2k}{k'^2 E(k')} \quad , \quad n = \sqrt{\frac{k^2 + k^2(Z/b)^2}{1 + k^2(Z/b)^2}}$$

and the rest of parameters are previously defined in Section 1.5.1. Through simplification for the polishing case, the maximum stress P_0 can be expressed as

$$P_0 = \frac{b}{E(k')\Delta} \qquad [50]$$

The stress distribution within an elliptic contact area is expressed as

$$P_{\text{seg}}(x, y) = P_0[1 - (x/a)^2 - (y/b)^2]^{1/2} \qquad [51]$$

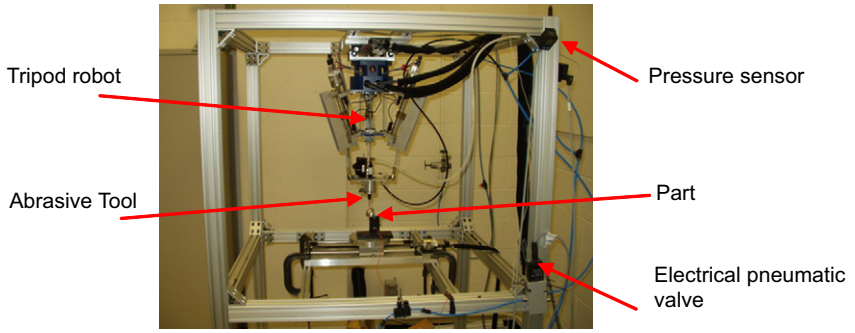

Figure 20 A polishing/deburring robot.[9]

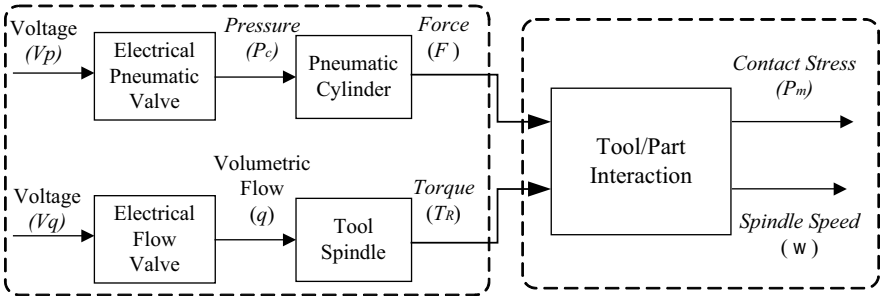

Figure 21 Control block diagram. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

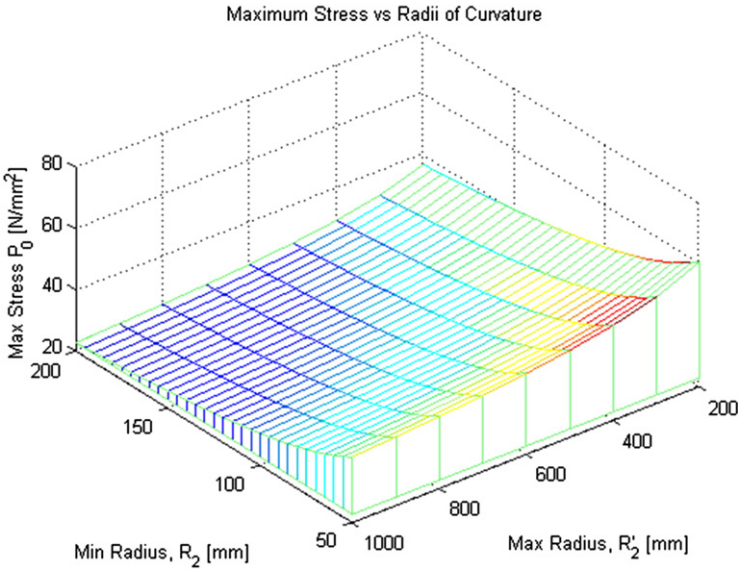

Figure 22 Variation in P_0 versus the radii of curvature. Roswell, A. *Modelling for Contact Stress Control in Automated Polishing* (MSc Thesis); Toronto, ON: Ryerson University, 2004.

The mean stress across the elliptic contact area is derived as

$$P_m = \frac{2}{3}P_0 \qquad [52]$$

In practice, the user specified polishing pressure (stress) is considered as the mean stress. **Figure 22** illustrates the relationship between the maximum stress (P_0) and the radii of curvature (R_2 and R_2') of the part when the applied force remains constant. It can be seen that the stress (pressure) is highest when the radii are smallest.

The mapping of contact stress on the surface radii of curvature proves the applied force cannot remain constant if contact stress is required to be constant. By solving for the force, an equation is obtained for determining the force variation necessary for keeping contact stress P_0 constant.

$$F = \frac{2\pi E^2(k')\Delta^2 {P_0}^3}{3k} \qquad [53]$$

1.5.3.3 Friction Torque Modeling

The second modeling is friction torque which is the minimum torque needed in order to provide reciprocal polishing motion. It is assumed the friction torque is equivalent to the polishing torque necessary to remove material from the part surface. There are two cases: non-Hertzian and Hertzian contact. The first case is to polish a flat surface using a disk, consequently the pressure is assumed constant across the contact region. The second case is for curved tool/part, and the mean pressure is considered. In general, the friction torque is given as

$$T_f = F_{sf}\, r \qquad [54]$$

where $F_{sf}=F_s\mu_k$, $F_s=PA_c$, μ_k is the friction coefficient, P and A_c are the cylinder pressure and area, respectively.

For non-Hertzian contact as shown in **Figure 23**, the contact area is formed when the circular flat polishing tool is in contact with a flat part. Therefore, the radius of the contact area is equivalent to the polishing toolhead's radius. The torque across the circular contact area is double integrated leading to the below:

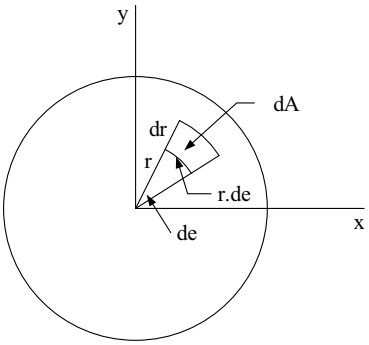

Figure 23 Circular contact area. Roswell, A. *Modelling for Contact Stress Control in Automated Polishing* (MSc Thesis); Toronto, ON: Ryerson University, 2004.

$$T_f = \mu_k P_s \int_0^{2\pi}\int_0^R r^2 \mathrm{d}r\, \mathrm{d}e = \mu_k P_s \frac{R^3}{3} \int_0^{2\pi} \mathrm{d}e = \frac{2}{3}\pi\mu_k P_s R^3 \qquad [55]$$

The first integral (the inner integral) gives the torque per unit radian, while the outer integral provides the total friction torque across 2π radians. This equation can be directly related to the applied polishing force as shown

$$T_f = \frac{2}{3}\mu_k FR \qquad [56]$$

For Hertzian elliptic contact given in **Figure 24**, since the focus is not on the pressure at particular locations within the elliptic contact area, rather on the pressure over the entire elliptic contact area, the pressure at the infinitesimal segment is taken to be the same throughout the contact area. Therefore, the average

or mean pressure is used. Therefore, the torque is given as

$$T_f = \mu_k P_m \int_0^{2\pi} \int_0^R r^2 \mathrm{d}r\, \mathrm{d}e = \mu_k P_m \int_0^{2\pi} \frac{R^3}{3} \mathrm{d}e \qquad [57]$$

where for the elliptic region, R is expressed as $R^2 = a^2\cos^2 e + b^2\sin^2 e$, then the torque is obtained as a function of mean contact stress as

$$T_f = \frac{\mu_k P_m}{3} \int_0^{2\pi} (a^2\cos^2 e + b^2\sin^2 e)^{3/2} \mathrm{d}e$$

$$= \frac{1}{3}\mu_k P_m \pi (a^3 + b^3) \qquad [58]$$

Further manipulation to express the torque as a function of force yields[10]

$$T_f = \frac{2}{9}\mu_k \pi (1 + 1/k) \times \left(\frac{3kF}{2\pi}\right)^{4/3} \times (E(k')\Delta)^{1/3} \qquad [59]$$

Figure 25 shows the friction torque under constant force. This value increases as the ratio of the maximum to minimum principal radius (R_2'/R_2) increases. Figure 26 displays the friction torque under constant contact stress. In this situation, as the contact region becomes less elliptic, i.e., the value of k increases, the friction torque increases.

Investigating the effects of friction torque on the polishing speed is critical to achieving the goal of maintaining a constant speed throughout the polishing process. The two parameters can be related as below

$$\omega = \frac{W}{T_R} \qquad [60]$$

Where W is the supplied power, $T_R = I\dot{\omega} + T_f$ is the resultant tool torque. Then, the rotational speed for the non-Hertzian circular contact is obtained as

$$\omega_C = \frac{W}{\left(I\dot{\omega} + \frac{2}{3}\mu_k F_s R\right)} \qquad [61]$$

and that for the elliptic Hertzian contact as

$$\omega_E = \frac{W}{\left(I\dot{\omega} + \left\{\frac{2}{9}\mu_k \pi (1 + 1/k) \times \left(\frac{3kF}{2\pi}\right)^{4/3} \times (E(k')\Delta)^{1/3}\right\}\right)} \qquad [62]$$

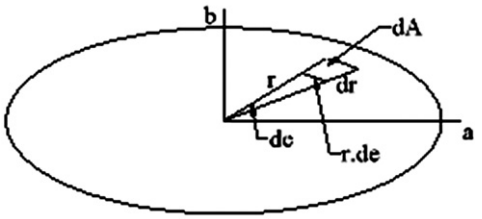

Figure 24 Elliptic contact area. Roswell, A. *Modelling for Contact Stress Control in Automated Polishing* (MSc Thesis); Toronto, ON: Ryerson University, 2004.

1.5.3.4 Polishing Parameter Planning

Equations [52], [61], and [62] show that both contact stress and spindle speed are a function of part geometry. For example, to maintain a constant contact stress throughout polishing, which would provide a uniform polishing quality, the polishing pressure should be computed to vary based on part geometry. Likewise, to maintain a constant spindle speed throughout polishing, which would provide a constant material removal rate, the spindle power should be computed to vary based part geometry as well. The process of planning these parameters is called parameter planning process. Based on the part coordinates obtained through polishing path planning, the polishing pressure (force) and the spindle power are computed.

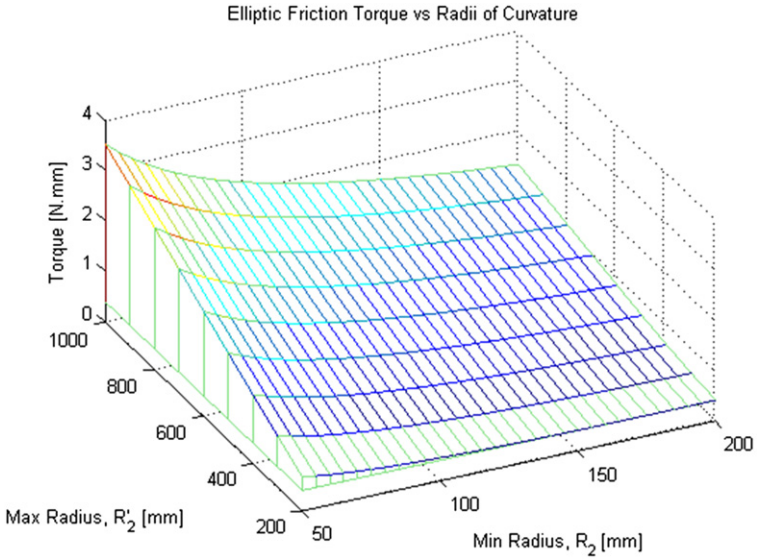

Figure 25 Friction torque under constant force. Roswell, A. *Modelling for Contact Stress Control in Automated Polishing* (MSc Thesis); Toronto, ON: Ryerson University, 2004.

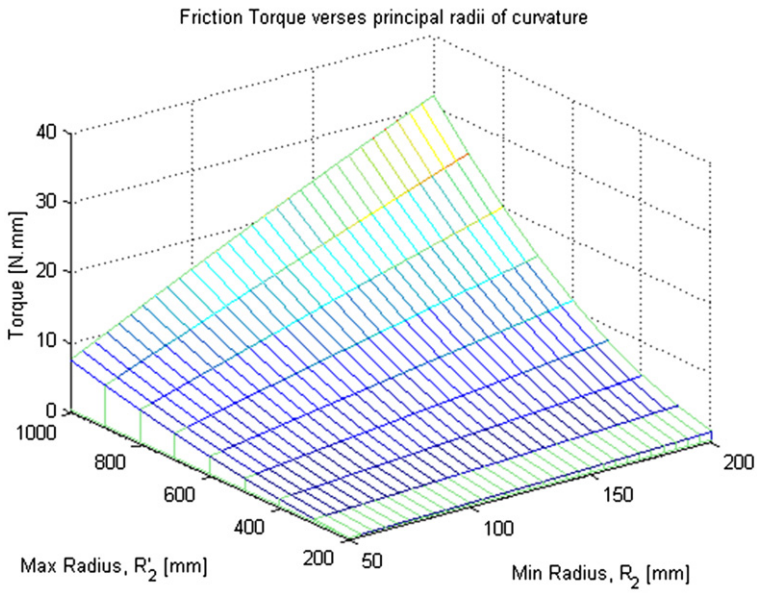

Figure 26 Friction torque under constant contact stress. Roswell, A. *Modelling for Contact Stress Control in Automated Polishing* (MSc Thesis); Toronto, ON: Ryerson University, 2004.

A number of tests were carried out for polishing a curved door stop with and without the application of the pressure planning. Part profiles were measured using a 2-D laser profile scanner (Cobra 2D from Optical Gaging Products Inc.), with accuracy of 10 μm and the dynamic resolution of 1.0 μm. For the constant force case, the pneumatic cylinder pressure was held constant at 2.25 bars. For the constant contact stress case, the parameter planning method was utilized, the pneumatic cylinder pressure varies from 1.71 to 2.30 bars; this range of pressure is according to a 50 N mm^{-2} desired surface contact stress. The 2.30 bars is required when the polishing tool reaches the top of the arc, while the 1.71 bar value is required when polishing the end of the arced edge.

Figure 27 shows the experiment result. Due to slight alignment inaccuracy, there are some measurement errors. Nevertheless, the general tendency is correct. Near the middle of the part (door stop), the radius of curvature is large, i.e., flatter, the constant force (varying contact stress) produced a similar profile to that by the constant stress, and both very close the original profile. However, at both ends where the radii of curvatures become small, the constant force case removed more materials due to high-concentrated force, and the polished profile deviated substantially from the original one. For the constant contact stress case, the polished profile is still very close to the original one. In general, polishing is only meant to improve surface finish not to alter the part geometry (profile).

1.5.3.5 Air Cylinder Pressure Control Modeling

After polishing parameters are planned, polishing control becomes a tracking problem. Similar to robot tracking control after joint motions are planned, polishing tracking control is to track the planned polishing parameters, such as supply pressure. Pressure control modeling is to relate the air cylinder pressure P_c to the control input voltage V_p as below

$$P_c = G_p V_p \quad [63]$$

where G_p is the transfer function relating the input voltage and the cylinder pressure. The relationship between the cylinder pressure P_c and the applied contact force F is given as

$$P_c = \frac{F+f}{A_c} \quad [64]$$

where A_c is the area of the piston inside the cylinder chamber, f is the spring return force of the cylinder which can be obtained through stiffness measurement. The relation between F and the mean contact stress P_m is given as

$$F = \frac{9\pi E^2 (k')\Delta^2 P_m^3}{4k} \quad [65]$$

Under the condition of a constant contact stress P_m, the cylinder pressure P_c can be precomputed from eqns [64] and [65]. Therefore, the control objective is to track the change of the cylinder pressure P_c. **Figure 28** shows a polishing path planning including pressure based on constant contact stress. Standard G-codes are implemented in our polishing/deburring robot, except letter P is used to indicate the cylinder pressure P_c instead of time.

1.5.3.6 Air Spindle Speed Control Modeling

Air spindles are commonly used for polishing and they can be modeled as[11]

$$W = (P_s - P_x)q \quad [66]$$

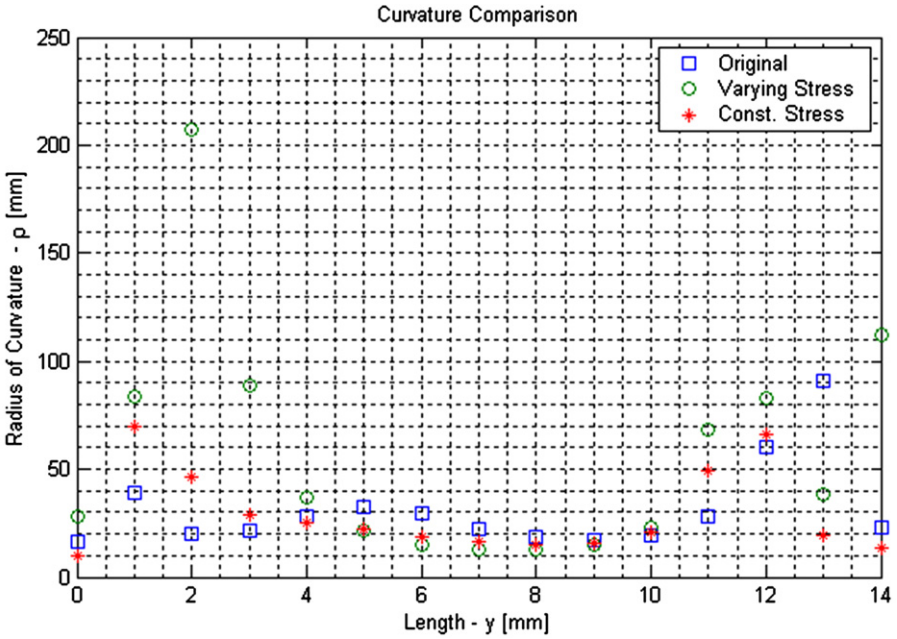

Figure 27 Experiment result between constant force and constant contact stress. Roswell, A. *Modelling for Contact Stress Control in Automated Polishing* (MSc Thesis); Toronto, ON: Ryerson University, 2004.

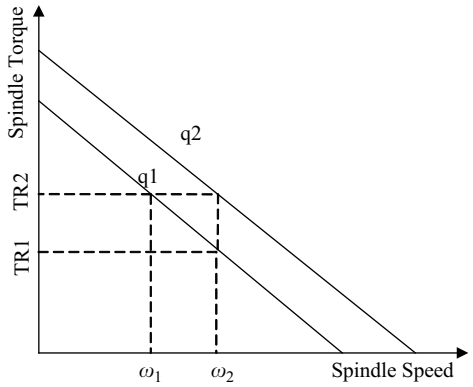

Figure 28 Spindle speed vs. spindle torque. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

where W is the power, P_s represents the supply pressure, P_x is the exhaust pressure, and q is the volumetric flow rate. The resistance of the fluid flow is defined as

$$R_f = (P_s - P_x)/q \qquad [67]$$

Substituting eqn [67] into eqn [66] yields

$$W = Rq^2 \qquad [68]$$

Using eqn [60] and considering power efficiency, the spindle torque can be expressed as

$$T_R = \frac{\eta R_f q^2}{\omega} \qquad [69]$$

By combining with eqn [59] for Hertzian contact, the dynamic equation of the spindle can be derived as

$$I\dot{\omega} = \frac{\eta R_f q^2}{\omega} - \frac{2}{9}\mu_k \pi \left(1 + \frac{1}{k^3}\right)\left(\frac{3kF}{2\pi}\right)^{4/3}(E(k')\Delta)^{1/3} \qquad [70]$$

When the polishing tool rotates at a constant speed, $I\dot{\omega} = 0$, eqn [70] reduces to

$$\omega = \frac{\eta R_f q^2}{\frac{2}{9}\mu_k \pi (1 + \frac{1}{k^3})(\frac{3kF}{2\pi})^{4/3}(E(k')\Delta)^{1/3}} \qquad [71]$$

The spindle does not produce torque at the free running speed, while it exerts a maximum torque when the spindle stalls. The spindle speed can be expressed as a function of output torque T_R by using the following equation

$$\omega = \omega_0\left(1 - \frac{T_R}{T_{\max}}\right) \qquad [72]$$

where $T_{\max}$ is the spindle maximum output torque, ω_0 is the free running speed of the spindle when no load. **Figure 28** shows a speed–torque relation. It can be assumed that the spindle rotates at ω_2 under flow rate q_1, i.e., on the lower line. When geometry changes, under the constant contact stress condition, the friction torque will change from T_{f1} to T_{f2}. Correspondingly, the output torque will change from T_{R1} to T_{R2}. Therefore, the spindle speed is reduced to ω_1. If the spindle speed is required to remain at the original ω_2, the flow rate must be changed from q_1 to q_2, i.e., from the lower line to the upper line. As a result, the spindle speed can be put back from ω_1 to ω_2.

1.5.3.7 Combined Control System

Now by combining eqns [63] and [69], the entire control system corresponding to Figure 21 can be expressed as

$$\begin{bmatrix} F \\ T_R \end{bmatrix} = \begin{bmatrix} G_p A_c & 0 \\ 0 & \dfrac{\eta R_f G_q^2}{\omega} \end{bmatrix} \begin{bmatrix} V_p \\ V_q^2 \end{bmatrix} \quad [73]$$

Noting that $q = G_q V_q$, where G_q is the transfer function of the flow value. This is a decoupled nonlinear control system, corresponding to the left-hand side of Figure 21. The right-hand side of Figure 21 is the tool/part interaction. Under the condition of a constant contact stress P_m, for a given part geometry, the applied contact force F can be determined using eqn [65], which can be directly related to the cylinder pressure P_c through eqn [64]. The goal of the pressure control is to keep actual P_c as close to planned P_c as possible. In other words, this is the problem of pressure tracking control. Under the condition of constant spindle speed ω, for a given part geometry, the flow rate q can be determined through eqn [71]. If only the contact stress is kept constant, then the spindle speed changes with change in part geometry under the constant input V_q. Figure 29 shows this change and the parameters of the geometry for this simulation are taken from the pressure planning given in Table 4. It can be seen that the spindle speed varies under constant flow rate.

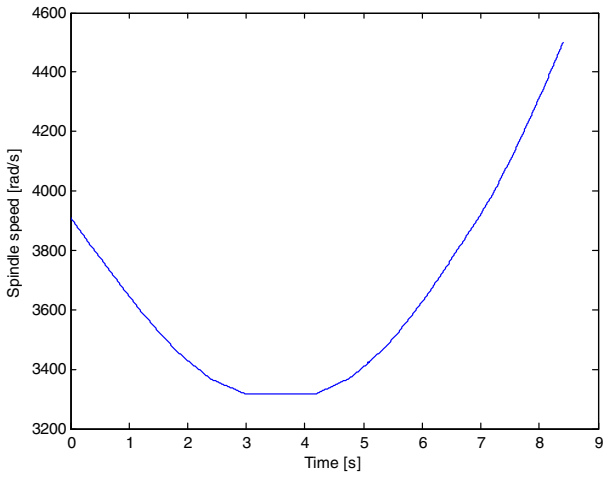

Figure 29 Spindle speed vs. varied geometry. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

1.5.3.8 Pressure Tracking Control

Under the constant contact stress, polishing control is to adjust the cylinder pressure P_c pre-planned based on the part geometry. This control can be treated as the problem of pressure tracking control. In our set up as shown in Figure 30, an active compliance toolhead is made of three spring return pneumatic cylinders (EZH-1.5x6.5–10 from Festo) to provide pressure in the axial direction controlled by a proportional directional control valve (MPYE-5–1/4–010B from Festo) with a response frequency of 100 Hz. A pressure sensor (PENV-A-PS/O-K from Festo) is used to measure the cylinder pressure to form a closed control loop.

A common PID controller can be applied to achieve this control goal. The control block diagram for the pressure tracking is shown Figure 31. The output pressure in the pneumatic cylinders is used as feedback to compare with the desired planned cylinder pressure P_{cd}. The error e is converted to the change of input voltage V_p by using the PID controller. The transfer function for PID control is

$$U(s) = K_{pp} E_p(s) + K_{pi} \frac{E_p(s)}{s} + K_{pd} s E_p(s) \quad [74]$$

where $E_p(s) = P_{cd}(s) - P_c(s)$ and K_{pp}, K_{pi}, and K_{pd} are the proportional gain, integration gain and derivative gain, respectively.

Figure 32 shows the planned cylinder pressure P_c of Table 4. Figure 33 shows the experimental results of the cylinder pressure tracking for the polishing control. From the time at 72 s, the toolhead started being in contact with the part. It ended at the time of 88 s when the tool left contact with the part. It can be seen that the measured cylinder pressure follows the planned cylinder pressure by using a PID controller. The PID controller gains are tuned experimentally to be 0.9, 0.9, and 0.1, respectively.

1.5.3.9 Robotic Deburring Control

Burr is an unwanted material left on the part after cutting. Burr location is generally predictable either at the entrance of cutting or at the exit, with the latter being dominant. However, the burr geometry varies. Burr is commonly measured by burr

height and thickness. Some experimental research has been done on milling and drilling. **Table 5** lists the basic types of burr geometry for milling as well as those for drilling. The experiment results[12] show that the depth of cut is the primary factor for the burr height; feed rate and cutting speed are secondary factor for the same tool geometry.

Since burr geometry is generally unknown, a deburring control method is presented with a burr height measurement. A linear encoder shown in **Figure 30** was integrated with our toolhead to form a closed-loop deburring control system.[13] For the development of this control system, a dynamic model of the tool system is described based on the axial compliant tool model, as shown in **Figure 34**.

In deburring, the tool is pressed against the part by three single acting pneumatic cylinders with spring return in the tool axial direction, denoted by z. The tool dynamic model is derived treating the tool system as a spring-damper-mass system subject to the control force and contact force

$$M\ddot{z} + C\dot{z} + Kz = u_p - F \qquad [75]$$

where M is the tool mass, C and K are the damping and stiffness of the spring inside the cylinder, respectively, u_p is the control force, and F is the contact force between the part and the tool. It is noted that the tool axial direction is the tool length direction. In other words, variable z represents the tool length.

The contact force is derived as follows. In light of the micro-cutting model,[6] the average micro depth of cut considering the multiple grains of the abrasive deburring tool can be expressed as

$$h = \frac{F/N}{2\pi r_g \mathrm{HB}} \qquad [76]$$

where HB is the hardness of the part (N mm^{-2}), r_g is the average radius of the grain (mm), and N is the number of grains inside the contact area. Assuming that the part is cut by h for each rotation, then the velocity at which the tool cuts into the part is equal to the spindle rotational speed ω multiplied by h as

$$\dot{z} = \omega h = \frac{\omega F/N}{2\pi r_g \mathrm{HB}} \qquad [77]$$

where the tool rotational speed ω is expressed in rps (revolutions per second). Then the contact force can be derived linearly

proportional to the tool axial cutting velocity (the same direction as the tool length) as

$$F = C_e\dot{z} \quad [78]$$

where C_e is given as

$$C_e = \frac{2\pi r_g \mathrm{HB}}{\omega} N \quad [79]$$

Substituting eqn [79] into eqn [75] yields the dynamic model of the tool system in terms of tool length variable z as

$$M\ddot{z} + (C + C_e)\dot{z} + Kz = u_p \quad [80]$$

Taking Laplace transform on both sides of eqn [80] yields the tool length response function for the open loop control system as[13]

$$Z(s) = \frac{U_p(s)}{Ms^2 + (C + C_e)s + K} \quad [81]$$

Based on eqn [81], a closed-loop tool length control can be formed for the deburring process and **Figure 35** shows its block diagram. This is the control method based on on-line burr measurement, because the tool length signal is fed back to compare with the desired tool length. The control effort is generated based on the tool length error by applying a tuned PID controller. The transfer function for the proposed tool length control is derived as

$$U_p(s) = K_{zp}E_z(s) + K_{zi}\frac{E_z(s)}{s} + K_{zd}sE_z(s) \quad [82]$$

where $E_z(s) = z_d(s) - z(s)$, K_{zp}, K_{zi}, and K_{zd} are the proportional gain, integration gain, and derivative gain, respectively.

The proposed deburring control based on on-line burr measurement has been implemented on the robotic deburring system described in **Figure 20**. **Figure 36** shows the block diagram for the entire deburring process including control system and tool/part interaction. The complete tool system also includes a pneumatic valve and three pneumatic cylinders that generate the tool force. Due to the high-response rate requirement, a flow valve is used instead of a pressure valve as done traditionally. Since the flow valve exhibits strong nonlinearity, a linearization method is developed to establish a proportional relation between the control voltage and the control force around a set point. The details are presented in Ref.[10]

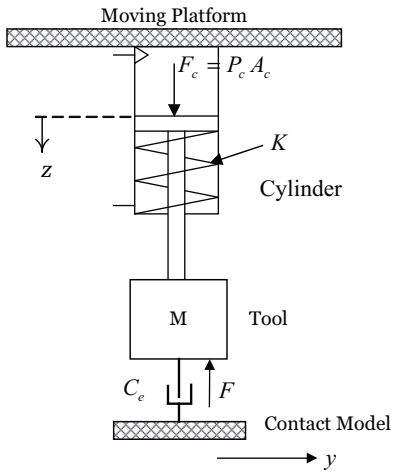

Figure 34 Tool system modeling. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

The first experiment presented here is the deburring of the edge of an aluminum plate. **Figure 37** shows the experiment setup. The control gains K_{zp}, K_{zi}, and K_{zd} for the actual control system are tuned at 0.9, 1, and 0.06, respectively. They are different from the simulation due to uncertainty in the actual control system. Since in this case the nominal tool path is a straight line, the desired tool length is set at a constant value of 4.5 mm. The objective of the proposed control method is to maintain the tool length at 4.5 mm. The experimental result of the deburring control is given in **Figure 38**. It can be seen that the total deburring period is approximately 60 s. The tool encounters the burrs in the first half of period as separated by a vertical dashed line in **Figure 38**. When hitting the burr, the tool is pushed upward to shorten its length, i.e., below 4.5 mm, as shown in the top figure of **Figure 38**. This negative tool length change informs the controller that there is a burr, hence to raise the control voltage to increase the control force, as shown in the bottom figure of **Figure 38**. In the second half, the top edge sags, causing the tool to extend, i.e., above 4.5 mm, as shown in the top figure of **Figure 38**. Correspondingly, the control voltage reduces to decrease the control force to avoid over-cut, as shown in the bottom figure of **Figure 38**. One may notice from **Figure 38** that though the control voltage signal follows the tool length change, the response is not sufficiently sharp. This is due to the long-time delay in the pneumatic system. An electrically actuated tool system would provide a better response rate.

The second experiment is on the same part to investigate the burr reduction rate for our deburring system. **Figure 39** shows the burr height changes after two paths of deburring. The edge profile is measured using a 2-D laser profile scanner. The resolution of the profile scanner is 10 μm in the *z*-direction, i.e., in the same direction as the burr height. It can be clearly seen from **Figure 39** that the burrs are effectively removed by applying the proposed closed-loop tool length control method. At the locations without burrs, the part

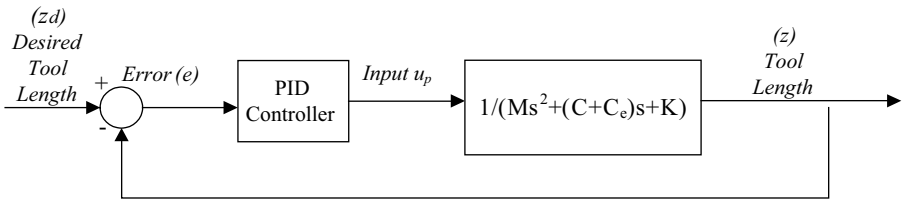

Figure 35 Closed-loop tool length control block diagram. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

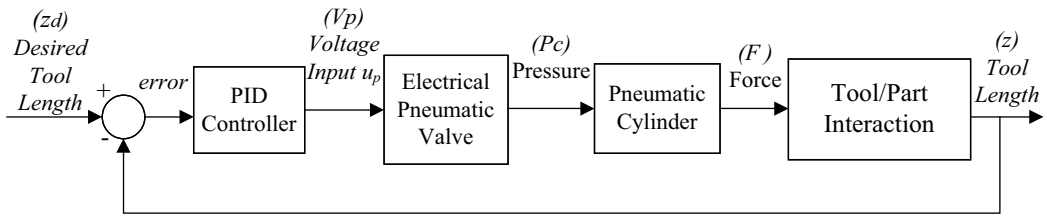

Figure 36 Block diagram for the entire deburring process. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

geometry is maintained as no over-cut, due to the regulation of the tool length. To quantify the burr reduction rate, the mean value and variance of the edge profile are obtained based on the measurement data given in Figure 39. Table 3 lists the calculation results. The mean value represents the average height of the profile, and the variance represents its roughness. It can be seen that the mean value is reduced by 0.08 mm from the first path of deburring and again by 0.03 mm from the second path. Hence the average burr reduction is about 0.05 mm, which is close to 0.06 mm of the simulation. Furthermore, a small variance indicates a smoother part surface. It can be clearly seen from Table 6 that the profile variance value decreases as the number of deburring paths increases, meaning that the edge profile becomes smoother.

The third experiment is on a zigzag path, mimicking the deburring of the fir trees of a turbine disk. The experiment set up is shown in Figure 40. Since this is an in-house prepared test piece, there is no CAD model. Therefore, the reverse engineering-based approach is used to measure and fit the zigzag profile as shown in Figure 41, based on which a tool path is generated as shown in Figure 42.

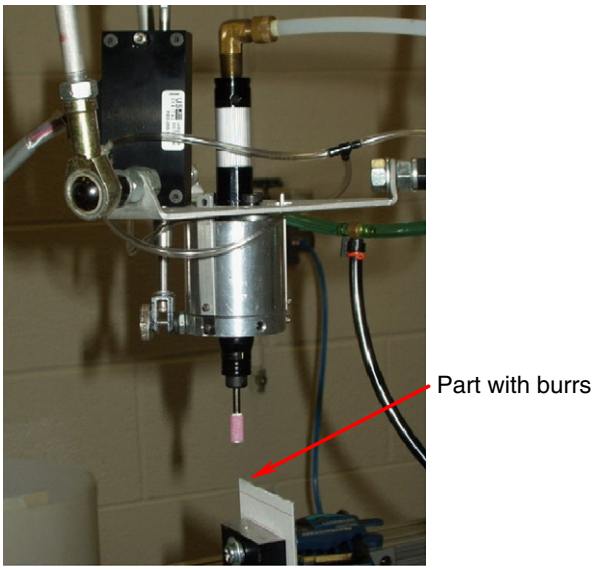

Figure 37 Edge deburring experiment. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

1.5.4 Polishing/Deburring Toolhead Design

Generally, there are two main categories of cutting tools: hard and soft. The former is used for cutting including turning, milling, and drilling, and the latter is used for finishing processes including polishing and deburring. A soft tool has built-in compliance, similar to a human hand, to provide varying stiffness for delicate finishing operation. There are two types of compliance tools: passive usually using springs without control and active using pneumatic actuators with control.

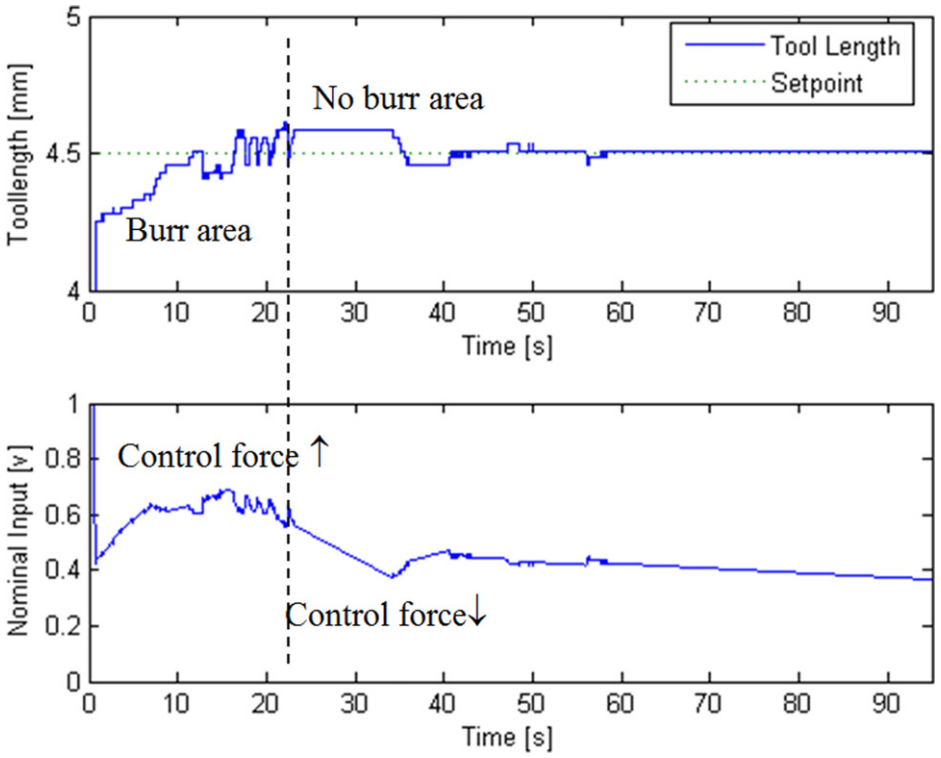

Figure 38 Experimental results of deburring control; top – the time history of the tool length; bottom – the control signal of the pneumatic valve. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

1.5.4.1 Hybrid Design

The design presented is for active compliance polishing/deburring toolheads. This design must be approached first by the principle of its design, compliance between tool tip and the part. See **Figure 43** below for a diagram of the tool tip contact with the part. This is a 3-D model in which the tool has three stiffness in the *x*, *y*, and *z* axis. An action plane is introduced to combine the *x* and *y* axis to one axis, i.e., the radial direction and the *z* axis is along the axial direction. So the tool model shown in **Figure 43** is for a hybrid model combining both the radial and axial direction.[14,15]

The design of the tool must be actively compliant in both axial and radial directions. As shown in **Figure 44**, the bottom part of the toolhead is for the axial compliance control. This is the same design as shown in **Figure 30**, that is to use three linear pneumatic actuators to control the axial force and is integrated with a linear encoder for the axial height measurement. The top part is for the radial compliance control, through a ring pneumatic actuator integrated with an *x*–*y* angular sensor. The two compliance systems are connected through a gimbal.

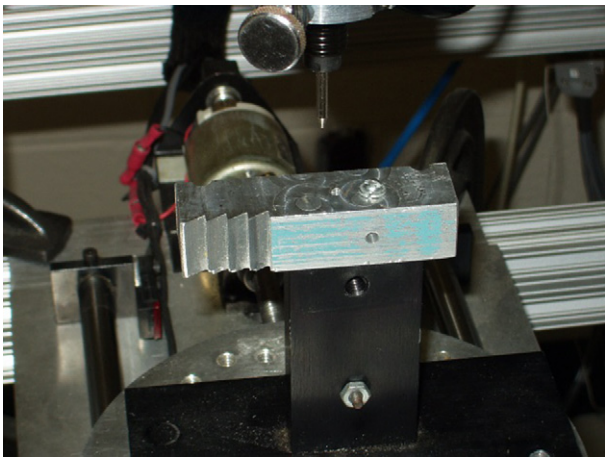

Figure 40 Zigzag path deburring mimicking the fir trees of the turbine disk. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

1.5.4.2 Toolhead Dynamic Modeling

As shown in **Figure 44**, the two gimbal axes are selected to be the *x* and *y* axes. The inner gimbal axis of rotation is the *x* axis

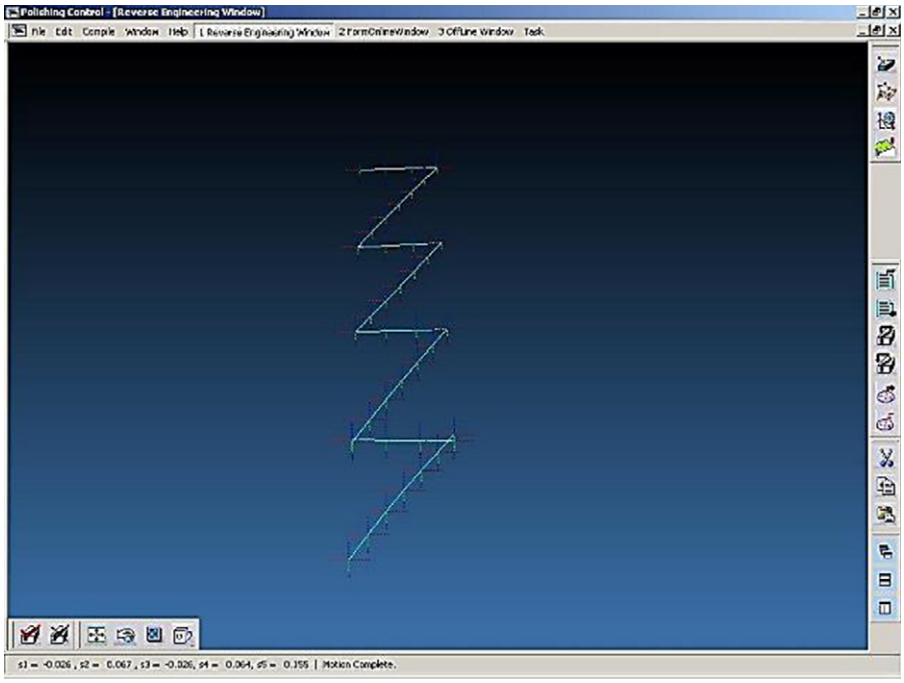

Figure 41 Zigzag path fitting. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

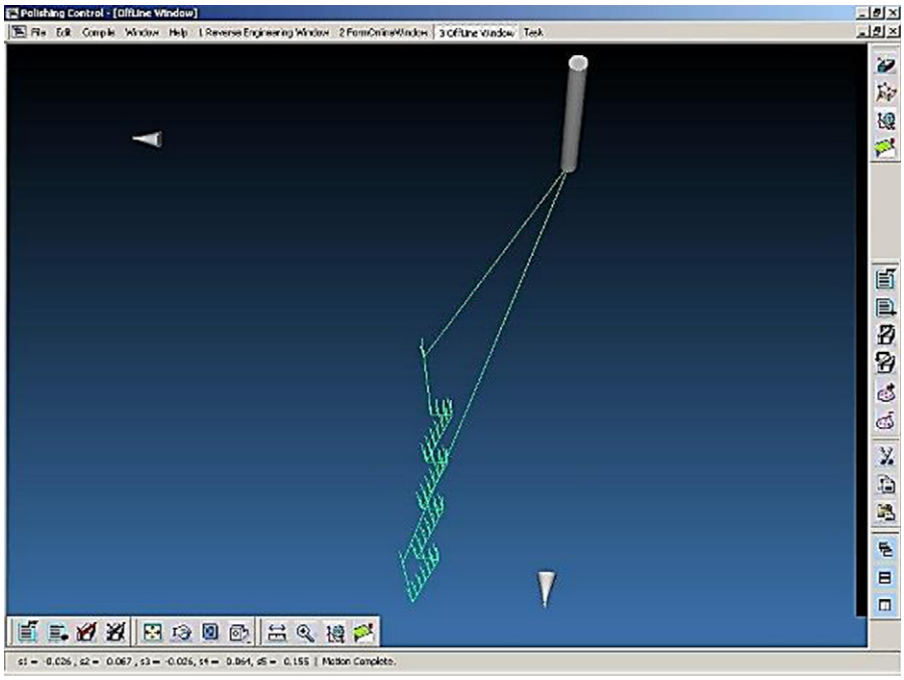

Figure 42 Zigzag tool path planning. Liang, L. *Modeling and Control of Automated Polishing/Deburring* (Ph.D. thesis); Toronto, ON: Ryerson University, 2008.

and the outer gimbal axis is the y axis. Again, the z axis is in line with the axial direction of the tool with the positive direction extending from the gimbal to the tool tip. In the radial direction, the tool's x and y axes are combined into a radial action plane. The action plane rotates parallel to the radial displacement/force direction. During radial actuation of the tool the action plane will describe the tool's full range of motion during manipulation of the radial actuator. **Figure 45** shows a model for the hybrid toolhead.

The tool has two displacements in the radial direction, r_l is the lower radial displacement and r_u is the upper radial displacement. The lower displacement is the displacement of the

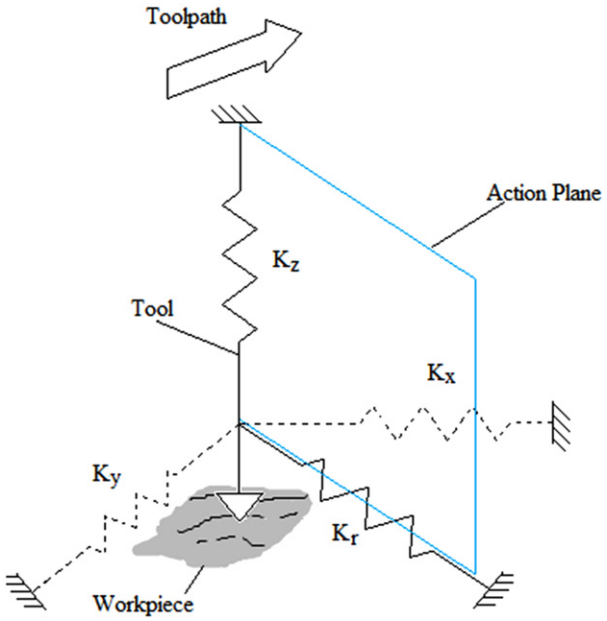

Figure 43 A 3D compliance tool model. Kroeker, J. *Design Analysis & Testing of an Enhanced Radial-Axial Hybrid Compliant Deburring Tool* (MSc thesis); Toronto, ON: Ryerson University, 2014.

tool shaft as a direct result of an encountered burr. The upper displacement is the resultant displacement of the tool shaft at the sensor as the result of the tool tip movement. The tool is split into an upper and lower half, b_l is the distance from the gimbal to the tool tip and b_u is the distance from the gimbal to the center of contact of for the tool shaft and actuator diaphragm. A relationship can be made between the four variables as can be seen in eqn [83].

$$r_l = \frac{b_l}{b_u} r_u \qquad [83]$$

The velocities and accelerations of the upper and lower radial displacements can be expressed by taking the derivative of [83] as

$$\dot{r}_l = \frac{b_l}{b_u} \dot{r}_u \qquad [84]$$

$$\ddot{r}_l = \frac{b_l}{b_u} \ddot{r}_u \qquad [85]$$

The angle of rotation of the tool shaft in the action plane θ_r can be determined by taking the sine of the components for upper and lower sides of the tool as

$$\sin\theta_r = \frac{r_u}{b_u} \qquad [86]$$

Due the scale of the components a small angle approximation can be made as

$$\theta = \frac{r_u}{b_u} \quad [87]$$

Angular velocity and acceleration can be expressed by taking the derivative of [87] as

$$\dot{\theta} = \frac{\dot{r}_u}{b_u} \quad [88]$$

$$\ddot{\theta} = \frac{\ddot{r}_u}{b_u} \quad [89]$$

A summation of the moments about the axis of pivot (M_{PIVOT}) is taken and can be seen in eqn [90].

$$M_{\text{PIVOT}} = M_{\text{RA}} + M_{\text{Cut}} \quad [90]$$

M_{RA} is the moment about the pivot caused by the radial actuator. M_{Cut} is the moment about the pivot caused by the cutting force of the tool tip on the part. Equation [91] further breaks M_{RA} into its respective components the force of the radial actuator (F_{RA}) multiplied by the moment arm (b_u) as

$$M_{\text{RA}} = F_{\text{RA}} b_u \quad [91]$$

The force of the radial actuator can be further broken down into the stiffness of the radial actuator (K_{RA}) multiplied by the radial displacement (r_u) it has traveled. The moment about the pivot due to the cutting force is similar to eqn [91]. They have different moment arms and therefore this yields

$$M_{\text{Cut}} = F_{r-\text{Cut}} b_l \quad [92]$$

Substituting eqns [91] and [92] into eqn [90] and rewriting M_{PIVOT} in terms of inertia will yield

$$\left(\frac{I}{b_l}\right)\ddot{r}_l + \left(K_{\text{RA}}\frac{{b_u}^2}{{b_l}^2}\right) r_l = F_{r-\text{Cut}} \quad [93]$$

Similarly, the axial modeling for the tool is the coupling of the actuator's stiffness with the tool tip and part stiffness relationship. Equation [94] gives the dynamic relationship between the mass of the moving axial component of the tool and stiffness relationship in the axial direction.

$$m_z \ddot{z} + K_z z = F_{z-\text{Cut}} \quad [94]$$

The combination of these two equations yields a complete model for the hybrid toolhead

$$\begin{bmatrix} \frac{I}{b_l} & 0 \\ 0 & m_z \end{bmatrix} \begin{pmatrix} \ddot{r}_l \\ \ddot{z} \end{pmatrix} + \begin{bmatrix} K_{\text{RA}}\frac{{b_u}^2}{{b_l}^2} & 0 \\ 0 & K_z \end{bmatrix} \begin{pmatrix} r_l \\ z \end{pmatrix} = \begin{Bmatrix} F_{r-\text{Cut}} \\ F_{z-\text{Cut}} \end{Bmatrix} \quad [95]$$

Each term is an important part of the dynamic model of the deburring tool. The terms $F_{r-\text{Cut}}$ and $F_{z-\text{Cut}}$ are defined by the tool/part interaction through the Hertzian contact mechanics. The term K_z is defined for the axial stiffness. As mentioned before, the axial actuators are made of three linear pneumatic actuators, and this stiffness is relatively easy to determined by measuring the ratio of the pneumatic cylinder force to its displacement. The term K_{RA} is the stiffness of relationship of the radial actuator. Since this is a ring pnuematic actuator, the stiffness in the radial direction is relatively complex to determine.

1.5.4.3 Ring Actuator Modeling

Figure 46 shows our ring actuator, the base structure being a donut shape ring evenly divided into four chamers. The inner side of each chamber is covered by a diaphragm which is clamped by an arc retainer to follow the circular shape of the hole. The outer side, top and bottom of the ring atuctor are covered with seal. Four air nozzles are used to supply air to four air chambers, which can be controlled under a single valve or separate valves. The stiffness of the ring actuator is determined by these four pressurized diaphragm chambers.

To provide radial compliance, the radial actuator has a 0.125in gap between the unpressurized diaphragm and the centered around the outer diameter of the tool shaft which is fixed to a two-axis gimbal. The gap between the diaphragm and the tool shaft will become filled with the inflated diaphragm upon a demand for pressure. When polishing or deburring, the tool tip will deflect and because of the two-axis gimbal this will cause a radial deflection of the tool shaft within the action plane. The deflection will cause a reactant force on the radial actuator that will be realized by a diaphragm causing a deformation of this diaphragm. The total deformation of the tool shaft will be the resultant of the cutting force and the inflating of the diaphragm due to the air pressure.

For stiffness modeling, hyperelastic material theory is adopted. Hyperelastic materials are defined by a constitutive model which derives the stress–strain relationship from a strain energy density function. Here, an Arruda–Boyce constitutive model is used and given as[16]

$$W_{8\text{ch}} = \frac{N k_B T}{2}\left[\beta\lambda_{\text{chain}} + \sqrt{n}\ln\left(\frac{\beta}{\sinh\beta}\right)\right] \quad [96]$$

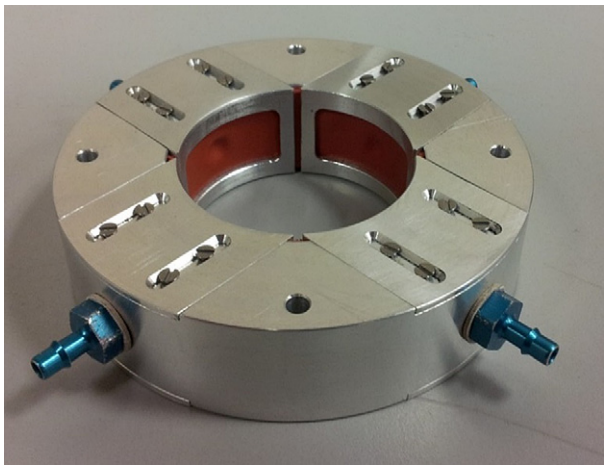

Figure 46 Pneumatic ring actuator. Kroeker, J. *Design Analysis & Testing of an Enhanced Radial-Axial Hybrid Compliant Deburring Tool* (MSc thesis); Toronto, ON: Ryerson University, 2014.

$$\lambda_{\text{chain}} = \sqrt{\frac{I_1}{3}} \quad [97]$$

$$\beta = L^{-1}\left(\frac{\lambda_{\text{chain}}}{\sqrt{n_{\text{chain}}}}\right) \quad [98]$$

where n is the number of chain segments for a hyperelastic material, I_1, is the first invariant of the left Cauchy–Green deformation tensor, k_B is the Boltzmann constant, T is temperature, and N is the number of chains in the network of a cross-linked polymer.

The strain energy density formula can be represented in polynomial form as

$$W_{8\text{ch}} = \mu \sum_{i=1}^{n} \left[\frac{C_i}{\lambda_m^{2i-2}}\left(I_1^i - 3^i\right)\right] \quad [99]$$

The locking stretch of the hyperelastic material is represented by λ_m, and the initial shear modulus is represented by μ. The strain energy density can be expressed in terms of the deformation gradient. The Langevin function is expressed in the series expansion form for the first three terms.

$$\overline{U} = \mu\left\{\frac{1}{2}\left(\bar{I}_1 - 3\right) + \frac{1}{20\beta^2}\left(\bar{I}_1^2 - 9\right) + \frac{11}{1050\beta^4}\left(\bar{I}_1^3 - 27\right) + \ldots\right\} + \frac{K}{2}(J-1)^2 \quad [100]$$

To this end, the stress–strain law for the Arruda–Boyce model is expressed as

$$\sigma_{ij} = \frac{\mu}{J^{5/3}}\left(1 + \frac{I_1}{5J^{2/3}\beta^2} + \frac{33{I_1}^2}{525\beta^4 J^{4/3}} + \ldots\right)\left(B_{ij} - \frac{I_1}{3}\delta_{ij}\right) + K(J-1)\delta_{ij} \quad [101]$$

The principle stress–strain relationship seen in eqn [101] can be used to define an engineering stress–strain relationship dependent on the type of deformation being modeled, from which the stiffness of the ring actuator might be obtained.

1.5.4.4 Simulation of Ring Actuator Stiffness

Since eqn [101] is difficult to solve, instead a finite element program is used for simulation to determine the stiffness. A tool shaft is assumed rigid and all the deformations are assumed to happen on the diaphragm. The input force is $F_{r-\mathrm{Cut}}$ from the tool tip resulting from cutting. This force is transferred to the actuator through the gimbal to F_{RA}. For our tool design, the gimbal axis to the tool tip b_l is 0.041 m, and the gimbal axis to the radial actuator b_u is 0.225 m.

The diaphragm is modeled as a single curved rectangular body contacting a cylindrical tool. For simplicity, only a chamber is model, which represents a quarter of the whole ring actuator, as shown in **Figure 47**. The force from the tool to the diaphragm is applied to the flat face of the tool shaft cylinder (the area in red on the right image), while the pressure from the back of the diaphragm is applied to the free surface opposite to the contact of the cylinder (the area in red on the left image).

The analysis was completed using large deflection for a nonlinear hyperelastic material analysis. The total deformation of the model was solved for using a static structural analysis

function in ANSYS Workbench. The deformation of the diaphragm, represented by $d_{simulation}$ must be considered with respect to the actual center position of the shaft to determine the displacement of the shaft from the center position represented by r_u. Figure 48 illustrates the relationship between $d_{simulation}$ and r_u.

Figure 49 shows a simulation of the diagram deformation as the result of 1 N of shaft force and 200 MPa of pressure on the diaphragm. Depending on the force and pressure applied, the simulated diaphragm deformation, $d_{simulation}$, may exceed the gap. When this happens, the actual gap value is taken as the maximum shaft displacement.

To determine the stiffness of the ring actuator, the pressure on the diaphragm and force on the shaft were varied within the design requirement. The force on the tool tip was varied between 5.50 and 16.49 N, and the pressure was varied between 100 and 400 MPa. The radial displacement of the tool shaft from the centered position was calculated by subtracting $d_{simulation}$ and the radial thickness of the tool shaft from the total radial distance of the diaphragm. The resulting displacement was used to determine the stiffness of the ring actuator based on the force on the tool shaft. The stiffness values were plotted against pressure based on tool shaft force as shown in Figure 50.

Data from these plots were curve fitted to an exponential function given in eqn [102] with the coefficients for different cutting forces shown in Table 7.

1.5.4.5 Experiment on Ring Actuator Stiffness

For experiment, the test tool was mounted to a table vice which was mounted to a rigid testing platform. A calibration setup was designed to achieve this, see Figure 51 for the

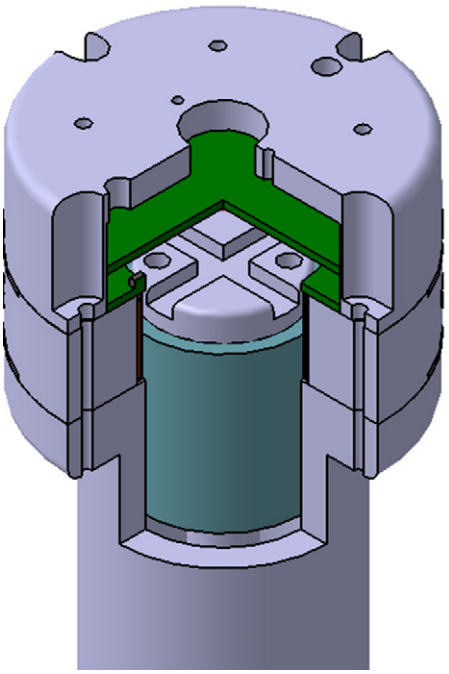

Figure 52 Centering collar (light blue). Kroeker, J. *Design Analysis & Testing of an Enhanced Radial-Axial Hybrid Compliant Deburring Tool* (MSc thesis); Toronto, ON: Ryerson University, 2014.

calibration stage. A two-axis stage with two micrometers was used to accurately determine the displacement in two degrees of freedom. The tool tip was attached to the stage via a close tolerance ball joint to which the shaft of the tool tip could freely slide within. The final calibration stage was created using adapter plates that linked each component together to the common fixed rigid testing platform.

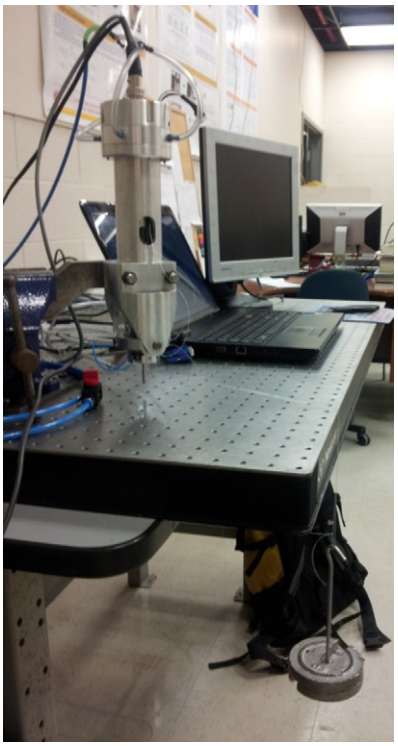

Figure 54 Stiffness testing setup. Kroeker, J. *Design Analysis & Testing of an Enhanced Radial-Axial Hybrid Compliant Deburring Tool* (MSc thesis); Toronto, ON: Ryerson University, 2014.

Calibration was completed on a two-axis stage from Newport with manual micrometers also from Newport. The custom board with two magnetic field sensors were made. Data was collected through a Measurement Computing USB data acquisition unit at 100 samples per second.

A bias was determined for each sensor using a removable plastic collar which fit within the tool between the inner shaft of the tool and the outer casing as can be seen in **Figure 52**. The collar will hold the tool shaft directly in the center to determine a bias. The bias is present due to tolerance stack-ups, magnetic cross-talk, and imperfections in the magnet placement. Once the shaft was centered and the bias determined, the collar could be slid downward and cleared away.

A filter was applied to the signals to reduce the noise within the signals. The calibration data was a combination of measurements from the micrometers and signals recorded from the data acquisition unit. In order to make recording and processing the data as simple as possible a pulse generator was use to record exactly one value of the voltage for both x and y sensors. This allowed time for the micrometers to be set before taking another recording.

The calibration resulted in a linear relationship for each sensor. **Figure 53** shows a plot of voltage vs. displacement, and eqns [103] and [104] are the two linear equations obtained through data fitting. To verify the accuracy of the voltage and displacement relationship the magnetic field sensor was calibrated at 22.5° increments 360° around the tool.

$$x = 5.922V_{x\ \text{sensor}} + 5.0682 \qquad [103]$$

$$y = -5.9129V_{y\ \text{sensor}} + 5.0377 \qquad [104]$$

Once calibrated, the tool could be tested for its stiffness behavior. This would be accomplished by loading tool tip and varying the pressure of the ring actuator. Using the calibrated sensor the position in the x and y directions could be recorded. Data was recorded using the same data acquisition unit. The addition of an Omega PX319 pressure transducer was used to accurately measure the pressure on the ring actuator over the duration of data recording. The displacement was measured using the magnetic sensors and converted using the voltage/displacement relationship determined through calibration. Weights were hung from fishing line fixed to the tool tip and left to hang off of the rigid testing table, see **Figure 54** for image of the experimental setup. The mass of each weight was measured and recorded for each test. The tool was pressurized and data recorded. The pressure was varied within the ring actuator and held for small time increments in order to create clear displacement and pressure data sets. Data was recorded continuously and sorted for stable pressure and displacement values.

The stiffness was determined based on the force on the tool tip and the displacement caused as a result of the force and pressure setting. As the pressure was varied for a constant tool tip force a noticeable change of displacement and therefore stiffness was observed. The stiffness and pressure relationships are plotted in **Figure 55**. The plots were curve fitted and like the simulation results and they too appeared to correlate to exponential functions.

The exponential functions were used for fitting the experiment data, with coefficient listed in **Table 8**. **Figure 56** combines between simulation and experiment data for comparison. It can be seen that both follow the same relationship and fall within a logical trend that appears to increase as the shaft force increases.

1.5.5 Conclusions

In this chapter, four fundamental issues for robotic polishing and deburring including contact area-based path planning, surface roughness modeling, contact stress-based control, and polishing/deburring toolhead design have been discussed. The methods developed to deal with these issues are based on contact mechanics. It is shown that the contact area during polishing/deburring between the tool and part varies depending on the geometry of the part, hence leading to a new method presented for polishing/deburring path planning. Then the micro depth of cut within the contact area is modeled leading a method presented for the determination of the surface roughness for the polishing/deburring process. Through further modeling of the relation between the contact stress and the friction force, a control method is developed for controlling the polishing force as well as the spindle speed. This control method is further extended by integrating an on-line sensor forming a closed-loop control for the deburring process. Finally, a design method is presented for the design of a toolhead with two directional compliances, i.e., axial and radial, for active force of the polishing/deburring process. The proposed methods have been tested on a robotic polishing/deburring system developed at Ryerson University.

1.6.1 Grinding/Lapping of Optical Glass

Grinding is a fundamental process in precision manufacturing where glass is machined to desired surface form and surface roughness is gradually decreased as well. Two sorts of grinding techniques, namely loose-abrasive and fixed-abrasive grinding are available at present to machine glass workpiece. Each type of grinding has a number of embodiments, which are presented in this section.

1.6.1.1 Loose-Abrasive Grinding

1.6.1.1.1 Conventional loose-abrasive grinding

Grinding, which is realized on most occasions in the form of loose-abrasive grinding, is the first step to achieve precision manufacturing of glass. The abrasives, usually harder than glass, for example, SiC, alumina, diamond, etc., are mixed with water and supplied intermittently onto the copper/cast iron laps engraved with regular V-shaped or flat-bottom grooves. The abrasives roll and/or slide against on the surface to fracture and plow glass surface, resulting in material removal and leaving a latent cracked layer.[1]

Material removal rate (MRR), one of the most important aspects in manufacturing, is found to be affected by several factors in loose-abrasive grinding, including supply of abrasives, abrasive size, relative speed, and pressure between glass and grinding tools, etc. The supply of abrasive slurry affects MRR. It is found that increasing the supply of abrasives can result in increased MRR but excessive supply may not necessarily lead to greater MRR, that is to say, there exists an optimum abrasive supply value in excess of which MRR will level off. The optimum supply is a minimum abrasive supply at which the maximum MRR is achieved during grinding of glasses. The optimum supply depends on abrasive size and grinding machines used as well as glass properties to be ground. The phenomenological results apply to various grades of abrasive size and most types of abrasives. Generally speaking, the maximum MRR is greater for coarser abrasives than finer ones and the corresponding optimal supply of abrasives is basically smaller for finer abrasives. The number of the particles of abrasives taking part in material removal will shrink as the supply of abrasive is cut down, so the MRR will also descend accordingly. On the other hand, decreasing the number of particles undertaking the external loading will increase the load upon a single particle of abrasives participating in material removal and therefore the probability of pulverizing the loaded particles, making the size of abrasives smaller, which will also decrease the MRR since smaller abrasives, in general, induce less MRR. **Figure 1** shows variation of MRR as a function of abrasive supply. MRR increases with supply of abrasives, but excessive supply does not increase MRR and there exists an optimum value. The value for coarse abrasives is greater than fine abrasives.

Relative slurry concentration (the ratio of abrasive weight to water weight) also plays an unignorably important role in MRR. MRR is clearly dependent on the relative concentration of abrasives. The MRR appears to increase sharply when the inverse of the ratio is elevated from zero and then slowly falls in loose-abrasive grinding. It is more conspicuous for larger abrasives. Higher concentration will give rise to higher MRR, but further increase in concentration does not get much higher

 doi:10.1016/B978-0-12-803581-8.09152-9

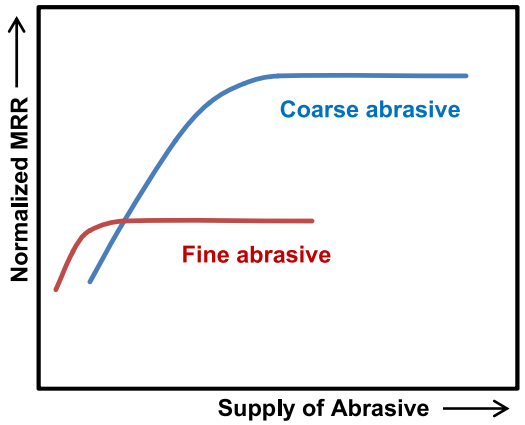

Figure 1 MRR vs. abrasive supply. Too much supply of abrasives does not mean greater MRR. MRR plateaus as abrasive supply exceeds a certain value.[1]

material removal. On the contrary, too high concentration will result in decreased MRR during loose grinding. The results indirectly imply the significant role of water in grinding process and there is a peak value of MRR in the plot of MRR versus concentration. Hence it is suggested to find out the most appropriate concentration and optimal abrasive supply before using a machine for loose-abrasive grinding. The variation of MRR with the concentration of abrasive is presented in Figure 2. The MRR first rises steadily with the concentration of abrasives and decreases for over-concentrated slurry.

The load and relative speed directly dominates MRR. According to well-known Preston's formula,[2] MRR is linearly proportionate to the pressure and relative speed between glass and lapping tools.

$$MRR = kPv$$

where P is the pressure, v is the relative speed, and k is an all-purpose coefficient. k may be decomposed into the following major factors: slurry concentration, abrasive size, abrasive properties, glass properties, properties of grinding tools, etc. MRR is in linear relation to the load exerted onto grinding lap on the condition that the supply of abrasive slurry is sufficient. Increasing the load means the need for increased abrasive supply, in which case the linear relationship also holds. Otherwise, MRR may not increase and even decrease when raising the load on grinding lap. However, MRR may not further rise linearly when load and velocity exceeds a threshold.

Abrasive size has overwhelming effect on MRR in grinding process. Opticians usually use coarse abrasives to elevate MRR and fine abrasives to obtain smooth surface that is ready for polishing process. Loosely speaking, the smaller the abrasives used, the smoother the resultant surface, the less the MRR (for abrasives of the same materials) and the shallower the subsurface damage. The size of abrasives (i.e., grade of abrasives) is chosen consecutively smaller in order to strike a balance between MRR and surface quality. MRR under the optimal supply of abrasive slurry is shown to depend directly on abrasive size for various types of abrasives, especially for fine abrasives. Figure 3 shows MRR-abrasive relationship for

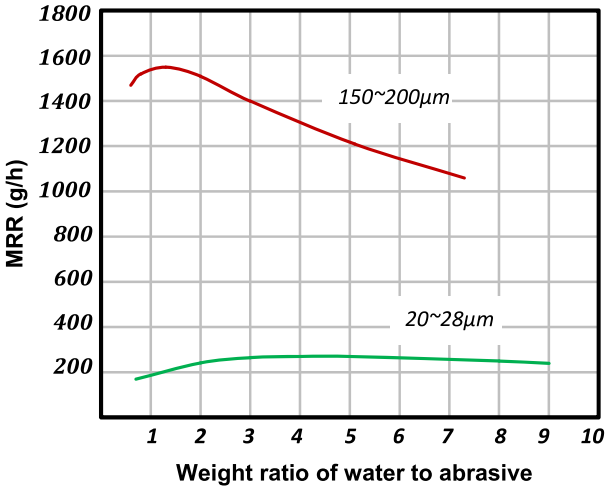

Figure 2 Variation of MRR with concentration of abrasive. An optimal concentration exists at which maximum MRR occurs.[1]

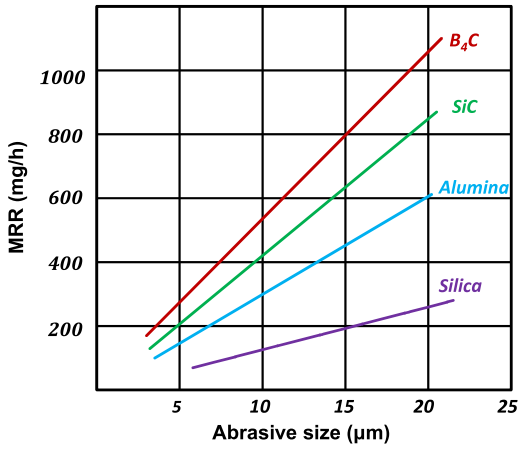

Figure 3 Variation of MRR with abrasive size for various abrasives.[1]

various types of abrasives. MRR is proportional to abrasive size for various abrasives. It is apparent that the properties of abrasives used in grinding process severely exert a big influence on MRR. The hardness of abrasives seems to correlate well with MRR. Figure 4 shows the influence of different micro-hardness of abrasives to MRR. Harder abrasives remove glass much faster than softer ones except garnet which exhibits similar MRR as SiC but with much lower hardness than SiC. An interesting phenomenon is found that MRR is much higher at the beginning of the grinding process where smaller grade abrasives begin to be employed to grind the surface of previous step with larger abrasives. Then MRR gradually lowers with grinding time and approaches a steady level. Figure 5 presents the variation of MRR with grinding time. The following may explain the underlying cause: the much deeper subsurface damage by the previous larger abrasive grinding exists on glass surface and the surface is transferred to finer abrasive grinding which makes the severer cracked layer detached from the surface and results in greater MRR. The characteristic cracked layer of finer abrasive grinding will form and the MRR goes stable as finer grinding process proceeds.

This way, greater MRR lasts for some time within the initial several minutes when glass surface is ready for finer grade grinding.

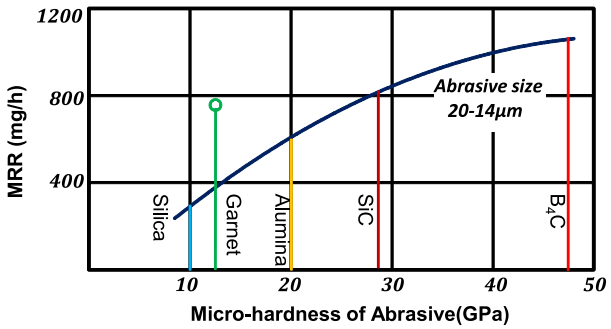

Figure 4 Influence of micro-hardness of abrasive to MRR.[1]

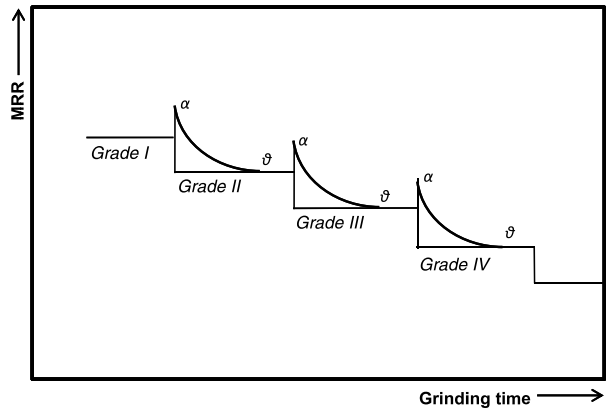

Figure 5 Variation of MRR with grinding time.[1]

Grinding/Lapping tool material also contributes to MRR. A variety of materials have been tested as grinding tool materials for MRR. The tested results plotted in Figure 6 illustrate that MRR is able to be raised by making use of hard grinding plates for soft-to-medium hardness of grinding materials (hardness < 1 GPa). High-hardness grinding materials (hardness > 2 GPa) behave much different from soft-medium ones. The MRR is little influenced by the hardness of grinding materials. The grinding plate will be smoothed when hard grinding plate is utilized, which will cause poor contact with abrasive particles and make the grinding process less effective.

Other two important issues, namely surface roughness and subsurface damage, concern precision manufacturing community, too. The subsurface damage is caused inevitably in the grinding of brittle materials (excluding ductile grinding) because material is removed due to factures in brittle mode. Glass surface is first fractured underneath the contacting point of abrasive with glass when contacting pressure is in excess of the fracture toughness of glass. The factures extend into glass randomly and they are able to grow. Once they intersect one another, glass debris surrounded by the fractures has the potential of detaching from the bulk. In this way, the glass surface is ground away and a surface full of tiny bumps and hollows forms, which can be quantified in terms of surface roughness. Some fractures may not interlace and may be concealed into the glass, which is referred to as subsurface damage. Subsurface damage must be eliminated in many applications because they weaken the strength and worsen the performance of components.

Surface roughness is experimentally verified to be related to the size of abrasives as follows[1]:

$$h \cong \alpha d$$

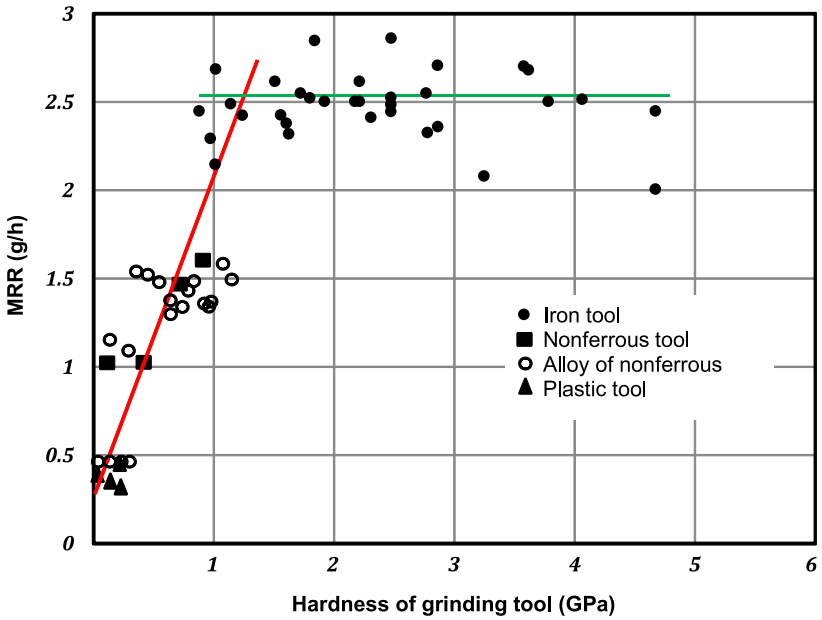

Figure 6 MRR vs. hardness of grinding tool. Greater MRR may be realized by using hard grinding plates. However, extremely hard plates make no difference to MRR.[1]

where h means the peak-to-valley surface roughness, d stands for the maximum size of the abrasive grade utilized to machine the glass, and α is the coefficient, relying on abrasive properties, equal to 0.17 for silica, 0.22 for garnet, and 0.27 for alumina, respectively.[1] This set of plots change much similarly to those of MRR versus abrasive size. It is not difficult to understand that increasing the size of abrasives will make the cracks spread inwards more, which is capable of reaching greater surface roughness and larger MRR as well as deeper subsurface damage. Correspondingly, surface roughness will deteriorate when using hard abrasive to grind glass, similar to MRR with respect to hardness of abrasives. The results for different grinding tools clarify that surface roughness of glass ground by soft grinding tool is slighter than by hard ones, similar to MRR. Plastic tools produce surfaces of lightest surface roughness. But load and velocity make no difference to surface roughness, which is much different from MRR. The mechanism is that surface roughness is governed by the pressure/load exerted on a single particle that is determined by the fracture strength of the particle which relies on the size of the abrasives used. Raising velocity will increase the number of particles per unit time taking part in material removal but does not change the fracture toughness and size. Thus the surface roughness seems not to be affected by velocity between grinding tools and glass workpiece. Likewise, the number of effective particles will rise when increasing load imposed onto grinding tools and furthermore the particles will fracture into smaller ones when the load surpasses the fracture toughness of the particles, leading into more and finer effective particles. Therefore, surface roughness will not be degraded even if the load is elevated. As to subsurface damage, it is found that the depth of subsurface damage is linearly proportional to surface roughness for ground glass, approximately four times peak-to-valley surface roughness in loose-abrasive grinding of glass.[1]

1.6.1.1.2 Unconventional loose-abrasive grinding

Ultrasonics has been used for cleaning for many decades and extended into the field of manufacturing. Abrasives are accelerated via fluid media by an ultrasonic generator. Figure 7 illustrates ultrasonic machining mechanism. The energetic abrasives impinge onto the surface of workpiece and induce material removal. The material removal can be realized in the form of cavitation erosion, sliding against the workpiece surface and hammering of abrasives. The MRR is related to ultrasonic power density, the clearance of ultrasonic horn from workpiece, etc. It is a noncontact grinding technique. The surface roughness of machined workpiece is affected by many factors, like the size and hardness of abrasives used, ultrasonic power, and so forth.

Another grinding process involves fluid jet abrasives. Abrasives are either pre-mixed with fluid (e.g., water) and then accelerated to a very high speed through a nozzle (over tens of m s^{-1}) or entrained and accelerated by a high-pressure jet.[4] The high-speed abrasives impact the glass surface and induce material removal. Because the abrasives are highly energized, the strong force will crack the glass or remove material in ductile or brittle mode depending on the velocity, hardness of abrasives, etc. To get a high-speed jet, the nozzle delivering fluid must be narrow-opened and be wear-resistant to abrasives. Figure 8 shows an abrasive waterjet machining system. MRR and surface roughness is dependent on several parameters, inclusive of hardness and size of abrasives, shape of abrasive grains, flow rate, impinging angles, etc. Generally speaking, harder and larger abrasives will remove material faster, but reach rougher surfaces. Increasing flow rate may also

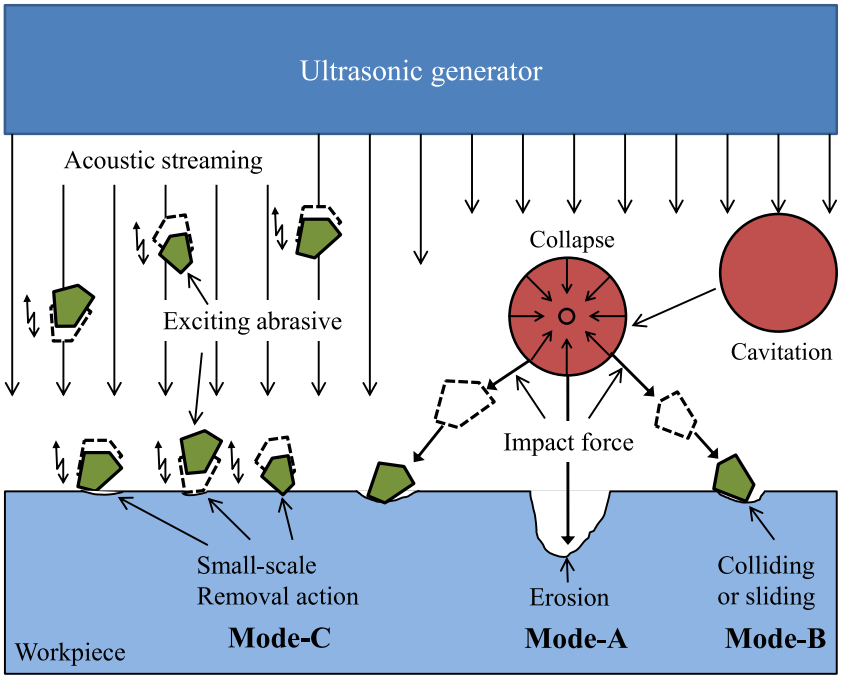

Figure 7 Mechanism of ultrasonic machining: Mode-A, cavitation erosion; Mode-B, collision and sliding due to cavitation collapse force; Mode-C, nanoscale removal by ultrasonics-driven abrasives.[3]

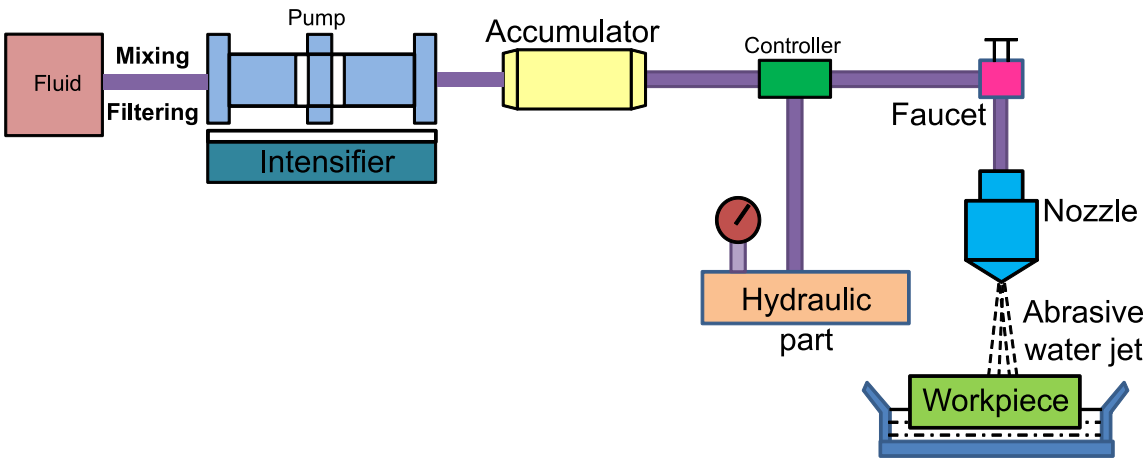

Figure 8 Schematic of an abrasive water jet machining system.[7]

increase MRR and lower surface roughness of workpiece. A potential drawback of the technology is contamination of workpiece surface by abrasives. Fluid jet abrasive polishing can be implemented when soft abrasives like ceria takes the place of hard SiC abrasives. Air abrasive jet grinding is similar to water jet process except that the media through which the abrasives are accelerated is air rather than water, which is sometimes referred to as sandblasting. Sandblasting machines glass surface due to the cracks by particle impacts at high speed. Low speed may not induce material removal and just clean the surface of workpiece. A microscopic photograph of glass surface underwent sandblasting as depicted in **Figure 9** shows that cracks appear around the impact points by abrasives.[5] On many occasions, cracks are undesirable, but a rough surface is preferred by substrates for organic light emitting diodes (OLED) in order to acquire uniform distribution of lighting, which can be realized by sandblasting.[6]

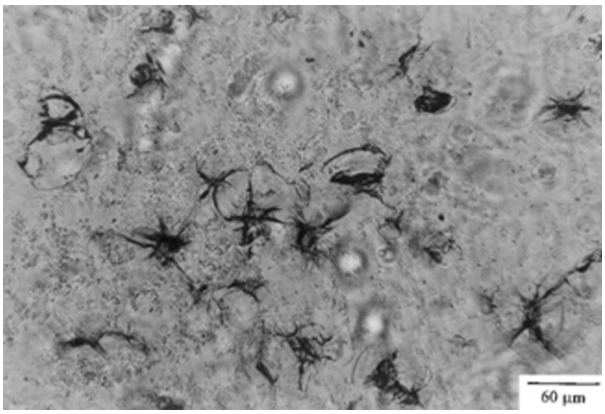

Figure 9 Micrograph of cracks by sandblasting after processing 30 min.[5]

1.6.1.2 Fixed-Abrasive Grinding

Fixed-abrasive grinding involves the use of pellets, pads, or wheels in which hard abrasives are bound. Pellet grinding resembles loose-abrasive grinding, a constant pressure process, except that the abrasives are now fixed into binding materials. The abrasives can be pre-arranged uniformly or even any desired distribution in principle so that material removal distribution can be formatted. The pellets can be formed into plane, spherical surfaces in order to conform to local surface of workpiece. The thing worth pointing out is that surface roughness and subsurface damage is reported to be improved as compared to loose-abrasive grinding and MRR is much better than loose-abrasive grinding. No extra supply of abrasives is needed during grinding process.

Abrasives can be coated onto the side surface of a wheel or top surface of cup wheel (referred to as wheel grinding). **Figure 10** shows a grinding machine with peripheral and cup-wheel grinding heads.[8] There are several types of wheel grinding processes.[9,10] They are categorized as constant feed grinding since feeding rate are prescribed to be constant in these processes. **Figure 11** illustrates various grinding modes.

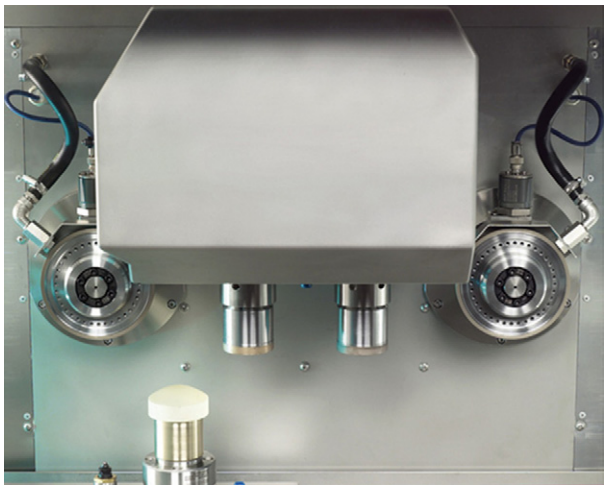

Figure 10 Schneider's SCG100 grinding machine with peripheral and cup-wheel grinding heads.

Many issues are worth research in wheel grinding, for example, bonding materials, abrasive concentration, grinding coolants, wheel wear, etc. Optical community is concerned with surface

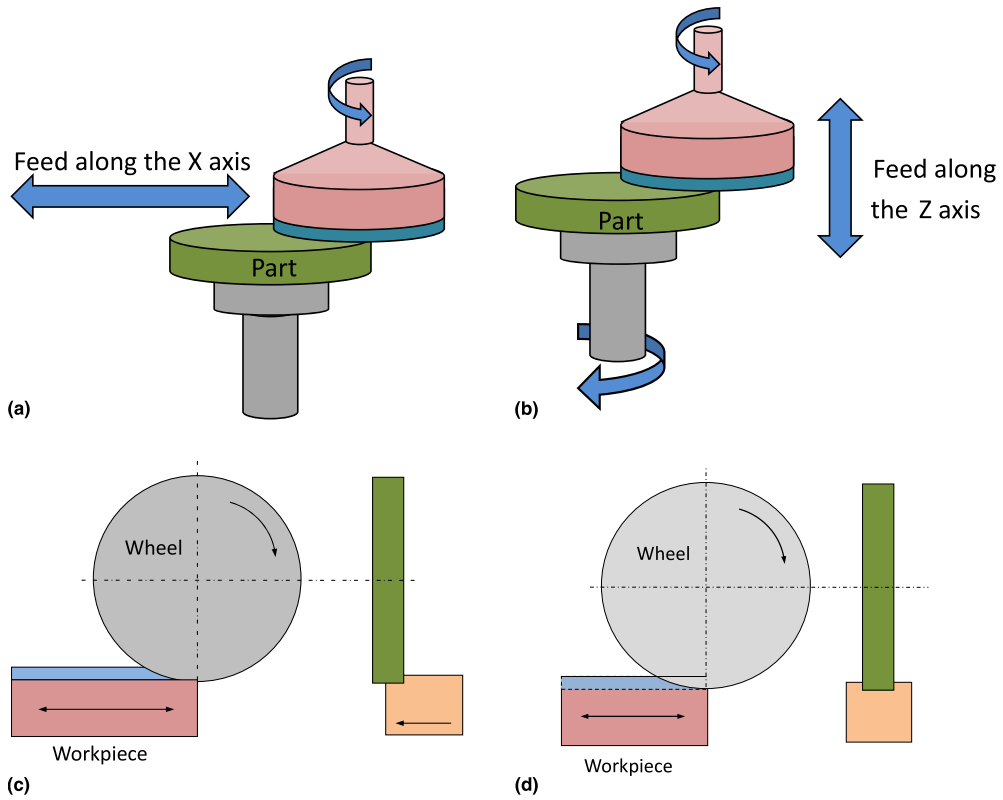

Figure 11 Different grinding modes: (a) vertical feed cup-wheel grinding and (b) horizontal feed cup-wheel grinding[9]; (c) horizontal spindle surface grinder-traverse grinding and (d) horizontal spindle surface grinder-plunge grinding.[10]

quality and subsurface damage of wheel grinding since subsurface damage defines the minimum thickness of material that has to be removed. Schoen[11] compared subsurface damage and surface roughness between fixed-abrasive grinding and loose-abrasive grinding/lapping. They found that surface roughness of fixed-abrasive process is almost one order of magnitude lower than lapping and fixed-abrasive grinding is superior over lapping from the viewpoint of subsurface damage. Figure 12 show that surface roughness and subsurface damage can be remarkably reduced by deterministic microgrinding (DMG). Li *et al.*[12] investigated subsurface damage of fixed-abrasive grinding and found that subsurface damage is predominantly governed by the size of abrasives used while other external factors have marginal effects on subsurface damage; subsurface damage diminishes with decreasing abrasive size in their experiments, unlike the results by Suratwala that smallest abrasives surprisingly increases the subsurface damage depth.[13]

Ultrasonics can be imposed onto grinding wheel or workpiece to get some interesting results. Some results indicate that although machining force is lessened surface roughness may be degraded by incorporating ultrasonics. If the relationship between surface roughness and subsurface damage remains to hold in ultrasonic assisted machining, subsurface damage should be greater upon using ultrasonics, which is undesirable. Electrolytic in-process dressing (ELID) grinding process has successfully applied to the grinding of hard-brittle materials. In ELID grinding, metallic-bonded super-abrasive wheel is capable of being dressed continuously during the course of grinding process so that new abrasives protrude out to grind workpiece smoothly. Because of incessant appearance of new abrasives, MRR can be stabilized and the quality of finished surface is improved compared to conventional grinding process. The grinding force versus stock material removal is much lower than conventional grinding and G-ratio is also much steady and enhanced.[14]

1.6.2 Polishing of Optical Glass

Polishing process follows grinding step to smooth surface to <1 nm and to finalize surface form to specifications. Polishing also relieves subsurface damage left by grinding process. Loose-abrasive polishing is prevailing, but some innovatory technologies have emerged during last several decades. With these novel technologies, polishing process is more deterministic than ever before. These technological innovations as well as conventional polishing processes are introduced in the section.

1.6.2.1 Loose-Abrasive Polishing

Classical loose-abrasive polishing is still widespread on optical shop-floors. It refers to the use of a polishing lap (usually soft metals, pitch, polyurethane, cloth, etc.) on a hardback-plate.[15–17] The polishing lap is pressed against surface of workpiece and relative motion is driven and meanwhile slurry is sprayed. Chemical mechanical polishing (CMP), widely

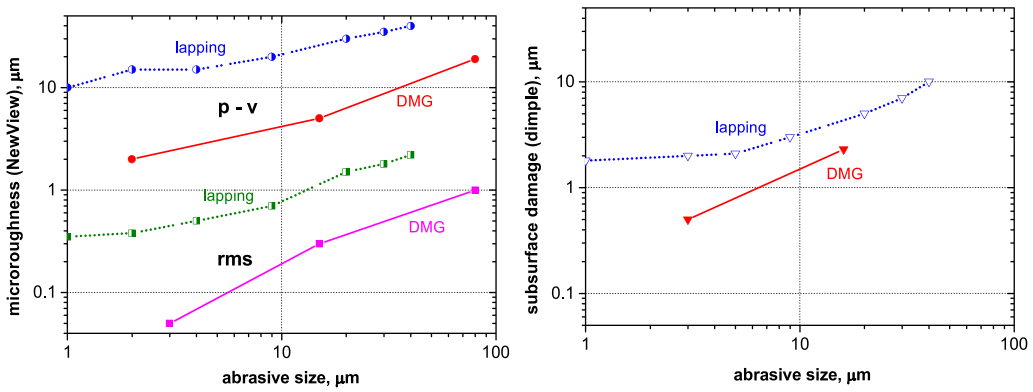

Figure 12 Surface roughness and subsurface damage in deterministic micro-grinding (DMG).[11]

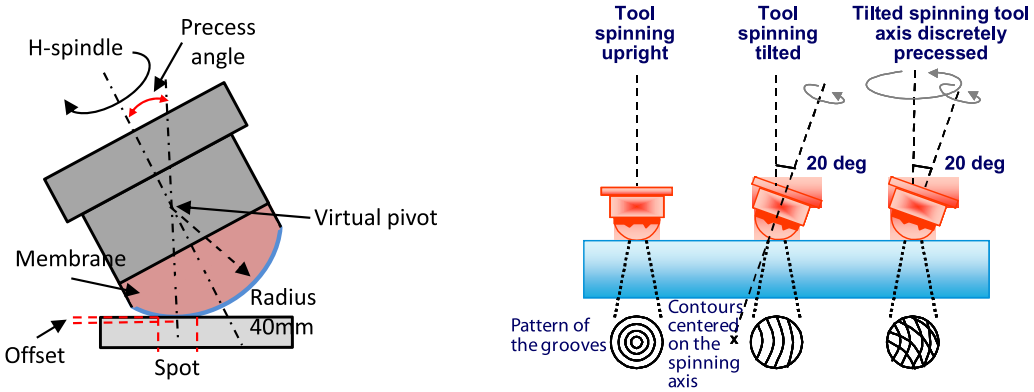

Figure 13 Bonnet polishing head presses with respect to the normal to the workpiece while the head rotates with its axis.[25,26]

used in semiconductor industry, is typical representative of loose-abrasive polishing.[18] In polishing process, chemical action is more prominent than grinding and sometimes is a key factor that makes polishing possible and enables the generation of sub-nanometer smooth surface. Super-smooth surface of glass (surface roughness 0.1 nm) has been obtained by using pitch polishing.[19,20] Modified loose-abrasive polishing, including bowl feed polishing, float polishing and elastic emission machining (EEM) can now produce glass with atomic scale surface.[21–23] Float polishing and EEM are non-contact polishing techniques. As to float polishing, workpiece can be polished due to cavitation in slurry that makes abrasives undulate and thus workpiece can be polished. EEM removes material in elastic mode where abrasives are carried by the motion of fluid induced by the rotation of a polyurethane ball. The abrasives come into contact with glass surface and chemically bond with glass surface. The abrasives are then forced to move owing to the fluid flow and there is a probability that glass bonds will rupture and adhere onto abrasives. In this way, material removal occurs and glass is polished with atomically ultra-smooth surface and damage-free. Polishing tool in EEM has evolved from original sphere type to pipe so that machining efficiency is able to be increased. EEM has been applied successfully to various materials (glass, ceramics, low-expansion glass, silicon, etc.).[24]

Bonnet polishing is a recently developed polishing technique by University College London/Zeeko, UK. **Figure 13** shows working schematic of Bonnet polishing head. The polishing head is an inflated rubber bag onto which membranes (polyurethane pad, etc.) are stuck. The rotation axis of polishing tool is inclined relative to normal line of workpiece so that the material removal function is near Gaussian and the polishing head presses with respect to the normal line of workpiece. The head is compatible with conventional polishing machines. The contacting spot can be varied in size by adjusting the position of the bonnet head. The removal function exhibits excellent linearity with tool speed. This technique can be used to polish flat, spherical, and aspherical surface. The surface roughness of finished workpiece has been down to <0.5 nm (R_a).[27] Afterwards, Zeeko started fluid jet abrasive polishing. Fluid jet polishing is similar to abrasive jet grinding except that soft abrasives are utilized such as ceria.[28] Fluid jet polishing is well suited for polishing complex surface and inner surface otherwise impossible to be reached with conventional methods.[29] The surface roughness of 1 nm is readily achieved.

Field can exert forces onto materials because of the interaction of field-matter. Magnetic materials are subject to forces when they are in a magnetic field. The forces can be taken advantage of to manufacture glass workpiece. This method is named as magnetic abrasive polishing. At first the abrasives and magnetic materials were sintered to produce abrasive of magnetism. Later, conventional abrasives mixed with iron particles were proposed to replace the magnetic abrasives due to complicated procedures of producing magnetic abrasives.[30] During polishing, the magnetos do not come into

direct contact with workpiece and polishing force is conveyed by magnetic particles. The polishing tool is actually flexible and compliant to any surface form. So the merits of magnetic abrasive polishing are the ability to polish internal surface, cylindrical surface, exotic surface, small tube internal surface, microstructures. Figure 14 shows magnetic abrasive polishing where the abrasives are constrained within two magnets. The process is able to polish external and internal surface as well as complex concave and convex surface.

In 1970s, Shlyago *et al.* employed magnetorheological (MR) fluid in the polishing of glass.[31] MR fluid stiffens or solidifies when it is subject to magnetic field and returns to liquid after removing magnetic field. The viscosity of liquid changes significantly with and without magnetic field. The solidified MR fluid can be applied to fabricate glass workpiece. Unlike conventional polishing tool, MR fluid tool will not be worn and is automatically renewed when the magnetic field is alternately turned on or off. This way, the polishing surface of MR tool remains sharp and keeps constant MRR with polishing time. Magnetorheological finishing (MRF) was commercialized by QED Inc., in late 1990s.[32] Figure 15 shows mechanism and process of MRF. When the magnetic field is turned on, magnetic particles lines up and MR fluid stiffens and is sheared to be appropriate to polish workpiece. MRF now can polish a wide range of materials, such as fused silica, BK7, CaF_2, KDP, ZnS, SiC, polymers, etc., and the surface roughness achievable <1 nm. Since it belongs to sub-aperture polishing, precise surface form is possible with few iterations of polishing runs by MRF, indicating MRF is a deterministic polishing process of high-convergence rate. The material removal in MRF is reported to be due to shear stress and the normal load between abrasives and workpiece is little, so subsurface damage that are common in conventional polishing is greatly reduced, which facilitates the enhancement of resistance of optics to laser damage.[33] Figure 16 shows subsurface defects. Few defects are found on the MRF finished surface whilst a great number of pits and tiny scratches are clear on pitch polished surface. The efficacy of improving laser damage resistance has been verified by combining MRF and wet chemical etching or laser conditioning.[34]

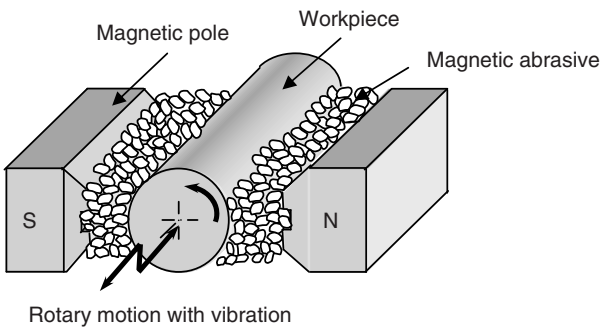

Figure 14 Magnetic abrasive polishing.[30]

Ultrasonics is a common technique in manufacturing society. As it is well known, machining performance, at least MRR, can be improved by introducing ultrasonic vibration into manufacturing processes. The easy-to-implement property adds to the universality of ultrasonics to machining processes. Ultrasonic vibration has been combined with CMP and satisfactory results have been demonstrated.[35] The vibration is superimposed onto a special wafer carrier and the carrier

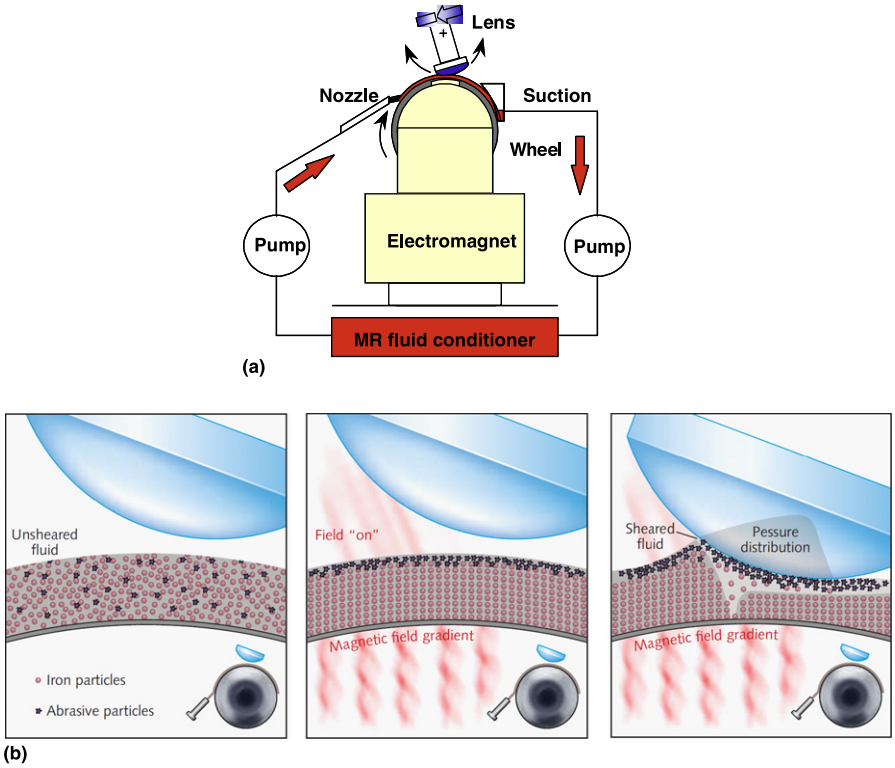

Figure 15 MRF polishing system (a) mechanism of MRF (b) process.[32]

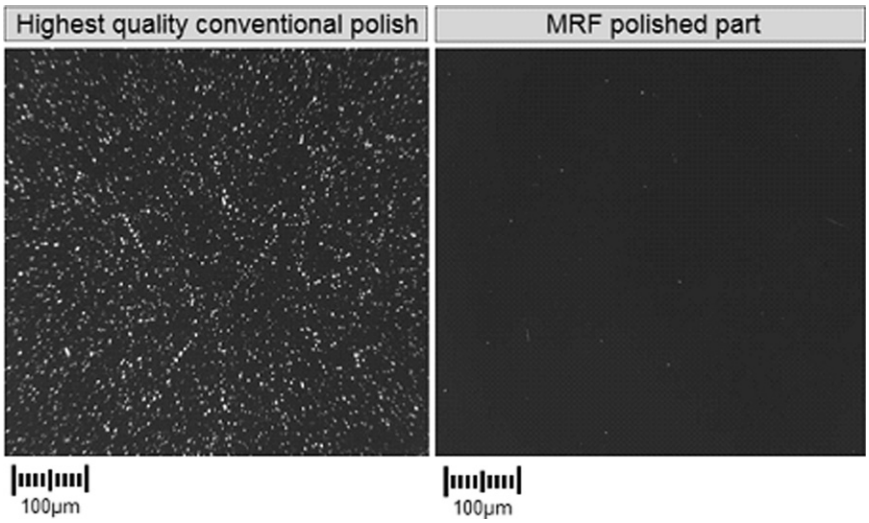

Figure 16 Subsurface defects caused by highest quality conventional pitch polishing and MRF finishing.[34] (with permission of the SPIE).

together with the wafer vibrates in vertical direction. The smoother surface and greater MRR have been confirmed. Although MRR and surface may be improved, expensive ultrasonic apparatus may lag the technique behind.

1.6.2.2 Fixed-Abrasive Polishing

1.6.2.2.1 Fixed-abrasive pad polishing

Loose-abrasive polishing proceeds in the form of pitch lap or pad with continuous or intermittent injection of polishing slurry. The loose-abrasive polishing (well-known as conventional CMP) has been extensively utilized to polish and planarize silicon wafer substrates and patterned wafers.[18] Typical loose-abrasive polishing is comprised of 3 factors: polishing tools, polishing slurry, and workpiece. The process is a three-body system: tool-abrasive-workpiece. The polishing is fulfilled by the interaction among tools, slurry, and glass. The motion of abrasives is stochastic and renders the process unpredictable, resulting in nondeterministic characteristics of the process. Aside from the physical nature of the loose-abrasive process, chemical reaction is considered to be of paramount importance to the polishing processes that employ abrasive softer or equivalent to the workpiece to be polished. This kind of loose abrasive polishing possesses obvious superiorities: generating ultra-smooth surface (surface roughness <1.0 nm), inducing little surface and subsurface damage. However, some innate drawbacks accompany the process, for example, lack of determinism, hard to achieve high uniformity and global flatness, minor 'active' abrasives ($<0.5\%$),[36] etc. Thus bound-abrasive pad polishing (bound-abrasive CMP) was proposed in order to overcome the shortcomings of conventional CMP. In bound-abrasive CMP, polishing abrasives were embedded into polishing pad, made usually of composites like polyurethane, in order to improve polishing performance.

IBM introduced a fixed-abrasive pad to polish magnetic disk substrates more than 30 years ago.[38] The pad is impregnated with diamond abrasives over $>50\%$ by weight. The abrasives are bound within polyurethane and may disintegrate but not detach from the binder during the polishing processes, avoiding the incurrence of deep scratches and the possible erosion of metals. The pad material was further improved to be self-conditioned by using special polymers to keep long-term stability.[39,40] Tani *et al.* developed a kind of high porosity (up to $>$vol. 50%) pad which can relieve pad-loading and accommodate abrasives of wider range of size.[41] Enomoto *et al.* recently proposed a new bound-abrasive polishing tool, consisting of acrylic resin and fiber as well as abrasives.[42] They adopted acrylic resin instead of polyurethane because of high hardness and potential ability to reduce adhesion to abrasives. The results reveal that the surface roughness of finished workpiece is as low as 1 nm for BK7 and the roll-off of the edge is also improved. Noritake Inc., claims a loosely bound-abrasive polishing pad that integrates both the merits of loose abrasive (high MRR, less scratching) and bound-abrasive polishing (smooth polishing).[37] A special type of resin is used as polishing material and the abrasives can be added differently for various substrates as needed. Figure 17 illustrates bound abrasive where the abrasives are loosely held in the pores, which can be silica, ceria, alumina, etc., as needed for various substrate materials.

This type of bound-abrasive polishing is relatively easy to be implemented and do not need much modification to conventional polishing machines. It has demonstrated several superior performances in defect control, flatness as well as controllability. The kind of polishing belongs to more three-body abrasion than two-body system since the abrasives are loosely bound and can be released during the polishing process.

1.6.2.2.2 Fixed-abrasive pellet polishing

If abrasives are firmly bound within a matrix, particularly a hard matrix, the polishing tool is different from the previous type because two-body mode is excited during the polishing process. The matrix can be shaped into a pellet, a grinding wheel or cup wheel, a ring, or bar to form a special distributed polishing tools. Figure 18 shows bound abrasive pad invented by 3M for the application of polishing SOI wafers. The

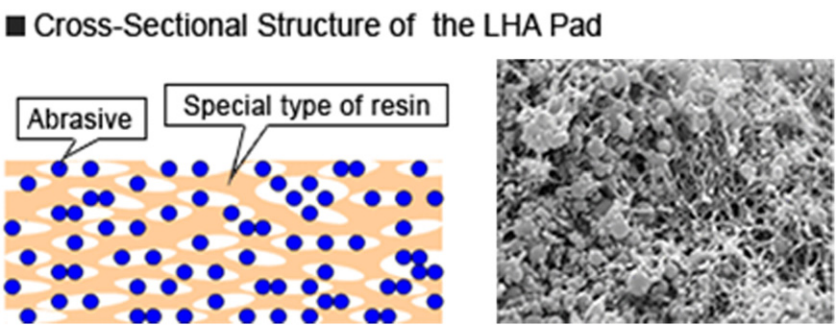

Figure 17 Bound-abrasive pad invented by Noritake.[37]

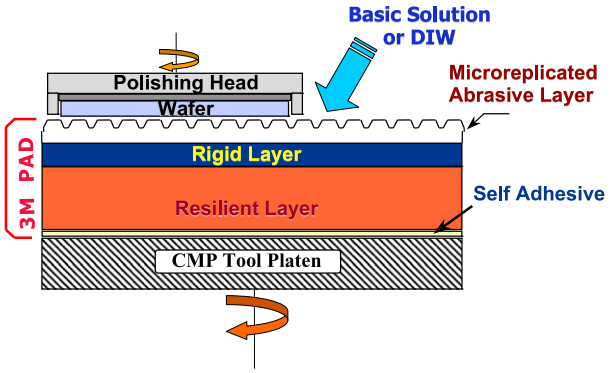

Figure 18 Bound-abrasive polishing pad configuration by 3M.

abrasives are fixed into the top layer that is patterned. The pad is composed of several layers of various materials and the top surface is characterized by molded 'posts' full of abrasives.[43,44] Since the abrasives have been embedded in the 'posts,' there is no need for slurry and only deionized water or basic solution is employed. The possibility of slurry drying and pad glazing is reduced, so the pad dressing is not necessary. It is reported that the planarization rate of bound-abrasive polishing is approximately three times that of conventional loose-abrasive process and the rate is much more stable. Furthermore, better flatness can also be obtained using this type of pads.

Gillman and Jacobs blended ceria and NH_4Cl or alumina in epoxy matrix to fabricate a sort of bound-abrasive polisher in the form of pellets, ring, and a full lap.[45] BK7 glass and fused silica can be polished to RMS surface roughness of ~1 and ~1.5 nm in 30 and 60 min, respectively. The polishers can be applied to polishing flats, spherics as well as aspheric surfaces and is interchangeable in most conventional polishing apparatus. The experiments show that production time may be cut down significantly by means of using the polishers.

Afterwards, Zhou invented a new bound-abrasive polishing tool intended first for the polishing of silicon.[46] The results for silicon substrates validate the effectiveness of polishing technique. Then the technique was extended to polishing quartz glass.[47] The surface can be polished to <0.5 nm (R_a) within 10 min. The process can function in both dry and wet situations with two kinds of polishing tools w/wo micro-pores. Li *et al.* incorporated ultrasonic vibration to bound-abrasive polisher and found MRR can be substantially improved after using vibrations and the surface roughness can be polished down to $R_a \sim 1$ nm.[48,49] Besides external downward load and relative speed, applied voltage and phase difference also impact the MRR and final surface roughness.[50,51] The mechanism of increase in MRR is to some degree explained using a mathematical model.[52] The pulsed impact due to vibrations may play an important role in removing material, especially for originally smooth polished surface. The smooth surface is cracked by the impact of pellet, resulting in degraded surface roughness and much higher MRR as compared to that without vibration.[53] Another reason is reckoned to be the excellent capability of discharging polishing debris that may keep chemical reaction from taking place between abrasives and glass.[52,54] The polishing can proceed with or without water or other liquids, but using water makes the final surface smoother and may lower MRR in some cases.[55] **Figure 19** shows surface roughness of fused silica with bound-abrasive polishing. The vibration-assisted polishing may incur some regular patterns on final surface on the order of nanometers in amplitude and deteriorate surface roughness mildly in most situations.[48–55] Ochiai *et al.*[56–57] have produced bound-abrasive polishing blocks by means of electrophoresis deposition (EPD). The manufactured EPD polishing tools contains ceria or silica and has polished glass to ~1.3 nm. The EPD cannot be used under dry conditions but can progress smoothly in the presence of water and the MRR is fairly high. Bouzid *et al.*[58] fabricated pellets of mixture of ceria and epoxy to polish BK7 glass and found fast reduction in surface roughness to 10 nm RMS within 5 min, very promising in rapid production of precision glass surface.

Another bound-abrasive polishing adopts ice as matrix material to accommodate abrasives.[59] Compared to cast iron and copper, ice possesses low hardness and is able to yield smooth surface of glass. Some materials have been tested for the effects of ice polishing and it shows that silicon wafers can be polished very well of surface roughness, R_a 0.57 nm and R_a 0.37 nm with alumina and ceria abrasives.[60] The copper workpieces were also evaluated to exhibit significant improvement of surface quality.[61] Since the melting point of ice is 0 °C at room pressure, cryogenic apparatus is necessary. With this polishing method, the additional fluid is not needed any more.

Much effect has been made to improve the performance of bound-abrasive polisher and to transfer the technology into industrial applications. Bound-abrasive has succeeded in some respects, for example, the polished surface quality, comparable MRR with loose-abrasive polishing, and the efficient use of abrasive, etc. In addition, slurry is unnecessary any more.

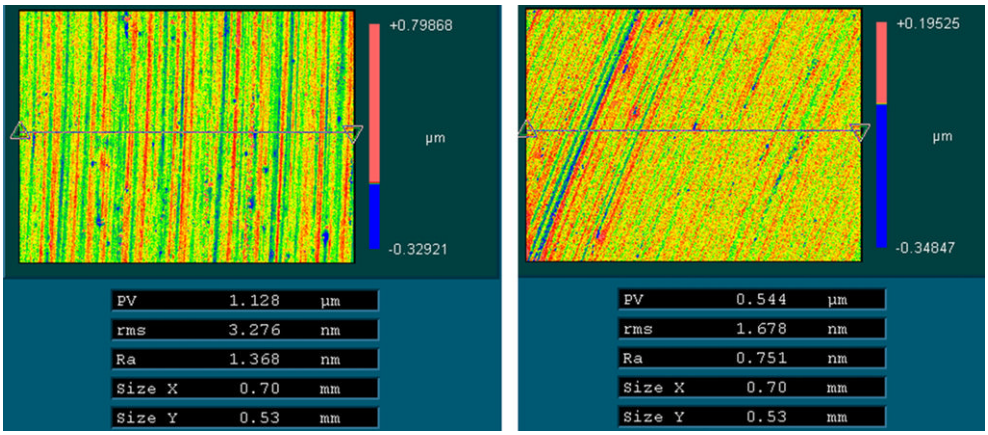

Figure 19 Surface roughness of fused silica with bound-abrasive polishing in dry and wet situations.[55]

The only thing is to supply water in the course of polishing run, which is eco-friendly. The process is much more deterministic and predictable than its loose-abrasive counterpart, but the manufacture of abrasive pellets/polisher is the most pressing issue. The technique will prevail once the cost and the fabrication time is cut down for mass production in that it is easy to implement and is compatible with mainstream machinery.

1.6.2.3 Nonabrasive Polishing

Some methods need not use abrasives to polish glass workpiece and they are listed out in the following. It is known long before that HF solution can etch glass. Therefore, chemical polishing with fluoride solutions is possible.[62] The solution can be HF and HF with additives of strong acids or NH4F. The products of chemical reaction contain gaseous silicofluoride and fluorides of metallic oxides. Polishing rate depends on the concentration of HF and composition of solutions as well as temperature. The subsurface cracks and contamination will be removed, at least ameliorated. Attributed to numerical control, the surface form can be precisely figured if controlled properly and surface roughness of 0.15 nm R_a has been attained for quartz glass with appropriate concentration and compositions.[63]

Plasma etching has been extensively applied in semiconductor for dry etching of thin film and patterning.[64] Most plasma etching processes remove materials due primarily to reactive ion etching (RIE). Researchers of optical fabrication started to employ low-temperature plasma as polishing tool to manufacture glasswares in 1960s and 1970s.[65,66] Glass is polished by chemical reaction in plasma polishing process in plasma-assisted chemical etching (PACE). Material is removed by a restrained reactive gas plasma moving over the surface of workpiece in PACE at low pressure (1–10 Torr). PACE smoothens glass by virtue of chemical reactions and is a type of noncontact polishing technique. Hence no mechanical damage occurs on the finished surface of glass workpiece. For different materials to be polished, different working gases are used. For example, CF_4, SF_6, are potential gases for manufacturing fused silica while for SiC NF_3 may be utilized in PACE.[67] During the course of polishing fused silica, CF_4 will react chemically with SiO_2 to produce gaseous byproduct SiF_4 and CO_2. The PACE will not induce edge distortion because of no solid contact between glass and polishing tool. Moreover, mid-spatial frequency can also be corrected by PACE.[68] Mori *et al.* initiated an atmospheric plasma etching process plasma chemical vaporization machining (PCVM), of which the pressure is nearly 1 atm. **Figure 20** shows PCVM apparatus. Plasma is ignited at the end of a pipe electrode by a RF system in a chamber where workpiece is located. The working gas was chosen to be SF_6 and He for fused silica machining and RF power supply excites plasma.[69] The MRR of PCVM is said $4 \sim 1100$ times faster than conventional smaller pitch polisher when fused silica glass is machined.[69] The attainable surface roughness of final fused silica surface is 0.37 nm RMS.[70] Recently, martial removal rate was further elevated to 0.55 $mm^3\ s^{-1}$ using reactive atom plasma technology.[71] The technology is being used to figure complex surface like continuous phase plate (CPP).[72]

Another nonabrasive polishing involves particle beam. It was found that highly energetic beams can sputter materials as early as 1920s, although it is not until 1960s that ion polishing was proposed.[73,74] The beams are usually composed of ions accelerated to much high energy and bombard the surface of workpiece. The use of energetic ions (e.g., Ar^+ ions) as high as 300 keV to machine materials is referred to as ion beam figuring (IBF). IBF can manufacture a variety of materials, inclusive of optical glass, ceramics, semiconductors, etc. It belongs to noncontact machining techniques and is able to be used for machining very thin workpiece. However, IBF may cause heating and surface roughening and vacuum is necessary, which puts limitations to the application of the technology. Ion beam smoothing will be realized when low-energy ions (<2 keV) is employed. IBS is capable of preparing ultrasmooth surface of <0.2 nm R_q. If ions (Ga^+ ions) are focused by means of electronic and electrical controls and directed toward material surface, focused ion beam (FIB) machining takes place. FIB is able to machine very hard materials and has been applied to dress diamond tools.[75] RAP uses very low-energy beam and processing is mainly by chemical reactions. **Figure 21** shows particle energy for various nonabrasive polishing processes. Different processes use different particle energy. The MRR and surface roughness are found to be relevant to ion energy, incident angle, etc. Ion beam polishing is

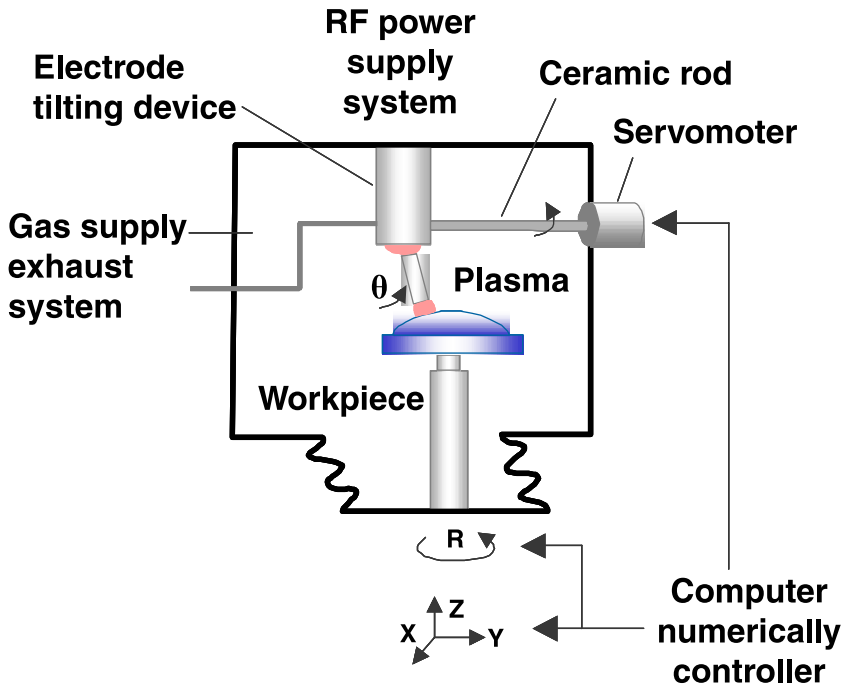

Figure 20 PCVM apparatus.[70]

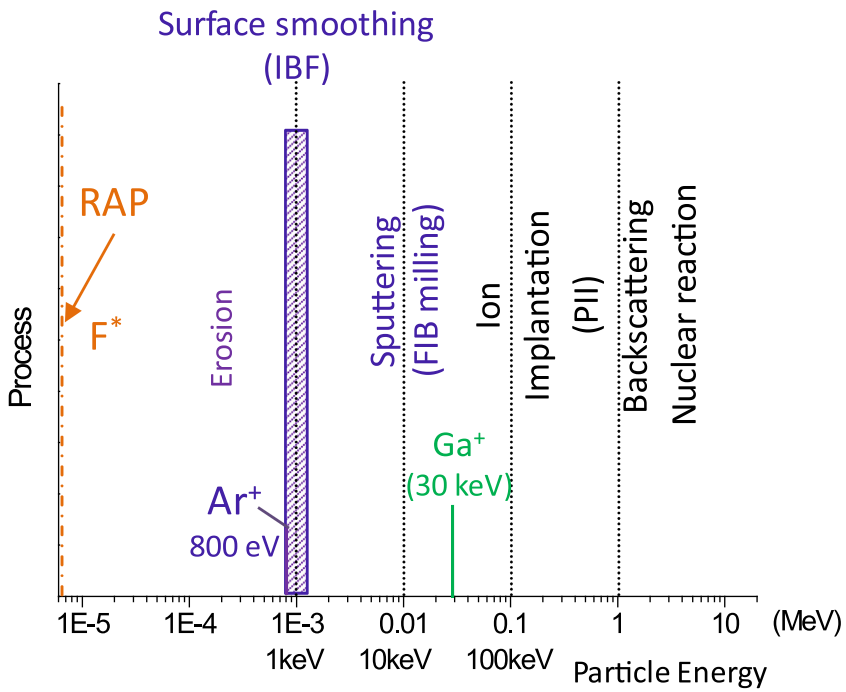

Figure 21 Different processes can be realized with different particle energies.[75]

generally less efficient than plasma polishing in that material is removed physically in ion polishing process while plasma polishing is a chemistry-dependent process.[76] Damage may be incurred in ion polishing process, dependent on ion energy. In general, the lower the energy of the atoms (ions), the less the damage induced by the atoms (ions). But it is difficult to accelerate a single atom (ion) to extremely low energy with conventional technology, so gas cluster ion beam (GCIB) was put forward by Yamada at the beginning of 1990s.[77] Molecular dynamics (MD) simulation demonstrates that material suffers less damage when impinged by larger cluster after undergoing the same acceleration energy.[78] GCIB technology shown in

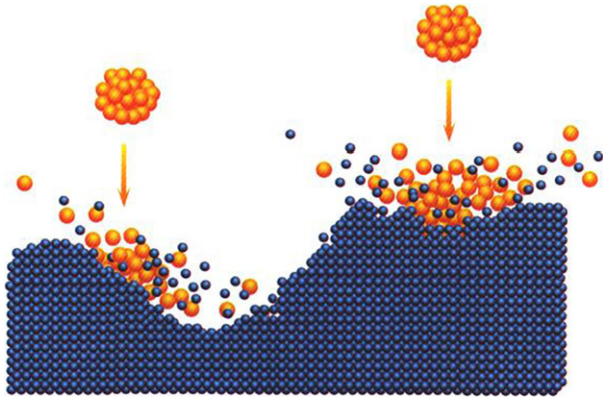

Figure 22 GCIB technology.[81]

Figure 22 accelerates several hundreds or thousands of atoms of singly or doubly charged and thus very low charge-to-mass ratio is practical, which is instrumental in machining material on atom-scale. GCIB ions are composed of a cluster of hundreds or thousands of atoms which are loosely bound. They splinter into smaller cluster or single atom and sputter atoms of workpiece surface. Subsurface of workpiece is impossible to be damaged since the energy of atoms is much low. The clusters can be formed with a wide spectrum of gases and gas mixtures, such as Ar, Xe, O_2, N_2, CH_4, B_2H_6, ethanol, water, C_{60}, etc.[79,80]

Laser polishing is a type of polishing taking advantage of energy field. Mechanism of laser polishing is thermal effect that softens/melts locally glass material and smoothens the surface because of the viscous flow of glass driven by surface tension. CO_2 lasers are a common tool to polish glass. The first laser polishing, to the best of our knowledge, is carried out by Temple who employed continuous wave CO_2 laser (10.6 μm) to polish fused silica for the purpose of increasing damage resistance of glass surface.[82] Vega utilized CO_2 lasers ($\lambda = 10.6$ μm) to reduce surface roughness of glass of 500–~1 nm.[83] Nowak lately pushed surface roughness down to <1 nm from initial ~1 μm using a well-controlled CO_2 laser of 10.6 μm, enabling the technique a precision polishing process.[84] Cracking in laser polishing may be the most important issue in laser polishing, which is due to thermal stress resulting from localized heating and cooling of glass surface. Xiao researched the effect of thermal stress on cracking during laser polishing of various glasses. They preheated samples to ~400 °C with an oven before laser polishing and the results show that thermal expansion coefficient plays a vital role in cracking glass in laser polishing. Glasses with low-expansion coefficient can be laser polished successfully.[85] Laguarta improved spatial and temporal uniformity of CO_2 laser beam to allow the fabrication of high-expansion coefficient glasses by laser polishing.[86] Nowadays, laser manufacturing is increasingly supplanting conventional techniques thanks to its easy-to-use property and versatility.[87]

1.6.3 Post-Processing of Optical Glass

Aside from surface roughness and surface form, resistance to laser damage is an issue of paramount importance for laser optics. The ultraviolet (UV) damage performance of optics has been an obstacle to the development of high-power giant laser systems. The surface damage threshold of fused optics is far lower than its intrinsic damage threshold. It is generally accepted that defects during the processing of optics account for low damage threshold in UV spectrum. Specifically speaking, cracks due to brittle facture of fused silica surface in grinding and/or polishing, metallic contaminants in the course of polishing and organic molecules in the handling and storage of optics play the most significant roles in the UV-nanosecond-laser induced damage. They therefore, must be eliminated so as to improve the damage resistance of optics. To that end, optics must be post-processed to obtain a clean and damage-resistance surface to meet the rigorous requirements of high-power lasers. Some post-processing methods are summarized in the following.

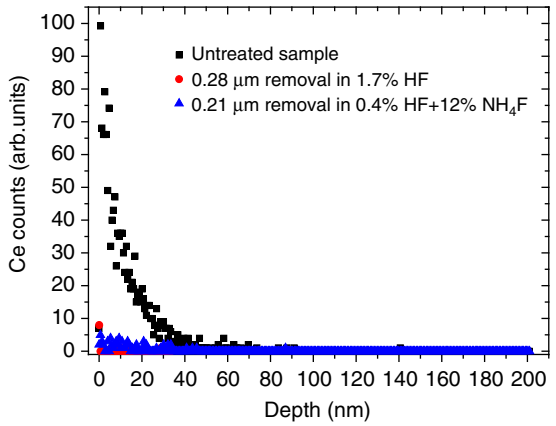

Figure 23 Ce elements on top surface of fused silica as polished and etched slightly with HF solutions.

1.6.3.1 Wet Chemical Post-Processing

It has been known that glass can be eroded by HF solutions at room temperature. Thereby HF solutions are selected to chemically polish glasses as previously stated. In addition, HF can be employed to clean/etch the top surface of polished glass as a thin layer (Beilby layer) covers the finished surface into which contaminants are embedded. Laser damage resistance can rise by means of chemically etching the surface of fused silica because absorptive contaminators in the layer are removed.[88,89] Further etching does not improve damage resistance but decrease damage performance of glass contrarily. There exists an optimum etching thickness where laser damage may be maximized. The thickness ranges from several hundreds of nanometers to several microns.[90–92] More recently, it was shown that nano-crystallites with wide energy gap may be the culprits for laser induced damage even if the bandgap of crystallites is wide enough to be transparent in UV region (355/351 nm). With the etching of glass in HF solutions, contaminants are indeed removed but the possibility for deposition of nano-crystallites also increases, shown in Figure 23.[93] HF etching can slightly clean surface of fused silica. That may account for the up-and-down of laser damage threshold as the etched thickness rises and the nano-crystallites may be the limitations to achieving higher laser damage threshold. As a consequence, dynamic etching was suggested

that ultrasonics and/or megasonics are imposed during the etching of fused silica in order to reduce the deposition of nano-crystallites throughout the course of etching.[94] The method sets a new record in damage threshold of fused silica optical components. **Figure 24** shows damage density as a function of laser irradiance where damage density continues to drop-down after relieving nano-crystalline deposits by ultrasonic/megasonic etching which can trigger laser damage in fused silica.

Glass leaching has been broadly researched by nuclear researchers.[96] Alkaline and alkaline earth ions possess great mobility in glass. Likewise, metallic contamination can be leached out in acid solutions like nitric and chloric acids. The leaching with the mixture of HNO_3 and H_2O_2 can dissolve metallic contamination in top surface of finished fused silica optics. Then the leached optics is subject to laser irradiation at 15 J cm^{-2} Fluence but no damage sites are found and the surface seems intact, indicating leaching is an effective way to reduce metallic contamination and to boost damage resistance of optics. **Figure 25** supports this statement where the surface contains no visible change or modification on leached surface.

1.6.3.2 Dry Post-Processing

Laser processing has been applied to increase damage resistance since 1980s. Temple radiated fused silica surface with a continuous wave CO_2 laser. The irradiated surface was damage-tested by 1064 nm nanosecond lasers. Small spot damage testing results indicate that damage threshold of processed surface is almost the same as the bulk damage threshold. Also, large spot damage tests show ~3–4 times enhancement of damage threshold over original polished surface.[82] Brusasco raster-scanned fused silica with a 10.6 μm CO_2 laser, leading to laser damage threshold from ~10–20 J/cm^2 to 30 J cm^{-2} at 355/351 nm.[98] Brusasco also treated fused silica with 355 nm UV laser of slim lower fluence than damage threshold to reduce damage density of fused silica.[99] Menapace combined MRF, wet etching, and UV laser conditioning to process fused silica optics. The processed optics shows a reduction of four orders in damage density.[33]

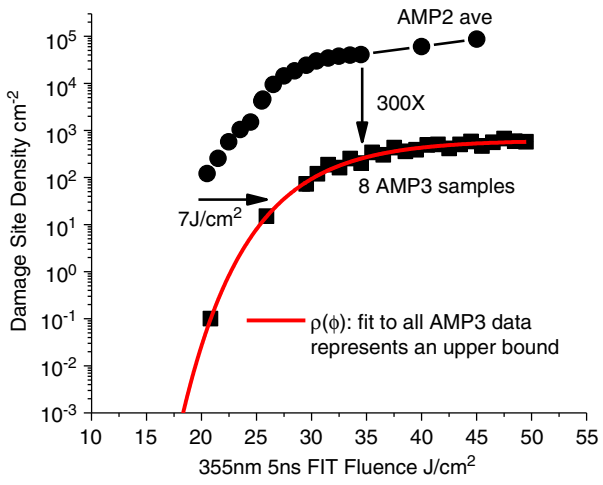

Figure 24 Damage density vs. laser irradiance[95] (with permission of the SPIE).

Ion beams can polish glass as mentioned before and can remove surface contamination as well. Kamimura removed ~90 nm of fused silica with ion beam etching and found that laser damage threshold was doubled from 7 to 15 J cm^{-2} (355 nm, 0.85 ns) when ion-beam voltage was <200 V.[100] Kamimura later chemically etched first and then ion-beam etched fused silica and obtained a threshold 2.8-fold higher than original unprocessed surface.[101,102] Xu and Yan improved damage threshold of fused silica with Ar^+ ion beam etching.[103,104]

Thermal annealing is another way to modify laser damage property of fused silica. Shen annealed fused silica at several temperatures to recover cracks in the surface of optics. The annealing can restore the damage of fractured surface and annealing time and temperature may determine the effect of annealing.[105]

1.6.4 Summary

The entire procedures involved in precision manufacturing of optics for high power laser systems are summarized. Grinding, polishing and post-processing are all indispensable in the fabrication of laser optics, which ensures the usability, operational lifetime, and performance of optics in laser systems. The optical components are first shaped to the desired surface form rapidly in grinding process. However, grinding generally incurs subsurface damage on the topmost surface of ground optics which is detrimental to laser systems and should be removed in subsequent steps. Then polishing process follows in which the surface form and surface quality are further improved and subsurface damage are relieved to designed specifications.

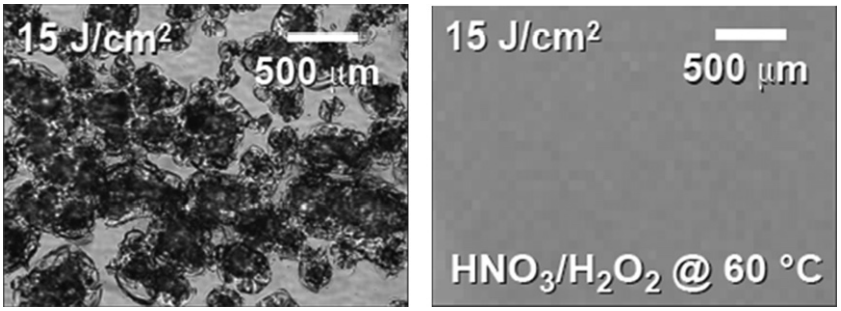

Figure 25 Laser damage morphology with and without HNO_3 leaching[97] (with permission of the SPIE).

Thereafter post-processing mostly enhances the damage performance of optical components to guarantee that the manufactured optical components fulfil the requirements of high power lasers. There are many technologies available in each step. With the development of science and technology, more new techniques will emerge. The intelligent, rapid but atomic controllable and eco-benign manufacturing will be future trends in precision manufacturing.

1.7.1 Introduction

Fabrication of machineries with high durability is a necessity for heavy-duty manufacturing components. Electrical discharge machining (EDM) is an advanced manufacturing technique for electrically conductive materials with any hardness property. By converting electrical energy to thermal energy,[1] a series of repeated sparks are generated on the workpiece surface facilitating[2] the material removal through surface material erosion. Great machinability of EDM has introduced this nonconventional technique to several major manufacturing industries included but not limited to aerospace,[3] biomedicine,[4] automotive, die and mold production, etc. Not only prominent cutability of EDM, elimination of any mechanical stress,[5] vibration issues, and chatter[3] are considered as some other advantages.

Despite the complex machining mechanism, EDM abilities have not been fully exploited due to its disadvantages. Primarily, the problem arises from the low material removal rate (MRR) and its inverse relationship with surface quality. Increasing the MRR sacrifices the surface quality of the machined workpiece. Also, repetitive spark between tool and workpiece causes an undesirable erosion of tool material increasing production cost. Furthermore, since the machined surface is exposed to heat and instant cooling by dielectric, surface cracks, heat-affected zone and residual stress[6] are considered as other drawbacks. Hence, presenting new methods to develop EDM capabilities has always been center of attention. Several techniques have been introduced as an enhancement method to boost EDM performance such as implementation of ultrasonic vibration in EDM, alternative tool materials, introducing alternative dielectric mediums, etc.

While there are benefits of EDM, drawbacks hinder widespread implementation of EDM within a majority of groundbreaking fields. To overcome the drawbacks, there are several improvement techniques that have been suggested primarily, the employment of water or gas as dielectric, ultrasonic vibration assisted EDM, and powder mixed electrical discharge machining (PMEDM). Furthermore, modeling and simulation of conventional or enhanced EDM process brings more understanding of the process performance. This chapter thoroughly analyses of accessible investigations through comprehensive

categorization to create a transparent map for further studies on EDM enhancement techniques.

1.7.2 Brief Overview of the EDM Process

The concept of EDM was introduced between World Wars I and II and later, Boris R. and Natalie I. Lazarenko developed the RC-relaxation circuit and servo system unit, which transformed EDM into a dependable machining technique.[7] Currently, EDM performance is considerably enhanced by advanced and sophisticated generators, servo systems, controllers, etc. As shown in Figure 1, a typical electrical discharge machine mainly consists of five core modules: the control unit and generator, servo system, circulation system, dielectric reservoir and pump, machining tank with a workpiece holder, and a X–Y table.

The electrical discharge machine performs the machining action while two important components, the tool and workpiece are immersed in dielectric fluid. Thus, the functionality of EDM is highly dependent on the dielectric fluid characteristics. As shown in Figure 1, the generator initially applies a potential difference between the tool and workpiece while these two components are immersed in dielectric. The servo controller maintains a narrow gap between the tool and workpiece and charging lasts for a predefined period (e.g., 200 μs). Then discharge occurs between the closest points on the tool and workpiece, where the spark strikes the tool and workpiece surfaces and current passes through the gap at a frequency range of 2000–500 000 times per second.[8] The spark's immense heat melts or/and evaporates workpiece material, resulting in the formation of cavities on the surface. Then charge and discharge occur repeatedly to complete machining, printing the electrode's pattern on the workpiece surface. Electrical discharge machines require for the tool electrode to have the exact opposite shape as the one to be printed on the workpiece.

As the EDM material removal mechanism involves surface melting and/or evaporation, no mechanical stress is applied on the workpiece. This feature highlights EDM as a viable tool for manufacturing fragile components, since mechanical stress is avoided on delicate parts with complex structures. Also in microscale manufacturing, EDM produces the finest outcome in terms of precision machining of difficult-to-cut materials with geometrically sophisticated shapes.[9] Machinability of high-hardness conductive materials, mechanical stress elimination, and vibration and chatter problem mitigation[3] are the main advantages of EDM.

1.7.3 Ultrasonic Vibration Assisted EDM

Applying ultra-sonication to different EDM elements appears to substantially boost performance, especially in micro-hole fabrication, as ultrasonic vibration facilitates easier ejection of debris from the gap. The vibration effect on the tool, workpiece, dielectric machining tank, or around the machining area has been shown to produce remarkable outcomes.

1.7.3.1 Tool Vibration

In 1995, the implementation of ultrasonic vibration pulse electro-discharge machining (UVPEDM) positively proved to enable machining of micro-holes in different substrate materials, including engineering ceramics.[10] Pulse discharge in the UVPEDM technique is generated by the ultrasonic vibration of the tool electrode rather than a special pulse generator in traditional EDM. It has been demonstrated that implementing UVPEDM produces higher MRR with low equipment cost and good operational performance. Later, Zhang *et al.*[11] proposed spark erosion by ultrasonic frequency from DC power instead of pulsed power supply where the pulse discharge was produced by the relative motion between the tool and the workpiece and the tool had sinusoidal vibration with ultrasonic frequency, facilitating easier ejection of melted and eroded material from the gap.

Also in drilling small holes ($\leq$1 mm Ø) in low electrical conductivity ceramic-coated nickel alloy, Thoe *et al.*[12] proved that the electrode's ultrasonic vibration achieves higher MRR. However, using a peck drill cycle was necessary to remove debris and maintain the MRR due to the adverse depth/diameter ratio of the hole. By adjusting the operating

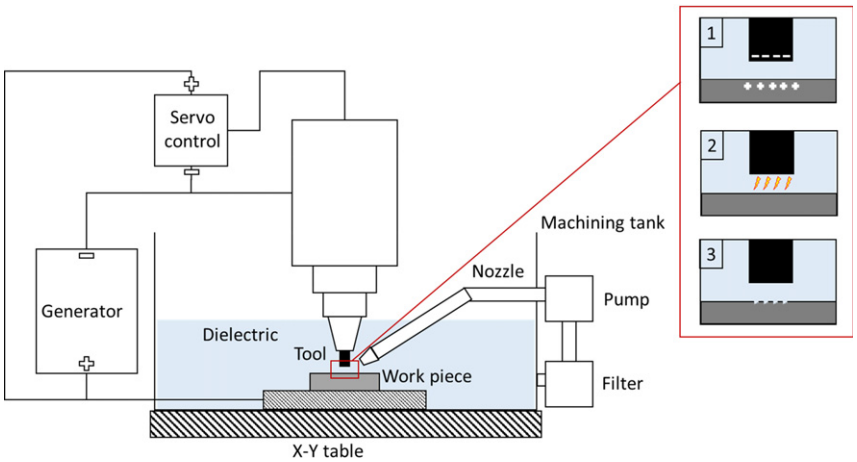

Figure 1 Schematic diagram of electro-discharge machine (1) charging, (2) spark, and (3) cavity formation.

parameters during the transition from ceramic to nickel machining, it was possible to preserve the integrity of any intermediate bonding layer. Although EDM process is suitable for titanium alloys, it is not ideal for small and deep holes because titanium alloys have low heating conductivity and high tenacity.[13] Applying ultrasonic vibration to the tool in micro-hole fabrication by EDM permits drilling holes with a diameter below Ø0.2 mm and depth/diameter ratio of over 15 in titanium alloys.[13] The influence of the tool's ultrasonic vibration on fabricating a micro-hole in nitinol has shown to boost machining efficiency to over 60 times and with no significant increase in electrode wear.[14] Furthermore, numerical simulation revealed that the efficiency improvement is attributed to the strong stirring effect caused by ultrasonic vibration, which results in excellent flushing in the micro-EDM process.

In machining cemented tungsten carbide, tool vibration was observed to significantly increase the MRR compared to conventional EDM at low pulse duration and low discharge current.[15] However, ultrasonic vibration resulted in higher surface roughness and TWR compared with conventional EDM. Additionally, tool vibration in EDM produced higher micro-hardness as well as a thinner heat-affected zone and recast layer on the machined surface.[16] EDM performance was more examined by Wei *et al.*[17] in machining SiC fiber-reinforced SiC matrix composite, which is an advanced ceramic matrix composite (CMC). It was found that implementing tool vibration or deep debris flushing reduced the negative effect of low workpiece conductivity in the EDM process by increasing the MRR and surface quality without increasing the TWR.

A parametric study was carried out on EDM for machining M2-grade high-speed steel using ultrasonic assisted cryogenically cooled copper electrode (UACEDM).[18] As shown in **Figure 2**, the electrode was cooled using liquid nitrogen and ultrasonic vibration was implemented using pulse generator, transducer, and horn. It was revealed that using UACEDM results in lower electrode wear ratio and surface roughness compared to conventional EDM. The electrode shape was also measured and it was found that the shape retention was better in the UACEDM process compared to conventional EDM. Similarly, another investigation[19] addressed the tool wear problem in the EDM process by designing a cryogenically cooled electrode with a tip made of copper (Cu)–titanium carbide (TiC). The performance of the newly formed cermet electrode tip was compared to a conventional copper electrode tip for the UACEDM process. Investigation revealed that the electrode wear ratio and out-of-roundness decreased while MRR and surface roughness increased when a cermet electrode tip was used compared to a conventional tooltip. Furthermore, the crack density and width on the surface machined by cermet tooltip appeared to be less than the specimen machined with a conventional tooltip.[19]

1.7.3.2 Workpiece Vibration

Ultrasonic vibration of workpiece have been taken under consideration by many research studies. Yan *et al.*[20] solved the problem with drilling micro-holes in borosilicate glass by applying ultrasonic vibration to the workpiece to produce precise micro-holes with high aspect ratios (ARs). When drilling a micro-hole with 150 μm diameter and 500 μm depth under appropriate machining parameters, the diameter variations between the entrance and exit could reach about 2 μm. Gao and Liu[21] induced ultrasonic vibration to the workpiece using the setup schematically illustrated in **Figure 3** and revealed that the efficiency increased 8 times compared to conventional micro-EDM for drilling holes in stainless steel with 0.5 mm thickness using a tungsten electrode with 43 mm diameter.

A set of experiments were conducted by Sundaram *et al.*[22] regarding the ultrasonic vibration of the workpiece during EDM. Based on the results, ultrasonic vibration at 60% of the peak power with 3300 pF capacitance appeared to be remarkably effective on achieving the highest MRR. In addition, machining time was found to significantly influence the TWR. Yu *et al.*[23] observed that the planetary movement of the electrode coupled with ultrasonic vibration of the workpiece in EDM micro-hole drilling yielded almost 2.5 times higher MRR than conventional micro-EDM in a high-hardness material. According to the cited research, tool rotation provides an

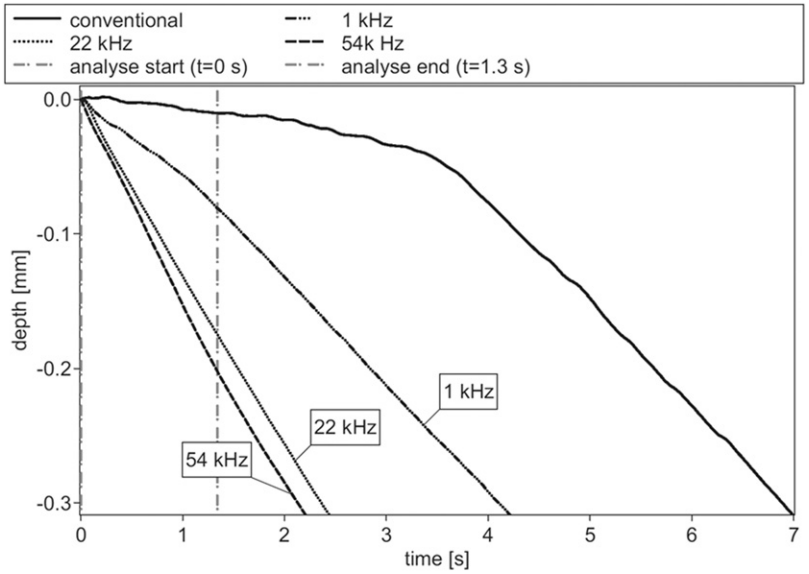

Figure 4 Electrode feed conventional and vibration assisted processes.[24]

uneven gap between the wall of the hole and the electrode, helping the bubbles to scape more easily from the gap. Besides, ultrasonic vibration of the workpiece boosts the penetration of dielectric into the gap, consequently increasing the wetting effect by weakening the boundaries between bubbles and dielectric.

Garn *et al.*[24] studied the effect of vibration on the electrical discharge in the micro-EDM process. Authors explained the micro-EDM boring process as three major subdivisions, the start-up process, the major boring process, and the workpiece breakthrough of the tool electrode. Extensive investigations have shown a delayed start-up process on the workpiece surface for conventional micro-EDM; however, this effect can be reduced by inducing vibration on the workpiece. As shown in Figure 4, the start-up process and machining time is considerably reduced for the vibration assisted EDM process compared with conventional EDM. The cause of this reduction was analyzed by single discharge analysis which also provided a means to investigate the effect of vibration frequency. In a dry EDM process, the implementation of a rotary magnetic field and ultrasonic workpiece vibration were deliberated by Teimouri and Baseri.[25] First, preliminary experiments were carried out to realize the influence of the magnetic field and determine the best tool design from material and geometry perspectives by considering the MRR. Then a parametric study on dry EDM was carried out with a brass tool with two eccentric holes by applying a rotary magnetic field, as selected in preliminary experiments. It was found that the magnetic field has positive effects on MRR and surface roughness and applying ultrasonic vibration results in the achievement of superior MRR.

1.7.3.3 Dielectric Vibration

Besides tool and workpiece vibration, employing vibration around the machining area affects electrical discharge machinability. A system with the ability to apply ultrasonic vibration around the electrode was designed and employed for micro-EDM hole fabrication,[26] which resulted in significant reduction of operational time and tool wear ratio (TWR/MRR). Furthermore, in terms of applying ultrasonic vibration in EDM, Liu *et al.*[27] proposed the production of a hollow nickel microsphere (Figure 5) by placing an ultrasonic transducer around the machining area.

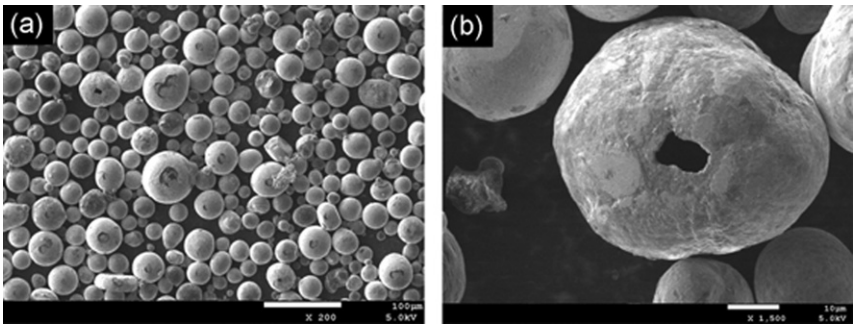

Figure 5 (a) Scanning electron microscope (SEM) micrograph showing a group of spherical microspheres at low magnification under ultrasonic wave; and (b) SEM micrograph of a thin hollowed sphere at high magnification.[27]

1.7.4 Dielectric Medium

The machining gap in EDM is continuously supplied by dielectric medium during the process, which leaves impact of dielectric specifications on the EDM product. It was found that the characteristics of a single discharge are significantly affected by dielectric type,[28] as the energy distribution and plasma diameter are specifically different for different dielectric materials,[29] thus affecting productivity, cost, and quality.[30]

Usually, paraffin-based oil dielectric is used in die-sinking EDM, but it does not provide a healthy machining environment as it releases toxic gases and causes air pollution. Furthermore, hydrocarbon oil decomposes during ignition, discharging harmful vapors such as CO and CH_4.[31] Operating with water or a gas like oxygen[32] have demonstrated to not only have a positive influence on the EDM process but to also provide a healthier working environment for the operators. In addition, the high discharge temperatures decompose kerosene, forming a layer of carbon element that adheres to both machined surface and tool[33] in the machining area. The presence of carbon in the machining gap eventually interrupts the normal discharge, resulting in arcing and short-circuiting.

1.7.4.1 Fluid Dielectric Medium

Dielectric liquid is supposed to form a barrier between the tool and workpiece, cool the machining area and eject debris particles from the machining gap. To find an appropriate liquid for EDM, different types of dielectric fluid have been used and their performance investigated. König and Jörres[34] employed highly concentrated aqueous glycerin solution as dielectric and found that dielectric containing glycerin is more advantageous than hydrocarbon dielectrics when working with long pulse durations and high-pulse duty factors and discharge currents. The glycerin dielectric proved superior to the hydrocarbon medium for roughing under optimized parameters.

Deionized water is one of the best known dielectric liquids for wire EDM due to its advantages over chemical compounds. [35] In order to improve the performance of deionized water as dielectric medium, Leão and Pashby[30] investigated the feasibility of organic compounds with large molecular structure as additives, such as ethylene glycol, glycerin, polyethylene glycol 200, polyethylene glycol 400, polyethylene glycol 600, dextrose, and sucrose. Yan *et al.*[36] modified the titanium workpiece surface by using urea solution in distilled water as dielectric during the process. The nitrogen element decomposed from the dielectric containing urea and migrated to the workpiece forming a hard TiN layer, which resulted in good wear resistance of the machined surface following EDM.

It is found that water-in-oil emulsion as dielectric results in the formation of a recast layer with great surface roughness, thickness, and micro-hardness compared with a recast layer formed in kerosene and deionized water.[37] Both carbide and oxide were identified on the recast layer formed on the samples in water-in-oil emulsion. However, only carbide was detected in the recast layer formed in kerosene. But due to the higher supersaturation of gases in the melted material, the recast layer formed in W/O emulsion possessed more microvoids than that formed in kerosene and deionized water. Zhang *et al.*[28] investigated the material removal characteristics of the EDM process using various dielectrics, including gaseous dielectrics (air and oxygen) and liquid dielectrics (deionized water, kerosene, and water-in-oil (W/O) emulsion). **Figure 6** depicts the craters formed when utilizing various dielectric materials. All geometrical parameters of the craters, including the recast material in the craters, were precisely determined by metallographic method. It appeared that there was a huge difference between the shapes of craters when different dielectrics were implemented. It was found that when using kerosene dielectric, less volume of material was melted compared to other dielectrics.

Jeswani[38] introduced the practice of using water as dielectric[2] and compared the performance of EDM in oil and water. Machining in distilled water exhibited higher MRR and lower wear ratio than in kerosene in a high-pulse energy range. Using distilled water as dielectric resulted in lower machining accuracy, but the obtained surface finish was superior. The machining characteristics of tap water, distilled water, and a mixture of 25% tap and 75% distilled water were inspected by Jilani and Pandey.[39] The results demonstrated that tap water performs more efficiently than deionized water and hydrocarbon oil and there was a possibility of achieving zero electrode wear when using water dielectric and copper tool with negative polarity.

Kruth *et al.*[40] studied the influence of workpiece material, electrode material, and type of dielectric on the surface composition and metallographic phases of the white layer.

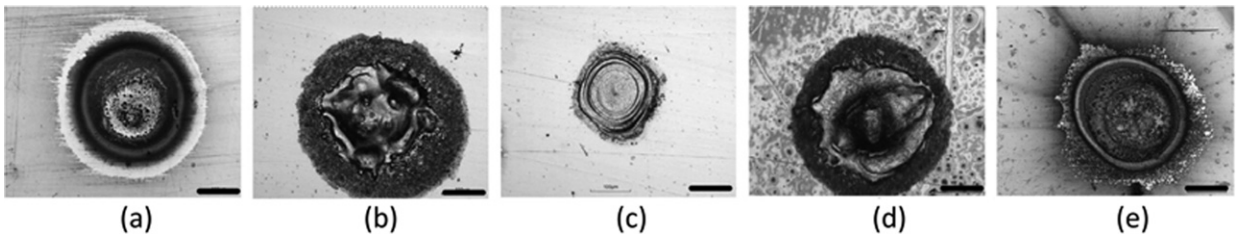

Figure 6 Comparison of the external appearances of craters formed in (a) air; (b) kerosene; (c) deionized water; (d) W/O emulsion; and (e) oxygen. Pulse duration = 105 μs, the length of the scale bar was 100 μm.[28]

Increasing carbon content was observed when using oil dielectric; however, with using water as dielectric, the carbon element formed iron carbides (Fe3C) in columnar, dendritic structures on the surface, which caused decarburization. The white layer contained about 4 times more carbon when using oil dielectric than base material. The white layer of samples machined in water dielectric contained about 50% less carbon than the base material. Also Chen *et al.*[41] verified that utilizing deionized water as dielectric produces higher MRR and lower TWR than kerosene.

Ekmekci *et al.*[42] observed that the amount of austenite phase retained and the intensity of micro-cracks were much less in the white layer of the samples machined in deionized water. In another study, Kang[43] investigated the effects of EDM conditions on the crack susceptibility of a nickel-based super alloy. According to the EDM dielectric fluid and post-EDM processes, such as solution heat treatment, the cracks existing in the recast layer propagated into the substrate when a 20% strain tensile force was applied at room temperature. Unlike the specimens machined in kerosene dielectric, those machined in deionized water after heat treatment underwent oxidation and showed no crack propagation behavior.

Casanueva *et al.*[44] proposed a new power supply for spark erosion based on a series-parallel resonant converter, resulting in great weight and size reduction, which is especially suitable for portable operations. The proposed control attained optimum stable operation when using tap water as dielectric fluid, preventing the generation of undesired impulses and maintaining the distance between the electrode and the workpiece within an optimum, stable range. This technology, initially meant for underwater operations in nuclear plants, may be extended for chip-less metal machining at low cost. Tang and Du[45] used a combination of gray relational analysis and Taguchi method for EDM parameter optimization in machining a Ti–6Al–4V workpiece in tap water dielectric. Under optimum condition, utilizing tap water led to an 87.3% increase in MRR as well as 25.7 and 18.9% reductions in TWR and surface quality, respectively.

Micro-slit EDM using pure water and negative polarity achieved high MRR, low electrode wear, small slit expansion, and low machined burr compared to positive polarity machining.[46] In comparing kerosene with pure water, pure water apparently caused low carbon adhesion to the electrode surface, did not drop the discharge energy and prevents the occurrence of abnormal discharges. Therefore, higher MRR and TWR were detected when using water as dielectric. In continual multi-slit EDM, pure water did not cause carbon element adherence on the electrode surface either, proving the lasting stability of material removal and electrode wear.[46]

Another application with water dielectric achieved complex EDM–electrochemical machining (ECM) machining, where EDM handled the shaping and ECM managed the subsequent finishing using a copper electrode.[47] Two types of EDM and ECM complex machining were taken under consideration: one with a formed electrode, and the other with simple-shape electrode scanning. **Figure 7** demonstrates the formed electrode and its related workpieces after EDM and ECM process, which indicated that after ECM the surface roughness was lowered from 1 μm (**Figure 7(a)**) to 0.6 μm (**Figure 7(b)**). The complex machining with electrode scanning was applied to produce small components of various shapes but without making a formed electrode. The EDM surface of 1 μm average surface roughness (R_a) improved to 0.2 μm R_a by applying ECM. Second, in order to get a smoother surface, a new EDM and ECM-lapping complex machining technology was developed. The surface roughness of a machined hole was improved to 0.07 μm R_a by applying ECM lapping for 2 min. The superior surface finish of the hole was evident with the complex machining technology.

Furthermore, in applying water as dielectric, a hybrid EDM–ECM machine was implemented by Nguyen *et al.*[48] Low resistivity deionized water used as a bi-characteristic fluid enhanced the performance in terms of finishing and machining accuracy. Low feed rate was instigated in the machining technique transition from EDM to EDM. Eventually, the heat-affected zone on the machined workpiece surface was dissolved by the chemical reaction owing to the changing machining characteristics. Thus, a novel hybrid machining process called simultaneous micro-EDM and micro-ECM (SEDCM) was proposed. Additionally, significantly higher surface integrity and dimensional accuracy were achieved when using SEDCM milling.[49] Besides, short voltage pulses localized the dissolution zone for greater precision and remove the micron-thick layer created by discharge craters on the machined surface. The three main factors of SEDCM presented were low-resistivity deionized water, low feed rate and short voltage pulses. SEDCM milling was also investigated.[50] As shown in **Figure 8**, covering the electrode walls with a thin insulating film enabled tool wear compensation during drilling of a blind hole with SEDCM due to the electro-deposition effect during the process.[51]

Using ethanolamine as dielectric medium was signified to facilitate achieving a titanium carbonitride (TiCN) coating by EDM as a result of using a titanium tool electrode and carbon and nitrogen atoms in the dielectric. As shown in **Figure 9**,

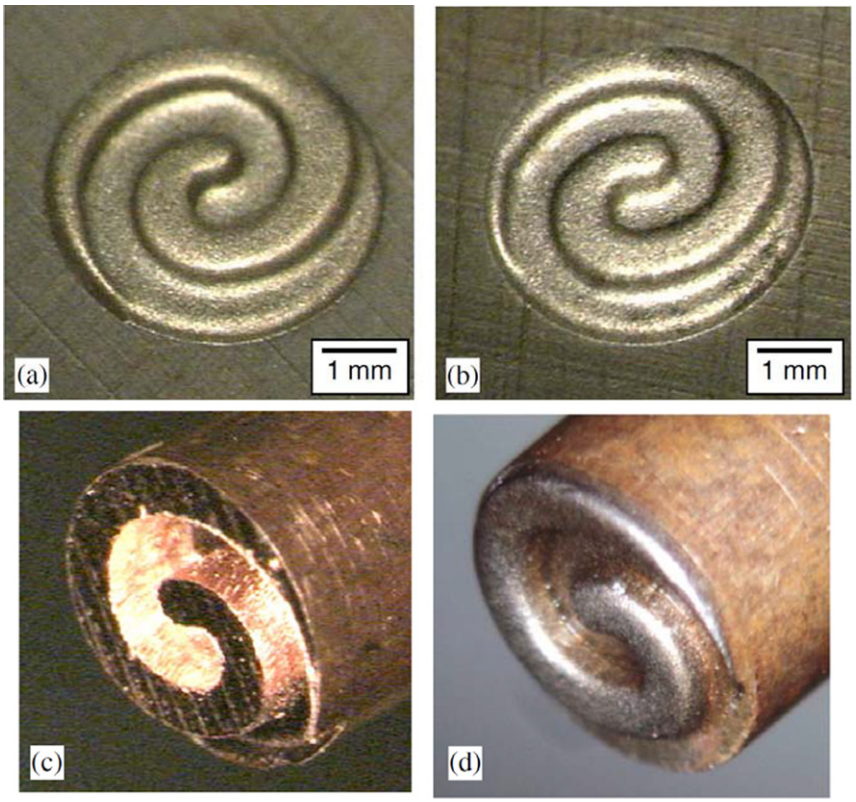

Figure 7 Photo of machined hole: (a) after electrical discharge machining; (b) after electrochemical machining (ECM); and formed electrode: (c) before machining; and (d) after ECM.[47]

a 15 μm thick layer mainly containing a TiC0.3N0.7 phase with fine-grain structure formed, which metallurgically bonded with the steel substrate and enhanced the hardness to 1780 HV for TiCN coating (4 times higher than the TiN coating obtained by magnetron sputtering).[52]

1.7.4.2 Gas Dielectric Medium (Dry EDM)

In 1991, Kunieda *et al.*[32] revealed a new method of improving EDM efficiency by supplying oxygen gas into the gap while using a water-based dielectric. It appeared that the stock removal rate increased due to the enlarged volume of the discharge crater and more frequent occurrence of discharge. Later, dry EDM was introduced as an innovative method, where the fluid dielectric was replaced by a gas medium. This method had positive effects on process performance, such as higher precision and lower electrode wear rate with less residual stress on the machined surface. Govindan and Joshi[53] presented an experimental characterization of material removal in dry electrical discharge drilling technique when using oxygen gas dielectric. According to a six-factor, three-level experiment using L27 orthogonal array, gap voltage, discharge current and electrode rotational speed influenced MRR. In most of the experiments, TWR was found close to zero, however, a predominant deposition of melted and eroded work material on the electrode surface instead of tool wear was evident.

As indicated in dry EDM setup in **Figure 10**, a pipe-shaped tool electrode supplies a pressured gas from the inside to eject debris from the gap. As tool rotation results in higher stabilization and enhanced MRR, a symmetric pipe-shaped tool electrode with inner channel was employed. This method provides a healthier and safer working environment, first by not producing toxic vapor from oil dielectric usage and second, by reducing the risk of fire hazards from flammable oil. Additionally, dry EDM reduces environmental damage as less industrial waste is produced.

Govindan and Joshi[54] presented a comprehensive and quantitative analysis of micro-crack formation, in terms of length, number, and orientation of micro-cracks formed on the machined surfaces in dry EDM. It was stated that average crack length (the best crack factor indicator) was considerably touched by voltage, current, pulse off-time and speed in both, the wall and bottom regions of the dry EDM surface. Furthermore, the causes of surface micro-crack formation were identified as (1) stresses due to contraction of diffused materials on work surface such as tool material (Cu), shield material (Al), carbon (C) and oxygen (O), (2) thermal residual stresses due to temperature gradient between region of sparking and other neighboring region of workpiece, (3) arcing in the interelectrode gap, due to high debris reattachment, and (4) mechanism of sensitization.

Kunieda *et al.*[55] showed that three-dimensional (3D) shapes can be machined very precisely using a special NC tool path that can supply a uniform, high-velocity air flow over the working gap. Furthermore, the MRR was improved as the concentration of oxygen in air was increased due to the heat generated from electrode material oxidation. Kunieda *et al.*[56]

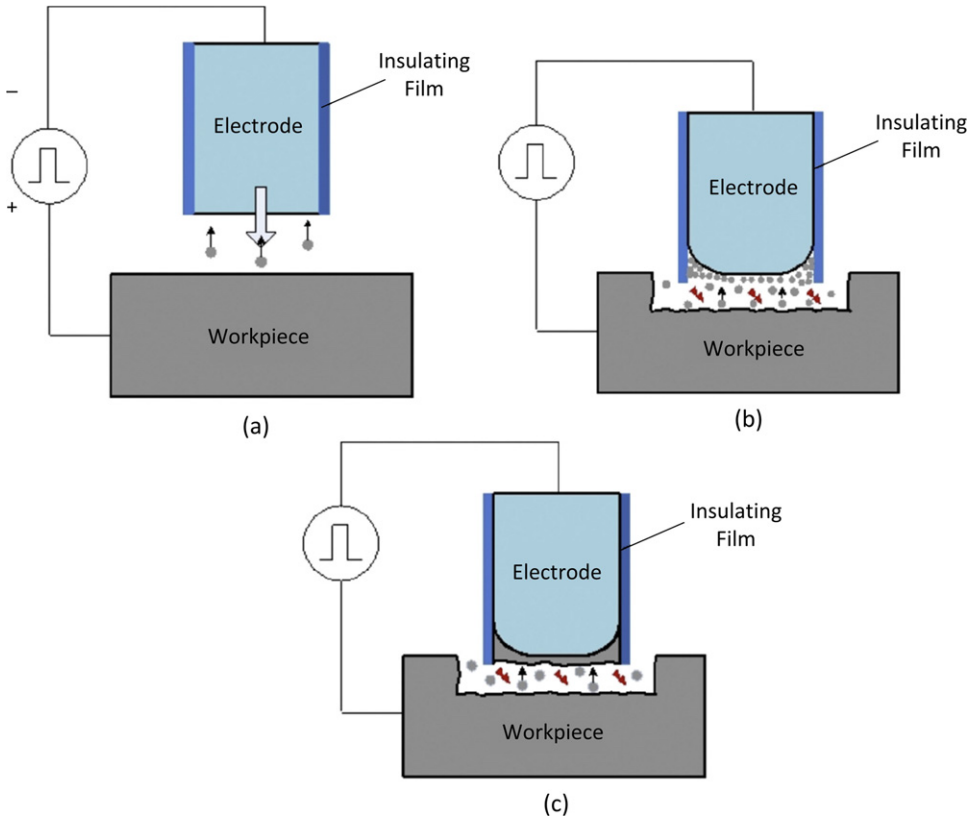

Figure 8 Principle of simultaneous micro-EDM and micro-ECM: (a) electrochemical dissolve, (b) discharge, and (c) discharge and electrodeposition.[51]

described the high-speed EDM milling of 3D cavities using gas as the working fluid. Remarkably small electrode wear and high MRR were obtained, especially when oxygen gas was used in the process. Machining accuracy considerably enhanced when the gas was sucked through the pipe electrode rather than jetted. Yu *et al.*[57] observed that between dry EDM milling, oil EDM milling, and oil die-sinking EDM, and dry EDM milling was the most advantageous for 3D machining of cemented carbide in terms of time and cost. The EDM milling operation with oxygen gas dielectric facilitated higher machining speed and lower TWR than oil EDM milling. In comparing dry EDM with oil die-sinking EDM for machining the same shape using cemented carbide, oil die-sinking EDM exhibited shorter machining time. However, since oil die-sinking requires time for producing electrodes, dry EDM should be more useful in actual production.

Several gaseous dielectric mediums have been proposed for dry EDM application. Roth *et al.*[58] studied process performance concerning MRR using air, CO_2, N_2, and O_2. **Figure 11** demonstrates the measurement of MRR as a function of different flushing gases. The graph shows that O_2 achieved the highest MRR, which is 4 times higher than using air as dielectric, whereas the lowest MRR was produced by N_2. It was evident that the heat energy from oxidation had little effect on the MRR and that the main difference between oxygen and less oxidizing gases was found at different stabilities and time efficiencies of the process.

Although dry EDM has many advantages over conventional EDM, instability and arcing are still serious concerns with the dry EDM process,[59] which have motivated researchers to find solutions for process stability. Kunieda *et al.*[60] presented a piezoelectric actuator with high frequency response to control the gap length in EDM to prevent frequent short-circuit occurrence in dry EDM due to the narrower discharge gap compared with conventional EDM. A hybrid dry EDM process was proposed in a pulsating magnetic field applied tangential to the electric field, to increase the movement of electrons and degree of ionization in the plasma.[61] Implementing the magnetic field in the dry EDM process led to 130% productivity improvement with zero electrode wear compared to dry EDM.

In order to enhance dry EDM process Liqing and Yingjie[62] proposed two methods, first based on oxygen EDM mechanism, a dry EDM approach using oxygen gas mixture followed by performing analysis validation. Second, dry EDM was considered for cryogenically cooled workpieces and the accompanying experiments were prepared. The experimental results showed an increase in the MRR with both oxygen-mixed EDM and cryogenically cooled workpiece techniques along with a decrease in the surface roughness value (R_a) with the latter.

In another study, a thermoplastic composite electrode was used instead of solid graphite to perform fine EDM finishing in air.[63] Employing a thermoplastic composite electrode with air rather than water or oil was efficient, as the peak-valley surface

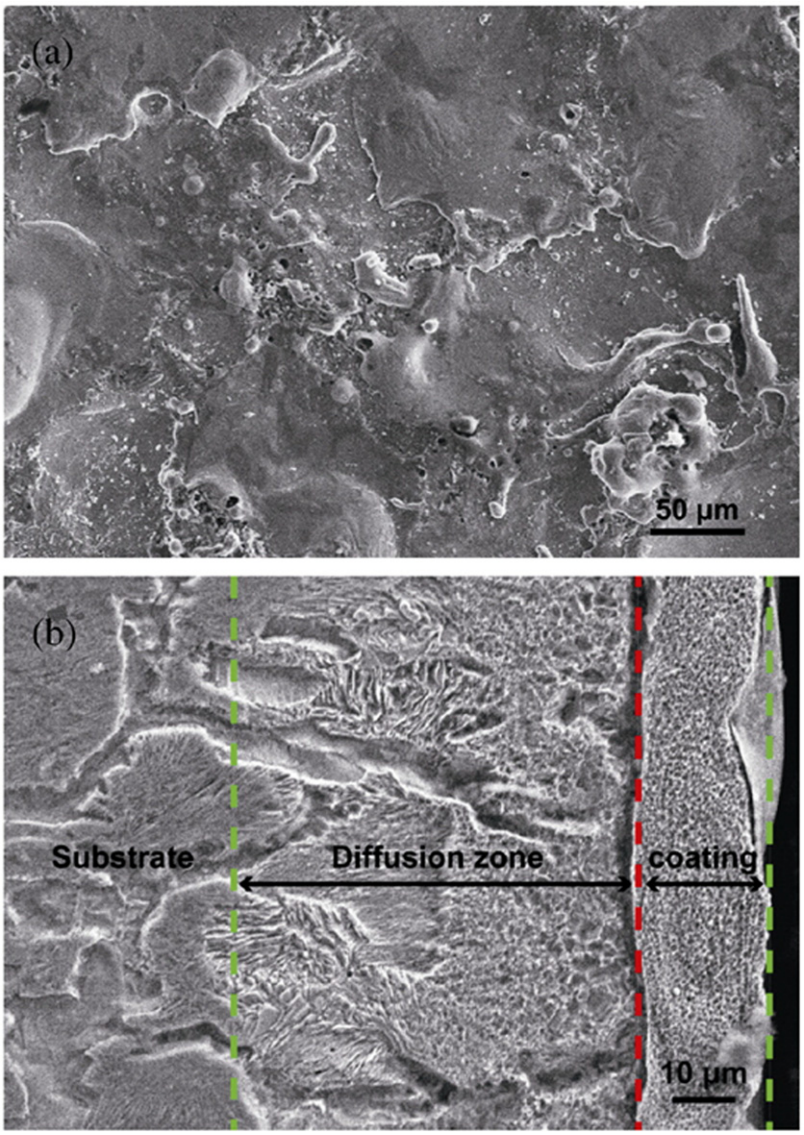

Figure 9 Scanning electron microscope of the top surface (a) and the cross-sectional and (b) morphologies of the deposited coating.[52]

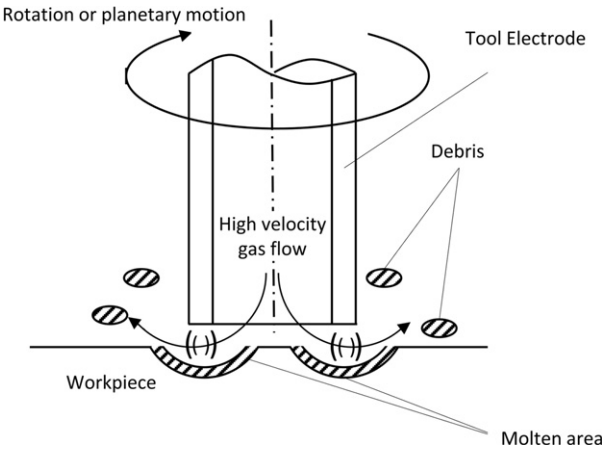

Figure 10 Principle of dry electrical discharge machining.[32]

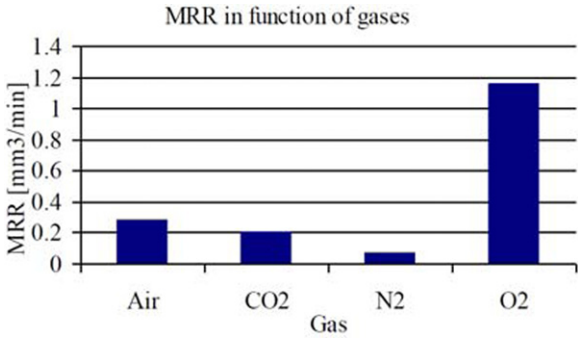

Figure 11 Material removal rate for different flushing gases.[58]

finish of a rough-machined tool steel part is iteratively flattened by 30 μm over three thermoplastic composite electrode forming, and EDM process cycle. Furthermore, abrasive jet

machine (AJM) integrated dry EDM was proposed for dry EDM application, where a pipe-shaped tool electrode supplies the abrasive and dielectric medium.[64] For both 6A and 9A peak current, higher MRR and lower surface roughness were obtained with hybrid AJ-EDM rather than dry EDM. Although increasing the peak current in dry EDM significantly increased the surface roughness, only a moderate increase was detected in the hybrid machining.

1.7.4.2.1 Near dry EDM

Near dry EDM is the EDM process when a mixture of liquid and gas is used as a two phase dielectric fluid where a minimum quantity lubrication (MQL) dispenser is engaged to supply a minimum amount of liquid droplets at a controlled rate to the gap between the workpiece and electrode. Kao *et al.*[65] employed mixture of water and air as the dielectric fluid for near dry EDM. It was indicated that near dry EDM achieves higher MRR, sharper cutting edge, and less debris deposition than dry EDM (Figure 12). In compare of conventional EDM (with liquid dielectric medium), near dry EDM found to obtain higher MRR at low discharge energy with a smaller gap distance. However, due to higher thermal load on electrode, electrode wear increased in near dry EDM. Further, a mathematical model was developed to quantitatively correlate the water–air mixture's dielectric strength and viscosity to the gap distance.

Fujiki *et al.*[66] studied the influence of electrode lead and tilt angles and dielectric fluid flow rate on MRR, tool electrode wear ratio, and surface roughness in near-dry EDM milling process. It was specified that the MRR is linearly proportional to the mass flow rate of air and kerosene mixture, the TWR is inversely related to the mass flow rate of air and kerosene mixture, and the R_a does not have a good correlation with the flow rate of the mixture. Furthermore, a new gap control strategy for five-axis milling using near-dry EDM was presented by Fujiki *et al.*[67] In conventional EDM control strategy only allows the retraction of the electrode in the direction of machining trajectory, which results in inefficient gap control when the electrode is not perpendicular to the workpiece. The new gap controller was capable of retracting the electrode in the direction of its orientation which facilitates more effective expansion of the discharge gap leading to faster recovery of average gap voltage. Experimental results specified a 30% increase in MRR while the TWR and surface roughness were not affected.

1.7.5 PMEDM

Amongst all enhancement techniques, adding powder to dielectric fluid is the most practiced approach in EDM improvement investigations. In PMEDM, adding powder to dielectric in the original circulation EDM system is not a feasible method. One reason is the existence of a filter in the system that may filter out the powder particles, and second, the original EDM circulation system's capacity is too high, which would increase the amount of powder required for the process. Thus, an external circulation system containing a small machining tank with a workpiece holder, pump, stirrer, magnetic filter, pipes, nozzle, etc., enables liquid circulation throughout the process. This circulation system with low dielectric capacity and filtration system enables the constant reuse of powder mixed dielectric (PMD).

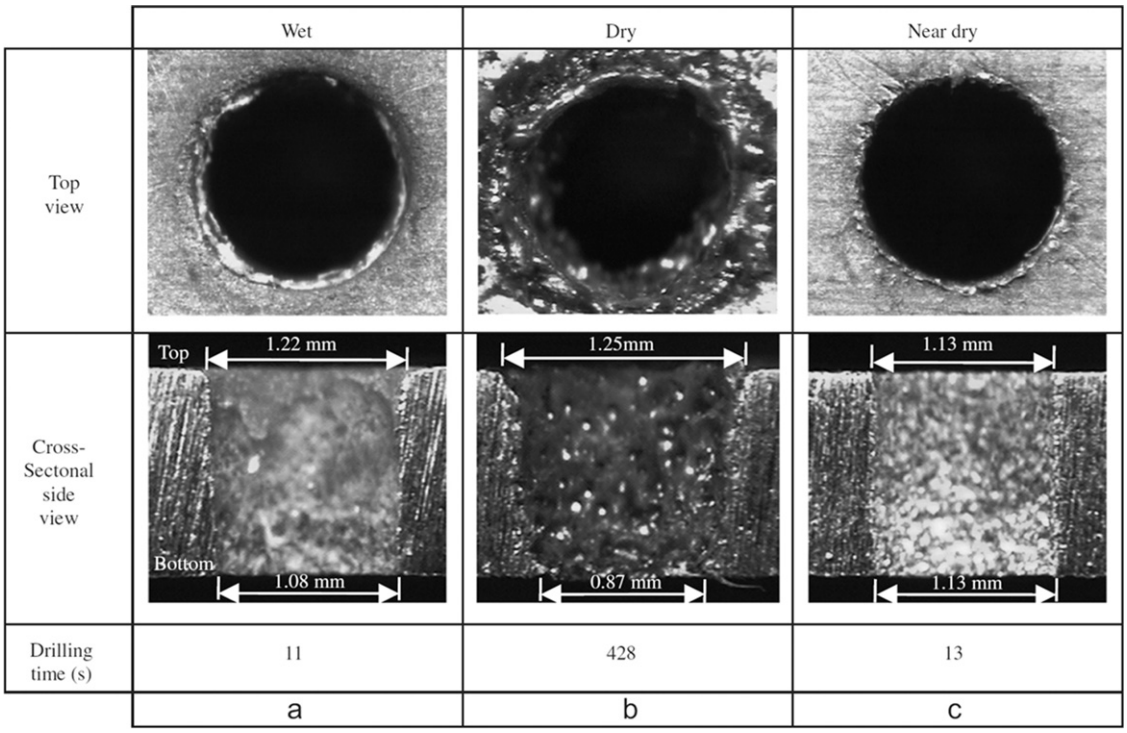

Figure 12 Optical micrographs on holes drilled on 1.27 mm Al6061: (a) wet, (b) dry, and (c) near dry electrical discharge machining conditions.[65]

Figure 13 displays the basic PMEDM dielectric circulation system. The magnetic filter is either placed in the small machining tank or the secondary dielectric reservoir. The powder particles are injected into the process or the process entails filling with the PMD liquid. In order to avoid powder suspension at the bottom of the tank, a stirrer is placed inside the machining tank. In some cases, both the pump and stirrer are located in the same tank in which machining is performed. The distance between the dielectric suction point and nozzle outlet is kept as short as possible (10 in) to ensure the complete suspension of powder in the discharge gap.[68]

To avoid aggregation and sedimentation, and to ensure homogeneous suspension of particles in the dielectric fluid the powder is usually mixed with dielectric by conventional methods like implementing a stirrer in the machining tank[70] or blending the powder with dielectric in advance.[71] With the promising application potential of ultrasonic vibration in EDM, the ultrasonic vibration of the machining tank in PMEDM was proposed to prevent powder suspension during the process.[72]

As shown in Figure 14, in PMEDM, the discharge does not directly strike the workpiece. In fact, the primary discharge

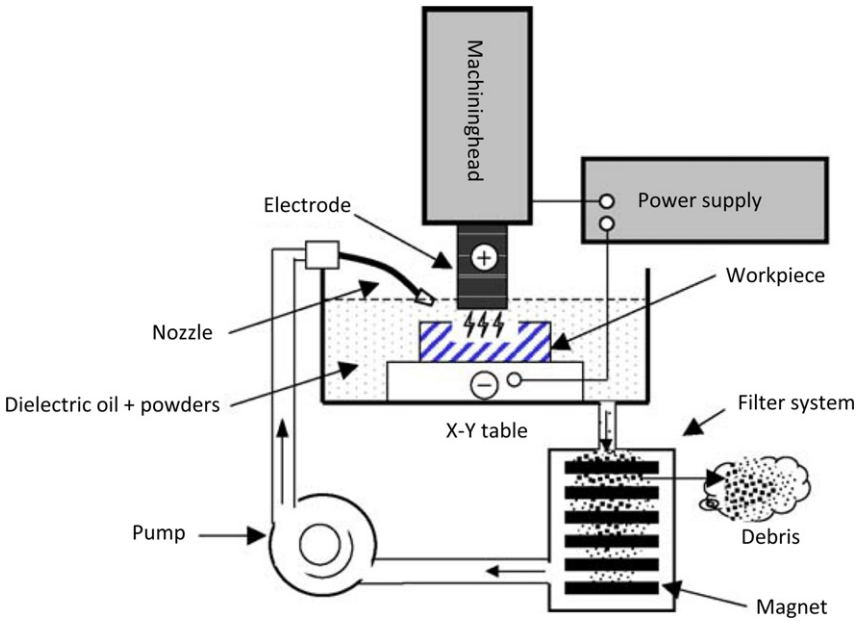

Figure 13 Schematic diagram of a self-designed filter system for the electrical discharge machining process used for the experiments.[69]

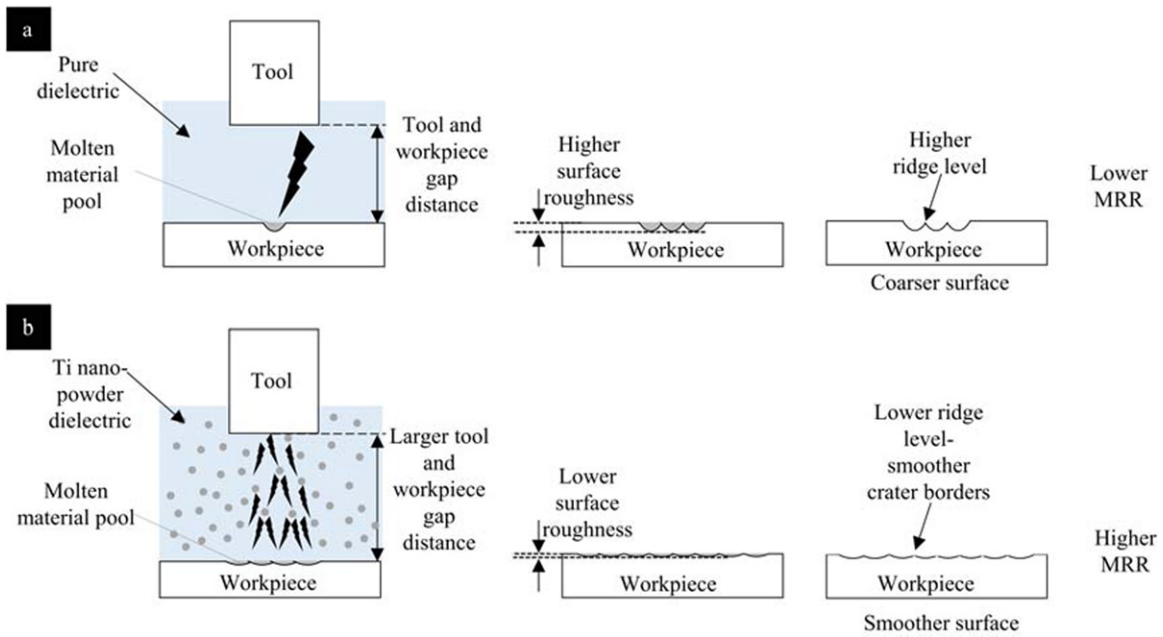

Figure 14 Discharge in (a) electrical discharge machining and (b) powder mixed electrical discharge machining.[76]

occurs between the tool and the conductive powder, after which a wave of diffused discharges hits the workpiece.[73] In the spark gap, powder particles move close to each other to form a chain like structure and build a bridge between the tool and workpiece. This results in declining dielectric insulating strength, leading to higher spark frequency in the gap. It has been proven that adding electrically conductive powder to dielectric increases the gap between the workpiece and tool, leading to energy dispersion and enhanced MRR as well as surface roughness.[2] It has been established that the particles contribute by enlarging the gap between the electrode and workpiece[74] due to the improved dielectric fluid's electrical conductivity.[33] A larger gap results in easier debris ejection from the gap, averting the occurrence of short-circuiting and arcing, subsequently resulting in a more stable machining condition. Greater electrical conductivity triggers more frequent discharges, which results in higher MRR. A larger gap with sparks hitting over the greater distance results in the formation of evenly distributed, 'large and shallow' etched cavities,[75] and ultimately improved surface quality.

1.7.5.1 Powder Addition to EDM and Micro-EDM

Powder particles mixed with dielectric fluid of water or oil in EDM is a common approach to enhance the EDM outcome in terms of machined surface quality as well as machinability. Several powder materials with different particle sizes for machining metallic or ceramic materials have been explored by researchers. Adding powder to dielectric fluid is meant to primarily boost the process by improving the performance factors. The EDM process specification is evaluated using a number of significant parameters like MRR, TWR, and surface quality. Depending on the process and powder specifications, either the machining process is enhanced in terms of process capabilities like increasing MRR or a situation is facilitated whereby EDM is used for new applications like coating. Therefore, research trend in PMEDM and powder mixed micro-EDM is categorized and explained in two parts: EDM performance improvement and surface modification.

1.7.5.1.1 EDM performance improvement

In using powder for EDM improvement techniques, Jeswani[77] observed that adding 4 g l^{-1} of fine graphite powder (10 μm average size) to dielectric increased the MRR and TWR by 60 and 15%, respectively. The TWR fell by about 28%, which is attributed to the decrease in the breakdown voltage of the kerosene dielectric caused by the graphite powder addition. Semi-conductive graphite nano-powder in both milling and sinking EDM of cemented tungsten carbide provided a smooth and defect-free nano-surface,[6] which assists the formation of shallower craters with more homogeneous distribution on the surface, thus producing a high quality glossy surface and reduced surface roughness. Increasing the powder concentration up to a certain level increased the surface quality, which again decreased after an optimum concentration due to the powder settling problem and bridging effect. The bridging effect results in frequent arcing and short-circuiting and may also cause more concentrated discharge energy and carbon accumulation on the workpiece surface, ultimately deteriorating the surface roughness. Nevertheless, the considerable improvement in surface finish, MRR as well as TWR was due to the increased spark gap, uniform discharge and breakdown strength of dielectric, which improved both surface topography and crater distribution.

The ability of EDM in machining high-hardness materials has captured interest to apply EDM in ceramic machining. However, the low conductivity of ceramics is an issue preventing the use of EDM for ceramic component production. According to Liew *et al.*[71] the electrical resistivity concern of reaction bonded (RB)-SiC ceramic is better solved by adding carbon nano-fiber to the dielectric during the μ-EDM process. It has been demonstrated that carbon nano-fibers (**Figure 15**) contribute to improving the machining process of this ceramic, leading to more frequent discharges and consequently higher MRR. As indicated in **Figure 16**, nano-fibers position themselves to form a bridging network between the tool and workpiece. The carbon nano-fibers high electrical conductivity may explain the performance improvement in PMEDM of RB-SiC by the reduced insulating strength of the dielectric, which results in enlarged gap distance.

Adding 10 μm silicon powder to dielectric has been seen to assist with producing high surface quality in a shorter period of time, reducing the surface roughness as well as producing a mirror like surface finish.[74] Although adding silicon powder considerably improved the surface quality, over larger areas the surface quality slightly deteriorated, which is explained by the capacitive effect. The capacitive effect entails higher peak current than the current set on the discharge generator, originating deeper and more irregular craters that increase with increasing electrode area. In order to assess the influence of silicon powder addition to complex shape polishing, a mold cavity with 110 mm width, 45 mm length and 10 mm height was machined. According to the results, the addition of silicon powder significantly enhanced the cavity polishing (**Figure 17**).[74]

Kansal *et al.*[78] studied the effects of process parameters when 20–30 μm silicon powder was added to dielectric. The experiments were performed using a newly designed experimental

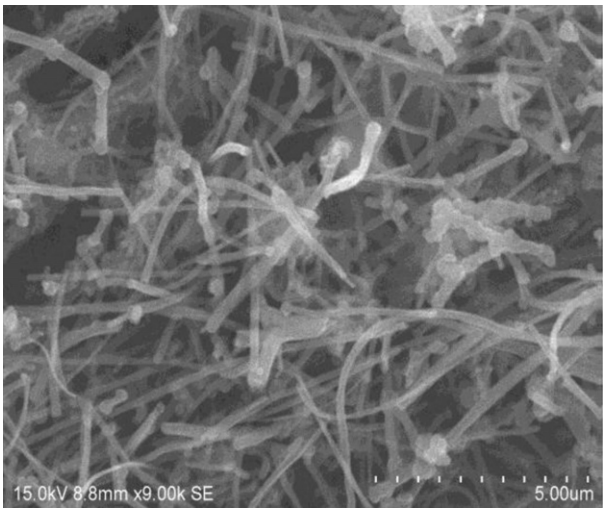

Figure 15 Scanning electron microscope micrograph of carbon nano-fibers.[71]

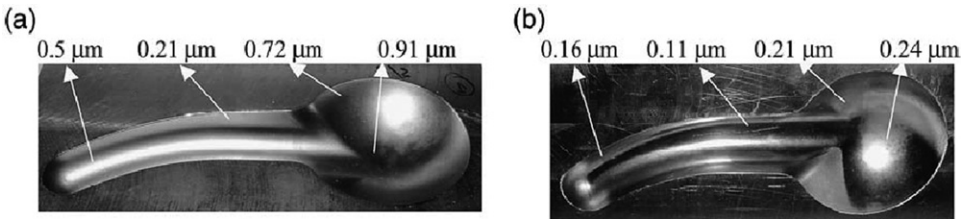

Figure 17 Mold cavity (a) without silicon and (b) with silicon powder for 100 min polishing time.[74]

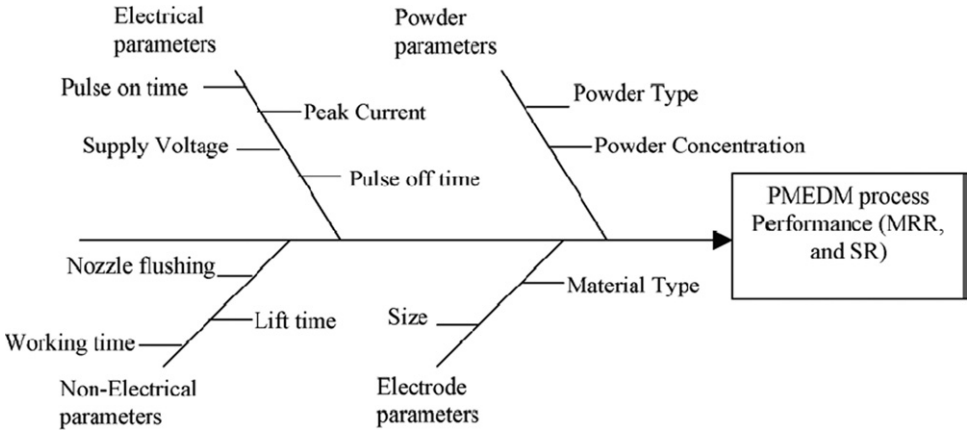

Figure 18 Cause and effect diagram.[78]

setup. Figure 18 shows the Ishikawa cause and effect diagram built for the machining parameters, which signifies that the powder parameters and electrode parameters were the most influential factors on the PMEDM process performance including MRR and surface quality. The analysis of variance (ANOVA) revealed that the peak current and concentration were the most significant parameters affecting MRR and SR.[78]

Kansal *et al.*[79] used ANOVA and obtained the most substantial process parameters along with optimized machining conditions for the EDM process with 30 μm silicon particles added. The most influential parameters introduced were peak current, powder concentration, pulse on-time, pulse off-time, and grain size, with the peak current and silicon concentration being the most critical parameters affecting MRR. Peças and

Henriques[80] observed that utilizing 10 μm silicon particle suspension in dielectric reduced the crater diameter and depth as well as white layer thickness (WLT). Furthermore, the short-circuiting and open circuit abnormal discharge occurring during conventional EDM decreased at 1 g l^{-1} silicon concentration. The optimum powder concentration to achieve the best surface roughness was found to be 2 g l^{-1}, and this effect was evident even at low powder concentrations. The highest efficiency and stability were observed at 2 g l^{-1} and 3 g l^{-1} silicon concentrations, when the abnormal discharge was completely eradicated. For silicon concentrations over 3 g l^{-1}, short-circuiting was detected, which was due to the bridge formation by excessive particles in the gap.

Adding 1 μm aluminum powder to dielectric to obtain fine surface roughness was proposed by Wu *et al.*[81] In order to overcome the electrostatic force that causes Al powder agglomeration, a surfactant was adopted to homogenously mix the powder in dielectric. The desired distribution effect was achieved when 0.1 g l^{-1} of Al powder and 0.25 g l^{-1} of surfactant were added to the dielectric. As shown in **Figure 19**, R_a of 0.172 μm was achieved under the following parameters: positive polarity, 0.3 A discharge current, 1.5 μs pulse duration time, 140 and 90 V gap voltage and 0.25 g l^{-1} surfactant concentration. The surface roughness improved by 60% from 0.434 μm in EDM oil to 0.172 μm in Ti/surfactant-added oil. Additionally, a thinner recast layer of 1–2 μm thickness was achieved compared to 5–8 μm using pure dielectric in EDM.

Zhao *et al.*[75] specified that adding 10 μm of Al powder at 40 g l^{-1} concentration in steel workpiece machining produced large and shallow craters, enhancing the surface roughness more than conventional EDM. However, due to energy loss in the discharge gap and reduced ejecting force on the melted material, the machining efficiency and surface roughness decreased compared to conventional EDM.

It was observed that adding Al powder during EDM of cobalt-bonded tungsten carbide (94WC–6Co) could effectively disperse the discharge energy, thus improving the machining efficiency.[82] Four parameters, namely discharge current, pulse on-time, grain size, and aluminum concentration were investigated. The TWR value tended to decrease with the aluminum powder concentration down to a minimum value, after which it tended to increase. MRR and TWR both increased with an increase in either grain size, current or pulse on-time.

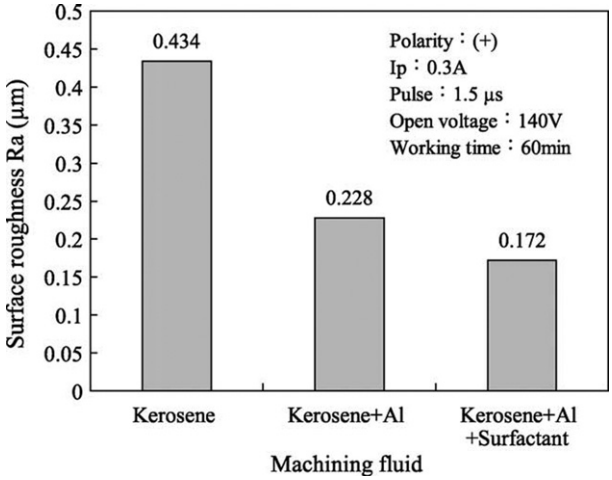

Figure 19 Influence of dielectric on surface roughness.[81]

Utilizing SiC abrasive mixed oil for deep micro-hole fabrication in SUS 304 stainless steel and Ti–6Al–4V titanium alloy plates has been shown to improve the shape precision and surface roughness of micro-holes.[83] An investigation of SiC powder (3 and 5 μm) added to water dielectric verified the MRR augmentation during the micro-slit EDM process.[33] According to this research, SiC powder addition causes bridging effect between the tool and workpiece in the gap besides discharge energy dispersion, thus creating two discrete discharge pulses from a single discharge period that could effectively disperse the discharge energy into several increments. The discharge could then generate minor craters and debris, whereby the minor debris would ease the gap exhaust and accelerate the MRR. The slight craters could lead to the production of refined surface roughness. Hu *et al.*[84] verified that adding SiC (2 μm) particles in the EDM process of Al matrix composites (SiCp/Al) considerably enhanced the machined surface properties compared to conventional EDM, with about 31.5% improvement in surface roughness and almost 100% increase in wear resistance reported.

The effect of alumina powder added to dielectric in machining SKD11 was investigated by Yan and Chen.[85] They determined that the non-conductive alumina powder addition to dielectric does not affect the gap distance, but it significantly affects the EDM characteristics. Under optimum condition, the MRR of SKD11 increased. Surface finish was achieved under the conditions of 1 μm particle diameter, 4 g l^{-1} concentration and 60 rpm electrode rotation speed. In another study, boron carbide was added to both kerosene and water dielectric by Kibria *et al.*[86] MRR, TWR, overcut, diametral variance at the hole's entrance and exit, and surface integrity during machining of titanium alloy (Ti–6Al–4V) were investigated. It was found that using deionized water increased both MRR and TWR, while a thinner white layer was produced than by using kerosene. Moreover, when suspended particles were applied, the MRR increased with deionized water but the TWR decreased with kerosene dielectric. The significant effect of adding boron carbide to deionized water dielectric was evident in enhancing the machining performance in micro-hole fabrication on titanium alloy with micro-EDM.

Through comparative studies on using various powder materials with the same machining conditions, Wong *et al.*[87] investigated the near-mirror phenomenon in EDM when graphite, silicon, aluminum, crushed glass, silicon carbide, and molybdenum sulfite powder particles with the properties shown in **Table 1**. To add powder to the system, the EDM flushing system was modified to add and distribute the powder in the machining gap. Adding powder to dielectric during machining expands the machining gap. The relative machining gaps of the powder materials employed are tabulated in **Table 2**. Particular powder and workpiece combinations were identified for producing mirror like finish or glossy-machined surfaces. Close scrutiny of the mirror-finished surfaces revealed shallow overlapping resolidified disks with smooth rims, unlike typical EDM surfaces that are normally covered with deep craters, pock marks, and globules. It was found that appropriate electrode polarity and pulse parameter settings

and correct combinations of workpiece material and powder characteristics significantly influence the mirror finish condition. It was stated that in order to achieve a mirror-finished surface, it is essential to apply negative polarity. The presence of powder increased machining stability and the surface had well-formed and small overlapping craters. Al powder generated a mirror like finish in machining SKH-51, but not in EDM of SKH-54. Si and C powders seemed to be effective in providing a very fine finish.

In micro-slit EDM, different dielectrics of kerosene, kerosene with aluminum powder, and kerosene with SiC powder were used with a thin copper diskette electrode to machine titanium alloy[88] with the setup exhibited in Figure 20. The effects were investigated on material removal depth, TWR, slit expansion, surface roughness, and the discharging condition waveform. Adding both SiC and Al powder to kerosene resulted in enlarged gap distance between workpiece and tool. The extended gap increased the debris removal rate as well as material removal depth. Moreover, a bridging effect was produced by the added powder drifting throughout the kerosene and, thus facilitating the discharge dispersion in several increments. Therefore, several discharge trajectories were formed within a single input impulse and several discharge spots were created within a discharge impulse as well. The effects caused by the discrete discharge pulses can be elucidated in terms of these effects minimizing the machined debris. The debris could be more easily removed, hence increasing the material removal depth and surface roughness. However, adding powder to kerosene disturbed the carbon nuclides' adhesion to the electrode surface, consequently increasing the electrode wear rate as well as the slit expansion.

Tzeng and Lee[89] studied the effect of aluminum, chromium, silicon carbide, and copper particles addition to dielectric on the EDM performance factors of MRR and TWR. Particle size demonstrated the greatest impact on machining outcome, where the smallest particles (70–80 nm) generated the least increase in spark gap, the highest MRR and the lowest TWR. The results established that increasing the particle size reduces the MRR growth and increases the TWR and spark gap. Chromium was identified to have the highest MRR and lowest TWR, followed by aluminum and then silicon carbide particles. Moreover, the copper particles had no significant influence on EDM performance.

To produce parts for ultrahigh vacuum such as in space environments, Furutani and Shiraki[90] used the lubricant deposition method during finishing EDM. Molybdenum disulfide (MoS_2) powder was added to the working oil to deposit a

Table 1 Powder characteristics[87]

Powder	*Mesh size (degree of purity)*
Graphite	#400 (38 ± 3 μm) (purum powder of 99% purity, ash content: 0.05%)
Silicon	#325 (45 ± 3 μm) (99.5%)
Aluminum	#325 (45 ± 3 μm) (99.5%)
Crushed glass	#10 (2.0 ± 0.07 μm)
Silicon carbide	#8 (2.36 ± 0.08 μm)
Molybdenum sulfide	Typical particle size: 1–3 μm (max 40 μm)

Table 2 Spark gap distances under different powder suspension conditions[87]

Dielectric condition	*Spark gap distance (μm)*
Without powder	10–15
Graphite	45–50
Silicon	33–27
Aluminum	120–160
Crushed glass	10–15
Silicon carbide	80–90
Molybdenum sulfide	44–48

lubricant layer on carbon steel and stainless steel. MoS_2 was perfectly deposited under the electrical conditions of high open circuit voltage, small discharge current, short pulse duration, and medium pulse interval. Furthermore, a smoother surface was obtained by adding aluminum powder to the mixture of MoS_2 and working oil. In friction testing, a surface finish achieved with a mixture of MoS_2 and working oil had a smaller friction coefficient than with normal working oil.

The effect of aluminum, chromium, silicon carbide, and copper particle addition on the machined surface quality of an SKD-11 workpiece during the PMEDM process was investigated.[69] The most critical powder characteristic factors governing surface roughness and the recast layer were identified as particle size, particle concentration, particle density, electrical resistivity, and thermal conductivity. It was revealed that the additive particle size influences the surface quality. The smallest particles (70–80 nm) produced the best surface finish, while larger particles reduce the surface roughness. However, particle size has an inverse relationship with the recast layer. The smallest particle size produced the thickest recast layer on the machined surface. Of the additives, Al powder generated the best surface finish and thinnest recast layer on the machined surface, while copper powder additive resulted in the worst surface characteristics.

1.7.5.1.2 Surface modification

In surface modification applications using PMEDM, graphite powder has demonstrated to be more suitable than aluminum powder in increasing the micro-hardness of EN31, H11 as well as high carbon high chromium (HCHCr) die steel workpieces.[91] The copper electrode was the best for EN31 and H11 die steels, whereas the tungsten–copper electrode was better suited for HCHCr steel to achieve higher micro-hardness. There was a nearly 80% increase in micro-hardness after PMEDM. Suspended powder particles deposited on all machined samples, resulting in the formation of a particle-rich phase. According to XRD analysis, a largely amorphous structure formed owing to the high temperature coupled with rapid cooling.

In a similar study,[92] the coated titanium carbide layer enhanced the machined surface hardness by 76.76% from 990 Hv to 1750 Hv with improved surface quality and completeness of tungsten carbide surface using PMEDM. Ti powder was added to the dielectric and the experiment was designed with varying currents and duty cycles, which resulted in modified titanium coating layer thickness. A small number of micro-cracks appeared on the surface, which were filled with and substituted by titanium powder and carbon (a hydrocarbon) that decomposed from the dielectric that acted as a combiner (TiC). As seen in **Figure 21**, at 20 A current and 50% duty factor, a 5 μm coating layer of titanium and carbon with fewer cracks and higher hardness was achieved. Furthermore, in machining AISI D2 steel, adding titanium nano-powder to dielectric diminished the surface micro-cracks, improved the surface morphology and surface roughness, and enhanced the MRR by ~69%. In contrast, elemental analysis signified negligible Ti deposition on the machined surface while the atomic concentration of Ti increased around the crack regions.[76]

The addition of Si, W, and graphite powder to dielectric was tested by Bhattacharya *et al.*[93] Powder concentration, current and pulse on-time were determined as the main factors influencing surface roughness. Of the dielectrics used, kerosene provided superior cooling effect while EDM oil provided better surface finish. Machined surface micro-hardness was influenced by the powder, concentration, current, pulse on-time, and electrode material. Tungsten–copper electrode and tungsten powder resulted in elevated micro-hardness.

The surface of a Ti workpiece was also modified using Ti powder mixed micro-current EDM at various working parameters. At $3\,g\,l^{-1}$ concentration, the surface cracks considerably reduced; however, at $6\,g\,l^{-1}$, no micro-cracks were observed on the modified surface at 0.1 A current and short pulse durations ($\leq$50 s). The recast layer thickness enhanced to approximately 4–11 μm at $6\,g\,l^{-1}$ concentration. Additionally, a TiO phase was detected in the recast layer when Ti powder was used in the dielectric fluid. **Figure 22** indicates that the Ti surface modified at 0.1 A current for 30 and 50 s in $6\,g\,l^{-1}$ concentration of Ti powder dielectric produced a hydrophilicity surface. Hence, an appropriate Ti powder concentration not only prevented the formation of surface cracks but also boosted the Ti surface wettability during micro-current EDM modification.[94]

Sidhu *et al.*[95] investigated the surface modifications of three types of MMC: 65 vol%SiC/A356.2, 10 vol% SiC–5 vol% quartz/Al, and 30 vol%SiC/A359 by PMEDM process. The micro-hardness and surface integrity were evaluated in terms of contributing process parameters. Evidently, the micro-hardness increased primarily with increasing density of reinforced particles in the matrix. There was also a significant amount of metal transfer from the copper electrode during the process as compared to graphite.[95]

Bhattacharya *et al.*[96] investigated the most appropriate parameter settings for rough and finished machined surfaces of EN31, H11, and HCHCr die steel materials in aluminum and graphite PMEDM process. Copper (Cu) electrode with aluminum suspended in dielectric maximized the MRR. Suspending powder in the dielectric resulted in surface modification. Graphite powder exhibited lower MRR but improved surface finish. HCHCr required higher current and pulse on settings to initiate a machining cut and functioned best in combination with a tungsten–Cu electrode and graphite powder for enhanced finish. The MRR for H11 was lower than EN31 but significantly higher than HCHCr under the same process conditions.

Besides surface quality improvement, surface modification by the material transfer during EDM has emerged as a key research area in the last decade. Kumar and Batra[97] investigated the response of three die steel materials, OHNS, D2, and H13 die steels, to surface modification by EDM using tungsten PMD. It was shown that under suitable machining conditions, a considerable amount of powder material transferred to the workpiece surface. Due to the breakdown of hydrocarbon oil during the process, the percentage of carbon element increased. At high plasma temperature, the availability of carbon and tungsten powder resulted in carbide formation. Adequate conditions for material transfer by EDM were found to be low discharge current (less than 5 A), shorter pulse on-time (less than 10 s), longer pulse off-time (more than 50 s) and negative polarity of the tool electrode. Surface alloying

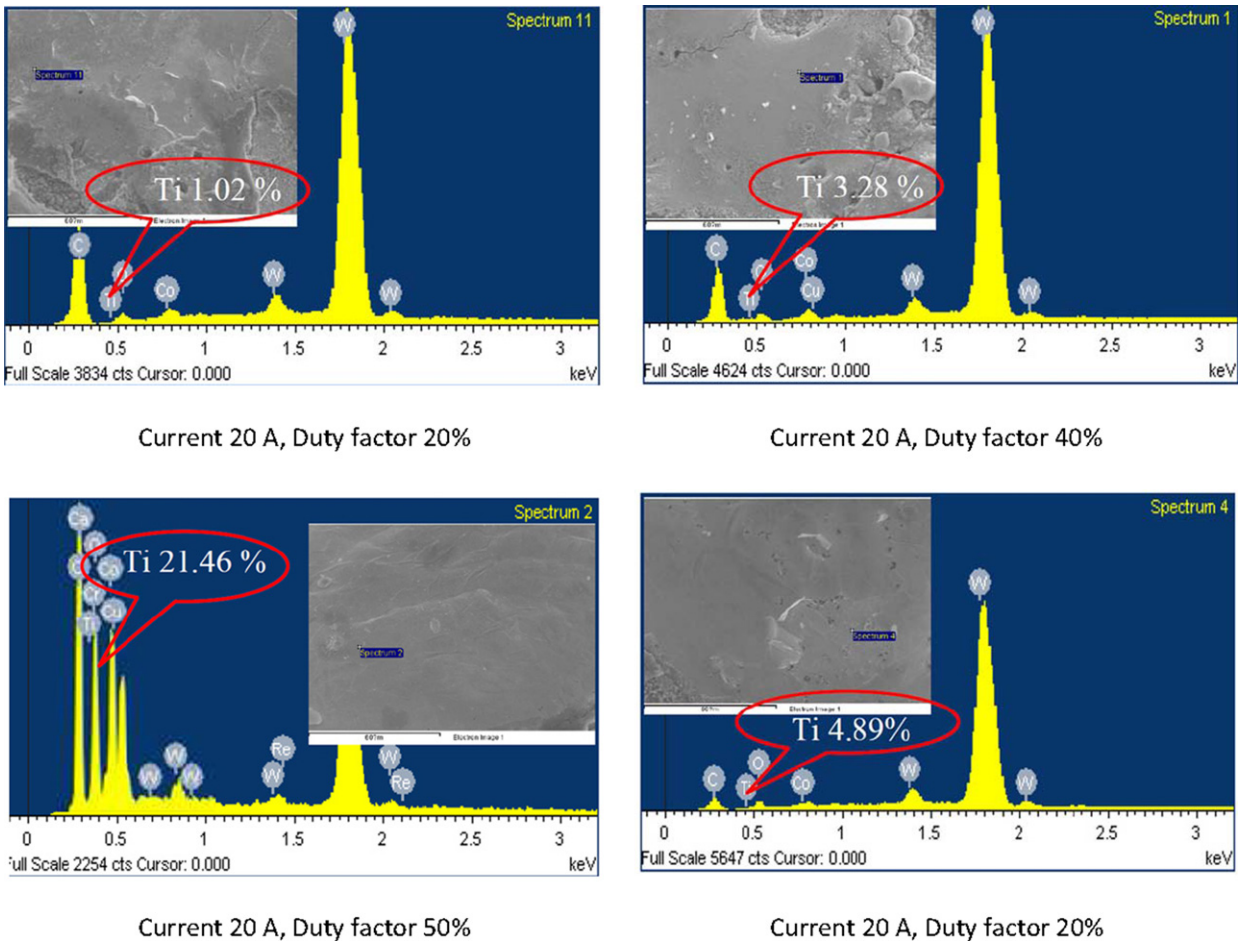

Figure 21 Energy dispersive X-ray spectra of the Ti coating surface.[92]

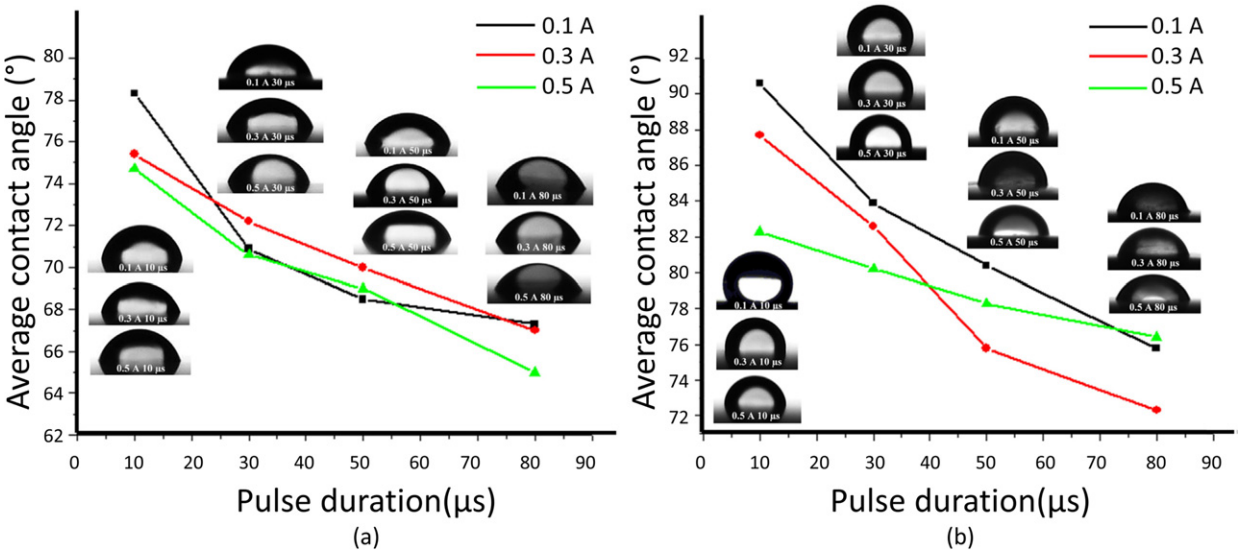

Figure 22 The relationship between the average contact angles and durations of modified Ti at various current levels in deionized water mixed with concentrations of (a) 3 g l^{-1} and (b) 6 g l^{-1} Ti powder dielectric solvent, respectively.[94]

appeared to improve the surface micro-hardness by over 100% for all three workpiece materials. The H13 die steel workpiece surface after machining (Figure 23) had the highest material transfer of 3.25%.

1.7.5.2 Powder Mixed Ultrasonic-Assisted EDM

Ultrasonic-assisted EDM can also be implemented when powder is mixed into dielectric. To enhance the machined surface of Al–Zn–Mg aluminum alloy, USM and PMEDM were combined.[98] SiC particles were added to the dielectric fluid to produce a particle-reinforced mechanism and solid solution strengthened structure to facilitate surface modification in a short working time. According to this research, the combined process of USM and PMEDM can attain an 80 μm deep modified layer on the machined surface of aluminum alloy after 240 s, which can significantly increase the hardness and wear resistance of the machined surface.

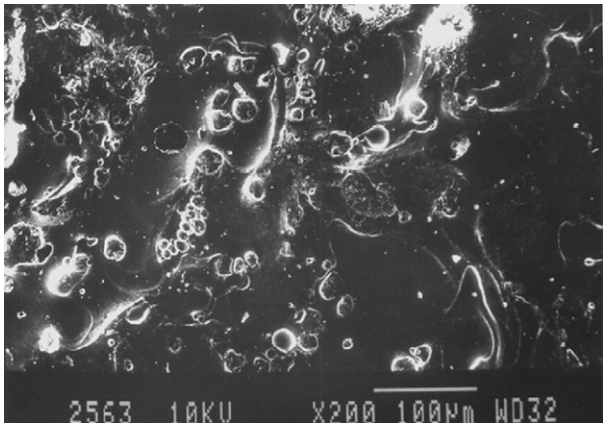

Figure 23 Scanning electron microscope of H13 die steel after machining with tungsten powder mixed dielectric (at $I_p = 4$ A, $P_{on} = 10$ s, and $P_{off} = 85$ s).[97] I_p, peak current; P_{off}, pulse off-time; P_{on}, pulse on-time.

EDM with tool vibration and addition of TiC particles to kerosene dielectric appeared to be considerable factors in the performance of machining Al–Zn–Mg.[70] Figures 24–26 indicate the influence of peak current on MRR, relative electrode wear ratio and surface roughness, respectively. Decomposed Ti particles from TiC added to dielectric migrated to the Al–Zn–Mg surface, resulting in fine grain consolidation during the solidification. Additionally, the penetration of some TiC particles into the machined surface during the process increased the hardness and wear resistance by alloying the external workpiece layer.

Other than applying ultrasonic vibration in PMEDM, workpiece vibration at 1000 KHz frequency overcame the improper ejection of debris from the gap in micro-EDM.[73] Using the setup in Figure 27, workpiece vibration in micro-EDM was investigated with the presence of graphite particles in dielectric. It was revealed that the effect of 55 nm graphite

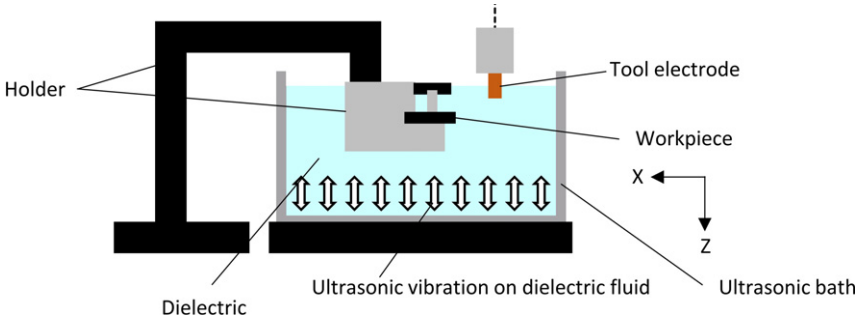

Figure 28 Setup for ultrasonic vibration of dielectric fluid.[99]

addition to dielectric on MRR enhancement was greater than workpiece ultrasonic vibration with 1000 frequency and 1.5 μm amplitude. In three machining conditions, i.e., workpiece vibration, with graphite powder addition, and a combination of both, significantly decreased machining time to a maximum of 6, 20, and 24 times faster than ordinary EDM, respectively. Additionally, the best surface was achieved at 15 g l^{-1} graphite powder concentration.

In PMEDM developments, when a specific powder concentration is added to the dielectric, particles are usually mixed with dielectric using conventional methods like implementing a stirrer in the machining tank[70] or blending the powder with dielectric in advance.[71] Ultrasonic vibration of the dielectric seems to be a means of properly utilizing the powder additive effect during the EDM process. Ultrasonic vibration of the dielectric fluid tank during graphite PMEDM of Silver–tungsten appeared to effectively improve the surface quality, eliminate micro-cracks as well as reducing the machining time by up to 35%.[99] **Figure 28** demonstrates a schematic design of ultrasonic tank vibration-assisted μ-EDM, with a developed independent tool holder and fixture to keep the workpiece in place so it would not be affected by the vibration from the bottom of the tank.

Prihandana *et al.*[72] implemented a PMEDM chamber ultrasonic vibration with 43 KHz frequency. It was reported that the suspension of 2 μm MoS_2 powder in dielectric during vibration-assisted micro-EDM was substantially effective in improving the MRR and surface quality. According to this research, the MRR rose owing to higher powder availability in the gap area as a result of the ultrasonic vibration. The vibration participated more in the discharge action and also diminished the adhesion of debris to the workpiece. **Figures 29** and **30** illustrate the machined surface obtained by micro-EDM processing using a pure dielectric fluid and 2 g l^{-1} MoS_2 powder with ultrasonic vibration of the dielectric fluid, respectively. Comparing these figures signifies the great enhancement in profile depth and machined surface quality by introducing tank ultrasonic vibration associated with MoS_2 powder addition to the dielectric. Moreover, powder addition resulted in a larger spark gap. Thus, easier flushing of debris, increased lubricity in the spark gap, distributed current path on the surface as well as dielectric breakdown are considered other advantages of the MoS_2 contribution to the discharge, which resulted in superior surface quality, free from black carbon spots. Ultrasonic vibration of the dielectric fluid, the addition of micro-MoS_2 powder at a concentration of 5 g l^{-1} and the use of copper as workpiece material are necessity for attaining a high MRR.

In micro-EDM of holes in ceramics, the simultaneous influence of carbon nano-fibers and ultrasonic vibration of the dielectric fluid around the machining area resulted in a hole almost 5 times deeper than using pure oil in a specific period of time.[100] **Figure 31** shows a probe-type oscillator horn designed to place around the machining area. As schematically illustrated in **Figure 32**, ultrasonic vibration of the horn-generated intense ultrasonic waves that traveled through the liquid, generating small cavities that enlarged and then collapsed. Ultrasonic vibration initially assisted to homogeneously mix the carbon nano-fibers with dielectric, and eventually, the cavitation vibration effect resulted in superior

debris ejection from the gap. The fabricated hole depth was considerably affected by the amplitude of vibration, where 10 µm amplitude achieved the maximum hole depth. On the contrary, the ultrasonic influence was negligible without powder additive. Furthermore, superior surface topography, more accurate geometry, and higher stability were obtained.

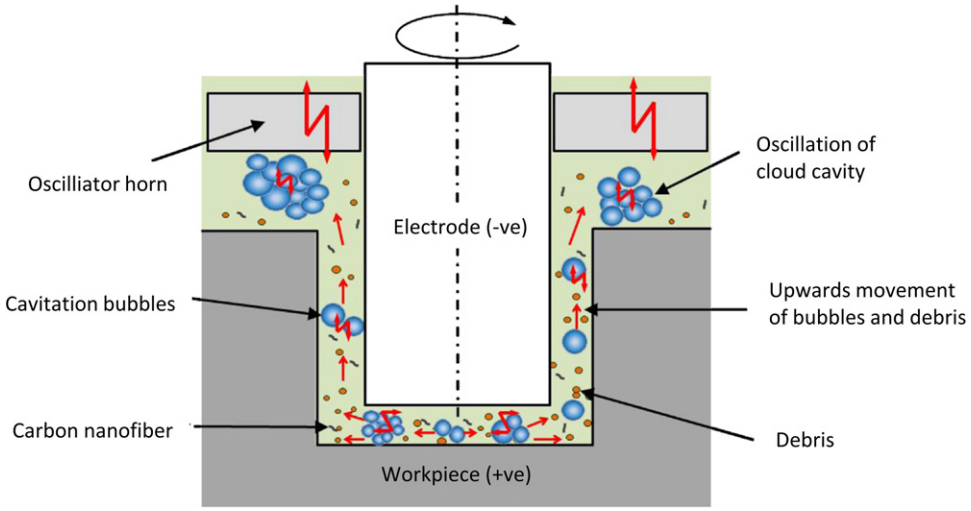

Figure 32 Schematic model of debris removal through cavitation-assisted micro-electrical discharge machining of a deep micro-hole.[100]

1.7.5.3 Powder Mixed Near-Dry EDM

In powder mixed near-dry electrical discharge machining (PMND-EDM), instead of one-phase conventional oil dielectric, a three-phase dielectric medium was proposed including a gas continuous phase (compressed air), liquid dispersed phase (EDM oil), and solid dispersed phase (silicon powder).[101] As a result, the dielectric's deionization effect, spark initiation, and MRR improved owing to the new dielectric breakdown mechanism, which considerably differs from conventional EDM. **Figure 33** shows the effect of peak current, pulse on-time, pulse off-time, flow rate, powder concentration, air pressure, and tool rotational speed on MRR based on the tool material. The optimum silicon powder concentration to achieve the highest MRR was found to be 9 g l^{-1}.

Similarly, in another study on PMND-EDM,[102] focus was on the influence of vital factors affecting MRR, including peak current, pulse on-time, pulse off-time, flow rate, powder concentration, air pressure, and tool rotational speed. As expected, MRR was directly influenced by peak current and pulse on-time due to the discharge energy enhancement. Conversely, increasing the pulse off-time reduced the discharge frequency, resulting in lower MRR. Nevertheless, in PMND-EDM, the deionization and dielectric field strength enhancement of the dielectric medium between tool and workpiece was mainly due to the fluid phase and dispersed silicon powder phase, respectively. It was demonstrated that the enlarged gap improved the deionization effect and facilitated discharge, resulting in higher MRR. Hence, increasing the concentration or flow rate led to higher MRR. Based on the analysis, the order of the various parameters' effects on MRR, from the greatest to the smallest, is as follows: peak current, pulse on-time, pulse off-time, flow rate, powder concentration, air pressure, and tool rotational speed.

Parametric optimization of MRR and TWR in chromium powder (45–55 μm) mixed EDM was investigated in machining EN-8 steel. Average current, duty cycle, electrode angle, and the concentration of chromium powder added to dielectric fluid in EDM were selected as process parameters. As shown in **Figure 34**, experiments were performed on the newly designed experimental setup developed in the laboratory.[103]

A cost-efficient method of fabricating carbon nano-tubes by EDM with 1000 μs pulse duration and 2.5 A peak current in air medium was developed.[104] An EDM was employed to synthesize nano-crystalline powder from scrapped cemented tungsten carbide.[105] Among deionized water, ethanol and kerosene, deionized water was the most suitable liquid for this application.

1.7.6 Electrode Modification

Electrode material and fabrication specifications have a direct impact on machining performance, especially for surface modification and coating purposes, as the tool fabrication method facilitates the coating. Electrical discharge coating refers to using an EDM for coating during the process. Titanium powder was used in EDM with a green compact electrode for surface modification or coating to create a thick TiC layer on the surface.[106] Ti particles in the EDM process of carbon steel (AISI-1049) adhered to the workpiece due to the heat from the discharge, resulting in the growth of a TiC layer. The powder concentration in the gap between the workpiece and a rotational disk electrode had to be kept high to obtain a wider accretion area by using the rotational gear-shaped electrode. A TiC layer with 150 μm thickness and 1600 Hv hardness developed on carbon steel surface when using an electrode with 1 mm diameter. Patowari *et al.*[107] used W–Cu powder metallurgy sintered tools in EDM for surface modification of C-40 grade plain carbon steel. A wide range of layer thicknesses were deposited with an average of 3–785 μm to increase the surface micro-hardness.

Hwang *et al.*[108] proposed multilayer electrodes on EDM for coating applications. A multilayer electrode (MLE) enhanced the composition of Ti and C as well as the surface hardness of the coated layer, reduced the surface roughness and microcracks, and increased electrical discharge stability and coating speed when applied to electrical discharge coatings. Additionally, the abrasion resistance of a coating layer is excellent at room temperature (30 °C) and it can be maintained at high temperature too (400 °C). However, this ability reduces with

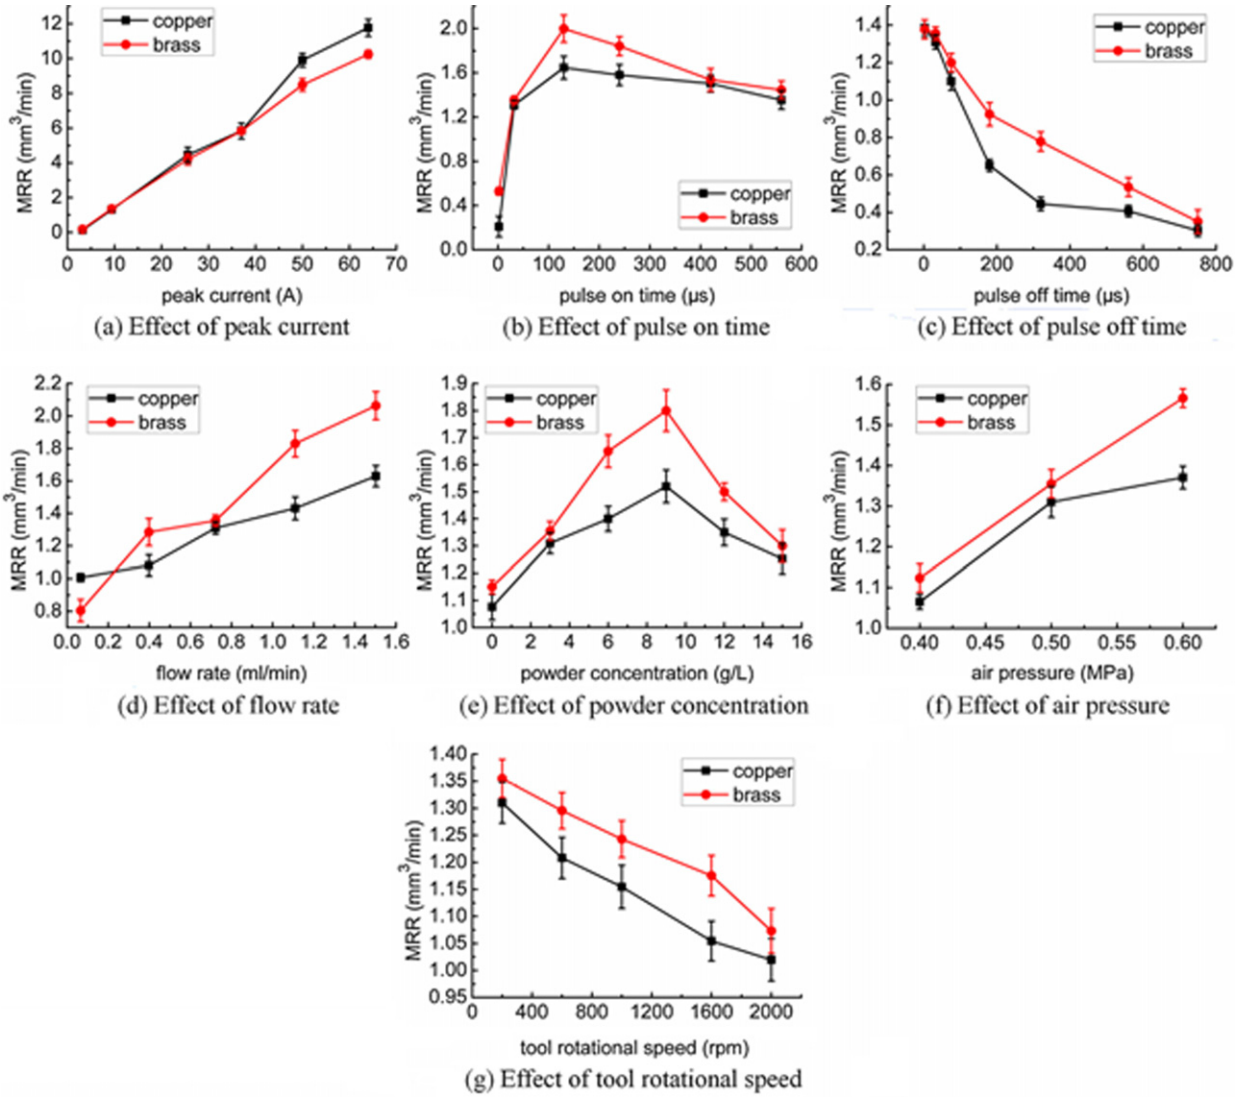

Figure 33 Effect of each process parameter on MRR based on different tool materials.[101]

increasing loading force, which mainly results from the stripping of the substrate (Ni) under the coated layer instead of the coated layer itself.

Suzuki and Kobayashi[109] employed a titanium carbide semi-sintered electrode as the source of coating material in EDM for coating the machined surface where a hard TiC layer formed on the surface owing to material migration from the tool to the surface and adhesion caused by single-pulse discharge. TiC was directly supplied from the electrode to the workpiece surface by single-pulse discharge without the presence of TiC between the electrode and workpiece. It was reported that when a temporary voltage drop occurs during discharge, clustered TiC powder that has maintained its powder form are present in the crater and adhesion is greater compared to when the voltage remains constant. Mohri *et al.*[110] proposed the rapid accretion of a thin electrode material and rapid manufacturing of a thin electrode. Through the explosion process in EDM, the electrode material can be accreted in the workpiece in an instant.

It was found that in low wear setting with EDM, a diamond like amorphous carbonaceous layer builds on the erosion front of the electrode surface in EDM, significantly disturbing the electrode erosion.[111] Parameters including applied current and pulse duration affect the microstructure of this layer, which has lower thermal conductivity and higher hardness compared to the base graphite material. A simple thermal model was proposed to simulate the pulse duration values at which a protective carbonaceous layer forms over the entire frontal surface of the microscale electrodes with a projection area below 1 mm^2. In order to achieve electrical discharge drilling with high AR > 30 micro-holes, implementing a tool with an insulated sidewall was proposed.[112] The concept was to promote the process stability of micro-EDM deep drilling by preventing secondary sparks to facilitate achieving micro-holes with 0.2 mm diameter and up to about 120 AR within 1 h.

Frohn-Villeneuve and Curodeau[113] proposed a new dry die-sinking EDM polishing method using a moldable graphite–polymer composite electrode as tool and evaluated

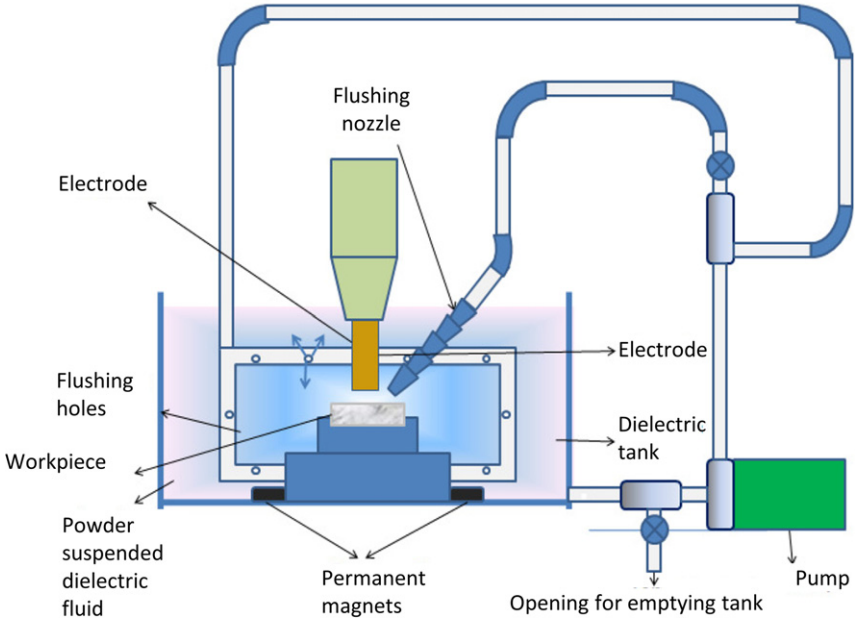

Figure 34 Line diagram of experimental setup.[103]

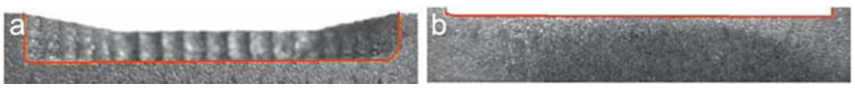

Figure 35 Section view of Ti6Al4V workpieces machined by, (a) a bundled electrode and (b) a die-sinking electrode.[114]

the influence of various process parameters on surface roughness, MRR and electrode relative wear rate. In order to attain higher MRR in EDM, Gu *et al.*[114] presented a bundled die-sinking electrode for machining Ti6Al4V. After studying the performance of this electrode compared to solid die-sinking electrode, the simulation results explained the high performance of the EDM process with a bundled electrode through the use of multi-hole inner flushing to efficiently remove molten material from the interelectrode gap and through the improved ability to apply a higher peak current. Figure 35 shows the cross-section of the surface machined with bundled electrode and die-sinking electrode. Bundled electrodes could tolerate a much higher peak current compared to die-sinking electrode, which resulted in a significantly higher MRR and a comparably lower TWR.

Muralidhara *et al.*[115] proposed a directly coupled piezo-actuated tool feed mechanism which was used to feed the tool and also to sense the tool displacement from a reference position. The hysteresis behavior of the piezoactuator is also integrated through an electromechanical model for estimating the actual tool displacement. Comparing the simulation and experimental results for piezoactuator displacement, a maximum error of 15% was observed. Further, in order to control the tool feed rate during machining, a tool feed controller based on the gap voltage feedback was developed. A contact-based measurement technique was integrated with the tool feed controller to measure the tool wear and the depth of material removed. The experimental results obtained through the contact-based measurement technique were in agreement with the tool-displacement simulations with a maximum error of about 10%.

El-Taweel[116] produced a novel tool electrode material of Al–Cu–Si–TiC composite using powder metallurgy and investigated the relationship of process parameters in EDM of CK45 steel. Titanium carbide percent (TiC%), peak current, dielectric flushing pressure, and pulse on-time as input process parameters and MRR and TWR were selected as output parameters. It was revealed that the new electrode is more sensitive to peak current and pulse on-time than conventional electrodes. The observed optimal process parameter settings based on composite desirability were TiC percent of 18%, peak current of 6 A, flushing pressure of 1.2 MPa, and pulse on-time of 182 μs for achieving maximum MRR and minimum TWR.

1.7.7 Simulation and Modeling

Understanding the discharge incident during the EDM process is a crucial challenge for enhancing process performance fundamentally. Process simulation and modeling and understanding the input parameters' effect on the outcome are beneficial to gaining a clearer vision of the process. Regarding the developed model, the numerically predicted and experimentally obtained values can be compared to evaluate the process behavior and model's estimation efficiency. Thus, the application of numerical modeling and simulation has emerged as a key research area for both prediction and optimization. In this section, numerical

investigations on the EDM process from the past decade are considered.

1.7.7.1 Mathematical Modeling

Fujun *et al.*[117] were the first to establish a universal mathematical model that lays a mathematical foundation for computer simulation, virtual machining and the establishment of real non-sphere machining systems by rotary EDM. The authors presented the shaping principle of machining a non-sphere with a rotary electrode and analyzed in greater detail the functions of a non-sphere machining system with a rotary electrode and the motion laws of machining rotary workpieces. Bleys *et al.*[118] introduced a new wear compensation technique, which incorporated real-time wear sensing based on discharge pulse evaluation, where the tool wear was continuously evaluated during machining, and the actual wear compensation was adapted on the basis of the real-time wear evaluation.

In 2008, Salonitis *et al.*[119] established a thermal-based model for determining the MRR and R_a as a function of the process parameters. The model predicts that an increase in discharge current, arc voltage or spark duration results in higher MRRs and coarser workpiece surfaces. On the other hand, a decrease in idle time increases the MRR with the additional advantage of achieving slightly better surface roughness values. A theoretical thermal model was proposed for the simulation of the die-sinking EDM process. The MRR and R_a were determined with an average deviation of 8.2 and 6.1%, respectively.

A 3D geometric simulation method of micro-EDM milling processes was introduced by Heo *et al.*[120] They presented a *Z*-map algorithm to precisely represent the geometries of a machined workpiece and the evolution of the tool shape caused by tool wear during machining. The micro-EDM milling process was mathematically and geometrically modeled. As illustrated in Figure 36, the performance of the developed simulator was evaluated by comparing the machined actual square cavity results with the simulation results. The developed EDM simulator can be used for tool path generation for tool wear compensation as well as for tool wear prediction.

Mathematical models were developed for modeling and analyzing the effects of process parameters, including discharge current, pulse on-time, duty factor, and capacitance value on the disintegration factor at the entrance edge of a drilled hole in the EDM drilling process of cobalt-bonded tungsten carbide.[121] In order to identify the optimum processing parameter settings, a quadratic model of response surface methodology associated with the sequential approximation optimization method was employed. From the experimental values of up to 95% confidence interval, it was found that the effect of interaction between discharge current and capacitance value had the highest impact on the disintegration factor, followed by capacitance value and the quadratic term of the duty factor. The optimal machining parameters reportedly diminished the disintegration factor by 5.53%.

An empirical model relating to electrical discharge drilling process parameters (working current and pulse on/off-time) was identified to predict the WLT at various hole depths.[122] Via ANOVA and Tukey's honestly significant difference methods, the experimentation outcome was analyzed. It was found that the electrical discharge drilling parameters' influence on the

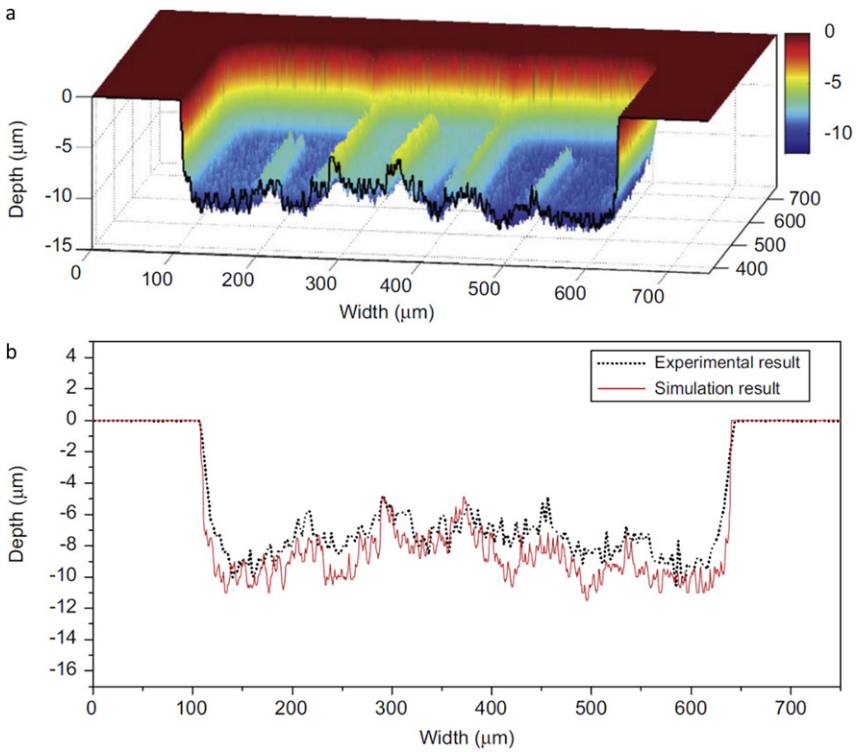

Figure 36 Workpiece surface generation simulation results: (a) graphical cross-sectional view generated by the simulator (solid line shows the contour of the cross-sectional edge) and (b) comparison of real machined and simulated surface profiles.[120]

variation in WLT was around 38–39%, while the impact of hole depth on WLT variation was 17%.

Shabgard *et al.*[123] simulated the temperature distribution over the workpiece and tool surface during a single discharge in the EDM process. The temperature dependency of material properties and the expansion of plasma channel radius were considered in the simulation stage, then the profile of temperature distribution was utilized to calculate the discharge crater dimensions. According to the simulation results, increasing pulse current and pulse on-time have converse effects on the plasma flushing efficiency, as it increases by pulse current and decreases by pulse on-time.

In 2015, Zhang *et al.*[124] proposed a fix-length compensation method. Their initial experiments showed that a cone-shaped tool end formed with this compensation method. Finally, they carried out a set of experiments to validate the simulation accuracy. The results revealed that the relative error of the simulation was below 4% compared to the experimental data under most machining conditions.

1.7.7.2 Finite Element Method

Finite element, a dominant numerical method, is used to find approximate solutions to boundary value problems for partial differential equations. Das *et al.*[125] developed a finite element-based model for EDM, with the ability to consider all process parameters including power input, pulse duration, etc., to predict the transient temperature distribution, liquid- and solid-state material transformation, final crater shape and residual stresses induced in the workpiece as a result of a single-pulse discharge. In 2004, Schulze[126] investigated the crater morphology in different processes and obtained an analytical relation between pulse parameters and roughness. For both single-discharge and a sequence of discharges, simulations of the thermal-affected zones were done. The crater geometry simulation refers exclusively to the thermal influence of the machining surface through the base of the plasma channel.

Process simulation and residual stress analysis for the micro-EDM machining of molybdenum was introduced by Allen and Chen.[127] Material removal was analyzed using a thermo-numerical model, which simulates a single-spark discharge process. Using the numerical model, the influence of important EDM factors including pulse duration on crater dimensions and tool wear percentage was investigated. The results from a coupled thermal-structural finite element analysis also defined how the thermal action of the micro-EDM process affects the machined workpiece surface integrity.

Kansal *et al.*[128] applied the finite element method and developed an axisymmetric two-dimensional (2D) model for powder mixed electric discharge machining. In order to predict the thermal behavior and material removal mechanism in the PMEDM process, the model considered several significant aspects of temperature-sensitive material properties, heat source shape and size (Gaussian heat distribution), heat percentage distribution among the tool, workpiece and dielectric fluid, pulse on/off-time, material ejection efficiency, and phase change (enthalpy). **Figure 37** displays the spark frequency in EDM versus PMEDM. The model initially calculated the temperature distribution in the workpiece material using ANSYS

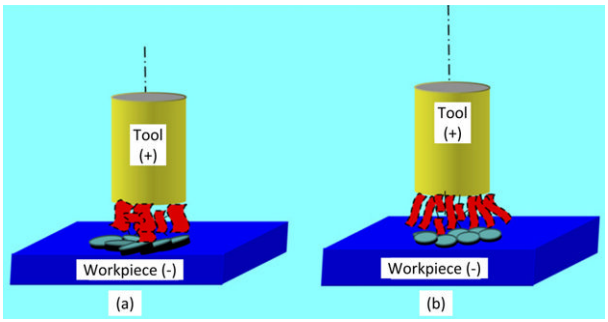

Figure 37 Spark frequency in (a) electrical discharge machining and (b) powder mixed electrical discharge machining.[128]

software and then projected the MRR from the temperature profiles. The effects of various process parameters on the temperature distribution along the workpiece radius and depth were stated. Finally, the model was verified by contrasting the theoretical with experimental MRR values attained.

Hosseini Kalajahi *et al.*[129] performed thermal modeling and finite element simulation of EDM to predict the thermal behavior and material removal mechanism in the EDM process. Several significant characteristics were taken into account, including temperature-dependent material properties, heated zone shape and size (Gaussian heat distribution), energy distribution factor, plasma flushing efficiency, and phase change. Furthermore, the influence of EDM parameters on MRR were inspected by using design of experiments and response surface methodology techniques. Finally, a quadratic polynomial regression model was recommended for MRR, and the model's accuracy was checked by means of analysis of residuals.

By using the finite element scheme, Izquierdo *et al.*[130] numerically calculated the temperature fields within the workpiece generated by the superposition of multiple discharges as they occur during actual EDM operation. According to the results (**Figure 38**), the model can predict surface roughness with less than 6% error. It can also predict MRR well, with less than 3% error. Joshi and Pande[131] proposed a thermo-physical model for die-sinking EDM. The analysis was constructed on realistic assumptions such as Gaussian distribution of heat flux, spark radius equation based on discharge current and discharge duration, latent heat of melting, etc., to predict the crater cavity shape as well as the MRR. Experiments were carried out to study the MRR and crater shapes produced during actual machining.

In another study, Joshi and Pande[132] used both finite element method and artificial neural networks (ANN) and reported the development of an intelligent model for the EDM process. For predicting crater cavity shape, MRR and MRR, a 2D axisymmetric thermal finite element model for single-spark EDM was established based on more realistic assumptions, such as the Gaussian distribution of heat flux, time- and energy-dependent spark radius, and so on. Upon model verification with experimental results, a neural network-based process model was presented for various work tool materials. The ANN model could reportedly precisely predict EDM process responses to selected process conditions.

An axisymmetric 3D thermo-physical model for EDM of titanium alloy was presented by Xie *et al.*[133] The numerical

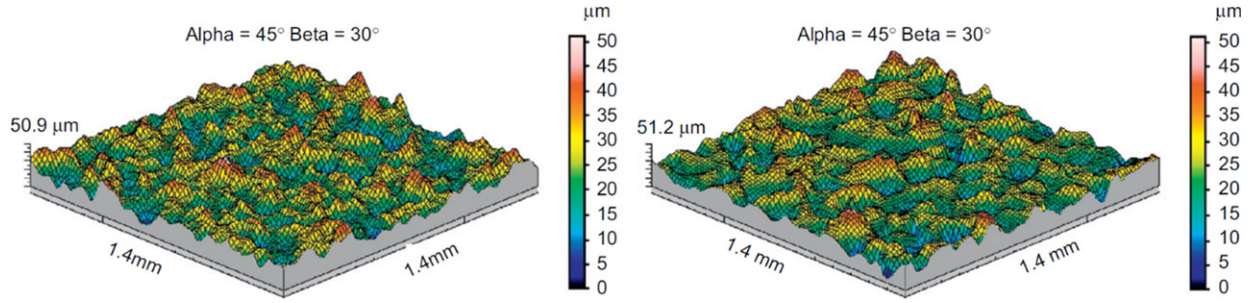

Figure 38 Comparison between simulated (left) and measured (right) surfaces.[130]

simulation of the single-spark discharge of titanium alloy machining in EDM and the influence of various process parameters on the temperature distribution along the workpiece radius were reported. Lastly, the model was verified empirically, demonstrating that it can predict the MRR efficiently. Shabgard *et al.*[134] also proposed an axisymmetric 3D model for temperature distribution in the EDM process. FEM was used to calculate the surface integrity characteristics of AISI H13 tool steel as the workpiece. White layer thickness, heat-affected zone depth, and arithmetical mean roughness consisting of the studied surface integrity features on which the effect of process parameters, including pulse on-time and pulse current were investigated. A comparison between the experimental and numerical results signified good agreement between these two values.

A fundamental study of micro-EDM based on the physics of single spark and electrothermal theory was implemented by Somashekhar *et al.*[135] Regarding a single-discharge crater, the experimental and simulation results were contrasted. The verification process results showed diameter-to-depth ratios of the crater of 2.92 and 2.67, respectively attained from the simulation and the experiment. Based on FEM, the heat flux of the plasma was investigated by comparing the melted material boundary in the crater as achieved by metallographic method and the isothermal surface of the thermal-physical model.[136] Evidently, the Gauss heat source was more consistent with the actual EDM process compared with other heat source types, such as point heat and circular heat sources. Moreover, Somashekhar *et al.*[137] proposed a numerical model based on the finite volume method in order to solve the micro-EDM model equations and predict the influence of spark ratio (spark on/off-time) on the temperature distribution in the material.

The powder-mixed micro-EDM process was analyzed using FEM analysis by taking into account the larger expansion of the plasma channel and reduction in heat flux distributed to the workpiece due to presence of powder particles. Analysis was based on FEMs and the multiple discharge approach. The heat source expansion factor owing to the presence of powder particles was estimated to be 1.07 at 0.02 g l^{-1} powder concentration. The fraction of heat flux to the workpiece found to decrease from 0.24 at 0.02 g l^{-1} to 0.11 at 0.2 g l^{-1} powder concentration. For model validation, simulated R_{max} and recast layer thickness values were compared with their corresponding measured values. The simulated and measured results varied with the same general trend, suggesting that the proposed model for PMD micro-EDM was fundamentally sound.[138]

Balaji and Yadava[139] identified a simulation model to simulate the complex electro-discharge diamond surface grinding (EDDSG) process, which entails simulating each constituent process, namely EDM and surface grinding for temperature and thermal stress distribution. The influence of various dielectric fluids, duty factors and energy partitions during EDM on the temperature distribution and MRR was specified. The prediction results could be used to determine the surface integrity of the machined surface. In another research work, Zhang *et al.*[140] simulated the evolution process of discharge-generated bubbles and investigated the influence of interelectrode distance on the characteristics of the bubbles through material removal mechanism simulation and experiment, respectively. They found that a smaller interelectrode distance can contribute to greater pressure and expansion velocity of the bubbles as well as higher force applied on the tool electrode and workpiece. A smaller interelectrode distance can contribute to a larger volume of both melted and removed material.

Gu *et al.*[114] aimed to identify an effective Ti6Al4V EDM process with a bundled die-sinking electrode. The simulation results explained the high performance of the EDM process with a bundled electrode through the use of multi-hole inner flushing that efficiently removes molten material from the interelectrode gap and through the improved ability to apply a higher peak current. Wang and Han[141] built a 3D model of flow field with liquid, gas, and solid phases for the machining gap in EDM. The mechanisms of debris and bubble movement in the machining gap during consecutive-pulse discharge were analyzed with the model and their movements were observed via experiments. The results showed that the proposed simulation model is feasible. Bubble expansion is the main way that the bubbles escape from the machining gap. Much debris moves outside the machining gap following the excluded bubbles, which is the principal way that the debris is ejected from the machining gap. The bubble expansion becomes stronger with increasing discharge current and pulse on-time.

A comprehensive electro-thermal model of micro-EDM has been used to simulate the crater formation process is presented. This model incorporates realistic machining conditions such as Gaussian distributed heat flux, temperature dependent thermal properties, and expending plasma radius. The heat transfer equation and experimental measurements of a generated crater dimensions are used to determine the energy distribution fraction to the electrodes, a crucial parameter of the micro-EDM modeling. Simulation results show a good agreement with experimental results.[142]

1.7.7.3 Molecular Dynamics Model

Yang *et al.*[143] simulated the formation process of discharge craters in 3D and analyzed the material removal mechanism in EDM using molecular dynamics (MD). They noted that the material removal mechanism in EDM can be explained in two ways: by vaporization and by the bubble explosion of superheated metals. Simulation of the distribution of removed materials from the gap showed that some part of the removed material became debris ejected from the gap, another part settled on the surface of the opposite electrode, and the last part returned to the surface of the electrode from which it was ejected.

Residual stress deteriorates the quality of produced component which might lead to premature failure when mechanical stress is applied. Yang *et al.*[144] simulated the formation mechanism of residual stress and its distribution using molecular dynamics methods. It was found that a larger pressure gradient formed in the melting area during discharge and a larger stress gradient in the melting region and the solid region in contact with the melting area. From the residual stress distribution, it was concluded that the residual stress on the electrode surface is tensile while inside the electrode it is compressive, indicating that cracks can easily generate in the resolidified layer.

Zhang *et al.*[145] used a computational simulation model combining the molecular dynamics simulation model and the two-temperature model for single discharge process in nano-EDM to study the machining mechanism of nano-EDM from a thermal point of view. The melting, cooling and solidifying processes were analyzed. They determined that during melted material cooling, tensile stress of more than 3 GPa arises, which leads to material disintegration. The white layer formation was attributed to the homogeneous solidification. Moreover, the resultant residual stress was analyzed.

Guo *et al.*[146] employed the atomistic–continuum modeling method, in which a two-temperature model and a molecular dynamics simulation model were integrated to construct a simulation model for a cathode in single-discharge micro-EDM process. By analyzing the evolution of temperature, stress, and microstructure of the material as well as the dynamic behavior of the material in the removal process, the mechanisms of the cathode material removal and crater formation were revealed. In addition, the removal process of the cathode material under a combination of pure thermal action and pure electric action was compared with that under the two pure actions, respectively, to analyze the interactive effect between the thermal and electric actions.

1.7.7.4 Supporting Vector Machine

The supporting vector machine was adopted by Zhang *et al.*[147] to establish a micro-EDM process model based on the orthogonal test. A new multi-objective optimization genetic algorithm based on the notion of nondominated sorting was proposed to optimize the processing parameters. Experimental results demonstrated that the proposed multi-objective genetic algorithm method is precise and effective in obtaining Pareto-optimal solutions of parameter settings. The optimized parameter combinations could significantly reduce the processing time while reducing electrode wear. Therefore, the proposed method is suitable for micro-EDM parameter optimization and can also enhance the efficiency and stability of the process.

Aich and Banerjee[148] applied support vector machines to develop a model of the EDM process. The Gaussian radial basis function and e-insensitive loss function were used as kernel function and loss function, respectively. Separate models of MRR and R_a were developed by minimizing the mean absolute percentage error of training data obtained for different sets of support vector machine parameter combinations. Particle swarm optimization was employed for the purpose of optimizing support vector machine parameter combinations. The models thus developed were then tested with disjoint testing data sets. The optimum parameter settings for maximum MRR and minimum R_a were further investigated by applying particle swarm optimization to the developed models.

1.7.7.5 Others

Also in terms of simulation, a geometric simulation model of the EDM drilling process with a cylindrical tool for predicting tool and drilled hole geometries was identified.[149] For accurate geometry simulation, tool motion, sparking gap width, spark frequency, the crater made by a single spark, and the TWR were selected as simulation parameters. The comparison of the prediction results with the actual experimental results revealed that geometry can be predicted within 13% error. The developed model can also be successfully introduced as an offline tool wear compensation method, which enables considering both end and corner wear of a tool with less than 2.9% compensation error.

The spectroscopic measurement of the arc plasma diameter in EDM was explained.[150] Unlike conventional plasma expansion models established based on observations of generated craters and unproven assumptions, it was revealed that arc plasma completes expanding within a few microseconds after dielectric breakdown, while the diameter of the craters grows slowly in comparison with the expansion speed of the arc plasma. Moreover, the increase in arc plasma diameter with rising discharge current or gap width was computed, enabling accurate simulation of discharge crater generation using the newly established heat source model.

In another study, the development of a sinking EDM simulation method by determining discharge locations was described.[151] The simulation repeats the routine modeling of the process of each discharge consisting of determining the discharge location, electrode removal, debris particles generation and displacement, and tool electrode feeding. The experimental results and the electrode shapes and gap width distributions simulated for different working surface areas were coherent.

A thermal model capable of simulating the superposition of successive discharges, which leads to the formation of EDM surfaces, was developed by Izquierdo *et al.*[152] Some process aspects, such as the percentage of discharge energy transferred to the workpiece, plasma channel growth, material removal mechanism, and the influence of convective cooling were discussed. Predictions of the extension of the recast layer and heat-affected layer for both regimes were also determined. Finally, the model was used to predict the extension of the white layer and heat-affected zone. It was observed that the

model performed well, with less than 3 μm prediction error in the analyzed EDM regimes.

In order to facilitate superior debris flushing in EDM, a rotary tool and magnetic field were implemented. Then two adaptive neuro-fuzzy inference system (ANFIS) models were designed to correlate the EDM parameters to MRR and surface roughness using the data generated from experimental observations.[153] To select the best process parameters of magnetic field intensity, rotational speed and product of current and pulse on-time, the continuous ant colony optimization (CACO) technique was used. According to the results, the CACO technique that comprises ANFIS models as objective and constrain functions, can successfully optimize the input conditions of the magnetic field-assisted rotary EDM process.

1.7.8 Conclusions

EDM as one of the most promising technologies for production of difficult-to-cut conductive materials, is the center of attention by researchers in the past decades. This chapter provides a detailed review of the available investigations with comprehensive categorization to build a clear mapping for further research in the area of EDM. The following can be concluded:

- Utilization of water-based dielectric or gas can be a better replacement for oil-based dielectrics since they provide a healthier and safer machining environment. Employing water dielectric produces thinner heat-affected zone and reduces the carbon content in the machining gap. Furthermore, the utilization of gas as dielectric is more cost efficient compared to hydrocarbon oil due to an extremely decreased TWR and reduced cost of dielectric medium compared to employing hydrocarbon oil. Application of water as a dielectric cause lower carbon generation which made it a suitable dielectric fluid, in some cases. Utilization of low resistivity deionized water has shown to facilitate achievement of simultaneous EDM–ECM process.
- Ultrasonic vibration assisted EDM is shown to have substantial impact for enhancing performance factors, where vibration of either tool and workpiece or dielectric results in higher cavitation effect. Majority of studies emphasize on micro-EDM and verified to obtain fabrication of microholes with significantly higher ARs. However, there is room for improvement and exploring the impact of ultrasonic vibration in conventional EDM for fabrication of cavities in complex shapes. Furthermore, the effects of vibration outside the ultrasonic frequency range can be recommended for further research.
- Introduction of ultrasonic vibration in dry EDM is feasible method owing to lack of dielectric fluid in the process. This enhancement seems to be a promising method for commercialization in terms of stability and effectiveness. Ultrasonic vibration have been identified as having higher machining efficiency in PMEDM, initially through homogenously mixing the powder with dielectric and secondly through improving the debris ejection effect throughout the process.
- Mixing powder with dielectric fluid shown to significantly improve the performance of EDM, however, deposition of powder particles at the bottom of the tank is still an issue which was addressed by solutions like ultrasonic vibration of the machining tank or addition of surfactant to dielectric fluid. Future studies should concentrate on introducing new solutions to homogeneously mix the powder with the dielectric liquid to avoid powder suspension at the bottom of the tank.
- The addition of titanium, tungsten, and titanium carbide to dielectric in PMEDM process is appropriate for surface modifications through alloying the external surface, which results in increased surface hardness, wear resistance. These powder materials can have substantial application for coating to address the steel oxidization issues in steel mold and die production manufacturing. In addition, adding conductive powder to dielectric increase the machinability of workpieces with very low conductivity might become possible with PMEDM.
- Although particle size is considered as essential factor in PMEDM investigations, a majority of investigations perform the experiment using micro-level solid particles. Whilst the occasionally available investigations on nano-size additives have obtained prominent outcomes.
- Mathematical modeling, finite element analysis, molecular dynamics model, supporting vector machine are the mostly used methods that could simulation and model the EDM process and its performance efficiently. Simulation and modeling of EDM and understanding the effect of input parameters on the performance factors significantly assist in providing a perfect vision for further enhancements.

1.8.1 Introduction

Composite materials are increasingly being used in the automotive manufacturing industry with the aims to reduce fuel consumption and CO_2 emission. A fiber-reinforced polymer (FRP) is a composite material consisting of a polymer matrix imbedded with high-strength fibers, such as glass, aramid, and carbon. Generally, polymer can be classified into two classes, thermoplastics and thermosetting. Thermoplastic materials currently dominate, as matrices for bio-fibers; the most commonly used thermoplastics for this purpose are polypropylene (PP), polyethylene (PE), and poly vinyl chloride (PVC); while phenolic, epoxy, and polyester resins are the most commonly used thermosetting matrices.[1] A lot of research has been done based on fiber-reinforced plastic composites, which is currently going through a transition phase. Material properties and theoretical properties have dominated in every research areas. In achieving fully automated large-scale manufacturing cycles, economical techniques of production are very important with increasing applications. Common problems in the material are due to the anisotropy and non-homogeneity, which is direct to the fiber pulled-out, delamination, burning, and fuzziness. When machined, this composite material is extremely abrasive. Hence the selection of good cutting tool and the cutting condition is very significant in the machining process.[2] For instance, glass-fiber-reinforced plastics (GFRPs) have been widely employed in automobile interior and exterior parts due to excellent mechanical, structural and durability properties at the expense of poor machinability[3] and potential health hazard. Similarly, other synthetic fibers exhibit these shortcomings. The main problem with the glass fiber composite is the non-recyclability and in assembly and production areas of the factory workers have complain about the skin irritation and respiratory diseases due to inhalation of fiber dust. The use of plant fiber will solve this problem. Natural fibers have always found wide applications from the time they gained commercial recognition.

The need of eco-friendly, sustainable, and biodegradable materials for automotive parts has made natural fiber a potential substitute to synthetic fiber.[4] Natural fiber offers numerous benefits which include renewability, less abrasiveness to equipment, low density, unlimited[5] and low weight and cost.[6] The versatility of natural fibers is based on the following desirable material properties:

- Plant fibers are a renewable raw material and their availability is more or less unlimited.
- Very good mechanical properties, especially tensile strength. In relation to its weight, the best bast fibers attain strength similar to that of Kevlar.
- Very good heat, acoustic, and electrical insulating properties.
- Combustibility: products can be disposed of through burning at the end of their useful service lives and energy can simultaneously be generated.
- Biodegradability: as a result of their tendency to absorb water, natural fibers will biodegrade under certain circumstances through the actions of fungi and/or bacteria.
- The abrasive nature of natural fiber is much lower compared to that of glass fiber, which leads to advantages in regard to technical, material recycling, or processing of composite materials in general.
- Reactivity: the hydroxyl groups present in the cell wall constituents not only provide sites for water absorption but also available for chemical modification (e.g., introduce dimensional stability, durability or improved oil/heavy metal absorption properties).

In recent years, Brazil become one of the country that has a large range of natural sources, including natural fibers like banana, coconuts, sisal, cotton, and curaua.[7] *Theobroma cacao L.* (Sterculiaceae) is a scientific name for the cocoa fruit which its natural habitat is the humid tropics. Every year, all the agricultural products like cocoa are harvested and the dried beans must be produced after fermentation to reduce the mass losses

and prevent spoilage. This happens in most tropical countries likes Southeast Asia, South America, West Africa and others.[8] Cocoa beans are used primarily in chocolate manufacturing, but instead of that, cocoa beans also have pharmaceutical and cosmetic importance in industry. The cocoa harvest worldwide production was greater than 3.5 million ton of dry beans which can be seen from October 2008 to September 2009 (ICCO, 2009), and almost 170 530 t of which were produced in Brazil (CEPLAC, 2009). The daily price averaged stated by the International Cocoa Organization (ICCO) was US \$2599 t^{-1} (ICCO, 2010). Meanwhile, the mean annual world billing was more than \$9 trillion, indicating the cocoa agro-industrial sector's great importance around the world. In Malaysia, the plantation of cocoa is over 20 643 ha (Malaysia Koko Board, 2011). Hence, it can be estimated at least 320 000 kg of cocoa pod husk (CPH) is generated after processing.

Nevertheless, along with its great economic importance, cocoa production generates substantial quantities of waste. In this chapter, particular attention is given to CPHs, which are generated after cocoa beans are extracted from the mature cacao fruit and are the main by-product of the cocoa/chocolate industry. Serious disposal problem happened when only 10 t of wet CPHs are generated from each ton of dry beans. In most cases, these husks are underexploited and considered an undesirable waste of the cocoa/chocolate industry. Normally, they are left to rot on the cacao plantation, which can cause environmental problems. Besides producing foul odors, rotting CPHs can propagate diseases, such as black pod rot, when left on the cacao plantations. Conventionally, these organic wastes is shipped away for processing or disposed to landfill. Currently, increases in the production and processing of cocoa beans have generated increasing waste, resulting in million tons of CPHs being disposed of every year. In Brazil and other cocoa-producing countries, processing this cacao waste could provide economic advantages and decrease some of the environmental problems. These large quantities of CPH could yield a large quantity of fibrous materials which might be suitable as alternative resources especially in pulp and paper making industries or automotive application. Because CPHs are readily available, they could be used also to recover value-added compounds such as pectin.[9,10]

In general, natural fibers contain four main components as shown in **Figure 1**, which are cellulose, hemicelluloses, pectin, and lignin. Every percentage of these components varies with the different types of fibers. Growing and harvesting conditions can also affect the variation. For the cellulose, it is a semi-crystalline polysaccharide and is responsible for the hydrophilic nature of natural fibers. Hemicellulose, compared to the cellulose has lower molecular weight and it is fully amorphous polysaccharide. This amorphous have been known as being partially soluble in water and alkaline solutions. Pectin is a polysaccharide like cellulose and hemicellulose. It main function is to hold the fiber together among them. Lignin has lower effect on water absorption and contributes mainly of aromatics unlike hemicellulose. It is an amorphous polymer in the natural fibers components.

In composite material, it consists of materials system composed of a mixture or combination of two or more micro- or macro-constituents that varies in form and chemical composition. Besides, it is essentially insoluble in each other. To improve the material properties such as toughness, stiffness

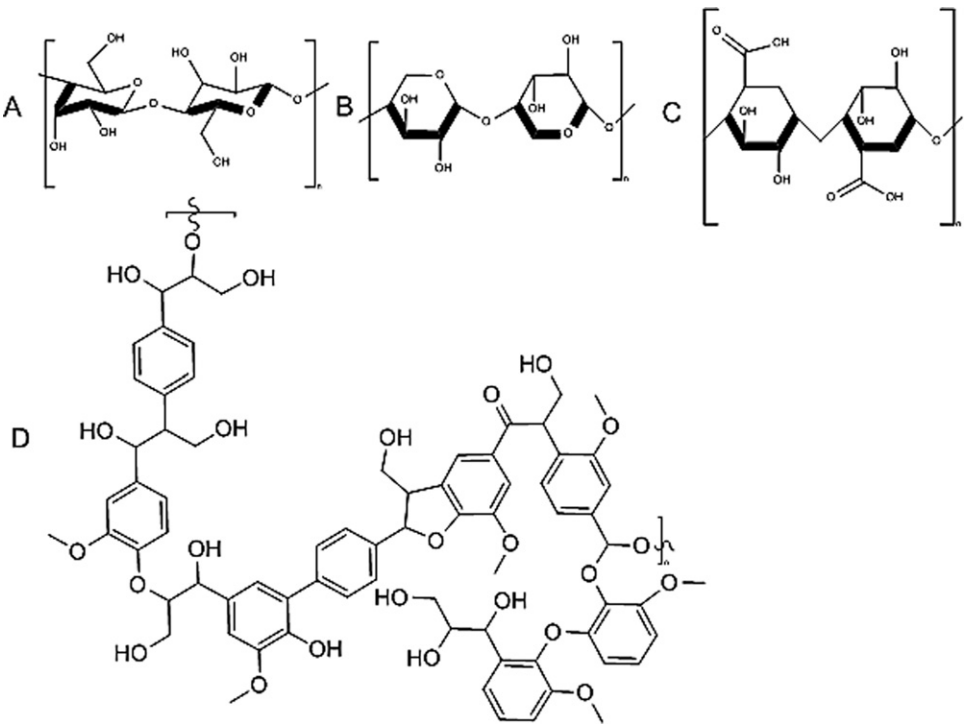

Figure 1 Structural representations of cellulose (a) hemicellulose (b) pectin (c), and lignin (d).[11]

and strength, these composites involve two or more component materials, which are generally combined in an attempt to improve the material properties.

1.8.2 Overview of Composites

In the last three decades, plastics, ceramics, and composite materials have been known as the main emerging materials in our industry. This composite materials have been increased dramatically and the applications have conquering and penetrating the new markets nowadays. Modern composite materials constitute a significant proportion of the engineered materials market ranging from everyday products to sophisticated niche applications. Composites have already proven their worth as weight-saving materials, although the cost is still become the current challenge. Several innovative manufacturing technique currently being used in the composites industry, which is to produce an economically attractive composite components. The cost hurdle is one of the problem and to overcome it, the improvement in manufacturing technology alone is not sufficient, especially for composites.

There must be some vital effort for composites to become competitive with metals, which are effort in design, tooling, quality assurance, manufacturing, material, process and even the program management. The composites industry has begun to recognize that the commercial applications of composites promise to offer much larger business opportunities than the aerospace sector due to the sheer size of transportation industry. Relentlessly, application in composite from aircraft sector to other commercial uses has become outstanding. Penetration of these advanced materials enabled by the introduction of newer polymer resin matrix materials and high-performance reinforcement fibers of glass, carbon, and aramid has witnessed a steady expansion in uses and volume. An expected reduction in costs is due to the increased of the volume.

There are applications that this high-performance FRP can be found such as in composite armoring designed to resist explosive impacts, windmill blades, industrial draft shafts, and fuel cylinders for natural gas vehicles, support beams of highway bridges and even in the paper making rollers. In fact, by using the composites material in the application rather than metals can highly savings in both cost and weight. Examples in applications are cascades for engines, curved fairing and fillets, replacements for welded metallic parts, cylinders, tubes, ducts, blade containment bands, and much more. Their advantages which is lighter construction materials and more seismic resistant structures has placed this composite in high emphasis on the use of new and advanced materials. Besides decreases in dead weight, it also absorbs the shock and vibration through tailored microstructures. Moreover, composites are now extensively being used for rehabilitation or strengthening of preexisting structures that have to be retrofitted to make them seismic resistant, or to repair damage caused by earthquakes or other vibrations of the earth and its crust.

The properties of the composite material can be designed by considering the structural aspects unlike the conventional materials such as steel. Both material and structural design will be involved in the design of the structural component using the composites. Stiffness and thermal expansion which are the properties of the composite can be varied continuously over a broad range of values under the control of the designer. Careful selection of reinforcement type finished product characteristics to be tailored to almost any specific engineering requirement. Material selection is very important whilst the use of composites will be the clear choice. It will depend on many factors such as the lifetime requirements of working, run length which is the number of produced items, complexity of product shape, possible savings in assembly costs and the designer skills and experience in tapping the optimum potential of composites. The use of composites in conjunction with traditional materials may give the best results in some instances.[12]

1.8.2.1 FRP Composites

1.8.2.1.1 Historical development

Since 1950s, the use of non-metallic fibers has been considered as particularly fiber-glass elements which bundled into continuous reinforcing elements. Polymer impregnated bundled fiber-glass fibers has been used as rods for anchorages in tunneling to make advances in polymer development. Nawy *et al.*[13] have conducted an extensive work on the use of bundled and resin-impregnated glass fibers formed into deformed bars as the main reinforcement in element of structure in mid 1960s. Until the late 1970s, the commercial application of bundled and resin-impregnated reinforcement in structural concrete elements was not recognized except for cases where the magnetic fields must be avoided to support the structure. It is important to state at this juncture that the term plastic could be misleading; hence, there is general consensus at this time to define FRP as fiber-reinforced polymer composites.

GFRP reinforcing bars have developed an interest in their using in early 1980s. This was important in supporting the magnetic resonance imaging (MRI) medical equipment or for reinforced concrete surrounding. Such equipment includes sensitive magnets and cannot tolerate the presence of any steel reinforcement. Besides, GFRP reinforcement is more durable and efficient as concrete reinforcement where the environmental and chemical attacks are present. Composite rebar is commonly used in the construction industry like seawalls, roof of decks, base pads for electrical, and equipment of reactor and also the concrete floor slabs in aggressive chemical environment. In Germany history of 1986, the world's first highway bridge had been built using composite reinforcement.

History in United States in 1990s has stated that at least nine major companies have been actively marketing this product since the significant funds have been expended on product evaluation and further development. In addition, glass fiber filaments has become a supplement to concrete matrices to improve the mechanical properties of concrete, but not as a replacement for the main bar reinforcement in supporting structural components. Glass fibers that are alkali resistant are also gaining wide use. These normally contain zirconium (ZrO_2) to minimize or eliminate the alkaline corrosive attack on glass present in the cement paste.

Nylon and PP are examples of synthetic fibers materials which recently begun to be utilized due to availability of information on their mechanical performance in matrix. This

both loose and woven into geotextile form also has better understanding of their structural contribution to crack resistance. The use of carbon fibers as the main reinforcement apart from its use in cement-based composites has grown interest nowadays although the use of other types of non-metallic fibers has been explored. The science of fibrous concrete and composites become an advanced to an extent now and can justify its extended use in years forward.[13]

1.8.2.1.2 Definition of composite

Composite had been broadly defined by world scholars such as Jartiz, Kelly, Beghezan and Van Suchetclan based on its used and applications. Each of it allows us to understand the meaning of composite widely and in depth.

1. The most common meaning of composite has been stated by Jartiz, 'Composites are multifunctional material systems that provide characteristics not obtainable from any discrete material. They are cohesive structures made by physically combining two or more compatible materials, different in composition and characteristics and sometimes in form.' This definition allows anyone to classify among the composites any mixture of materials including the very banal, meaningless mixture. The weakness of this definition does not indicate the specificity of the mixture of materials which is needed to make it distinguishable from any other inappropriate mixture.
2. Kelly had clearly stated that the composites should not be simply regarded as a mixture of two materials. In more appropriate definition, the combination must have its own distinctive significant properties. For example, in terms of strength, resistance to heat or any other desirable quality, it is better that either of the components must be different from either of them.
3. Beghezan defines as 'The composites are compound materials which differ from alloys by the fact that the individual components retain their characteristics but are so incorporated into the composite as to take advantage only of their attributes and not of their short comings,' in order to obtain improved materials.
4. Van Suchetclan explains composite materials as heterogeneous materials consisting of more than one solid phases, which are in intimate contact with each other on a microscopic scale. They can be also regarded as homogeneous materials on a microscopic scale in the sense that any portion of it will have the same physical property.[12]

1.8.2.1.3 Characteristics of composites

In general, composite materials have been divided into two phases. It consists of one or more discontinuous phases embedded in a continuous phase. The continuous phase is known as the 'matrix' whereas the discontinuous phase is usually harder and stronger than the continuous phase and is termed as the 'reinforcement' or 'reinforcing material.' More ductile and less hard can refer to the matrix. It holds the dispersed phase and shares a load with it. Besides, matrix is composed of any of the three basic material types such as polymers, metals, or ceramics. Moreover, the matrix forms the bulk form of the part of product. Meanwhile, for the secondary which embedded in the matrix is a discontinuous phase. Compared to the continuous phase, it usually harder and stronger. It improves the overall mechanical properties of the matrix and gives strengthen to the composites.[14]

Some properties such as their constituent materials, their distribution and the interaction among them are the examples of properties for the composites. It may be the sum of the fraction volume of the properties of the constituents. To improve or to get better properties, the constituent may interact in a synergistic way. The geometry of the reinforcement such as shape, size, and size distribution influences the properties of the composite to a great extent. Besides the nature of the constituent materials stated above, the orientation of the reinforcement and concentration distribution also affect the properties. Spherical, cylindrical, or rectangular cross-sanctioned prisms and platelets are examples of the shape of the discontinuous phase. Meanwhile, the size and size distribution will control the texture of the materials. For the volume fraction, it will determine the interfacial area of the material. All of this three properties; shape of the discontinuous phase, size distribution and the volume fraction plays an important role in determining the extent of the interaction between the reinforcement and the matrix.

Concentration is not only the single most important parameters which influencing the composites properties. Usually, it measured as fraction of weight or volume and determines the contribution of a single constituent to the overall properties of the composites. Apart from that, this concentration also an easily controllable manufacturing variable used to alter its properties.[15]

1.8.2.1.4 Advantages and merits of composites

Advantages of composites compared to their conventional counterparts are the ability to meet various design specifications with significant weight savings and strength-to-weight ratio. The advantages of composite materials compared to conventional ones are as below:

- Composites have a high tensile strength which is 4–6 times higher than that of aluminum or steel (depending on the reinforcements).[16]
- Lower embedded energy compared to other structural metallic materials like aluminum, steel, and etc.
- Composites offer an improved torsional stiffness and impact properties.
- 30–40% lighter compared to other metals, for instance any particular aluminum structures designed to the same functional requirements.
- High fatigue endurance limit (up to 60% of ultimate tensile strength).
- Composites are more versatile than metals and can be tailored to meet complex design requirements and performance needs.[17]
- Composites exhibit long life cycle which offer excellent fatigue, improved impact, and environmental resistance as well as reduce maintenance.
- Composites enjoy reduced life cycle cost compared to metals.
- Composites provide less noise during operation and produce lower vibration transmission than metals.

- Composites exhibit excellent corrosion resistance and fire retardancy.
- Improved appearance with smooth surfaces and readily incorporable integral decorative melamine are other characteristics of composites.
- Composite parts can eliminate joints/fasteners, providing part simplification and integrated design compared to conventional metallic parts.[18]

1.8.2.2 Natural FRP Composites

Natural fiber-polymer composites are made from petroleum or bio-based matrices composed of natural fibers such as kenaf, jute, hemp, pineapple, oil palm empty fruit bunch fibers. Natural fibers are used as reinforcement materials or fillers for the polymer matrices and they readily combine with a thermosetting or thermoplastic matrix.[19] The manufacture of natural-fiber composites includes the use of either a thermoset or thermoplastic polymer binder system combined with the natural-fiber preform or mat. In automotive applications, the most common system used today is thermoplastic PP, particularly for nonstructural components. PP is favored due to its low density, excellent process ability, mechanical properties, excellent electrical properties, and good dimensional stability and impact strength.[20] However, several synthetic thermoplastics are utilized including PE, polystyrene, and polyamides.[21]

Recently, natural FRP composite materials has grow rapidly in terms of their industrial applications and fundamental research. They have such positives properties such as cheap, renewable, completely or partially recyclable, and most important is biodegradable to environment. For plants fiber, they are more and more often applied as the reinforcement of composites and also used as a source of lignocellulosic fibers. Banana, pineapple, kenaf, sisal, ramie, hemp, jute, cotton, flax, bamboo as well as wood are examples for plants fiber, which are normally used nowadays. Wide applications in natural fiber can be seen in their used in transportation, military applications, packaging, consumer products and building or construction industries. Automobiles, railway coaches and aerospace are the examples in transportation application while ceiling paneling and partition boards are two examples that always be used in the building and construction industries. Natural fiber which containing composites are more environmentally friendly. Their advantages like availability, low density, renewability, and price as well as satisfactory mechanical properties have make them an attractive ecological alternative to glass, carbon, and man-made fibers used for the manufacturing of composites.[22]

As stated, natural fibers in Asia such as kenaf have some advantages in terms of cost, density, recyclability, abrasiveness, renewability, and biodegradable over the traditional reinforcement materials. The fiber matrix and the ability to transfer the load from the matrix to the fiber can affect the performance of the fiber-reinforced composites. In addition, one of the key structures in automobiles is the bumpers which protect the passengers from any incoming impact. With proper materials and careful design is very important and should be considered in order to achieve good energy absorbing behavior. Besides that, weight reduction plays an important role in automobiles to achieve the fuel efficiency. Weight reduction can be achieved without compensating the mechanical properties of the traditional materials by considering the safety. Besides, crash worthiness and safety should also be considered as preconditions in light weighting the bumper beam with the introduction of the automotive safety legislation. Furthermore, thermoplastics composites are being used in a variety of application such as mass transit, automotive, and military structures. They have an edge over traditional materials such as steel and aluminum. Variety of good properties like high-specific strength, corrosion resistance, and good damping capacity makes the thermoplastic a highly recommended because of their widely used in the bumper beams long fiber.

Generally, inexpensive polymers, nylon, PE, and PP are matrix elements in the thermoplastic composites. E-glass fiber, also known as lime-alumina-borosilicate glass is commonly being used in the industrial and civil structures and this glass can be obtained from raw materials such as sand.[16] This fiber also categorized in the reinforced material. Lately, long fiber thermoplastic composites show the highest growth rates in the plastic industry, which is approximately 30% per year. The mechanical properties of the long glass fiber thermoplastics can be decided by the fiber length in long glass fiber. By providing hybridization method of natural fiber with glass fiber can improve the mechanical properties of natural-fiber composites.[23]

1.8.2.2.1 Classification of natural fibers

Fibers are materials that similar to pieces of thread- and hair-like class that are continuous filaments or in the pieces of indiscrete elongated shape. They can be spun into filaments, thread, or rope. Besides, they can be used as a components in the composites materials. Furthermore, products can be made such as paper or felt by matting them into sheets. There are two types of fibers. First is from natural fiber and the other one is man-made or synthetic fiber. Natural fibers type include those made from plant, mineral, and animal sources. Also, natural fibers can be classified into three sections which are animal fiber, mineral fiber, and plant fiber.

1.8.2.2.1.1 Animal fiber

Generally, in animal fiber it comprise of protein such as mohair, wool, silk, alpaca, and angora. Examples of the animal fiber are animal hair, silk fiber, and avian fiber which has been divided as below:

- Animal hair (wool or hair): this fiber can be found from hairy mammals animals such as sheeps wool, goat hair, alpaca hair, or horse hair. Cashmere and mohair are the examples for the goat family.
- Silk fiber: this fiber comes from collected dried saliva of bugs or insects during cocoons preparation. Examples of the silk fiber are silk from the silk worms.
- Avian fiber: avian fibers such as feathers which comes from birds.

1.8.2.2.1.2 Mineral fiber

The second natural fiber is mineral fibers. Although it is naturally occurring fiber but it also can be a slightly modified fiber procured from minerals. These can be categorized into

three categories as below:

- Asbestos: asbestos is the only naturally occurring mineral fiber-like serpentine, amphiboles, and anthophyllite.
- Ceramic fibers: examples from the ceramic fiber are glass fibers, aluminum oxide, silicon carbide, and boron carbide. Glass wood and quartz can be categorized into the glass fiber group.
- Metal fibers: aluminum fibers is one of the examples in the metal fiber family.[24]

1.8.2.2.1.3 Plant fiber

Cellulose is the main fiber which contain in the plant fiber. Examples of cellulose fibers are cotton, jute, flax, ramie, sisal, and hemp. In recent times, manufacture of paper and cloth comes from the cellulose fiber. These plant fiber can be divided into several fibers as follows:

- Stalk fiber: stalk fiber comes from the stalk of the plants such as straws of wheat, rice, barley, bamboo, and grass. Tree wood also can be categorized into stalk fiber.
- Leaf fiber: examples of the leaf fiber are sisal and agave and this fiber comes from the leaves of the plant.
- Seed fiber: cotton and kapok are collected from the seed or seed case of the plants.
- Skin fiber: skin fiber can be collected from banana skin, hemp, jute, flax, soybeans, and others. All these fibers have higher tensile strength compared to other fibers. Hence, these fiber can be applied and used for paper, packaging, durable yam, and fabric. Method to collect the fibers are by getting it from the skin or bast surrounding the stem or their respective plant.

Figure 2 shows the classification of plant fibers.

Thermosetting and thermoplastic matrices can be reinforced also by using the natural fibers. This is because the composites require higher performance applications and that is why epoxy, polyester, polyurethane, and phenolic are normally used in natural fiber composites. This examples are belongs to the thermosetting resins matrices. They provide sufficient mechanical properties, in particular stiffness and strength, at acceptably low price levels. Replacing the synthetic fiber by natural fiber is only a first step to consider the ecological aspects of material selection. New materials based on the renewable sources become future development because of the several effects nowadays. The effects such as emission of green house which has free the gases such as CO_2 into the atmosphere and because the finiteness of fossil energy resources has increased the awareness among community to develop new sources.

Two primary physical limits that severely restrict the development of thermoplastic natural-fiber composites are the process temperature and interfacial adhesion between the natural fiber and polymer matrix. This can determine the properties of the physical composite by compatibilizing or couple the blend. There are different between the compatibilization method and the coupling. Coupling is a process in which dissimilar polymers or fillers are made into an alloy by use of external agents called coupling agents. Meanwhile, compatibilization is any operation performed on the fiber and polymer that increases the welling within the blend. This can be achieved by modifying several criteria like polymer matrix, modifying the fiber, adding surface-active agents, and by high shear compounding.[20,25]

The second physical limits are the upper temperature. This include the significant difference between the polymer matrix and the wood surface energy. In natural fiber applications,

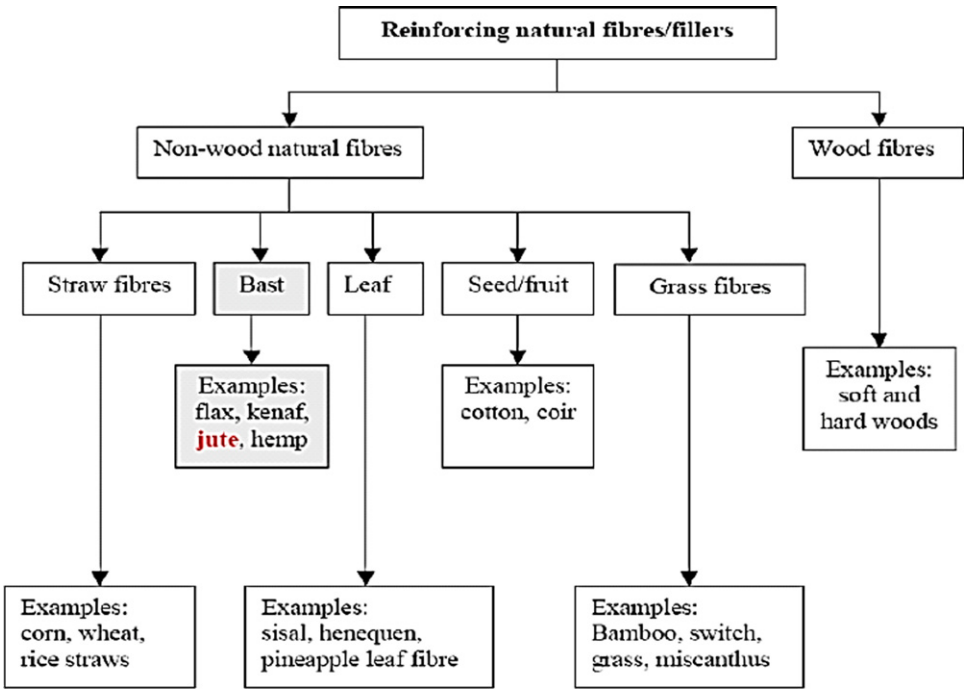

Figure 2 Classification of natural fibers which can be used as reinforcement of polymer.[22]

these process temperature is some kind of limiting factor. The generally perceived upper limit before fiber degradation occurs is on the order of 150 °C for long processing durations, although fibers may withstand short term exposures to 220 °C.[26]

1.8.2.2.2 Applications of natural fiber composites

Many applications involves the natural-fiber composites. It may be very cost-effective material for every applications. Building and construction industry is the popular application for the natural-fiber composites. It parts such as panels for partition and false ceiling, partition boards, wall, floor, window and door frames, roof tiles, mobile or pre-fabricated buildings, and many more. Advantage from the parts is they can be used in times of natural disaster such as earthquakes, cyclones, and floods. Besides that, storage devices also contribute their materials such as post-boxes, gain storage silos, and bio-gas containers. In addition, other applications like furniture, electrical devices, toy, and everyday applications also accounted in everyday life. Besides construction industry, automotive parts under transportation also have higher demand on natural fibers.

There are variety of reasons why natural fibers are the one in the automotive industry. First is because of their low density which can reduce the reduction of weight up to 10–30%. Besides that, they have good acoustic properties that make the mechanical properties of the materials is acceptable. They also have properties that suitable to process for instance low wear on tools. In addition, they are favorable in most aspects like ecobalance for part production and during vehicle operation due to weight savings and also for accident performance which give high stability and less splintering. In the health aspect, they give some benefits compared to glass fibers during production. Besides they can reduced the fogging behavior, the price also give advantages for both the fibers and the applied technologies nowadays.

1.8.2.2.3 Advantages of natural fiber composites

Natural-fibers composite have some main advantages which make them become more popular nowadays. As stated before, these natural fibers constribute to low specific weight than glass fiber and resulting in a higher specific strength and stiffness. Good thermal and acoustic insulating properties also gives them such a good condition. Known as a renewable source, they need less energy in the production process by releasing the oxygen to the environment while using the CO_2. Besides, it is not just can reduce the wear of the tool but also can give a healthier working conditions like no irritation can happen on the skin. Compared to the glass which can causes problem in combustion furnaces, thermal recycling is more possible to be used. Countries which produces low wages will be interested because producible of this fiber are with low investment at low cost.[22]

Automotives become one of the demand sectors in the global market. Their continuing need for the incorporation of natural fiber based materials also creates a simultaneous pressure to address the issue of sustainability. All factors must be taken into action by following the environmentally safe manner. Recent research has focus to the compostable natural-fiber based composites which has been created so that it can be safely disposed of after their intended use without polluting the atmosphere. The history and growth of transportation system shows an enlightening picture of how scientific, technological, social, and economic factors interplay to change the environment in his world. Automotive growth is strongly related to the economic growth that took place in the early part of twentieth century.

Automotive play an important role in the transportation of people both individually and in groups, as well as goods. Large-scale manufacture of these automobiles, operation of the transportation (road) network system, and construction of the required infrastructure has a dominant impact on economic growth of the country.[27] Continuous efforts are on developing newer or alternative materials to achieve cost effectiveness, fuel efficiency, reduced emissions, increased safety, and always with a target on future ability to recycle, or biodegrade. However, today's rising cost of fuel is a major factor in the move to utilize composites for all transport vehicles, and thereby to achieve a light weight construction with an ultimate goal of reduction in fuel consumption and emissions.

According to an estimate, about 25% reduction in the weight of the vehicle is equivalent to a savings of 250 million barrels of crude oil and reduction in CO_2 emissions to the tune of 220 billion pounds per annum. Automobiles today have better fuel economy and safety features than they had 25 years ago. It is estimated that, out of 10 gallons of fuel pumped to the car only 1.7 gallons goes in motion. One way of improvement would be to make the vehicles lighter by using composite based structures. Composites made of two or more materials are superior to their starting materials. FRP composite materials provide a new range of performance materials for an automotive industry. Generally, composites are strong, light, and resistant to corrosion and wear. They have been used in space and military vehicles; performed well, thus could play bigger role in automotives than they do today. As many as 40 automotive components such as trunk and hood liners, floor mats, carpets and padding, speakers, package trays, door panels, and oil and air filters contain fiber products.[28] Natural fibers are about 30–50% lower in density when compared to E-glass fibers and roughly the same as the aramid commercial grade systems.[29]

Furthermore, these fiber based materials can contribute greatly to the automotive manufacturer's final goal constituting weight reduction of 30% and cost reduction of 20%.[30] According to an estimate, there are more than 500 million passenger vehicles in use in this world and about 50 million new cars are produced every year. At an average of 1500 kg of materials for an automobile, the consumption of materials is in the tune of 70 million tons per year. It means, this quantity has to be produced, used and ultimately recycled or disposed at the end of useful life. Nearly as many as 40 automotive components such as trunk and hood liners, floor mats, carpets and padding, speakers, package trays, door panel and oil, and air filters uses fiber products. If these fibers can be replaced by the natural fibers there would be nearly 30% weight reduction and which in turn reduce nearly 20% of cost. However, glass-reinforced plastics exhibit shortcomings such as their relatively high-fiber density (approximately 40% higher than natural fibers), difficulty to machine, and poor recycling properties,

not to mention the potential health hazards posed by glass-fiber in particular.[26,28]

Amounting to a total of only 4000–5000 t in 1996, the use of natural fibers in the European automotive industry has quintuplicate with more than 28 000 t in the year 2000. In this decade, a total use between 50 000 and 100 000 t can be expected in this area. At present time, almost all European automotive producers employ interior parts reinforced by natural plant fibers. Natural fibers are also being used in polyurethane composites. The first commercial example is the inner door panel for the 1999 *S* Class Mercedes-Benz, made in Germany of 35% Baypreg F semi-rigid polyurethane thermoplastic elastomer from Bayer and 65% of a blend of flax, hemp, and sisal. Until now, use of flax, sisal, coconut fiber, cotton, and hemp has been limited to the interiors of DaimlerChrysler vehicles – in upholstery, door paneling, or the rear panel shelf. Elaya and Venkateshwaran[31] conducted experiments on Curacua, jute, coir, ramie, and kenaf with PP mixed at different proportion. The results show that with 50:50% of natural-fiber and polymer ratio provide the better mechanical properties.[31] There are many factors that can influence the performance of natural fiber-reinforced composites. Apart from the hydrophilic nature of fiber, the properties of the natural fiber-reinforced composites can also be influenced by fiber content/amount of filler. In general, high-fiber content is required to achieve high performance of the composites. Therefore, the effect of fiber content on the properties of natural fiber-reinforced composites is particularly significance. It is often observed that the increase in fiber loading leads to an increase in tensile properties. Another important factor that significantly influences the properties and interfacial characteristics of the composites is the processing parameters used. Therefore, suitable processing techniques and parameters must be carefully selected in order to yield the optimum composite products. Generally, the tensile properties of composites are markedly improved by adding fibers to a polymer matrix since fibers have much higher strength and stiffness values than those of the matrices.

In general, higher fiber content is desired for the purpose of achieving high performance of short-FRP composites. It is often observed that the presence of fiber or other reinforcement in the polymeric matrix raises the composite strength and modulus. Therefore, the effect of fiber content on the tensile properties of fiber-reinforced composites is of particular interest and significance for many researchers.[1]

A number of studies demonstrated the effects of fiber loading on mechanical properties (hardness, stiffness, strength, etc.) of natural fiber-reinforced composites. Singha and Rana[32] varied the fiber loading (10–30% by weight) and discovered the optimum tensile strength of Agave fiber-reinforced polystyrene composite at 20% fiber loading. Arrakhiz *et al.*[33] also found a significant increase in the tensile strength of high density polythene after reinforcing with 20% by weight of chemically treated coir fibers. El-Shekeil *et al.*[34] measured that the hardness of kenaf fiber-reinforced thermoplastic polyurethane (TPU) composite increases from 55 to 66 (shore D) as a result of 30% fiber loading. The increase in hardness is attributed to the increase of fiber loading since hardness is a function of the relative fiber volume and modulus of the composites.[35] Similar trend was observed in bamboo fiber filled natural rubber composites.[36] It is noted that machining efficiency of the composite, however, depends on their respective mechanical properties.

The applications of natural fiber-reinforced composites are growing rapidly, due to their inherent properties of light weight, easy availability, and environment friendliness.[37] The mixing of natural fibers with synthetic fibers increases its strength, and it is found to be a good alternative reinforcing material. The banana, sisal, and roselle fiber-reinforced composites are fabricated by the mould method, and the drilling is carried out, using HSS twist drills. From the experiment they found that, the cutting speed, feed rate, and drill diameter are the most significant factors affecting the thrust force. They further observed that the thrust force and torque increases with the increase in the feed rate, and decreases with the increase in cutting speed. Composite materials have become valuable construction materials in the aerospace, defense and automotive industries, due to their higher specific strength, stiffness, and fatigue characteristics. Composite components are joined by mechanical fasteners; and accurate, precise high quality holes need to be drilled to ensure proper and durable assemblies. The drilling of composite materials causes several damages, such as: delamination, fiber-pull out, edge chipping, uncut fibers, and others. It causes poor assembly tolerance, reduces the structural integrity of material, and deterioration of the potential for long-term performance. Drilling is carried out by using the HSS-Co twist drill, the multi construction twist drill, and the brad and spur drill, and reported that the brad and spur drill produced less induced damage around the whole surface, and lesser thrust force than the other two drills. The HSS-Co twist drill is always a bigger delamination factor, which means higher damage in a composite laminate.

Natural fibers have many advantages, such as low density, high-specific strength and modulus, non-abrasiveness, and low cost, when compared to synthetic fibers. Natural fiber-reinforced composite materials are recognized as better materials for structural applications, and the machining of these composites causes a number of problems. In order to overcome these problems an experiment has been carried out by using a cemented carbide end mill cutter and the results are compared with those of the GFRP composites. From the experiment, they found that the delamination factor and surface roughness of the natural fiber-reinforced composites are better than those of glass-fiber-reinforced composites. The effect of cutting speed and feed rate on delamination in drilling glass, hemp, and sandwich fibers-reinforced composites with different fiber volume fractions, is observed by Naveen *et al.*[38] It is found that the damage around the hole is predominant at higher feed rates, and a partial elliptical shape along the direction of fibers. Optimization of the machining parameters in drilling hemp fiber-reinforced composites was carried out by Dilli Babu *et al.*[39] and it was found that the feed rate and cutting speed made the largest contribution to the delamination.

An investigation has been carried out to study the mechanical and machinability characteristics of coir-polyester composites by Jayabal *et al.*[40] They found that the drill diameter of 6 mm and the spindle speed of 600 rpm gave the minimum value of thrust force, torque, and tool wear. An effort has been made for the development of hybrid

composites from natural fibers instead of orthopedic alloys, for internal fixation of fractured bones in the human body by Chandramohan and Marimuthu.[41] From the study it is revealed that composites made from natural fibers are the best materials, when compared with orthopedic composites made from orthopedic materials.[42]

Coir fiber-reinforced composites have been developed; the thrust force, torque, and tool wear during drilling optimized by Jayabal *et al.*[43] An experiment has been conducted to carry out the mechanical and machinability characteristics of glass coir-polyester composites, using factorial design methodology. A regression model is developed for correlating the drilling parameters and their effects by design of experiment techniques, and it is found that the feed rate plays a major role than the other variables. A desirability function based method is applied for optimizing the drilling parameters, based on multiple performance characteristics, by Rajmohan and Palanikumar.[44] The results indicated that the medium spindle speed and lower feed rate are optimum, for the minimum burr height during drilling, and the surface roughness of the hybrid composites.

In the present research, the glass–sisal–jute fibers-reinforced hybrid composites have been developed, and the drilling characteristics of these composites are analyzed, by varying the cutting speed, feed rate, and tool geometry. The results indicated that all the above said parameters affect the drilling characteristics, and subsequently drilling induced damage.[45,46]

1.8.3 Types of Composite Based on Matrix Material

Basically, composite materials can be categorized into three groups on the basis of matrix material. They are:

a. Metal matrix composites (MMC)
b. Ceramic matrix composites (CMC)
c. Polymer matrix composites (PMC)

1.8.3.1 MMC

A lot of advantages such as higher specific modulus, higher specific strength, better properties at elevated temperatures, and lower coefficient of thermal expansion makes the metal matrix a good composite over monolithic metals. Applications for MMC have been widely used such as in combustion chamber nozzle which normally used in rocket and space shuttle. Besides, housings, tubing, cables, heat exchangers, and structural members also part of consideration for wide range of applications.

1.8.3.2 CMC

One of the main objectives in producing CMC is to increase the toughness. Naturally it is hoped and indeed often found that there is a concomitant improvement in strength and stiffness of CMC.[22]

1.8.3.3 PMC

Synthetic polymeric composites are one of the most commonly used matrix materials. Typical examples include glass fiber-reinforced, carbon fiber-reinforced or polymer fiber-reinforced, thermoplastic or thermosetting resins, carbon-reinforced rubber, polymer blends, silica-reinforced resin or mica-reinforced resins, and polymer-bonded or impregnated concrete or wood. Generally, polymer composites are the combinations or compositions that comprise two or more materials as separate phases and at least one of which is a polymer. It is often possible to get unique combinations or levels of properties when combining the polymer with another material such as glass, carbon, or another polymer. Apart from that, it is also often useful to consider as composites such materials as coatings (pigment-binder combinations) and crystalline polymers (crystallites in a polymer matrix).

Generally, wood and bone include in the natural composites which wood can be defined as cellulosic fibers bonded with lignin and bone as mineral bonded with collagen. Otherwise, polymeric compositions cannot be considered as composites if it has very low proportions of pigments or processing aids or compounded with a plasticizer. Meanwhile, typical goal for polymeric compositions are to increase the efficiency of the materials by improving the strength, stiffness or toughness, and also the stability of dimensional. This can be done by embedding particles or fibers in a matrix or binding phase. The next goal is to minimize the price of the filler by using inexpensive and readily available fillers to extend a more expensive or scarce resin. This is very important nowadays as petroleum supplies become costlier and less reliable. Moreover, there are industries which include the use of some filler in their applications such as glass spheres and molybdenum sulfide. Function of fillers is to reduce permeability of materials. On the other hand, glass spheres and molybdenum sulfide is to improve process ability and to make a self-lubricating bearing in incorporation of dry-lubricant particles, respectively.[47]

Particularly, polymers have lower strength and stiffness compared to metals and ceramics. Besides, their mechanical properties are inadequate for a lot of structural purposes. To overcome this, these polymers can be reinforced with other materials so that their disadvantages can be reduced. In the meantime, high pressure is very significant in PMC processed instead of high temperature. High temperature does not require in the processed. Also equipment's required for manufacturing PMC are simpler. Applications for structural in PMC become famous because of the rapid development in this composites industry.

Composites are used because overall properties of the composites are superior to those of the individual components, for example, polymer/ceramic. Composites have a greater modulus than the polymer component but are not as brittle as ceramics. Two types of polymer composites are:

- Fiber-reinforced polymer (FRP)
- Particle-reinforced polymer (PRP)

1.8.3.3.1 FRP

Fibers and matrix are the two main components that made up the fiber-reinforced composites. Commonly, fibers are the main reinforcement and the main source of strength meanwhile for matrix, it glues all the fibers together in shape and besides that, it also transfer stresses between the reinforcing

Figure 3 Schematic illustration of fiber types: unidirectional, chopped, and woven.[48]

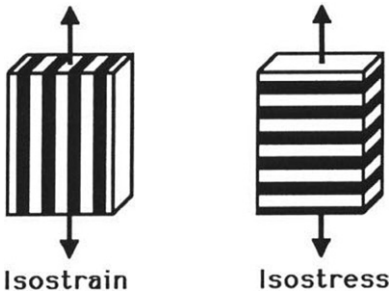

Figure 4 Geometry of idealized unidirectional composite materials.[48]

fibers. Therefore, the functions of fibers are to carry the loads along their longitudinal directions. Occasionally, the fillers also help a lot to smooth the process of manufacturing by adding it to the fibers. Besides, these fillers give special impact properties to the composites and also can reduce the product cost. In fact, fibers are available in three basic forms as shown in Figure 3:

- Continuous fibers are long, straight and generally layed-up parallel to each other.
- Chopped fibers are short and generally randomly distributed (fiber-glass).
- Woven fibers come in cloth form and provide multi-directional strength.

Properties of composite material when combining the fiber and matrix materials may differ from most of engineering materials. This is due to the mechanical properties of composites are highly dependent on the direction in which the loads are applied. Anisotropic, where the material properties are a function of loading direction can include the strength and stiffness of the composites.

From Figure 4, it shows the strength and stiffness are generally much higher along the fiber direction and known as isostrain, while the isostress stated that it is perpendicular to the fiber direction.[49]

- Loading parallel to fiber direction (isostrain).
- Loading perpendicular to fiber direction (isostress).

Composite laminates are formed into a multi-layered structure when combining the individual layers, which is known as lamina. Meanwhile, the continuous fiber composites combine the unidirectional lamina and shows different directions in their fibers oriented as depicted in Figure 5. The combination of fibers aligned turns it into a layered structure with different layers in a laminate. Unidirectional lamina also known as fibers aligned.

Typically, glass fibers, asbestos, carbon/graphite fibers, beryllium, beryllium carbide, beryllium oxide, molybdenum, aluminum oxide, polyamide, natural-fiber, and others is a common based for FRP composites embedded in a matrix of an epoxy or polyester resin. Compared to steel, carbon fiber composites have five times more relative stiffness. It is one of based materials in the reinforced thermosetting resins besides boron and polyaramides. In addition, it also gives high levels of strength and stiffness. Applications such as components in new jet aircraft, boat hulls, and rocket motor cases are normally suited for epoxy and polyester composites because of their excellent properties stated before. Besides that, parts for automobiles and chemical reaction vessels also two examples that can be included in the applications. Polycarbonates, PE, and polyesters are among the resins available as glass-reinforced composition. Although epoxy and polyester resins plays important roles in the properties of reinforced thermosetting resins, there are others significant reinforced thermoplastic resins as well. The properties of reinforced thermoplastics have made these materials a good one to replace with the metals. Less cost, one step fabrication by injection moulding with improved properties has made it possible to apply in applications of appliances, instruments, automobiles, and tools. Polyamide resins are one of the examples for various matrices which show excellent matrices for glass fibers and also give a high-performance composite in the development of other composite systems. Different fibers are of potential interest, including polymers, single-crystal ceramic whiskers, and various metallic fibers. Poly which is also known as vinyl alcohol and sapphire is the example for polymers and single-crystal ceramic whiskers, respectively.

Usually, FRPs are commonly being used in many applications such as in aerospace, construction industries, marine, and automotive parts. As stated before, composite materials are specially or naturally occurring materials which have different physical or chemical properties. Made from two or more constituent materials, these composite materials remain separate and distinct within the finished structure. Most composites have strong, stiff fibers in a matrix which is weaker and less stiff. Example for good properties such as low density is the main objective for strong and stiff component. Commercial material commonly has glass or carbon fibers in matrices based on thermosetting polymers, such as epoxy or polyester resins. After initial production, thermoplastic polymers may be preferred sometimes, since they are moldable. They can be categorized in several classes of composite in which the matrix is a metal or a ceramic. Higher costs in manufacturing become the problems which must have to be overcome and that is why these are still in a developmental stage for the most part. It is often rather complex for adding the fibers or in some cases called particles in these composites. Such examples are improvements may be sought in creep, wear, fracture toughness, and thermal stability. There are varieties of usage for FRP ranging from aircraft, helicopters and spacecraft through to boats, ships and offshore platforms, and to automobiles, sports goods, chemical processing equipment and civil infrastructure such as bridges and buildings. FRP are

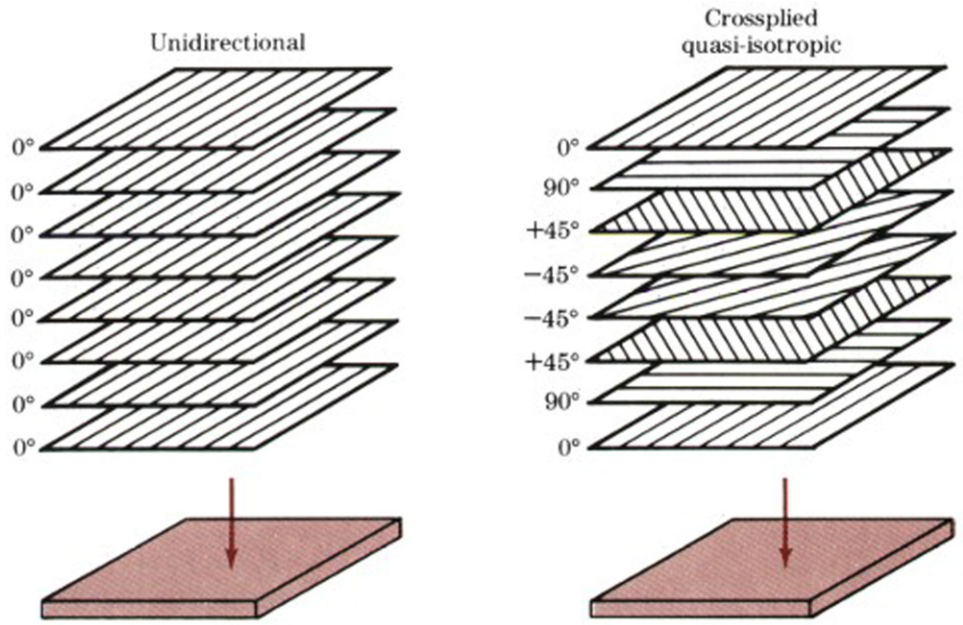

Figure 5 Schematic illustration of lamina being combined to form a laminate.[48]

composites used in almost every type of advanced engineering structure.

The development of new advanced forms of FRP materials has increased the applications of composites over these recent years. FRP materials are famously become established in relatively new market such as in biomedical devices and civil structures. Moreover, this composite continues to grow at an impressive rate as these materials are used more in their existing markets. Carbon nanotubes and nanoparticles can be the examples for new styles of reinforcement and in the developments in high-performance resin systems. FRPs also is a system that are constructed of traditional civil engineering materials, which known as steel and concrete and besides that, it is increasingly being considered as an enhancement to or substitute for infrastructure components. As stated before, the good properties that FRPs have are light weight, no-corrosive, can easily be constructed exhibit high-specific strength and specific stiffness and can be tailored to satisfy performance requirements. Because of their advantageous characteristics, composites have been included in new construction and rehabilitation of structures through its use as reinforcement in concrete, bridge decks, modular structures, formwork, and external reinforcement for strengthening and seismic upgrade. There have been actively studied in numerous research laboratories and professional organizations around the world that the compatibility of FRP to concrete structures as a substitute for steel bars or pre-stressing tendons.

A lot of good properties or high number of advantages for FRP reinforcement such as corrosion resistance, non-magnetic properties, high tensile strength, light weight, and ease of handling. However, besides the good advantages, they generally have cons like relatively poor transverse or shear resistance and have a linear elastic response in tension up to brittle failure. Also, when expose to high temperatures, their resistance to fire is poor. Furthermore, they are more sensitive to stress-rupture effects and will lose significant strength upon bending. Moreover, their cost, whether considered per unit weight or on the basis of force carrying capacity, is high in comparison to conventional steel reinforcing bars or pre-stressing tendons. When view through engineering perspective, the most serious problem that can be detected with the FRP reinforcements are the very low shear strength in the transverse direction and the lack of plastic behavior. This can lead to the rupture of premature tendon, notably when the present of the effects, such as at shear-cracking planes in reinforced concrete beams where dowel action exists. In fact, this dowel action plays a role to reduce shear resistance in the tendon and also to reduce tensile. For the upcoming future, more expectation in continuous improvement is needed and solutions and limitations of use have been offered.

Increasing in the demand and market share will decrease significantly in the unit cost of FRP reinforcements. However, there are applications where FRP reinforcements are cost effective and justifiable, even today. Applications such as the use of FRP meshes or textiles or fabrics in thin cement products and also include the use of bonded FRP sheets or plates in repair and strengthening of concrete structures. Meanwhile, the cost of repair and rehabilitation of a structure is always, in relative terms, substantially higher than the cost of the initial structure. Generally, repair section must be a relatively small volume of repair material yet relatively high commitment in labor. The cost of material becomes secondary because of the labor cost in developed countries significantly so high. Thus, the more the cost-effective in material repair, the highest the performance and durability of the repair material. This indicates that the material cost is not a serious issue in repair. In fact, the FRP repair materials are costly also not a constraining drawback. The argument for FRP composites in a sustainable built environment is questionable when considering the appearing of only energy and material resources on the surface. However,

such a conclusion needs to be evaluated in terms of potential advantages present in use of FRP composites related to considerations such as ocean environments, space systems, defense systems, seismic upgrades, rehabilitating existing structures, and extending their life. Besides that, other examples are longer lasting, higher performance, lighter weight, and higher strength.

FRP composites is one of a sustainable material and because of that, the environmental concerns appear to be a barrier to its feasibility particularly when considering smog, air pollution, acidification associated with its production, and fossil fuel depletion. Additional fact, the structural components of FRP cannot be reused to perform a similar function in another structure unlike steel and timber. That is why the ability to recycle these FRP composites is limited. Nevertheless, direct and indirect benefit may be revealed if the environmental impact of FRP composites in infrastructure applications is evaluated, specifically through the life cycle analysis. Since the first introduced, the composite materials have developed very greatly. However, a number of needs remain before the composite materials can be used as an alternative to conventional materials as part of a sustainable environment.

Ultimately, in order for composites to truly be considered a viable alternative, they must be structurally and economically feasible. Numerous studies regarding the structural feasibility of composite materials are widely available in literature. However, limited studies are available on the economic and environmental feasibility of these materials from the perspective of a life cycle approach, since short term data is available or only economic costs are considered in the comparison. Additionally, the long-term effects of using composite materials needs to be determined. The by-products of the production, the sustainability of the constituent materials, and the potential to recycle composite materials needs to be assessed in order to determine of composite materials can be part of a sustainable environment.

1.8.3.3.1.1 Failure modes

Structural failure can occur in FRP materials when:

- Tensile forces stretch the matrix more than the fibers, causing the material to shear at the interface between matrix and fibers.
- Tensile forces near the end of the fibers exceed the tolerances of the matrix, separating the fibers from the matrix.
- Tensile forces can also exceed the tolerances of the fibers causing the fibers themselves to fracture leading to material failure.[26]

1.8.3.3.1.2 Material requirements

The matrix must also meet certain requirements in order to first be suitable for the FRP process and ensure a successful reinforcement of it. The matrix must be able to properly saturate, and bond with the fibers within a suitable curing period. The matrix should preferably bond chemically with the fiber reinforcement for maximum adhesion. The matrix must also completely envelope the fibers to protect them from cuts and notches that would reduce their strength, and to transfer forces to the fibers. The fibers must also be kept separate from each other so that if failure occurs it is localized as much as possible, and if failure occurs the matrix must also debond from the fiber for similar reasons. Finally, the matrix should be of a plastic that remains chemically and physically stable during and after reinforcement and molding processes. To be suitable for reinforcement material fiber additives must increase the tensile strength and modulus of elasticity of the matrix and meet the following conditions; fibers must exceed critical fiber content; the strength and rigidity of fibers itself must exceed the strength and rigidity of the matrix alone; and there must be optimum bonding between fibers and matrix.

1.8.3.3.1.3 Applications of FRP

FRPs are best suited for any design program that demands weight savings, precision engineering, finite tolerances, and the simplification of parts in both production and operation. A molded polymer artifact is cheaper, faster, and easier to manufacture than cast aluminum or steel artifact, and maintains similar and sometimes better tolerances and material strengths. The Mitsubishi Lancer Evolution IV also used FRP for its spoiler material.[25–27,49,50]

1.8.3.3.1.4 Structural applications of FRP

FRP can be applied to strengthen the beams, columns, and slabs in buildings. It is possible to increase strength of these structural members even after these have been severely damaged due to loading conditions. For strengthening beams, two techniques are adopted. First one is to paste FRP plates to the bottom (generally the tension face) of a beam. This increases the strength of beam, deflection capacity of beam, and stiffness (load required to make unit deflection). Alternatively, FRP strips can be pasted in 'U' shape around the sides and bottom of a beam, resulting in higher shear resistance. Columns in building can be wrapped with FRP for achieving higher strength. This is called wrapping of columns. The technique works by restraining the lateral expansion of the column. Slabs may be strengthened by pasting FRP strips at their bottom (tension face). This will result in better performance, since the tensile resistance of slabs is supplemented by the tensile strength of FRP. In the case of beams and slabs, the effectiveness of FRP strengthening depends on the performance of the resin chosen for bonding.[20,22] Examples of applications and advantages of FRP are shown in the **Table 1** below:

1.8.3.3.1.5 Advantages and limitations of FRP

FRP allows the alignment of the glass fibers of thermoplastics to suit specific design programs. Specifying the orientation of reinforcing fibers can increase the strength and resistance to deformation of the polymer. Glass-reinforced polymers are strongest and most resistive to deforming forces when the polymer fibers are parallel to the force being exerted, and are weakest when the fibers are perpendicular. Thus this ability is at once both an advantage and a limitation depending on the context of use. Weak spots of perpendicular fibers can be used for natural hinges and connections, but can also lead to material failure when production processes fail to properly orient the fibers parallel to expected forces. When forces are exerted perpendicular to the orientation of fibers the strength and elasticity of the polymer is less than the matrix alone. In cast resin components made of glass-reinforced polymers such as unsaturated polyester (UP) and epoxy resin (EP), the

Table 1 Applications and advantages of FRP

Fiber-reinforced polymer	*Application and advantages*
Carbon fiber-reinforced polymers	Rudder of commercial airplane Advantages over a traditional rudder made from sheet aluminum are: ● 25% reduction in weight ● 95% reduction in components by combining parts and forms into simpler molded parts ● Overall reduction in production and operational costs, economy of parts results in lower production costs and the weight savings create fuel savings that lower the operational costs of flying the airplane
Glass fiber-reinforced polymers	Engine intake manifolds are made from glass fiber reinforced PA 66 Advantages over cast aluminum manifolds are: ● Up to a 60% reduction in weight ● Improved surface quality and aerodynamics ● Reduction in components by combining parts and forms into simpler molded shapes Automotive gas and clutch pedals made from glass fiber reinforced PA 66 (DWP 12-13) Advantages over stamped aluminum are: ● Pedals can be molded as single units combining both pedals and mechanical linkages simplifying the production and operation of the design ● Fibers can be oriented to reinforce against specific stresses, increasing the durability and safety[51]

orientation of fibers can be oriented in two-dimensional and three-dimensional weaves. This means that when forces are possibly perpendicular to one orientation, they are parallel to another orientation; this eliminates the potential for weak spots in the polymer.[47]

1.8.3.3.1.6 Design considerations

FRP is used in designs that require a measure of strength or modulus of elasticity those non-reinforced plastics and other material choices are either ill-suited for mechanically or economically. This means that the primary design consideration for using FRP is to ensure that the material is used economically and in a manner that takes advantage of its structural enhancements specifically. This is however not always the case, the orientation of fibers also creates a material weakness perpendicular to the fibers. Thus the use of fiber reinforcement and their orientation affects the strength, rigidity, and elasticity of a final form and hence the operation of the final product itself. Orienting the direction of fibers either, unidirectional, two-dimensionally, or three-dimensionally during production affects the degree of strength, flexibility, and elasticity of the final product. Fibers oriented in the direction of forces display greater resistance to distortion from these forces and vice versa, thus areas of a product that must withstand forces will be reinforced with fibers in the same direction, and areas that require flexibility, such as natural hinges, will use fibers in a perpendicular direction to forces. Using more dimensions avoids this either or scenario and creates objects that seek to avoid any specific weak points due to the unidirectional orientation of fibers. The properties of strength, flexibility and elasticity can also be magnified or diminished through the geometric shape and design of the final product. These include such design consideration such as ensuring proper wall thickness and creating multifunctional geometric shapes that can be molding as single pieces, creating shapes that have more material and structural integrity by reducing joints, connections, and hardware.[25]

1.8.3.3.1.7 Disposal and recycling concerns

As a subset of plastic FR plastics are liable to a number of the issues and concerns in plastic waste disposal and recycling. Plastics pose a particular challenge in recycling processes because they are derived from polymers and monomers that often cannot be separated and returned to their virgin states, for this reason not all plastics can be recycled for re-use, in fact some estimates claim only 20–30% of plastics can be material recycled at all. Fiber-reinforced plastics and their matrices share these disposal and environmental concerns. In addition to these concerns, the fact that the fibers themselves are difficult to remove from the matrix and preserve for re-use means FRP amplify these challenges. FRP are inherently difficult to separate into base a material that is into fiber and matrix, and the fiber-reinforced plastic matrix into separate usable plastic, polymers, and monomers. These are all concerns for environmentally informed design today, but plastics often offer savings in energy and economic savings in comparison to other materials, also with the advent of new more environmentally friendly matrices such as bioplastics and UV-degradable plastics, FRP will similarly gain environmental sensitivity.[26]

1.8.3.3.2 PRP

Particles used for reinforcing include ceramics and glasses such as small mineral particles, metal particles such as aluminum and amorphous materials, including polymers and carbon black. Particles are used to increase the modules of the matrix and to decrease the ductility of the matrix. Particles are also used to reduce the cost of the composites. Reinforcements and matrices can be common, inexpensive materials and are easily processed. Some of the useful properties of ceramics and glasses include high-melting temperature, low density, high strength, stiffness, wear resistance, and corrosion resistance. Many ceramics are good electrical and thermal insulators. Some ceramics have special properties, some ceramics are magnetic materials, some are piezo electric materials, and a few special ceramics are even superconductors at very low temperatures. Ceramics and glasses have one major drawback: they are brittle. An example of particle-reinforced composites is an automobile tire, which has carbon black particles in a matrix of poly-isobutylene elastomeric polymer. Polymer composite materials have generated wide interest in various

engineering fields, particularly in aerospace applications. Research is underway worldwide to develop newer composites with varied combinations of fibers and fillers so as to make them useable under different operational conditions. Against this backdrop, the present work has been taken up to develop a series of polyetheretherketone (PEEK) based composites with glass fiber reinforcement and with ceramic fillers and to study their response to solid particle erosion.[20,22]

Particle-reinforced composites include the most used (by weight) construction material in the world – concrete. Sand (fine particles) and gravel (coarse particles) compose from 60 to 75% of standard concrete.

Note that the particulates (sand and gravel) are combined with the Matrix (cement), which acts as a bonding agent between the particles. The addition of water to a particle-cement mixture results in a complex hydration reaction that produces a network of strong ionic/covalent bonds. The reinforcing particles are generally stiff and hard and restrain deformation of the cement. As with polymers, additives (termed admixtures) are added to concrete to affect its reactions and properties:

- Accelerators speed-up the curing process,
- Retarders slow down the curing process,
- Surface hardeners produce an abrasion resistant surface, etc.[49]

1.8.4 Manufacturing Process

1.8.4.1 Polymers

The linking of small molecules (monomers) to make larger molecules is a polymer. Polymerization requires that each small molecule have at least two reaction points or functional groups. There are two distinct major types of polymerization processes, condensation polymerization, in which the chain growth is accompanied by elimination of small molecules such as H_2O or CH_3OH, and addition polymerization, in which the polymer is formed without the loss of other materials.

1.8.4.1.1 Polymerization

Polymerization, emulsion polymerization any process in which relatively small molecules, called monomers, combines chemically to produce a very large chain-like or network molecule, called a polymer. The monomer molecules may be all alike, or they may represent two, three, or more different compounds. Usually at least 100 monomer molecules must be combined to make a product that has certain unique physical properties – such as elasticity, high tensile strength, or the ability to form fibers – that differentiate polymers from substances composed of smaller and simpler molecules; often, many thousands of monomer units are incorporated in a single molecule of a polymer. The formation of stable covalent chemical bonds between the monomers sets polymerization apart from other processes, such as crystallization, in which large numbers of molecules aggregate under the influence of weak intermolecular forces. Two classes of polymerization usually are distinguished. In condensation polymerization, each step of the process is accompanied by formation of a molecule of some simple compound, often water.

In addition polymerization, monomers react to form a polymer without the formation of by-products. Addition polymerizations usually are carried out in the presence of catalysts, which in certain cases exert control over structural details that have important effects on the properties of the polymer. Linear polymers, which are composed of chain-like molecules, may be viscous liquids or solids with varying degrees of crystallinity; a number of them can be dissolved in certain liquids, and they soften or melt upon heating. Cross-linked polymers, in which the molecular structure is a network, are thermosetting resins (i.e., they form under the influence of heat but, once formed, do not melt or soften upon reheating) that do not dissolve in solvents. Both linear and cross-linked polymers can be made by either addition or condensation polymerization.

1.8.4.1.2 Polycondensation

The polycondensation a process for the production of polymers from bifunctional and polyfunctional compounds (monomers), accompanied by the elimination of low-molecular weight by-products (for example, water, alcohols, and hydrogen halides). A typical example of polycondensation is the synthesis of complex polyester. The process is called homopolycondensation if the minimum possible number of monomer types for a given case participates, and this number is usually two. If at least one monomer more than the number required for the given reaction participates in polycondensation, the process is called copolycondensation. Polycondensation in which only bifunctional compounds participate leads to the formation of linear macromolecules and is called linear polycondensation. If molecules with three or more functional groups participate in polycondensation, three-dimensional structures are formed and the process is called three-dimensional polycondensation. In cases where the degree of completion of polycondensation and the mean length of the macromolecules are limited by the equilibrium concentration of the reagents and reaction products, the process is called equilibrium (reversible) polycondensation.

1.8.4.1.3 Polyaddition

The polyaddition reactions are similar to polycondensation reactions because they are also step reactions, however, without splitting off low-molecular weight by-products. The reaction is exothermic rather than endothermic and therefore cannot be stopped at will. Typical for polyaddition reaction is that individual atoms, usually H-atoms, wander from one monomer to another as the two monomers combine through a covalent bond. The monomers, as in polycondensation reactions, have to be added in stoichiometric amounts. These reactions do not start spontaneously and they are slow. Polyaddition does not play a significant role in the production of thermoplastics. It is commonly encountered with cross-linked polymers. Polyurethane, which can be either a thermoplastic or thermosets, is synthesized by the reaction of multifunctional isocyanates with multifunctional amines or alcohol. Thermosetting EPs are formed by polyaddition of epoxides with curing agents, such as amines and acid anhydrides.

In comparing chain reaction polymerization with the other two types of polymerization the following principal differences should be noted: chain reaction polymerization, or simply called polymerization, is a chain reaction as the name implies. Only individual monomer molecules add to a reactive growing chain end, except for recombination of two radical chain ends or reactions of a reactive chain end with an added modifier molecule. The activation energy for chain initiation is much greater than for the subsequent growth reaction and growth, therefore, occurs very rapidly.[47]

1.8.4.2 Natural Fiber-Reinforced Composites

1.8.4.2.1 All process description

FRP involves two distinct processes, the first is the process whereby the fibrous material is manufactured and formed, and the second is the process whereby fibrous materials are bonded with the matrix during the molding process. Having known the role of design for manufacturing process, this section is now devoted to the manufacturing processes reported to be used in the development of products or components from natural-fiber composites. Ho *et al.*[52] performed extensive literature review composite manufacturing processes that are related natural-fiber composites. They reported that majority of the work related to natural-fiber composites used conventional composite manufacturing processes such injection moulding, compression moulding, resin transfer moulding (RTM), vacuum infusion moulding, and hot press processes. In this chapter only selected manufacturing processes are reviewed.

1.8.4.2.1.1 Fiber process

Fiber preforms are how the fibers are manufactured before being bonded to the matrix. Fiber preforms are often manufactured in sheets, continuous mats, or as continuous filaments for spray applications. The four major ways to manufacture the fiber preform is though the textile processing techniques of weaving, knitting, braiding, and stitching.

- Weaving can be done in a conventional manner to produce two-dimensional fibers as well in a multilayer weaving that can create three-dimensional fibers. However, multilayer weaving is required to have multiple layers of warp yarns to create fibers in the z-direction creating a few disadvantages in manufacturing, namely the time to set up all the warp yarns on the loom. Therefore, most multilayer weaving is currently used to produce relatively narrow width products or high value products where the cost of the preform production is acceptable. Another fiber-reinforced plastic three-dimensional one of the main problems facing the use of multilayer woven fabrics is the difficulty in producing a fabric that contains fibers oriented with angles other than 0° and 90° to each other, respectively.
- The second major way of manufacturing fiber preforms is braiding. Braiding is suited to the manufacture of narrow width flat or tubular fabric and is not as capable as weaving in the production of large volumes of wide fabrics. Braiding is done over top of mandrels that vary in cross-sectional shape or dimension along their length. Braiding is limited to objects about a brick in size. Unlike the standard weaving process, braiding can produce fabric that contains fibers at 45° angles to one another. Braiding three-dimensional fibers can be done using four-steps, two-step, or multilayer interlock braiding. Four step or row and column braiding utilizes a flat-bed containing rows and columns of yarn carriers that form the shape of the desired preform. Additional carriers are added to the outside of the array, the precise location and quantity of which depends upon the exact preform shape and structure required.

  There are four separate sequences of row and column motion, which act to interlock the yarns and produce the braided preform. The yarns are mechanically forced into the structure between each step to consolidate the structure in a similar process to the use of a reed in weaving. Two-step braiding is unlike the four-step process because the two-step includes a large number of yarns fixed in the axial direction and a fewer number of braiding yarns. The process consists of two steps in which the braiding carriers move completely through the structure between the axial carriers. This relatively simple sequence of motions is capable of forming performs of essentially any shape, including circular and hollow shapes. Unlike the four steps process the two steps process does not require mechanical compaction the motions involved in the process allows the braid to be pulled tight by yarn tension alone. The last type of braiding is multi-layer interlocking braiding that consists of a number of standard circular braiders being joined together to form a cylindrical braiding frame. This frame has a number of parallel braiding tracks around the circumference of the cylinder, but the mechanism allows the transfer of yarn carriers between adjacent tracks forming a multilayer braided fabric with yarns interlocking to adjacent layers.

  The multilayer interlock braid differs from both the four-step and two-step braids in that the interlocking yarns are primarily in the plane of the structure and thus do not significantly reduce the in-plane properties of the perform. The four-step and two-step processes produce a greater degree of interlinking as the braiding yarns travel through the thickness of the preform, but therefore contribute less to the in-plane performance of the preform. A disadvantage of the multilayer interlock equipment is that due to the conventional sinusoidal movement of the yarn carriers to form the preform, the equipment is not able to have the density of yarn carriers that is possible with the two-step and four-step machines.
- Knitting fiber preforms can be done with the traditional methods of warp and (weft) knitting, and the fabric produced is often regarded by many as two-dimensional fabric, but machines with two or more needle beds are capable of producing multilayer fabrics with yams that traverse between the layers. Developments in electronic controls for needle selection and knit loop transfer and in the sophisticated mechanisms that allow specific areas of the fabric to be held and their movement controlled. This has allowed the fabric to form itself into the required three-dimensional perform shape with a minimum of material wastage.
- Stitching is arguably the simplest of the four main textile manufacturing techniques and one that can be performed with the smallest investment in specialized machinery.

Basically the stitching process consists of inserting a needle, carrying the stitch thread, through a stack of fabric layers to form a three-dimensional structure. The advantages of stitching are that it is possible to stitch both dry and prepreg fabric, although the tackiness of prepare makes the process difficult and generally creates more damage within the prepreg material than in the dry fabric. Stitching also utilizes the standard two-dimensional fabrics that are commonly in use within the composite industry, therefore, there is a sense of familiarity concerning the material systems. The use of standard fabric also allows a greater degree of flexibility in the fabric lay-up of the component than is possible with the other textile processes, which have restrictions on the fiber orientations that can be produced.

Reinforcing fiber is manufactured in both two-dimensional and three-dimensional orientations:

- Two-dimensional fiber-reinforced polymer is characterized by a laminated structure in which the fibers are only aligned along the plane in x- and y-direction of the material. This means that no fibers are aligned in the through thickness or the z-direction, this lack of alignment in the through thickness can create a disadvantage in cost and processing. Costs and labor increase because conventional processing techniques used to fabricate composites, such as wet hand lay-up, autoclave and RTM, require a high amount of skilled labor to cut, stack and consolidate into a preformed component.
- Three-dimensional fiber-reinforced polymer composites are materials with three-dimensional fiber structures that incorporate fibers in the x-, y-, and z-direction. The development of three-dimensional orientations arose from industry's need to reduce fabrication costs, to increase through-thickness mechanical properties, and to improve impact damage tolerance; all were problems associated with two-dimensional FRP.[47]

1.8.4.2.1.2 Molding process

A rigid structure is usually used to establish the shape of FRP components. Parts can be laid-up on a flat surface referred to as a 'caul plate' or on a cylindrical structure referred to as a 'mandrel.' However, most fiber-reinforced plastic parts are created with a mold or 'tool.' Molds can be concave female molds, male molds, or the mold can completely enclose the part with a top and bottom mold.

The moulding processes of FRP plastics begin by placing the fiber preform on or in the mold. The fiber preform can be dry fiber, or fiber that already contains a measured amount of resin called 'prepreg.' Dry fibers are 'wetted' with resin either by hand or the resin is injected into a closed mold. The part is then cured, leaving the matrix and fibers in the shape created by the mold. Heat and/or pressure are sometimes used to cure the resin and improve the quality of the final part. The different methods of forming are listed below.[51]

1.8.4.2.1.2.1 Bladder molding

Individual sheets of prepreg material are laid-up and placed in a female-style mould along with a balloon-like bladder. The mould is closed and placed in a heated press. Finally, the bladder is pressurized forcing the layers of material against the mould walls. The part is cured and removed from the hot mould. Bladder molding is a closed molding process with a relatively short cure cycle between 15 and 60 min making it ideal for making complex hollow geometric shapes at competitive costs.

1.8.4.2.1.2.2 Compression molding

Compression moulding is a composite manufacturing process normally used to produce composite components in high production volume such as automotive components. There are two types of compression moulding process, i.e., cold compression and hot compression moldings. In this process, for thermosetting matrices, normally an intermediate material called moulding compound is used. It is really a semi-cured composite. Sheet moulding compound and bulk moulding compound (BMC) are two widely used thermosetting-based moulding compounds. For thermoplastic polymer, moulding compound normally used is glass mat thermoplastics (GMT). For preparing composite specimens in the laboratory scale compression moulding, composite pellets are normally prepared using internal mixer and twin screw extruder. In compression moulding process, pressure is applied in cold compression and pressure and temperature in hot compression moulding after the moulding performs are placed in a mould cavity. In cold compression moulding, curing process takes place at room temperature while for hot press it takes place by applying heat to the mould and it in turn being transferred to the composites. Matrices used in this process include UP, vinyl ester and phenolic for thermosetting polymers while among the thermoplastic polymers, PP, polyamide, and PEEK can be used.

Wirawan *et al.*[53] and El-Shekeil *et al.*[54] used laboratory scale compression moulding (**Figure 6**) to prepare composite specimens from sugar cane bagasse and PVC, and kenaf and TPU, respectively. The intermediate materials were made using internal mixer. The intermediate materials were placed into the mould and the heat and pressure were applied to form the composite plates. Hot pressing was then carried out at a temperature around 170 °C for 12.5 min and the mixture

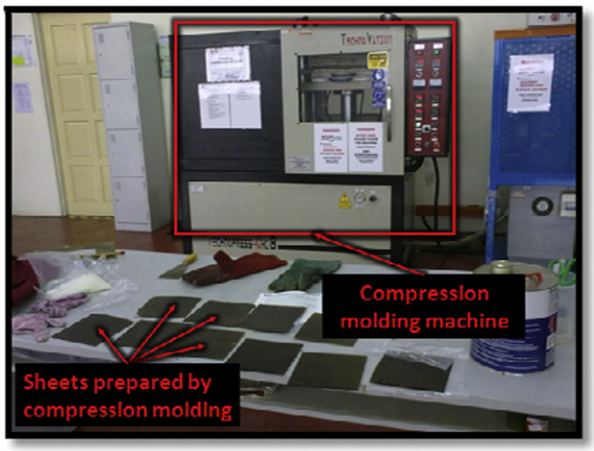

Figure 6 Hot compression moulding machine. Courtesy of Yousuf El-Shekeil.[55]

was cooled under pressure to room temperature. The mechanical and thermal properties of the composites were then determined.

1.8.4.2.1.2.3 Vacuum bagging

Vacuum bagging is one of the processes in the category of prepreg moulding. Another process is called autoclave moulding. The different between these two processes in on the way curing process was done; one in vacuum bag (oven) and the other in an autoclave. Vacuum bagging is a composite manufacturing process that utilizes a vacuum bag to provide compaction pressure and consolidation of plies within the laminate. It is an extended version of hand or wet lay-up process. It also sometimes called vacuum bag moulding.[56] In this process, a mould base is placed horizontally. Then composite prepreg laminates are stacked onto the mould base. Then a series of equipment's and materials are covered onto the composite layers such as release film layer, air-bleeder layer, blocked film layer, and breather layer. Finally, a vacuum bag is placed to cover the composite laminate and all the layers. The vacuum bag is then sealed by means of sealers. Polymer materials that can be used in this process include epoxy, phenolic, and polyimide.

Mariatti and Abdul Khalil[57] used vacuum bagging process to prepare samples of bagasse fiber reinforced UP composites. Two components of bagasse, i.e., rind (outer part) and pith (inner part) were used as reinforcement fibers in composites. The hardener used in this experiment was methyl ethyl ketone peroxide (MEKP). Pressure was applied to the laid-up laminates in order to consolidate the final composites and the bonding between composite plies. Volatiles and trapped air in the laminates were drawn out using vacuum and void contents were minimized. Curing process took place at room temperature. Composite specimens were then tested mechanically to determine tensile, flexural, and impact properties of the composites. Improvements were made on mechanical properties of bagasse fiber UP composites by fiber chemical treatment using sodium hydroxide and acrylic acid.

1.8.4.2.1.2.4 Mandrel wrapping

Sheets of prepreg material are wrapped around a steel or aluminum mandrel. The prepreg material is compacted by nylon or PP cello tape. Parts are typically batch cured by hanging in an oven. After cure the cello and mandrel are removed leaving a hollow carbon tube. This process creates strong and robust hollow carbon tubes.

1.8.4.2.1.2.5 Hand lay-up

Hand lay-up is an open moulding process to produce polymer composite product. This is a labor intensive process where high skill operator is required to perform the fabrication task. A mould release agent is applied onto the mould surface for ease of removing of finished composite products. The laying-up of a component begins with applying gel coat to the mould surface. It is resin rich layer and the purpose is to prevent the fibers appearing on the mould surface. The composites are then prepared by placing a fiber reinforcement and by adding polymer resin onto it. A roller is used to consolidate the composites and composites are made layer by layer. The process is repeated with more layers until the desired thickness is obtained. Then the composites are cured at room temperature or in an oven. Thermosetting resins like UP, vinyl ester, and epoxy are among the most commonly used resins.

Hand lay-up or also known as wet lay-up has been used to produce components from natural-fiber composites for many decades now. Ford had used hand lay-up process to fabricate automotive body from natural fiber-reinforced soya-based polymer composites around a decade ago. Misri *et al.*[58] have used hand lay-up process to develop a small boat from hybrid glass-sugar palm fiber reinforced UP composites. The fabrication work was carried out in association with an established boat builder. This process was labor intensive and required high skill operators to fabricate the boat. The mould was made from glass fiber-reinforced polyester composite and it was developed in such a way that a very high quality surface was obtained. Then mould release agent was placed onto the mould surface to prevent the component sticking to the mould. Then glass fibers were laid-up followed by resin and they were consolidated using a roller. MEKP was used as a hardener. The process is repeated with sugar palm fibers and the process continued, layer by layer until the desired thickness of the composites was achieved. **Figure 7** shows hand lay-up process of hybrid glass-sugar palm fiber composite boat.

1.8.4.2.1.2.6 Chopper gun

Continuous strand of fiber-glass are pushed through a hand-held gun that both chops the strands and combines them with a catalyzed resin such as polyester. The impregnated chopped glass is shot onto the mould surface in whatever thickness the design and human operator think is appropriate. This process is good for large production runs at economical cost, but produces geometric shapes with less strength than other molding processes and has poor dimensional tolerance.

1.8.4.2.1.2.7 Filament winding

Filament winding is a composite manufacturing process to produce components that are normally circular in shape. It can be considered an open mould process and the mould is actually a rotating mandrel. In this process, continuous fiber rovings are being drawn by a puller through a resin bath. The

Figure 7 Hand lay-up process for hybrid glass-sugar palm composite boat. Courtesy of Sairizal Misri.[55]

Figure 8 Pultrusion process of kenaf fiber composites. Courtesy of Mohd Fairuz Abdul Manab.[55]

pre-impregnated composites are in turn being wound around the rotating mandrel. The composites are also being traversed in x-direction so that even distribution of the composites along the length of the mandrel can be achieved. There are three types of winding patterns in the filament winding process, i.e., hoop, helical, and polar windings.

Misri *et al.*[59] developed kenaf fiber reinforced UP composite hollow shafts and studied their mechanical behavior. Continuous kenaf fiber rovings were pulled through a drum type resin bath and the pre-impregnated fiber composites were wound around hollow aluminum rotating mandrel. They studied various properties such as tensile and torsion properties of the composites and such findings were compared with the results of FEA. The major problem with developing filament wound kenaf fiber composites is to obtain consistently smooth surface of shafts. Secondary processing like milling is required.

1.8.4.2.1.2.8 Pultrusion

Pultrusion is a combination of two words; pull and extrusion. The process is similar to extrusion process but in pultrusion, the product is developed by pulling the materials rather than pushing the materials through the die as in the case of extrusion. Continuous fiber rovings or tapes are pulled by means of a puller through a resin bath of thermosetting polymer. Examples of thermosetting polymers that can be used in this process include epoxy, and UP. The resulting impregnated fiber composites leave the resin bath and are being pulled and passed through a series of forming dies. The shape of the final product follows the shape of the cross of the dies and the shape can be circular, rectangular, square, I shaped, and H shaped sections. The composite is also cured in one of the dies. The end products are normally in the form of rods, and bars. At the end of the pultrusion process, the products are cut to the required lengths.

Fairuz *et al.*[60] reported the work on pultruded kenaf fiber reinforced vinyl ester composites using pultrusion process. Kenaf composite rods were produced. In this study, three different parameters were investigated, i.e., speeds, temperatures and filler loadings. Taguchi's design of experiment was used to determine the number of experiments to be conducted. Specimens in the form of rods were produced at three different speeds by fixing temperature and filler loading. Then the same is repeated for different parameters; temperatures and filler loadings. Mechanical properties of the composite rod specimens such as tensile, flexural, and impact properties were tested for each parameter. **Figure 8** shows the pultrusion process of kenaf fiber-reinforced composites.

1.8.4.2.1.2.9 Resin infusion

Fabrics are placed into a mould which wet resin is then injected into. Resin is typically pressurized and forced into a cavity which is under vacuum in the RTM process. Resin is entirely pulled into cavity under vacuum in the VARTM (vacuum assisted resin transfer molding) process. This molding process allows precise tolerances and detailed shaping but can sometimes fail to fully saturate the fabric leading to weak spots in the final shape.

1.8.5 Machining of Natural Fiber-Reinforced Composite

There are various new methods for machining of composites, such as waterjet machining and laser machining. Due to the high cost of such processes, drilling is still used widely as a major secondary machining process, due to the need for structural joining of composites materials. Machining involves the removal of any extra or unwanted material. Some of the most common machining processed are drilling, turning, and milling. Machining of composites brings with it some major problems, including rapid tool wear due to the abrasiveness of composites, fiber fracture, and matrix breaking. Another known nuisance has been delamination, or the breaking of materials fibers, which creates a bad surface finish and caused stress concentrations at such regions. Earlier composites were machined like metals. But poor surface finish and faster tool wear led to the further study of composite machining. Unlike

metals, composites need separate tools and working conditions. Although tools used for machining of metals can still be used for composites, care must be taken to maintain optimum levels of, feed rate, thrust force, and other factors. One of the main advantages of composites has been the fact that an entire part can be manufactured. This minimizes the machining of composites. However with part integration, sometimes composites need to be joined to form a larger part, which means that a certain amount of machining needs to be done for composites too. Since the last decade, a great deal of emphasis has been focused on the development and application of natural fiber-reinforced composite materials in many industries. Needless to say, this called special attention of the automotive industry for the application of many parts such as interior panels. Increased use of natural-fiber composites implies that there is demand for joining of some of the parts together.

Machining of a fiber-reinforced composite depends on the properties of the fibers and the matrix as well as its response to the machining process. In addition, the choice of the specific process depends upon the following factors: type of machining operation, part geometry and size, finish and accuracy requirements, number of parts, diversity of parts including the materials of the parts, availability of appropriate machine and cutting tools, availability of in-house technology, current machining practice, manufacturing schedule, capital requirements and justification for new equipment, and overall costs. Certain machining operations may not be possible at all with some composite materials. For example, it is not possible to machine SiC whisker reinforced alumina with a single-point cutting tool, even with a diamond tool. It may, however, be possible to shape it by diamond grinding or by some of the nonconventional machining processes, such as laser machining or ultrasonic-assisted machining. In other cases more than one process may be candidate processes and the specific process chosen depends on the factors outlined earlier. Of course, the general tendency is to use current machining practices by adopting existing equipment for this application. This is particularly true of composite machining in small manufacturing shops in view of capital limitations for procuring new machinery or new technology. This may not be the case with large companies, such as Boeing, Lockheed, or General Dynamics, where resources are normally available, if justified. Even a particular process chosen now for machining composites may have to be abandoned at a later date because of changes in the factors outlined earlier. For example, the lot size may be increased significantly, necessitating a review of alternate manufacturing processes, or new technology or a technology not currently practiced in the plant may become available or be economically attractive.

1.8.5.1 Safety Considerations

Safety is the main aspect when machining. It can release some finer fractions to atmosphere when machining the fiber-like composites. Besides, it can be very harmful when some of the chemicals from polymer-based composites are released. This is because of the heat and thermal damage when machining take part. In the case of health, it has been established that fibrous materials like asbestos and glass can cause cancer and become suspected agents respectively. Also, there will be other medical problems such as respiratory complications if constant exposure comes from both inorganic fibers and organic compounds, which are released during the machining of polymer-based composites.

It has been reported that fibers used in composites have diameter ranges from 9 to 24 J Lm, with a median length of 10–17 J Lm. Fibers of this size are not respirable and may not reach the lung. If, however, these fibers are longitudinally split during machining they can be potentially harmful. Antonson and Runmark[61] studied the effect of airborne fibrous glass and dust originating from machining-reinforced plastics. They examined the possibility of longitudinal fiber division during machining of reinforced polyester plastic and whether respirable glass fibers can be produced. Their results show that such a division does not occur in the machining of glass-fiber-reinforced polyester composite.

Doyle and Kokasa[62] conducted laser-machining tests on a Kevlar fabric poly (p-phenylene terephthalamide) using a CO_2 laser at a rate of 150 in. min^{-1} and l-kW power. They collected the chemical by-products produced during cutting and analyzed these products using a gas chromotography, mass spectroscopy and found a number of toxic- and cancer-producing compounds. They recommended adequate ventilation and appropriate safety procedures to prevent exposure of personnel to these gases in the laser-cutting facility. In machining GFRPs, they found glass particles. According to Doyle and Kokasa,[62] the *E*-glass fibers vaporize during laser cutting and then condense as small beads ranging from 200 nm to 0.5 μm. Since particles less than 0.5 μm can permeate into the deepest recess of the lungs, they can pose a health danger to the workers in the cutting facility. Konig and Rummenholler[42] investigated, among other things, the safety aspects of the milling of glass and carbon fiber-reinforced plastics. Fine dust particles that can cause respiratory problems were found to be about 1% of the total dust collected during milling. Also, fine dust settles considerably slower than coarser particles, so they could represent a risk to the health of the operator even after the operation is completed.[63]

1.8.5.2 Factors Affecting the Cut Quality of Natural Fiber-Reinforced Composites

Carbon, glass, and aramid are the examples of synthetic fiber-reinforced composites, which become famous in machining sector because of their wide applications in various industries. Besides, the natural fiber-reinforced composite also shows interest and slowly gaining momentum in the machining and cutting nowadays. Generally, the performance and cut quality of the latter composites can be measured in terms of the size of kerf width, surface roughness, burr height, and tool wear. But in this chapter, only two cut quality has been taken into account.

1.8.5.2.1 Kerf width

Kerf width is the width of the material that has been removed during the cutting process. These can be described how much the composite is removed by a saw. This is because every teeth

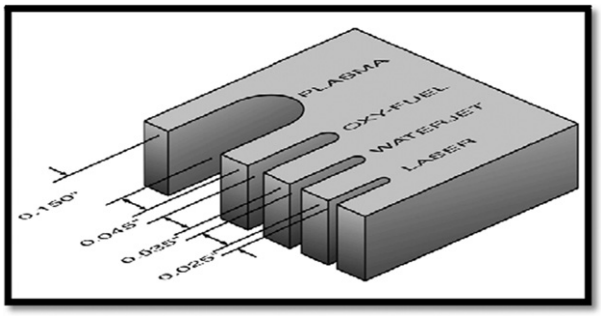

Figure 9 Comparison of kerf width using different types of machine.[64]

on a saw are bent to the side make it remove more material than the width of the saw blade itself. Also, it can prevent the blade from getting stuck in the composites. Recently, when referring to the angle on the edge of the part, some people use that term but it is the incorrect use of the word. Actually, for consistency, the word 'kerf' should only be used when talking about the actual cut width.

1.8.5.2.1.1 Different in process of kerf

Each cutting process removes a different amount of material, or kerf. The more precise processes, like waterjet and laser, remove a smaller amount of kerf, which is one of the reasons they can be more precise. A typical example shown here in **Figure 9**, is for 1/2″ thick mild steel.

Typical kerf width for 1/2″ thick commercial standard:

- Plasma: 0.150‴
- Oxy-fuel: 0.045″
- Waterjet: 0.035″
- Laser: 0.025″

1.8.5.2.1.2 Kerf variations

Not only does kerf width vary from one process to the next but also there are lots of things that affect the kerf width for each process. Of course, as the thickness of material increases, it takes more power to cut through it. In the case of plasma, that means higher current and a larger nozzle. Laser increases power. Oxy-fuel cutting uses a larger nozzle with a wider cutting oxygen stream and hotter preheats. Waterjet uses either a larger nozzle/orifice combination, or a slower cutting speed. Regardless of the process, as the plate gets thicker, the kerf gets wider. There are variations within each process too. For example, when plasma cutting, the actual kerf width depends not only on the cutting current but also on the torch height, speed, and gas settings.

1.8.5.2.2 Surface roughness

There are several types of surface texture which includes roughness, waviness, lay and flaws, see **Figure 10**. Nano roughness and microroughness are the examples for the roughness texture while macroroughness is in waviness part. If we go further into the parts, this roughness are formed by fluctuations in the surface of short wavelengths which characterized by hills and valleys of varying amplitudes and spacings. Hills and valleys also can be defined as local maxima and minima, respectively. Local maxima or known also as asperities are referred to as peaks in a profile and summits in a surface map. Nano- and microroughness include those features intrinsic to the production process. These are considered to include traverse feed marks and other irregularities within the limits of the roughness sampling length. Waviness is the surface irregularity of longer wavelengths and is referred to as macroroughness. Waviness may result from such factors as machine or workpiece deflections, vibration, chatter, heat treatment, or warping strains. Waviness includes all irregularities whose spacing is greater than the roughness sampling length and less than the waviness sampling length. Lay is the principal direction of the predominant surface pattern, ordinarily determined by the production method. Flaws are unintentional, unexpected, and unwanted interruptions in the texture. In addition, the surface may contain gross deviations from nominal shape of very long wavelength, which is known as errors of form. They are not normally considered part of the surface texture.

The evaluation of surface roughness of machined parts using a direct contact method has limited flexibility in handling the different geometrical parts to be measured. Surface roughness also affects several functional attributes of parts, such as friction, wear and tear, light reflection, heat transmission, ability of distributing and holding a lubricant, coating, etc. Therefore, the desired surface finish is usually specified and appropriate processes are required to maintain the quality. Hence, the inspection of surface roughness of the workpiece is very important to assess the quality of a component. Alternately, optical measuring methods are applied to overcome the limitations of stylus method, but they are also sensitive to lighting conditions and noise. The technique proposed in this work, requires no apriority information about the lighting conditions and source of noise. It is important that the specification should include a 'maximum' transverse surface roughness requirement. scanning electron microscopy revealed that the samples with a high surface roughness are heavily damaged by the polishing operation, whilst those with low surface roughness are relatively undamaged, showing only light scoring of the surface.[66,67]

Of these measures, the first two criteria are deemed important from the manufacturing perspective and dependable upon other parameters such as:

- Blade speed,
- Feed rate,
- Fiber loading (fiber content) within the composite, and
- Coolant conditions.

As the number of both measurements and parameters increases, the interactions are becoming increasingly laborious to interpret. The relationships between cut characteristics and processing parameters can be inherently complex and multivariate. This is usually observed in high-volume cutting of numerous fiber composites. Such systems often are called as 'gray.' Gray system theory has been widely used and has shown useful results especially in situations where the data is limited and/or incomplete.[68,69] Besides, it provides an efficient solution to the uncertainty, multi-input and discrete data problem. For example, according to the Taguchi quality design concept, a L18 mixed-orthogonal-array table was chosen for experiments. With both Gray relational analysis (GRA) and statistical method, it is found that the table-feed rate has a significant

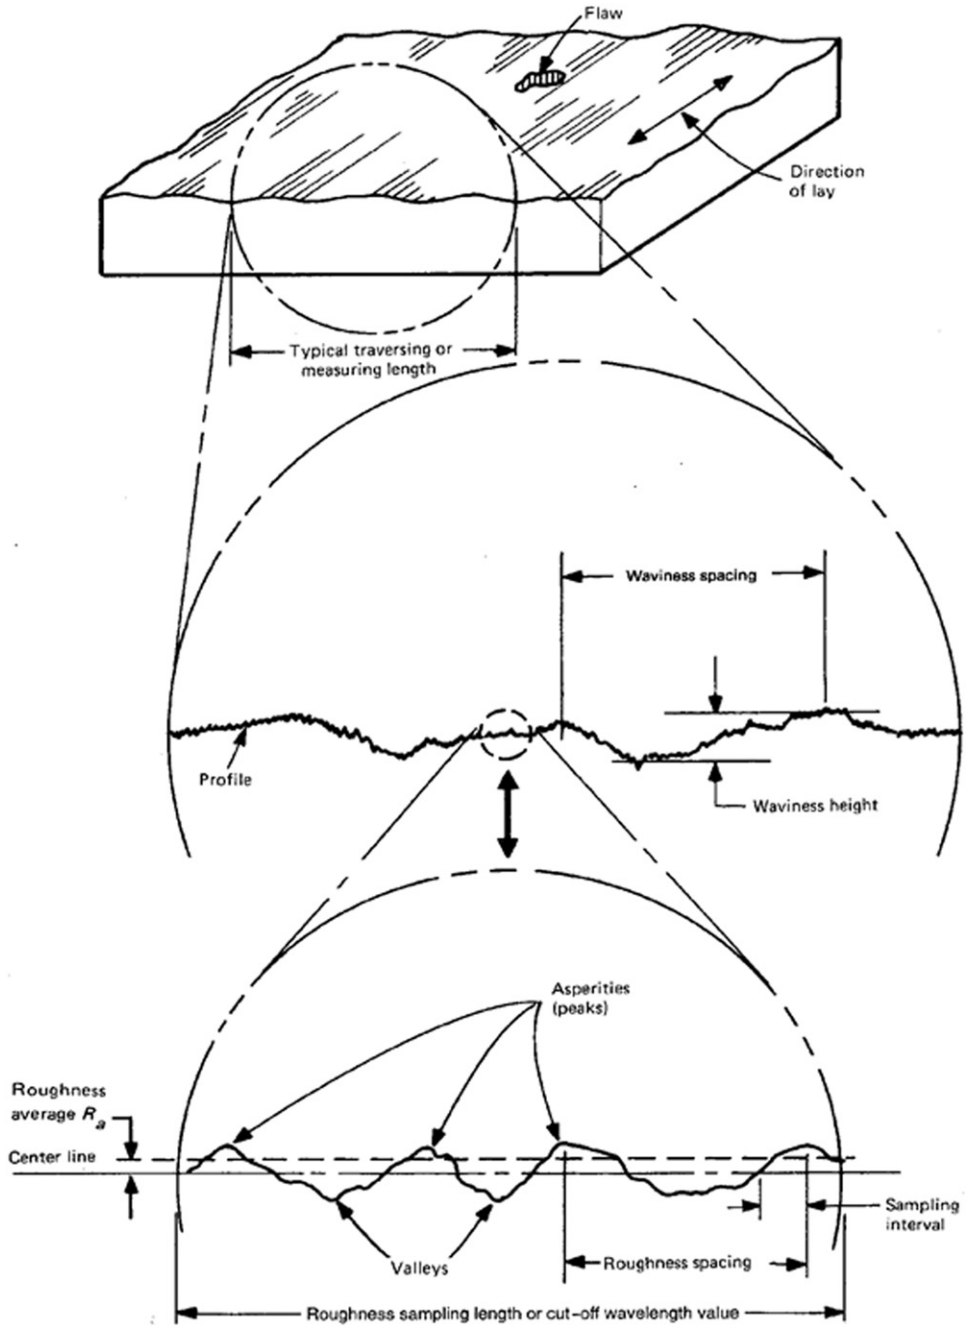

Figure 10 Pictorial display of surface texture.[65]

influence on the machining speed, whilst the gap width and the surface roughness are mainly influenced by pulse-on time. Also, the Gray relational grade will utilize the discrete measurement method to measure the distance.[70]

1.8.6 Application of GRA Technique in Optimization of Cut Characteristics

The purpose of this chapter is to present an efficient method to find the significant parameters affecting machining performance by integrating GRA and statistical method. Also, the optimal machining parameters setting for maximum machining speed and minimum surface roughness can be obtained by applying GRA. Furthermore, it is feasible to obtain optimal machining parameters for a desired surface roughness and maximum metal removal rate by the GRA.

This study concerns the employment of GRA to determine the optimized cut characteristics in precision cutting of CPH fibers-reinforced TPU composites.[71] Polyurethane is widely found in the form of thermoset and thermoplastic properties. Polyurethane thermosets have been reinforced with hard

wood,[72] flax and jute,[73] rice husk,[74] and sisal.[75] However, the study pertaining to natural fiber reinforcement of TPU appears limited to kenaf substrate only.[34,76–79] To the authors' knowledge, there is no published work on CPH fibers-reinforced TPU composites. CPH is a waste product after extracting cocoa bean from cocoa pod and it is abundantly found in Malaysia.[80] Since CPH fiber has properties comparable to synthetic fibers, use of CPH to reinforce TPU has immense economic and environmental benefits.

In this paper, the cut characteristics, namely kerf width (material loss) and surface roughness (surface finish) are optimized as a function of blade speed, feed rate of the blade and cocoa fiber loading in the composite.[81] Minimum size of kerf width signifies minimum material loss whilst low value of surface roughness can be understood as good surface finish. These two important characteristics are desirable to reduce cost associated with post-processing step and minimize waste. Here we report a central composite design (CCD) method in combination with GRA to optimize the cutting process with consideration of the aforementioned multiple cut qualities. The experiment is described in the following section.[82]

1.8.6.1 Experimental Methods and Measurements

1.8.6.1.1 Cocoa fiber composites

Cocoa fiber-reinforced composite was made up of raw CPH and polyester-based TPU. The CPH was obtained from Cocoa Research & Development Centre in Pahang, Malaysia, while TPU was supplied by Bayer Co. (Malaysia) Sdn. Bhd. The main properties of the composite constituents are given in Table 2.

1.8.6.1.2 Preparation of cocoa fiber composite

TPU/CPH composite was initially mixed using Haake Polydrive R600 internal mixer at the optimum processing parameters of 190 °C, 11 min and 40 rpm temperature, time and rotating speed, respectively. Matrix was charged into the mixer until torque was stabilized then fiber was added into the mixer. The sample was preheated for 7 min and then hot pressed for 10 min at 190 °C. The mold was then cold pressed for 5 min. The composite were prepared with different fiber loadings were prepared: 20, 30, and 40% (by weight). It should be noted that as a result of this process, the measured thickness of all composites vary in the region of 3–4 mm.

Table 2 Selected properties of thermoplastic polyurethane

Specific gravity	*Tensile strength*	*Melting temperature*	*Hardness*
1.21	48 MPa*	210 °C	55D

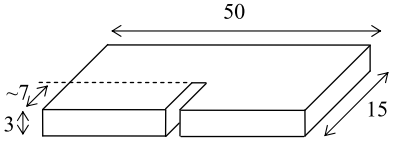

Figure 11 Schematic of a cut profile (dimensions in mm). The cut depth is manually controlled to about 7 mm, i.e., slightly less than the width of the composite.[83]

Finally, the prepared composite was manually cut to the desired dimension as shown in Figure 11.

1.8.6.1.3 Specification of cutting machine

A precision linear saw (Buehler IsoMeT® 5000) was used to precisely cut the composite substrates. It has maximum blade speed of 5000 rpm and maximum feed rate of 19 mm min^{-1}. The saw can be set to virtually cut all sorts of materials including metals, ceramics, composites, laminates, plastic, and biomaterials with minimal deformation. To ensure process repeatability with minimum variation between experiments, the composite was firmly clamped using a custom-made jig. The composite was made stationary throughout the experiment with its surface positioned parallel to the table top. Figure 11 shows the schematic diagram of the cut profile. It was experimentally found that cut depth that is longer than ½ of the width could result in unwanted vibration on both sides of the composites due to their interaction with the blade. Consequently, a large kerf width was formed. For this reason, the depth of the cut was set to be slightly lesser than the sample's width. An abrasive blade of about 450 μm thick was used to perform the cut. In this experiment, no coolant was used since the hydrophilic nature of natural fibers adversely affects the composite properties.[84]

1.8.6.1.4 Selection of cutting parameters

The experiment involved a number of fixed and variable parameters. The fixed parameters are material thickness, blade properties (thickness, diameter, and material) whereas the variables are blade speed, feed rate of the blade, and fiber loading. The selected levels of all parameters are listed in Table 3. Due to conversion from imperial to metric unit, the programmable feed rate values in the machine are no longer integers.

1.8.6.1.5 Design of experiments

A CCD method was used to determine the multi-performance characteristics of cut using precision linear saw. The experimental layout for the cutting process parameters and the corresponding experimental data is presented in Table 4. The first eight experiments composed of 2^3 factorial designs while the center point (experiment number 9) consists of one single set of experimental parameters. Although not explored in this paper, the CCD is often employed in response surface methodology to determine the complex interaction between all parameters while the center point is used to estimate pure error.[85] Mathematical relations will be discussed in the future manuscript. In total, nine experiments were performed.

Table 3 Precision cutting parameters and their levels[82]

Notation	*Parameter*	*Level*		
		−1	*0*	*1*
F	Feed rate (mm min^{-1})	12.1	15.2	18.0
S	Blade speed (rpm)	2500	3500	4500
C	Fiber loading (%)	20	30	40

1.8.6.1.6 Evaluation of cut quality characteristics

In order to evaluate the characteristics of the cut, all specimens are subjected to surface roughness and visual inspections. A digital microscope of $\times 40$ magnification giving a resolution of 0.01 μm on the plane of focus was used for measuring the kerf width. On the other hand, a Perthometer (Mahr) was used for measuring the surface roughness. These two parameters were measured three times for each set of experiment and the averages were calculated and reported in Table 4. In all cases, the width of kerf was measured approximately 500 μm, comparable with the thickness of the blade.

An actual sample featuring the differences in terms of cut characteristics between manual and machine cuts are shown in Figure 12. The characteristics of the machine cut are significantly better with regards to cut straightness and surface roughness.

In addition, variation in the surface roughness with kerf width is also studied (see Figure 13), however, a correlation between the two cannot be established directly. It appears that high-blade speed and high-feed rate at minimum fiber content (experiment number 4) result in large kerf width and high surface roughness. On the other hand, low blade speed and low feed rate at minimum fiber content (experiment number 1) produce small kerf width and low surface roughness. Interestingly, this trend reverses when the composite has maximum fiber content (experiment number 5 and 8).

Table 4 Experimental layout and multi-performance results

Experiment no.	*Run order*	*Cutting parameters*			*Surface roughness,* R_a *(μm)*	*Mean kerf width (μm)*
		F	*S*	*C*		
1	1	−1	−1	−1	1.035	476.19

1.8.6.2 Determination of the Optimal Joining Condition

1.8.6.2.1 Gray relational analysis

Although it is straightforward to determine the optimal parametric configuration (small kerf width with minimum possible surface roughness) by referring to Figure 13, a systematic approach is necessary when one has to machine a number of different composites with varying fiber and parent polymer contents. The complexity to determine the optimum process parameters can be simplified using GRA. GRA is employed to analyze the degree of relation in a discrete progression. The procedure entails the following steps:

1.8.6.2.2 Normalization of original data

The experimental data of kerf width and surface roughness are initially normalized at the scale varying between 0 and 1.0. The desired characteristics of both kerf width and surface roughness are 'lower-the-better' therefore the normalization, x_{ij}, for the 'lower-the-better' quality characteristic can be expressed as:

$$x_{ij} = \frac{\max_j \gamma_{ij} - \gamma_{ij}}{\max_j \gamma_{ij} - \min_j \gamma_{ij}} \quad [1]$$

where γ_{ij} is the ith quality characteristic in the jth experiment. Normalized results with larger values correspond to the better quality. Table 5 shows the normalized results for both types of quality characteristics.

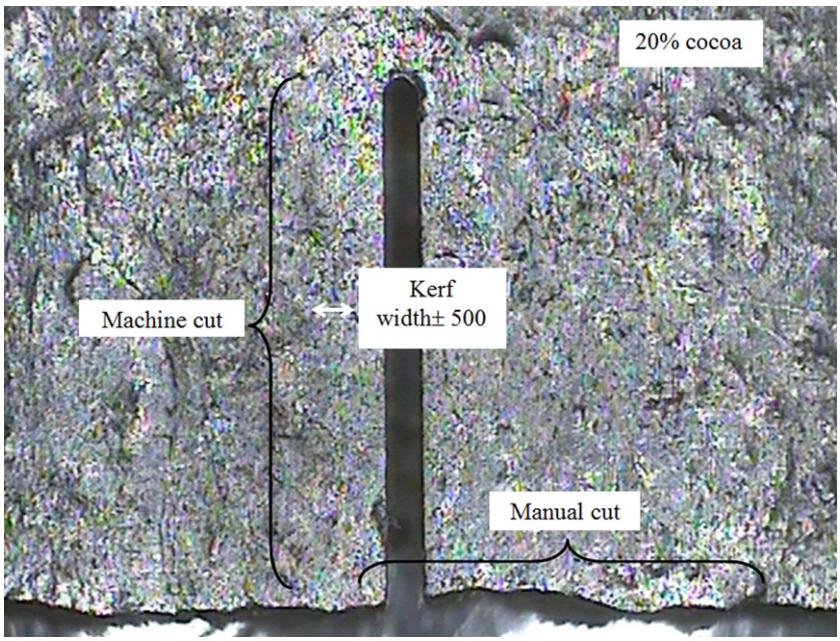

Figure 12 Actual sample showing cut edges between manual and machine cuts.

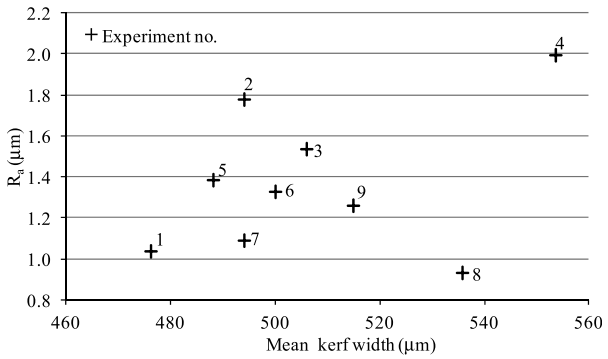

Figure 13 Variation of the surface roughness with kerf width.

Table 5 Data pre-processing of the experimental results.

7	0.8511	0.7692
8	1.0000	0.2308
9	0.6909	0.5000

1.8.6.2.3 Calculation of gray relational coefficient

Next, the actual experimental results are compared to an ideal experimental data which can be coined as relational coefficients, ξ_{ij}, and is calculated such that:

$$\xi_{ij} = \frac{\min_i \min_j |x_i^0 - x_{ij}| + \zeta \max_i \max_j |x_i^0 - x_{ij}|}{|x_i^0 - x_{ij}| + \zeta \max_i \max_j |x_i^0 - x_{ij}|} \quad [2]$$

where x_i^0 is the ideal normalized result (i.e., best normalized result = 1.0) for the ith quality characteristics and $\xi[0, 1]$ is distinguishing coefficient. Deng[10] noted that $\xi = 0.5$ is usually applied. **Table 6** lists the gray relational coefficients using equal weights for each set of experiment based on CCD procedure.

1.8.6.2.4 Calculating the gray relational grade

Gray relational grade is an indicator of the multiple quality characteristics. It is calculated by integrating the gray relational coefficients of each experiment using a weighting method and is given by:

$$\gamma_j = \frac{1}{m} \sum_{i=1}^{m} w_i \xi_{ij} \quad [3]$$

where γ_j is the gray relational grade for the jth experiment, w_i is the weighting factor for the ith quality characteristic, and m is the number of quality characteristics. Experiments on the precision cutting were aimed to get small kerf width and low surface roughness. Small kerf width can be understood as minimal material loss while low surface roughness avoids the need of post-processing step to improve edge finish. For the calculation of gray relational grades, the weighting ratio for all qualities is set as:

$$\text{Surface roughness} : \text{kerf width} = 0.5 : 0.5 \quad [4]$$

This implies that both surface roughness and kerf width characteristics have an equal importance in precision cutting process. The allocation of weighting ratio, however, vary and generally depends on some desired machining/manufacturing requirements.[2,3] The resulting grades are tabulated in **Table 7**. Higher values of the gray relational grade signify a close match between the experimental result and the ideal value.

In the present work, experiment number 1 shows best multi-response characteristics out of total 9 experiments having highest gray relational grade (as shown in **Figure 14**). The second highest gray relational grade is represented by experiment number 7. Both experiments number 1 and 7 have equal feed rate of 12.1 mm min^{-1}, however, the blade speed for experiment number 1 is lesser than that of number 7. In addition, the sample in experiment number 1 has minimum fiber content (20% by weight) whereas experiment number 7 has maximum fiber content (40% by weight). By referring to **Figure 14**, it is also clear that experiment number 4 (20% fiber content, high-feed rate, and high-blade speed) has the lowest gray relational grade. On this basis, one may conclude that the effects of fiber content on cut characteristics are insignificant as compared to feed rate and blade speed. This may be attributed to the low abrasiveness of natural fibers as compared to the synthetic fibers, which are very

abrasive to the blade. Therefore, variation in fiber loading has insignificant effect on cut characteristics.

1.8.7 Conclusions

Natural fiber-reinforced composites becomes the new options recently to supersede the others synthetic fibers. With higher advantages like biodegradable, renewable, and of course much cheaper makes this natural fibers the main choice in the industrial sector. In this chapter, a CCD method along with GRA was used to determine the optimum precision cutting process parameters having several quality characteristics. The complexity of dealing with a number of variables was simplified using CCD method. The optimum parameters were quantitatively determined based on the highest gray relational grade (experiment number 1). The experiment was performed at minimum feed rate (12.1 mm s^{-1}), minimum blade speed (2500 rpm), and minimum fiber content (20% by weight). The influence of each parameter on cut quality was also discussed. It was found that the feed rate and blade speed have dominant effects compared to the fiber content.

1.9.1 Introduction

Wire electrical discharge machining (WEDM) is one of the most commonly known and applied nonconventional machining processes in today's industrial practice. WEDM is an electro-thermal machining process for electrically conductive materials. In this procedure, improvements in WEDM components have rapidly taken place, along with improvements in the control unit.

In WEDM, the cutting tool (wire electrode) never touches the workpiece during the machining process. Because WEDM does not involve cutting forces, it is commonly used in cases requiring low residual stresses. Any electrically conductive material can be cut using WEDM, regardless of the hardness, ranging from public metals, including copper, aluminum, tool steel, and brass, to uncommon new alloys such as tungsten carbide, wafer silicon, cast alloys, Inconel, titanium, carbide, and polycrystalline diamond. Moreover, WEDM can machine high strength, highly corrosive-resistant, highly wear-resistant, and difficult-to-machine materials such as metal matrix composites (MMCs) and cemented carbides.[1] Besides machining electrically conductive materials, some insulating ceramics and nonconductive materials have also been cut with WEDM.[2,3] With WEDM, it is also possible to machine complicated shapes that cannot otherwise be achieved using conventional machining processes, such as turning, milling, and grinding.[4] Applications of WEDM are also found in fuel injector nozzles, extrusion dies, turbine blades, and aircraft engine.[5,6]

The Russian Lazarenko couple was the first to design an electro-discharge machine in 1955.[7] A computer-based numerically controllable component (CNC) wire-cut machine was developed 10 years later. The machine for mass commercial production was constructed in 1969. However, the WEDM machine was able to yield corners with smaller radii in 1972. In the early 1970s, the WEDM machine yield was limited to cutting around 13 $cm^2\ h^{-1}$, which gradually reached 40 $cm^2\ h^{-1}$ by the early 1980s.[1] CNC components played a major role in improving the majority of wire electric discharge controllers for WEDM.

WEDM technology has an increasing demand for machining at higher speeds and with better precision to yield better productivity and superior quality workpieces. Productivity and surface quality are the most important performance parameters of WEDM. Although the productivity affects the cost-efficiency of a process, the quality determines the overall utility of products. The productivity is expressed as cutting speed, whereas the surface quality is defined by surface parameters such as roughness as well as white layer thickness (WLT). These parameters have varying significance depending on the machining process.[8] Productivity increases with increasing spark energy (voltage, current, and pulse duration). However, the increases in discharge voltage, current, and pulse duration play roles in the increasing surface roughness and WLT.[9–11]

In the WEDM process, WLT plays a vital role in the operational characteristics of the part (e.g., fatigue, corrosion, creep life, fracture resistance, surface friction, and coating ability). To achieve a low WLT value, the part must be machined more than once. Therefore, a target WLT is set prior to selecting processing steps that are appropriate for yielding the desired quality.[10] Many investigations were performed by previous researchers, and they observed that the white layer was clear under any cutting condition when water was used as the dielectric fluid.[13,14]

El-Hofy[12] and Levy and Maggi[15] reported the formation of a thin, heat-affected region with thickness of 1 μm and spark energy of 5 μJ, which increased to 25 μm at high spark energy. Moreover, the zone under the machined surface was annealed, producing the white layer. In addition, several molten materials were not discharged into the dielectric fluid, and the heat conduction in most of the workpieces rapidly developed detachments deteriorating the surface integrity. The WLT was developed proportionately with the impact of the discharge energy in the WEDM machining process. The thickness was reported to range from 50 μm for finished machining to approximately 200 μm for high cutting speeds, as shown in **Figure 1**.[12,16]

There are many factors that control the complex WEDM process, as shown in the fishbone diagram (**Figure 2**). These factors can be categorized as electrical (peak current, pulse on-time, pulse off-time, etc.), wire electrode (shape, tension, material, and speed), workpiece (high and material), and nonelectrical (dielectric fluid and flow rate). Any small variations in one of these parameters will affect the cutting quality, including the surface integrity (surface roughness and WLT), and cutting speed.[17] Many research works have reported the best cutting factors to achieve high product quality by decreasing the WLT.[18,19] The WLT has shown an increase following the increase in pulse on-time, and has shown a decrease with the increase of pulse off-time.

In addition, the WLT depends on wire electrode properties such as electrical, mechanical, physical, and geometrical properties. WEDM factors including the mechanical machine theory, machine intelligence, type of pulse generator, and the dielectric flushing system affect the machining performance.

Wires used in WEDM are an important component of the machining process. Copper–zinc alloy (brass) wire electrodes are extensively used as WEDM tools. However, along with current and continuous variations in the manufacturing applications field, there is an expanding demand for higher-performance wire electrodes over traditional wire electrodes made of brass. High-performance wires are known to possess high conductivity and tensile strength with good sparking ability. In practice, coated, porous, composite, and diffusion-annealed wires are categorized as high-performance wires. These wire electrodes are usually made of copper–zinc alloy or steel core with a coating of pure zinc or brass with a small proportion of chromium or high-zinc concentration. Currently, WEDM users are interested in shortening the cutting time without compromising good surface quality of products.[20] A novel and improved version of high-performance WEDM should offer both high cutting rate for productivity and enhanced cutting accuracy to ensure the quality.

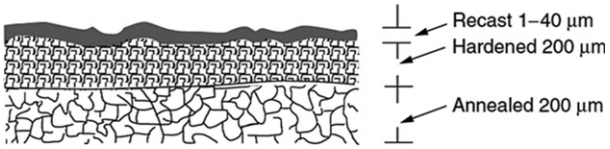

Figure 1 Electrical discharge machining heat-affected zone.[12]

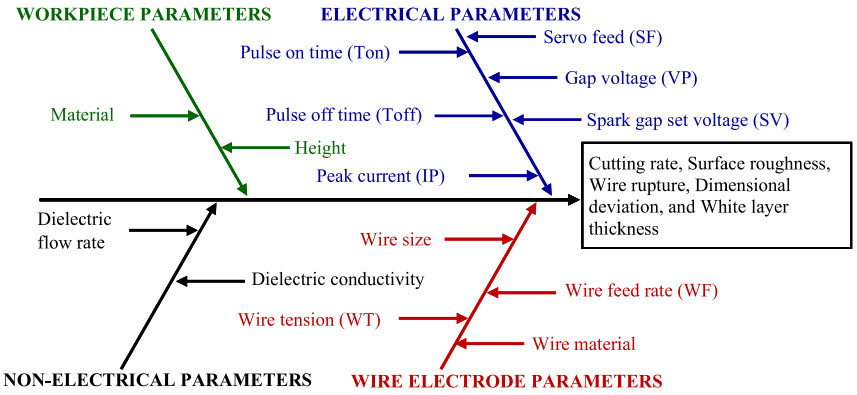

Figure 2 Fishbone diagram of the wire electrical discharge machining factors and performance measures.[17]

The dielectric fluid plays an important role as the working fluid. During cutting, heat from the molten material is rejected into the dielectric fluid. The presence of very small metal particles pollutes the dielectric fluid. This affects the cutting speed and surface integrity because they exist in the spark gap between the workpiece and wire electrode. The dielectric fluid has many functions, such as cooling, cleaning of machined particles, ionization, and electrical insulation. When the voltage reaches the spark gap set voltage, the dielectric fluid ionizes and becomes an electrical conductor. When the spark terminates, the water serves as a coolant and flushes away the machined particles.

Actual WLT monitoring can be accomplished by either an intensive postprocess inspection or a prediction system. Although the postprocess inspection is the easiest to implement, it cannot prevent the parts from being processed before a defective batch is discovered. Ultimately, the WLT prediction system can be used to determine the thickness indirectly.[8] This requires identifying an efficient machining strategy by taking factors affecting the WEDM process into consideration. Furthermore, methods for optimizing the conditions and performance of machining processes should be sought.[21]

There have been prior works that aimed to enhance the process performance based on electro-thermal concepts. These works can be categorized as theoretical,[22,23] numerical,[24,25] or empirical[26,27] and involve performance parameters and guesstimated results associated with the machining process. As mentioned, the generation and distribution of spark energy within the discharge zone determine the WEDM efficiency.[28,29] In practice, spark energy and pulse frequency parameters are varied to obtain efficient control of the WEDM process. However, there remains a challenge in studying the impacts of spark energy and pulse frequency simultaneously on the machining performance. Moreover, discharge parameters need to be low and have a high dielectric flushing rate, which would yield low surface roughness and WLT. This parameter setting eventually decreases the cutting rate in WEDM. Because of this technical trade-off, a set of process parameters fails to obtain a high cutting rate with the least surface defects. Manufacturers should have access to mathematical models for the input parameters and output performance characteristics for effective machining throughputs. The WEDM process is usually modeled after either theoretical or empirical methods.[30] Theoretical models are found to produce high errors when compared to the experimental results. The application and effectiveness of empirical models are limited to certain machining procedures. The relationship between a set of input parameters and output responses is commonly determined using the Taguchi method and response surface methodology (RSM).[31,32] The correlation between input parameters and output measures was studied from a process model developed by a feed-forward neural network.[33] Moreover, machine performance is estimated from an adaptive neuro-fuzzy inference system (ANFIS)-based model of the machining process.[34,35]

In absence of a proper mathematical model, soft computing techniques are efficient. In contrast to traditional computing, these techniques suffer from approximation, partial truth, met heuristics, uncertainty, and inaccuracy. The relationship between input and output parameters can be modeled by soft computing techniques like ANFIS,[36,37] which uses an adaptive neural network to develop a fuzzy inference system. ANFIS can build an input–output mapping model based on both human knowledge as fuzzy if–then rules and known input–output data pairs to train neural networks in a hybrid learning procedure. It provides fuzzy models as a way to learn about the known data set, which estimates parameters of the membership function that allow detection using given input–output data.[38–40]

The following conclusions can be reached after a comprehensive review of the published research works in this field. A few research works have been conducted to discover changes in mechanical properties and surface integrity of the workpiece. Therefore, many options to explore this area for future research remain.[41,42] There are a limited number of studies that involve WLT prediction models.[43] Empirical models have been proposed for a majority of works in surface quality prediction following laboratory experiments. Furthermore, there remains a practical challenge in controlling all factors necessary to yield reproducible results. Hence, the aim of this work was to obtain the best parameters (pulse off-time, pulse on-time, peak current, wire speed, and wire tension) to minimize WLT in the WEDM process. The next goal was to enhance the white layer performance and micro-characteristics in the WEDM process by developing an ANFIS model. In this case, titanium alloy grade 5 (Ti6Al4V)

and AISI 1050 carbon steel-worked materials were cut using brass and coated wire electrodes in the WEDM process.

1.9.2 WEDM Process

WEDM uses electrical discharges to form desired shapes in the manufacturing process, whereas the NC table can make X–Y movements (Figure 3). Due to the involvement of spark and wire burning, it is also termed spark eroding, wire burning, or wire erosion.

WEDM produces a series of electrical discharges between the workpiece and electrode to conduct the machining of the workpiece. Alternating high-frequency current or direct current is discharged through a very small spark gap between the wire electrode to the workpiece with a nonconductive dielectric fluid.[45] The sparks due to discharge can be easily seen instantaneously at the cutting zone (Figure 4) because sparks take place at a rate of more than 100 000 times during 1 s.[12]

1.9.2.1 Analysis of WEDM Pulse Generator

It is possible to attain continuous machining at the time of operating the wire electrode. The spark and burning processes melt and vaporize a small amount of workpiece and wire electrode, resulting in residuals, which are contained in plasma. However, the plasma is a transient state that eventually breaks down at the pulse off-time. The discharged

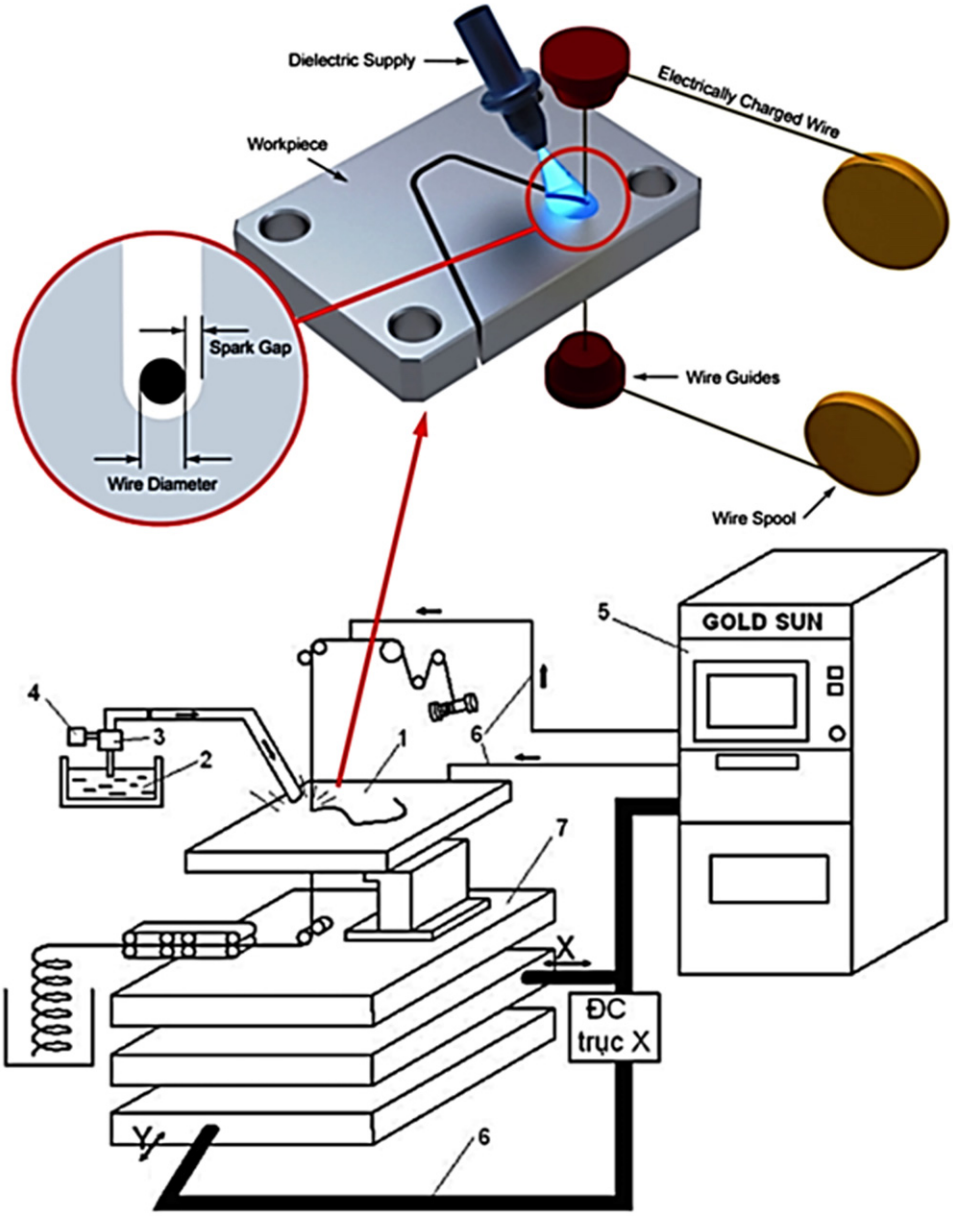

Figure 3 Wire electrical discharge machining–computer controlled machine components (1, workpiece; 2, dielectric fluid; 3, pump; 4, pressure gage; 5, power supply; 6, X–Y control unit; 7, machine table).[44]

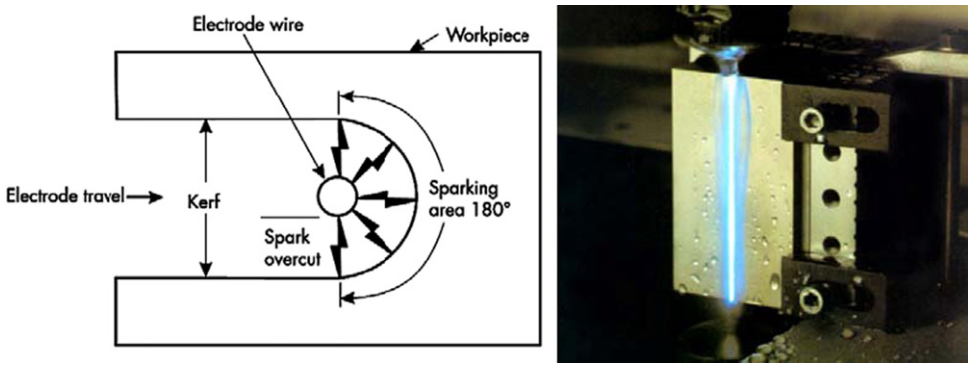

Figure 4 Wire electrical discharge machining discharge sparks.[44]

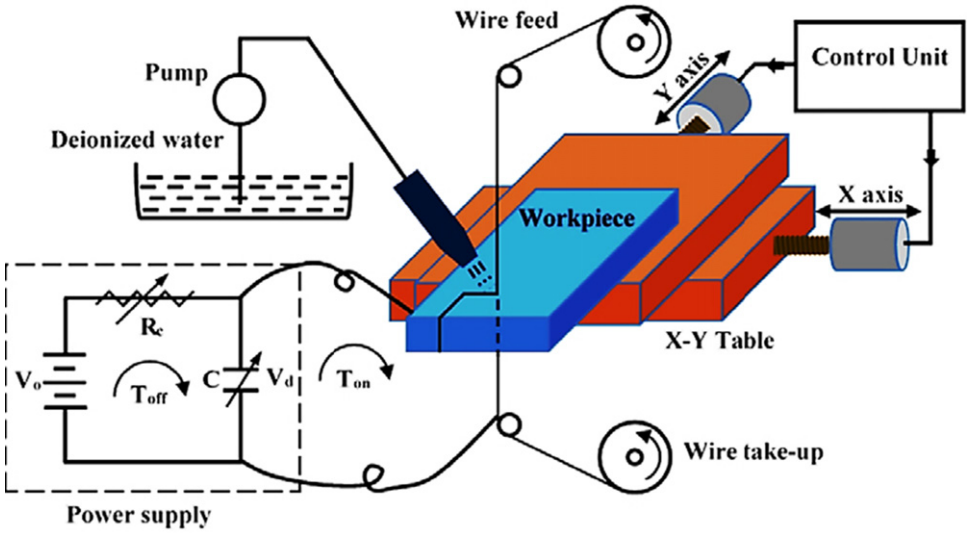

Figure 5 Pulse generator and components of wire electrical discharge machining.

material residues in liquid and vapor states are condensed in solid debris using dielectric fluid. This process repeats in nanoseconds along the length of the wire in the cutting zone.[46] **Figure 5** illustrates the WEDM machine components and a detailed description of the pulse generator used in WEDM.

In a pulse generator, the capacitor is charged from a DC source (V_o). As long as the voltage in the capacitor does not reach the breakdown voltage of the dielectric medium under machining conditions (T_{off}), the capacitor (C) continues to charge. Once breakdown voltage (V_d) is reached, the capacitor starts discharging and a spark is established between the tool and workpiece, leading to machining. Such discharge continues as long as the spark can be sustained. Once the voltage becomes too low (V_d*) to sustain the spark, capacitor charging would continue, as shown in **Figure 6**.[12]

An electrical discharge involves time-varying voltage and current impulses. The following variables are used to determine electric impulses: discharge voltage (V_d), pulse off-time (T_{off}), pulse duration (T_{on}), peak current (IP), pulse cycle time (T_c), pulse frequency (F), and duty factor (DF). The most important WEDM parameters are spark energy and duty factor.

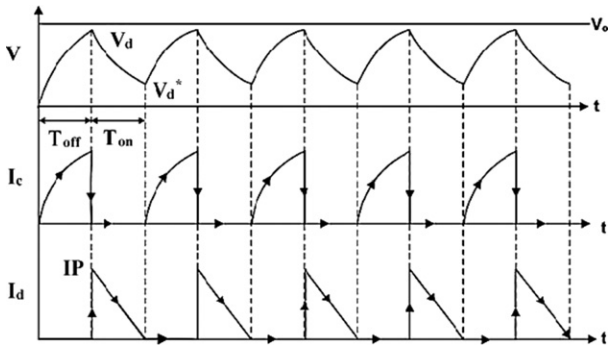

Figure 6 Analysis of RC type electrical discharge machining generator.[12]

The spark energy is defined by electrical energy in each spark, which can be expressed by the following equation:

$$E_s = V_d \times IP \times T_{on} \quad [1]$$

According to eqn [1], spark energy is proportional to three variables: discharge current, the discharge voltage, and pulse

duration. The discharge voltage depends on the properties of the wire electrode and workpiece pair.[47] The spark intensity develops because of discharge current and pulse duration (Figure 7). The spark energy determines the spark size and, hence, the chip size. High spark intensity leads to long sparks, thus increasing the cutting speed and chip size, but deteriorates the surface finishing, as shown in Figure 7(a).[48]

The other most important electrical parameter that significantly influences WEDM performance is the pulse frequency (F), or duty factor (DF). The duty factor determines the weight and number of pulses (eqns [2] and [3]). The duty factor is the percentage of the pulse duration over a total cycle time. In machines with duty factor settings, the pulse interval is set indirectly by setting the pulse duration and duty factor. Pulse frequency is used to set the pulse interval on some machines and to determine the number of chips per second. The pulse frequency and duty factor equations, respectively, are given by:

$$F = \frac{1}{T_{on} + T_{off}} \quad [2]$$

and

$$DF = \frac{T_{on}}{T_{on} + T_{off}} = T_{on} \times F \quad [3]$$

Selecting a spark microsecond cycle time depends on the workpiece thickness, flushing condition, and required surface quality. High pulse frequency leads to short sparks and therefore decreases the chip size (Figure 7(b)). This condition is consequently recommended to improve surface finish. Low pulse frequency leads to long sparks and therefore increases the chip size (Figure 7(a)), so it is recommended for increasing cutting speed.[44]

1.9.2.2 Electrical Discharge Machining Wire Electrode

The wire electrode is the central component of the WEDM system in the process of producing a steady electrical discharge. Therefore, the WEDM performance is largely affected by the wire electrode.[49] Wire rupture is a critical phenomenon that affects the quality and productivity in the WEDM process. It requires some prior knowledge about the characteristics of the wire electrode and workpiece in the cutting process to avoid such rupture for continuous operation of the process.[50] The parameters that define these characteristics are wire tension, thermal load, electrical discharge impact, and flushing rate. The wire rupture is likely to occur when the developed stress exceeds the strength of the wire. The effect of developed stress is determined by factors such as reduction in cross-section reduction and increase in the wire temperature. The wire strength is directly affected by high process temperature and varying thickness of the workpiece, both of which eventually lead to wire rupture.

In early 1970s pure copper wire electrodes were used, compromising the machining accuracy and strength. By the

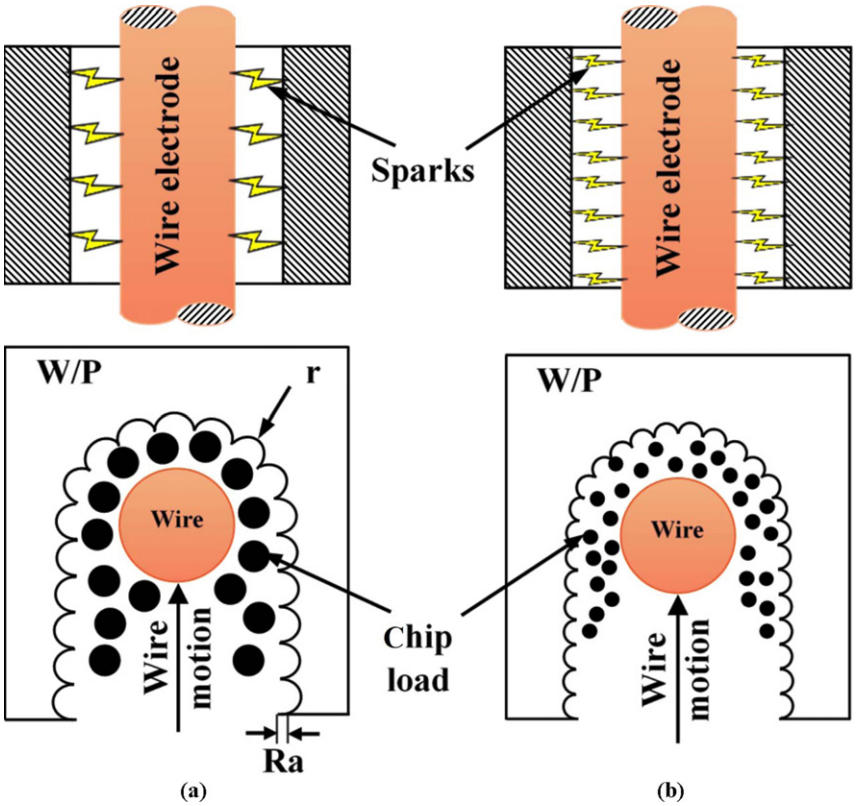

Figure 7 Chip size and load at different spark energy and pulse frequency: (a) high spark energy with low pulse frequency and (b) low spark energy with high pulse frequency.

mid 1970s, brass wire started to replace copper wire electrodes. Following these developments, wire electrodes made of copper and coated with zinc appeared in the machining application in 1980. In the following years, these were replaced by brass wire electrodes coated with zinc, and brass wire electrodes were developed with aluminum or chromium. Since 1990, brass wire electrodes were developed in different compositions to achieve different processing goals. To ensure quality in high-precision cutting, a zinc coating is used over the brass wire electrode and high-speed cutting for productivity is achieved using Cu–50%Zn coating. Subsequently, for higher productivity or cutting speed, wire electrodes made with an increased proportion of zinc have been found to be effective. In cutting thick materials, the heat resistance is improved with the application of brass wire electrodes composed of titanium and aluminum.[51] Moreover, other special wire electrodes were tailored to meet the desired conditions for cutting and characteristics of the workpiece, such as steel, tungsten, molybdenum, abrasive-assisted, and porous wire electrodes.[52]

In practice, the cutting efficiency in the WEDM process relies on complex consideration of mechanical, electrical, geometrical, and physical properties of the wire electrode. However, the overall cutting performance is controlled by several WEDM process factors, such as the mechanical effect, machine intelligence, pulse generator improvements, and the dielectric flushing methods. The following section discusses electrical discharge machining (EDM) wires in terms of their physical properties and their relationships with practical cutting processes.[53,54]

Conductivity determines the transfer of power from the feed source to the target point of cutting. It enables the EDM wire to transfer energy over distances, and thus serves as a key property of the wire. When the cutting process involves an open guide to clear a workpiece obstruction, the distance for power transfer can be considerable. Low conductivity is responsible for a considerable voltage decrease over the distance between the power source and cutting target, which eventually results in power loss at the cutting point. This loss can be significant because the modern power supplies usually produce electric currents more than 100 A. The conductivity values of metals and alloys are determined relative to that of the standard annealed copper based on International Annealed Copper Standard (IACS). Conductivity is expressed as a percentage of IACS, which is 100% for the standard copper wire.[55]

Tensile strength is a mechanical property of the wire that refers to its ability to withstand the applied tension in a cutting procedure aiming at a vertically straight cut.[56] EDM wires with tensile strengths of 900 MPa or more are categorized as 'hard,' whereas 'half-hard' wires possess tensile strengths of approximately 490 MPa and 'soft' wires have tensile strengths less than 440 MPa. In practice, hard wires are used for most cutting processes. However, in taper cutting, hard wire will resist bending at the guide pivot, resulting in faulty taper cutting. In this case, half-hard and soft wires are the primary choices when the taper angle is more than 5°. In general, half-hard and soft wires are not appropriate for automatic threading unless the machine is tailored to work with such wires.[57]

Elongation defines the amount of deformation the wire produces prior to the breakdown. This is a key property of the wire, which is commonly subjected to high-tension load and countless sparks during the cutting process. The percentage of gage length is used to estimate the elongation in a given test. Elongation also determines if a type of wire is more brittle than another. Hard wires possess relatively much less elongation than half-hard wires. Therefore, a brittle wire is more likely to breakdown early due to an overload condition, whereas a more ductile wire may survive in a temporary overload.

Melting point is not listed as a specification parameter for a given wire; however, it plays a significant role during the spark erosion process of the WEDM. In addition, the wire electrode should possess certain resistance to the rapid melting caused by the sparks.

Straightness is rarely specified for EDM wires; however, it plays an important role in successful auto-threading and cutting thicker workpieces.

Flushability indicates the quality of the cut in the WEDM process. Although it is not a specified item for a given wire, better flushability refers to a faster cut by the wire.[58] It depends on the metallurgical property of the alloy components of the wire.

Cleanliness is also not found in the specification of EDM wires. This refers to the quality of the wire being free of contamination. The contamination may appear as dirt from residual metal powder during the drawing process or as drawing lubricant, or may be due to added paraffin prior to spooling. These chemical and metallic contaminants can accumulate over time and eventually clog guides and power feeds or slipping belts or rollers.

Geometrical properties specify the diameter, shape, and coating and layer structure of the given EDM wires. In general, WEDM involves wires with diameters ranging between 0.02 and 0.36 mm. A larger diameter yields an increased supply of pulse energy to the working gap, which improves the overall material removal rate.[59,60] In contrast, micro-WEDM involves ultra-fine wires less than 30 μm in diameter to handle predominantly small pulse energies.[61] Considering the application and process conditions, many patents are available proposing a number of other wire electrode shapes.[62–64] Meanwhile, the high manufacturing cost of modified cylindrical wires limits their usage in practical applications. Improved heat transfer in wire electrodes has been found to yield a 15–20% increase in the cutting rate. Wire electrodes with twisted grooves have been patented to resist sparks occurring at the same point.[65] Regarding their patents, several inventors have disclosed that the change in the direction of the wire's rectangular cross-section played a vital role in moving the generated sparks very near to the workpiece and in preventing hotspots on the wire electrodes during the WEDM process.[66,67] **Figure 8** illustrates several wire shapes that are patented to improve the material removal rate.[65,68]

In 1969, the maximum possible cutting rate was achieved by a 0.15-mm-diameter wire, which was later increased to 0.36 mm. **Figure 9** depicts how the wire diameter is increased every time to facilitate an improved wire electrode for the WEDM process.[69] The effects of several important force factors such as electromagnetic, electrostatic, wire traction, dielectric flushing, and wire feed on the application of the smaller diameter wire electrode (0.03 mm) have been analyzed.[70,71] Prior

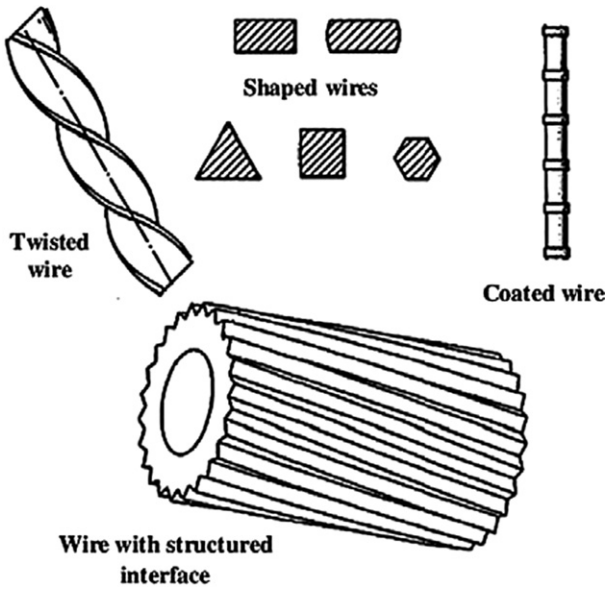

Figure 8 Customized wire shapes.[65,68]

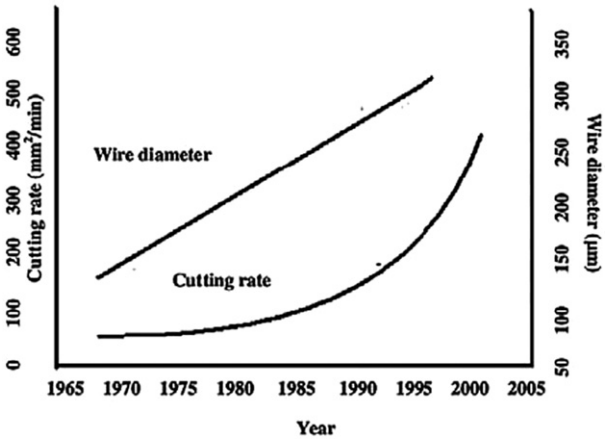

Figure 9 Cutting rate improvement in relation to wire diameters.[74]

works have been conducted to enhance the power supply and transportation system suitable for fine wires with a diameter less than 80 μm.[61,72] To achieve a successful operation, selecting the suitable wire electrode is a very challenging task in WEDM.[73] This requires the study of a variety of wire electrodes to yield the optimal result for this process.

1.9.2.2.1 Development of EDM wire electrodes

The cutting machines in the early 1970s had an extremely low yield, with cutting rates of approximately 21 $mm^2\ min^{-1}$. By the early 1980s, cutting rates increased to 64 $mm^2\ min^{-1}$, whereas the current machines are able to cut at a speed more than 20-times higher than the earliest machines. **Figure 10** shows the advancement rate of WEDM with brass wire and performance of wire electrodes since its development.[69,75–77]

The existing brass-coated wires are in one of the following categories: high falcon (HIF), high hawk (HIH), high eagle (HIE), high sonic (HIS), or high real (HIR).[49] HIS and HIR wire electrodes are suitable for high cutting speed and have been commonly used in applications involving mass production, such as electronic and metal molds for integrated circuit lead frames. However, HIE and HIH wire electrodes were used for high-precision machining and utilized for precise applications such as biomedical and aerospace products. **Figure 11** shows different wire electrodes produced to offer faster cutting speed with improved surface finish and flatness.[79]

The electrical discharge property can be regulated by adding zinc to the wire electrode, which consequently helps to enhance the machining performance. Properties like clarification and heat release can be controlled by alloying conductive elements to the core surface of wire electrodes.[80] Several inventors have considered these properties as the primary control parameters to improve wire electrode performance.[81–83] Prior studies involving plain, alloyed, or coated (zinc-coated, diffusion annealed, etc.) wire electrodes report a significant enhancement in WEDM performance.[84,85] Due to stable discharge, brass wires are the most popular electrodes in machining, but they suffer from low electrical conductivity. The electrical conductivity and heat resistance of the core or coating of the wire have been commonly considered in developing many wire electrodes. Fracture toughness is one of the properties that control the WEDM performance. Fracture toughness is the ability of the wire electrode to resist breakdown and withstand the formation of craters on its surface.[86–88] Wires with high tensile strength are likely to break during the machining process. The issues associated with fracture and electrical conductivity have been addressed using composite materials with the steel core wire electrode. Under the applied preload tension, a discharge may cause a flaw greater than a critical flaw that sets off a catastrophic failure. This event may break an EDM wire, as shown in **Figure 12**.[89] High-strength materials used in EDM wire manufacturing are vulnerable to small flaws because they tend to fail because of their low fracture toughness. Each discharge in the WEDM process results in a flaw in the form of a crater in both the wire and workpiece. These flaws gradually grow larger with the deteriorating flushing conditions and eventually lead to catastrophic wire failure.[90–92]

1.9.2.2.2 Plain EDM wires

The manufacturing of brass wire starts with a continuously cast rod 20 mm in diameter. The rod is made approximately 6 mm round or in a hexagonal cross-section using either a cold-rolled or a cold-drawn procedure. The wire is then shaped approximately 0.9 mm through annealing and drawing by a series of dies. This state is usually termed as a redraw wire. Prior to forming the final size, the wire is redrawn through another series of diamond dies. In the final stage, the wire is resistively annealed or thermally tempered in an inert atmosphere, cleaned, and then spooled.[93–95] According to the convention, the term 'plain' simply refers to the wire that consists of a single homogeneous component without involving coating or alloying of other materials.[57]

1.9.2.2.2.1 Copper wire

Figure 13 shows a copper wire that is the original component in the WEDM process. There was a common notion that the high electric conductivity of copper wire would make it an ideal EDM wire. Unfortunately, copper wire suffers from low

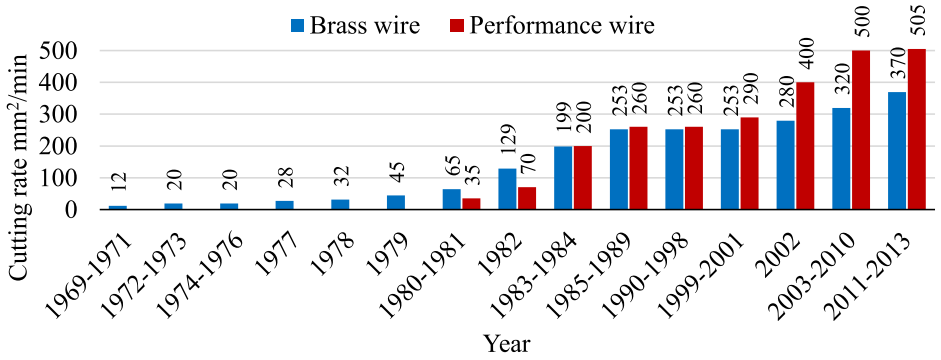

Figure 10 Advancement rate of the wire electrical discharge machining since its development.[78]

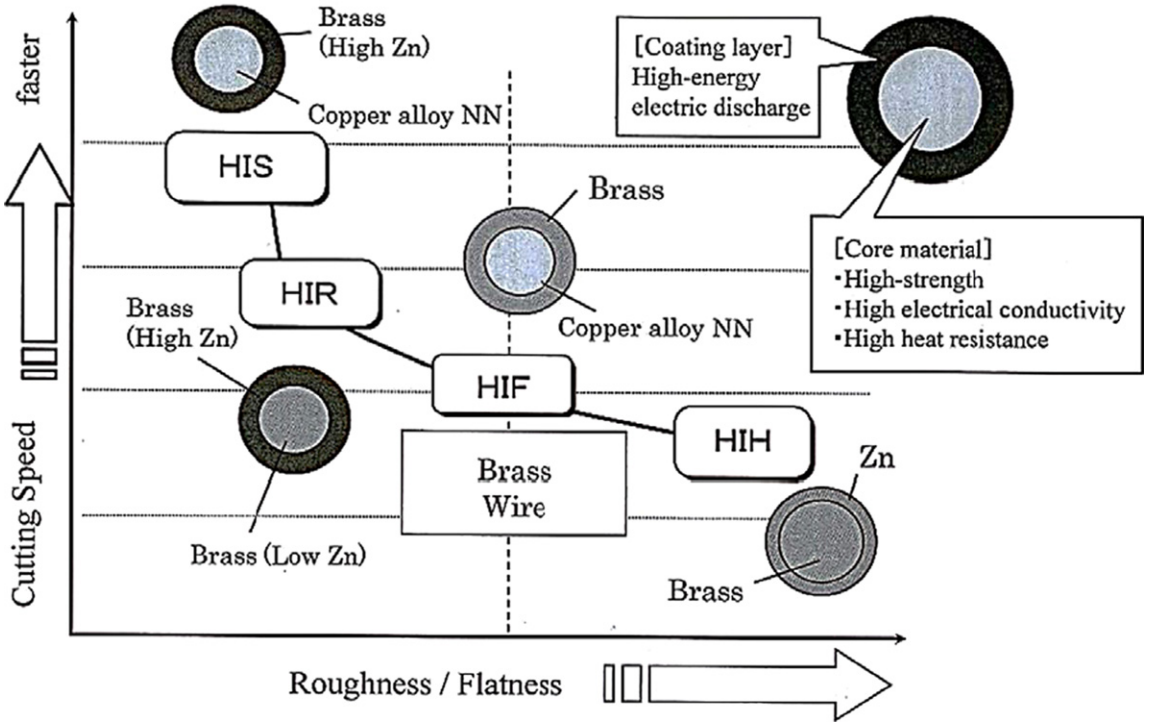

Figure 11 Characterization of electrical discharge wire electrode.[79]

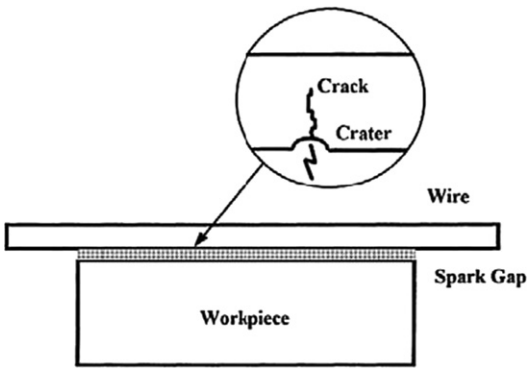

Figure 12 Defect and fracture in the wire electrical discharge machining process.[90–92]

tensile strength, high melting point, and low vapor pressure rating.[96] This became evident at the advent of the second generation of pulse power supplies; hence, brass wire had to take over copper wires in the WEDM process. However, copper wires are occasionally found in applications where the zinc contaminant, contained in either brass or coated wires, is not acceptable.[57,97]

1.9.2.2.2.2 Brass wire

There have been numerous efforts to enhance the performance of wire electrodes. Brass wire is an alloy of copper and zinc, with compositions in the range of 63–65% Cu and 35–37% Zn (**Figure 14**). It has been reported that increasing the proportion of zinc enhances cutting speed and performance.[98]

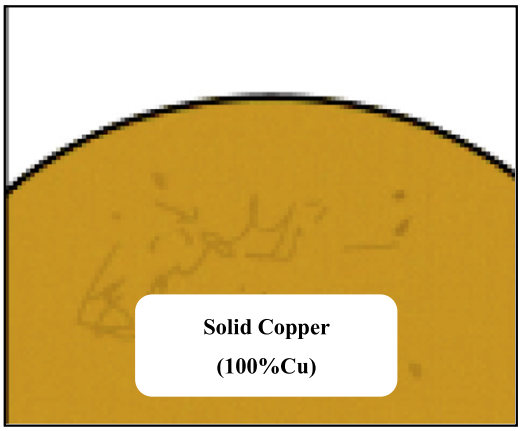

Figure 13 Solid copper wire.[57]

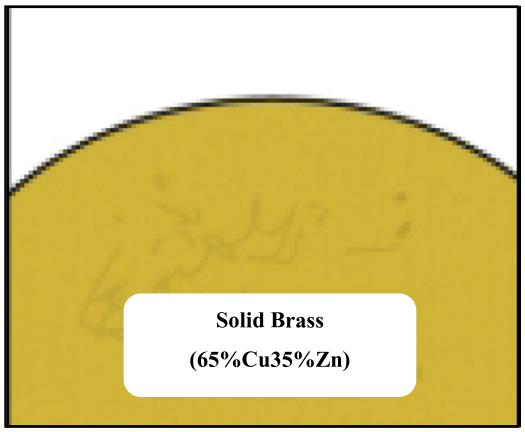

Figure 14 Solid brass wire.[57]

The zinc in the brass wire evaporates during the cutting process and provides more energy yield by cooling the wire. Adding zinc provides significantly higher tensile strength and a greater vapor pressure rating, which compensate for its loss of conductivity. In addition, the dielectric fluid may not be able to clean some zinc particles that will stay between the workpiece and wire electrode gap to facilitate necessary ionization and cutting process.[69] These qualities make brass one of the most popular choices of materials for WEDM electrodes. However, the addition of zinc to any extent significantly reduces the conductivity of the electrode. For example, hard brass wire possesses only 20% of the conductivity of copper wire. Because of the improved flushability with zinc wire, a high-zinc brass composed of Cu60%Zn40% is currently available. This additional zinc content speeds the cutting process up to 5% in some optimized applications.[99] However, zinc proportion more than 40% is not practical for cold-draw wire. The change in the grain structure of wire may make the wire too brittle to process into a fine diameter required for WEDM. In several cases, there can be significant amount of brass deposit on the workpiece after the cutting process, which is more difficult to remove. These findings have encouraged the formation of coated wires.[20,100,101]

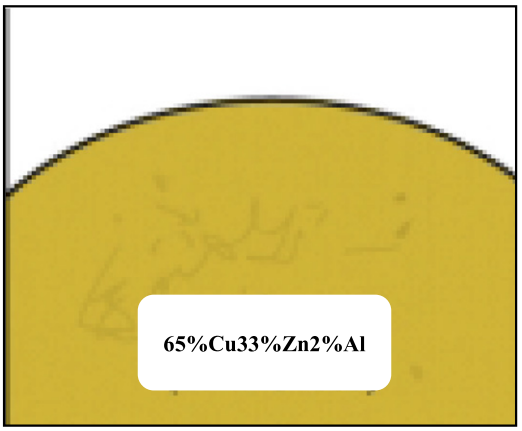

Figure 15 Aluminum–brass alloy wire.[57]

1.9.2.2.2.3 Aluminum–brass wire

A special type of alloy wire is made by alloying a small amount of aluminum with a brass wire, as shown in **Figure 15**. The tensile strength of the wire can be improved by such an alloying process, which can raise the tensile strength as high as 1200 MPa without deteriorating the elongation. These alloyed wires are less prone to damage than the wires made of plain brass.[57]

1.9.2.2.3 Coated EDM wires

US patent US1896613-1933 refers to one of the earliest patents on zinc-coated wires aimed to enhance the cutting performance of EDM wires.[102] Because the limit for raising the zinc content is 40%, zinc is alternatively used to coat the core wire material to enhance the quality of the wire.[103] Coated wires are developed by plating or hot-dipping redrawn wire and then drawing it to the final size. This process is challenging because the zinc surface has to withstand the final drawing process. Currently, the coating is not deposited on the final shape of the EDM wire. The existing wires usually consist of a core made of either brass or copper to facilitate conductivity and tensile strength. In addition, to enhance the spark formation and flush characteristics, pure or diffused zinc is electroplated as the coating on the wire surface.[104–109]

1.9.2.2.3.1 Single-layer-coated wires

One of the earliest strategies used to add zinc to the wire surface is the development of zinc-coated brass wire. One of the standard EDM brass alloy wires consists of zinc coating over the core as thin as 5 μm (**Figure 16**). The zinc-coated brass wire yields a significant increase in the cutting speed over the plain brass wire without compromising with any other important properties.[110] The wire can provide an excellent surface finish when cutting tungsten carbide, and this wire is commonly used to cut polycrystalline diamond and graphite. This wire is also utilized in certain cases where the brass wire creates undesirable plating of brass on the workpiece.

To attain the benefits of the conductivity of copper and flushability of zinc together, zinc-coated copper wire was one of the earliest attempts in the wire development. It does not

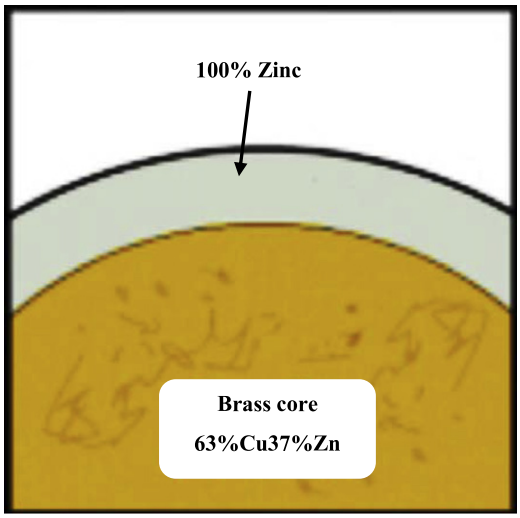

Figure 16 Zinc-coated brass wire.[57]

currently exist in application because the spark penetrates the thin zinc coating and the copper core inside slows the cutting process.[111,112]

US patent US4287404 revealed that electrode wires coated with metals of low vaporization temperature, such as bismuth, tin, zinc, lead, cadmium, antimony, or alloys, protect the core from thermal stress from the electrical discharge. Additionally, it allows an increase in the frequency of electrical discharge without causing damage to the wire.[113] US patent US6300587 refers to a wire electrode with a copper core coated with a peripheral layer. The coating layer is composed of 55.5–75 wt% copper and one or more of the following metals: Zn, Cs, Se, Te, or Mg. The coating layer only forms a natural oxide film.[114] US patent US6348667 is identified as a wire electrode that prevents corrosion, particularly of the noneroded surfaces of the hard metal block. This anticorrosion property is achieved by using a wire electrode in the spark-erosive cutting of hard metals. The coating of the wire consists of either a metal or an alloy. During the cutting process, the outer coating comes loose as small metal particles and remains in the dielectric. However, because these small metal particles are not nobler than the metal contained in the hard metal, the electrochemical corrosion, namely pitting of the hard metal, cannot occur as soon as the small metal particles make contact with the hard metal block. Consequently, the pitting phenomenon in the hard metal block can be avoided. As a rule, the hard metal block consists of cobalt, aluminum, magnesium, zinc, or iron.[115]

1.9.2.2.3.2 Double-layer-coated wires

The wire electrode referred by US patent US4968867 has a core with higher thermal conductivity, an inner coating made of a material with a low boiling point, and an outermost layer of brass offering high mechanical strength. The core of such wires is made of a single metal such as copper, silver, aluminum, or alloys (**Figure 17**). Such wires are found to increase the cutting speed due to several properties, such as the vibration dumping, heat transfer, and resistance to breakage. **Figure 17(a)** shows a cross-sectional view of the first invented sample of the wire electrode. A coating layer (7) covers a core wire (6). In this sample, the coating layer over the core is prepared by brass with 35%Zn, and the core wire is a Cu–Sn alloy with 0.15%Sn. Besides brass, the coating layer is also formed by alloying secondary components such as less than 50%Mg and/or Cd with copper. In another sample of current invention, a wire electrode was designed by considering the area of cross-section of the coating layer that is approximately 50–90% of the entire area of the cross-section of the wire electrode. The larger thickness of the coating layer yields higher tensile strength. The cross-sectional area of the coating layer is approximately 69% of the total cross-sectional area of the wire electrode. In the third embodiment, two layers (7 and 8), one after another, cover the core wire (6), as shown in **Figure 17(b)**. One of the metals, such as Zn, Cd, or Mg, primarily forms the outermost layer because they have a relatively lower boiling point. Accordingly, machining speed can be improved. **Figure 17(c)** shows a cross-sectional view of the fourth embodiment. The outermost layer (9) represents an oxide film in the coating layer (7). This oxide layer can reduce undesired electric discharges at the lateral side of the wire electrode. This realizes a narrow machined groove width. In the fifth embodiment, the wire electrode consists of a core (6) made of Cu alloy, ensuring higher thermal conductivity. A layer on this core (10) is formed by twisting thin wires of brass with high mechanical strength, and the outermost layer (11) is formed by Zn or Zn alloy (**Figure 17(d)**). This design improves the electric discharge characteristics that, in turn, improve the roughness of the workpiece surface. This is because a layer of material with a low boiling point covers an intermediate coating layer with high mechanical strength. **Figure 17(e)** shows a cross-sectional view of the sixth embodiment. The wire electrode has a coating layer (12) of Zn plating on the core surface and an outermost layer (13) formed by brass. A linear material made of a Cu alloy including 0.15%Sn balanced by Cu is subjected to zinc plating to obtain the core wire (6). **Figure 17(f)** presents a cross-sectional view of the seventh embodiment. Here, brass with 35%Zn is used as the coating layer, whereas the core is essentially a Cu alloy including 0.15%Sn balanced by Cu. At least one piano wire may be added in the twisted linear elements to enhance the mechanical strength of the wire electrode.[116]

Patent US4977303 refers to a method of producing an EDM wire electrode that consists of a Cu core with zinc coating. The coated wire is then heated in an oxidizing atmosphere to produce two layers: a copper–zinc alloy layer over the core and a zinc oxide layer over the alloy layer. The resulting electrode wire allows greater current density and traction force, which in turn speeds the cutting yield in the EDM process.[117]

1.9.2.2.3.3 Multilayer-coated wires

US patent US4341939 provides an increase in the cutting speed by eradicating the short circuit phenomenon that reduces the machining performance. In other words, it rapidly affects the transformation of nonerosive short-circuited electrical discharges into electro-erosive effective discharges. The electrode design incorporates a wire core coated with one or more layers of another material and a thin film of nonmetallic material. The thickness of the thin film is sufficient to provide a semi-conductive effect when the film contacts the workpiece

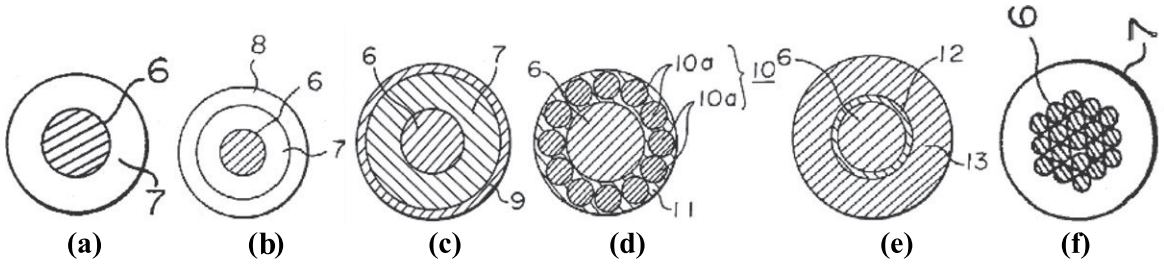

Figure 17 Construction of wire electrodes.[116]

at a small-applied voltage between the electrode wire and the workpiece. However, the film turns into a conductor by electrical and/or thermal breakdown when the applied voltage increases from a few volts to approximately 100 V. The wire has at least a layer of metal with a low vaporization temperature (such as zinc) that is coated with a metal oxide film. The metal layer is treated with electrolytic or thermal oxidization to form a thin film of zinc oxide on the metal surface. **Figure 18(a)** shows a schematic of a cross-section of an electrode wire with a copper core (1) superficially coated with a copper–zinc alloy film (2), which is further layered by a thin film (3) of zinc oxide. The wire core can be made of brass or steel (1), provided that they offer essential qualities such as good electrical conductivity, mechanical strength, and resistance to rupture. Good machining performance has been obtained using bismuth, tin, magnesium, lead, cadmium, antimony, or metal alloys as the coating material. Experiments reveal that satisfactory machining performance can be achieved with other metallic oxides beyond zinc oxide. It has been found useful to create a film of another metal a few microns thick over the zinc coating, where the metal film can be oxidized during the high heating process. The metal oxides known for their semi-conductive properties are CuO, Cu_2O, CdO, In_2O_3, PbO, TiO_2, MnO_2, MgO, and NiO. Nonetheless, dielectric oxides such as $A1_2O_3$ can also be used. There can be nonmetallic films covering the metallic layer surface such as carbides, borides, silicides, sulfides, and nitrides of various metals. **Figure 18(b)** shows the cross-section of a Cu core (1) layered by two copper–zinc superimposed coatings (2 and 4). These coatings are covered with films of zinc oxide in (3) and (5), respectively. As mentioned, heat treatment oxidizes the first coating (2) of 2–4 μm to form a thin film (3) of ZnO. The thin oxide film (3) is then covered with a second zinc coating (4) of approximately 4 μm. A second heat treatment is applied to create a thin film (5) of ZnO covering the surface of the second zinc coating (4). **Figure 18(b)** shows similar phenomena of copper diffusion into zinc and vice versa, as well as coating porosity causing irregularities and coarseness in the outer surface.[118]

The US patent 20080245773 offers a multi-coating EDM electrode wire capable of fast and quality machining in shaping a workpiece without requiring changing the wire.[119] The wire is composed of two or more coating layers with an outer layer of zinc for precision machining and an inner layer of zinc alloy that facilitates fast machining, which in turn offers uninterrupted machining service. Moreover, this type of electrode wire can be produced at a relatively low cost. In addition, discharging occurs at the time of machining a workpiece

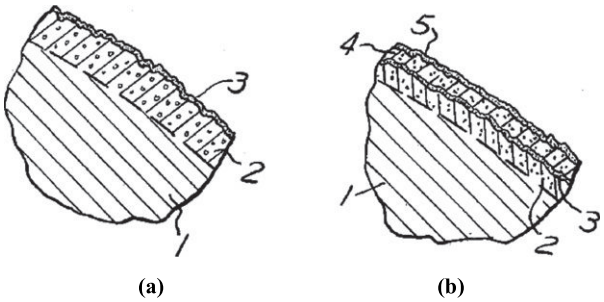

Figure 18 Schematic section of wire electrodes.[118]

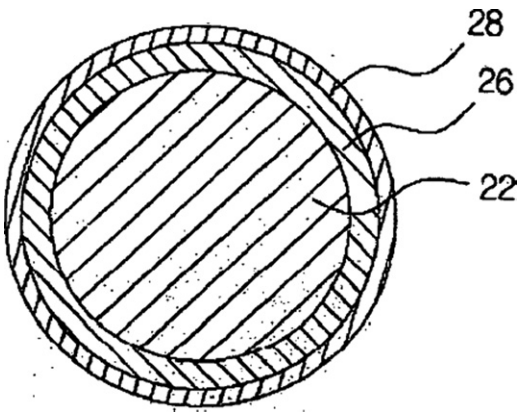

Figure 19 Cross-section of wire electrodes.[119]

without producing debris from the core wire; therefore, the machining work is not interrupted by the electrode wire. **Figure 19** shows the multicoated electrode wire with a core (22) made of copper or brass. The lower layer of coating (26) is made of zinc alloy (CuZn80–CuZn95), which has a higher sublimation point required for fast machining. The upper layer (28) made of zinc alloy (CuZn90–CuZnl00) has a lower sublimation point for precise machining and is formed onto the lower layer (26). Therefore, this wire electrode provides fast and precise machining without interrupting the EDM process.

US patent US5196665-93 was geared toward improving the mechanical strength of electrodes without compromising properties like the heat-shield effect and the elimination of short circuits. The multiple layers on the core surface possess essential properties like high electrical conductivity and low melting and vaporization temperatures in an alternating

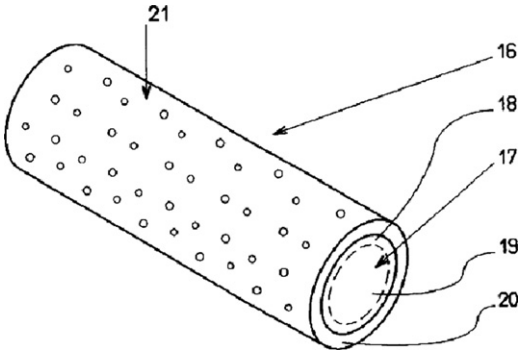

Figure 20 Diagram of wire electrode.[121]

fashion. The alternating layers on the wire electrode surface may form alloys of required structure and composition by diffusing into one another. In this case, the core is made of metal like brass, copper, steel, or copper-clad steel and is coated with layers of zinc, copper, and zinc alloy with 30–60% zinc that are less than 0.5 μm thick.[120] Patent US5721414 developed an electrode wire with a thicker surface layer from diffused copper–zinc alloy following a thermal diffusion method, such that spark erosion machining was accelerated.[121] The wire surface prepared following the patent is just coarse enough for the spark erosion, thus requiring no mechanical surface treatment other than sizing. The wire electrode has a core (17) of copper or copper alloy (19) covered with an upper layer (18) of copper or copper alloy (20) of diffused copper and zinc alloy or copper alloy. The surface layer (20) has a slightly granular surface (21), as shown diagrammatically in **Figure 20**.

1.9.2.2.4 Diffusion-annealed coated wires

In theory, a pure zinc coating would produce the perfect wire with superb flushability. However, in practice, the thin layer of zinc on the core surface is blasted off by electric discharge intensity because of its low melting point. Therefore, zinc hardly gets the chance to provide its full potential.[122] Therefore, the coating should contain a high-zinc content with materials of relatively higher melting points to ensure better adhesion to the core wire. A heat-treating process known as diffusion annealing can obtain this better adhesion. In a diffusion process, atoms transfer from higher to lower concentration regions. The zinc atoms with higher concentration diffuse into the brass, and the copper atoms from the brass diffuse into the zinc. This diffusion process between the core and coating materials eventually produces a zinc–brass alloy that is rich in zinc but possesses a relatively higher melting point and is metallurgically bonded to the core material.[123]

1.9.2.2.4.1 Alpha phase wires

The brass alloy can have several phases suitable for EDM wires, such as alpha, beta, gamma, and epsilon phases, as shown in **Figure 21**.[124] The alpha phase has the highest melting point, which is approximately 910 °C at its highest available zinc content of 35–39 wt%. The beta phase is second to the alpha phase in terms of the melting point, which is approximately 890 °C in a diffusion-annealed coating containing between

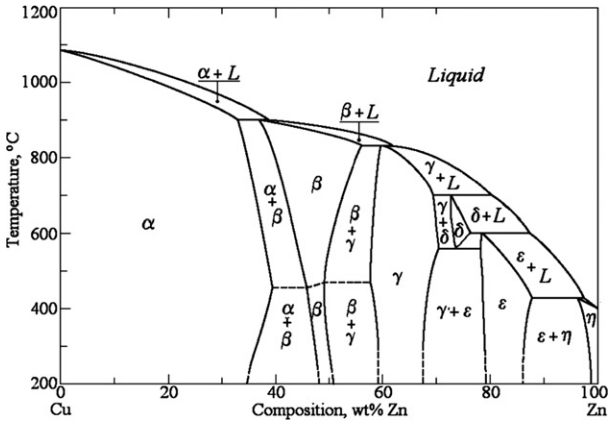

Figure 21 Cu–Zn phase diagram.[124]

40–53 wt% zinc. The gamma phase has the third highest melting point, which is approximately 800 °C in a diffusion-annealed coating containing between 57 and 70 wt% zinc. The epsilon phase has the lowest melting point, which is approximately 550 °C in a diffusion-annealed coating with a typical 85 wt% zinc content.[125]

1.9.2.2.4.2 Beta phase wires

The X-type wire was the earliest type of diffusion-annealed wire, usually termed SWX, Bronco Cut-X, Beta Cut-X, or X-Kut. A beta brass is coated over a pure copper core of this type of wire as shown in **Figure 22(a)**. It combines the advantages of the high conductivity of copper and coherent zinc-rich coating. However, it comes with limitations, such as 50% decrease in tensile strength, poor straightness, and higher cost when compared to solid brass wires. However, it has a significant yield in aerospace applications, offering alloys like inconel and titanium.[126]

Figure 22(b) shows the D-type wire, which is the second diffusion-annealed wire, typically termed Cobra Cut-D or D-Kut. The wire has a copper core alloyed with 20% zinc and a beta brass coating. Its advantages include enhanced conductivity of the 80%Zn to the 20% copper core, a coherent zinc-rich coating, and relatively high tensile strength (800 N mm^{-2}). High production cost is its major shortcoming. This wire yields significantly high productivity in a number of different machines.[57]

Patent US4935594-90 presents a wire electrode that has an erosive wear-resistant outer coating on the common eroding electrode. In **Figure 23**, an eroding electrode has a core (2) 0.1–0.6 mm in diameter. A coating (3) of cadmium, antimony, zinc, bismuth, or an alloy made of these metals can be layered on the core surface (3) (**Figure 23(a)**). Such a wire (1) is best prepared when annealed at 700–850 °C and is cooled to less than 80 °C while passing through a protective gas. In such a way, an altered coating (3′) (**Figure 23(b)**) with the previously mentioned useful properties is achieved. The core (2) of the wire (1′) is made of electrolytic copper with more than 99 wt% copper and a very low oxygen content. A copper–zinc alloy with 79.5–80.5 wt% Cu, with the remainder being Zn, can also be useful in practice. The altered coating (3′) has multiple layers of metallic phases, and its content of metal with a low volatilization temperature gradually decreases from the outer

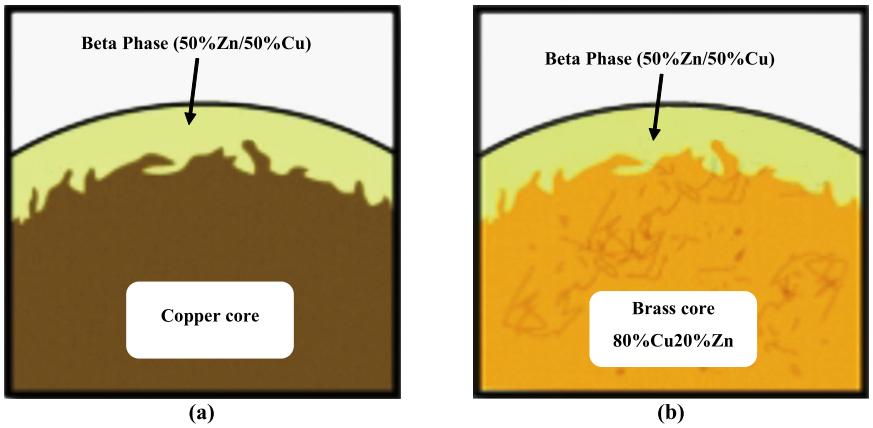

Figure 22 X and D types of wire electrodes.[57]

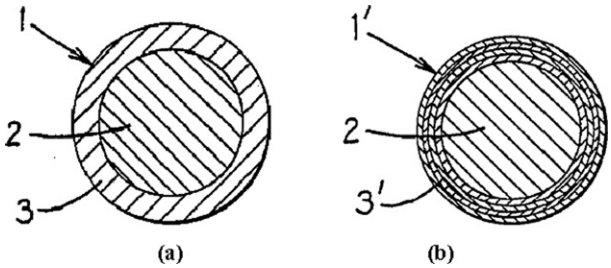

Figure 23 Cross-section of wire before and after the process.[127]

surface to the core of the wire (2). The metallic phase layers include alpha–beta phases and beta–gamma phases.[127]

European patent EP0526361A1 introduced an electrode to obtain high-stability electric discharge during the machining process. The Zn coating is used onto the surface of Cu or Cu alloy wire. The wire is heat-treated to form an outer layer (31) of a homogeneous beta prime phase. In such heat treatment, the temperature is maintained below the beta prime–beta transition temperature of the binary Cu–Zn alloy. Then, the wire is drawn at a drawing ratio more than 100% to obtain an electrode (1), as shown in **Figure 24**. For electro-erosion, the electrode has a Cu–Zn alloy outer layer (3) in the homogeneous beta prime phase free of oxide contents with a junction (32) of low thickness. The wire (20) is primarily made of copper or copper alloyed with at least one of Fe, Co, Ti, P, Mg, Cr, Zr, or Si at a content of between 0.1 and 1 wt%. Alternatively, at least one of the secondary elements such as Al, Sn, or Ni up to 4 wt% overall is also used. The weight concentration of the outer Zn layer (3) is in the range of 46.5%$\pm$1, which is substantially constant throughout its thickness.[128]

Patent US5858136 refers to the copper wire with zinc layer, which is heated at a temperature up to 750 °C to yield a brass beta phase. The heat treatment is continued to ensure complete diffusion of zinc, as shown in **Figure 25(a)**. The temperature is then raised to 950 °C to produce a brass phase, and the Cu core of the wire transforms into a brass alpha phase (**Figure 25(b)**). It offers both benefits of high conductivity and tensile strength.[126]

Patent US7687738 refers to an electrode wire with a single copper core with a diffused zinc alloy coating. The thickness of the coating is more than 10% of the wire diameter. A surface contact film is optionally formed on this coating layer using one of the following elements: Zn, Cu, Ni, Si, or Au. In any of these cases, the spark erosion rate increases by approximately 30% when compared to a brass wire or zinc-plated brass wire of the same diameter. The effect of overall conductivity of the wire on spark erosion performance is another key aspect of this patent. Considering the conductivity property, it is assumed that higher conductivity of the design wire can lead to a higher machining rate because more electrical energy can be supplied from generators that are more powerful. It has been found that such an electrode wire has overall conductivity within the range from 65% IACS to 75% IACS. Conductivity less than 65% IACS is considered inadequate to attain optimum spark erosion cutting performance. At low electrical conductivity, the wire is more prone to breakage due to the impact of heating in the sparking area. This results due to the Joule effect following the reduced cooling related to lower thermal conductivity. Conductivity more than 75% IACS cannot be obtained for this type of electrode wire, because it would restrict the thickness of the diffused layer to less than 10% of the electrode wire diameter. If this procedure fails, then the wire was formed too rigid and brittle and must not be drawn during fabrication. The most recommended overall electrical conductivity of the electrode wire is approximately 69% IACS for a 0.33-mm electrode wire with 35-µm-thick diffused layer (relative thickness approximately 11%). This combination of relative thickness (11%) and overall electrical conductivity (69% IACS) yields good machining performance for wires ranging in diameter from approximately 0.20–0.35 mm.[129]

1.9.2.2.4.3 Gamma phase wires

Gamma phase brass has a higher zinc content than beta phase brass. The brittleness of gamma phase brass typically limits the gamma coating thickness to less than 5 µm. A thicker coating will fracture and strip off during the final drawing process. The brittleness of the gamma phase brass causes discontinuity on the surface as fractures during the final drawing process. This coarse surface improves flushing as the wire passes through the cut, enhancing water flow and scouring debris from the gap, which eventually increases the machining speed. However, the discontinuity in the surface may result in a slightly dirtier surface than other zinc-coated wires.[119] The gamma brass type

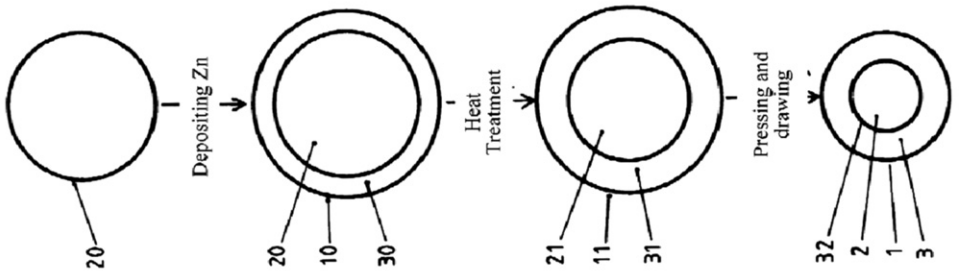

Figure 24 Different processing steps of the wire electrode.[128]

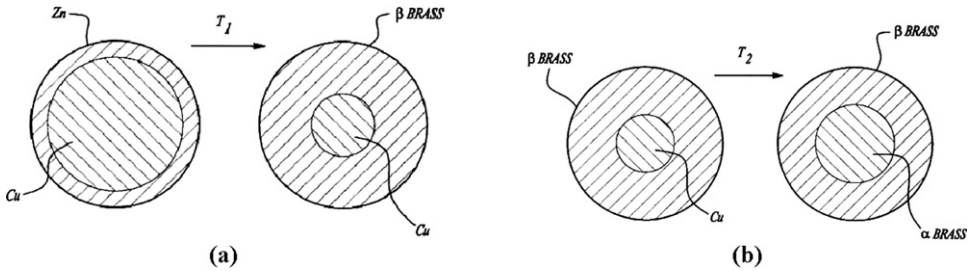

Figure 25 Wires with different coating thickness.[126]

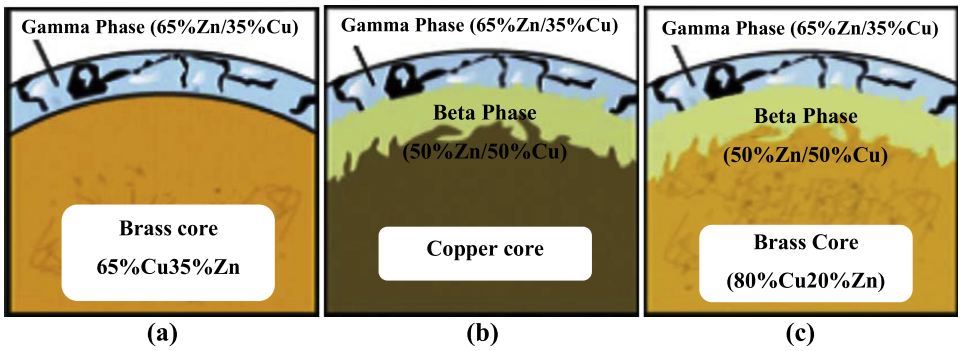

Figure 26 Gamma phase wire electrodes.[57]

of wire consists of a brass core coated with a gamma phase brass outer layer, and it usually has trade names such as Z-Kut, Topaz, Gamma-Z, and Delta Cut. A gamma phase brass coating replaces the pure zinc coating of the zinc-coated brass wire, as shown in **Figure 26(a)**. This construction usually yields 10–25% faster cutting performance than pure zinc-coated wires.[57] Patent US6566622B1 features the wire electrode core made of copper (X-type wire) or copper alloy (D-type wire). Such an electrode is first diffusion heat-treated to yield a beta phase, and then a stabilization treatment is performed to obtain an outer layer of the gamma phase (**Figures 26(b)** and **26(c)**).[130] The application of such electrodes can be similar to those of traditional X and D wire types, but it improves the machining performance by approximately 10%.[131] The diffusion-annealed beta phase brass has a high melting point and is composed of zinc in the range of 45–50%, thus providing excellent tenacity. Gamma wire offers a low-cost method of plating the gamma phase layer over the wire electrode surface. These wires offer an increased removal rate to reduce the cost of rough cuts, which enables them to decrease the cycle time.[132] The upgrades in technology suggested by various inventors have led to numerous efforts to improve gamma-coated wires by using low-temperature diffusion annealing.[114,116] A number of inventors attempted to coat the conductive core with multiple layers of film. The alloys of desired structure and composition are obtained by forming alternating coating layers on the core, where the layers are diffused into one another. These layers offer properties of high conductivity and low melting and vaporization in an alternating fashion.[120,133] The gamma coating phase is subjected to cladding surface passivation to build resistance against corrosion.[134]

Patent US5945010-97 revealed an electrode wire with a coating of a copper–zinc gamma phase alloy or a nickel–zinc alloy. The core of the wire usually contains any one of the following metals: copper, copper-clad steel, or brass. The second coating is formed of a metal such as Zn, Mg, or Al by using

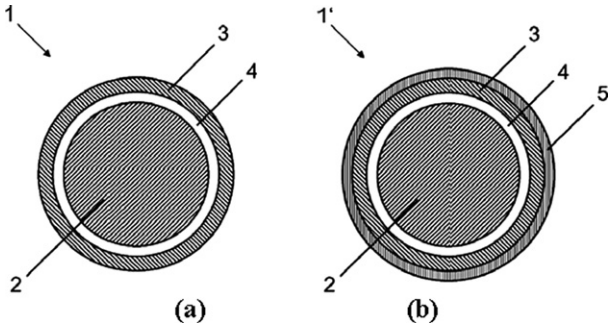

Figure 27 Cross-section of electrode wire.[137]

low-temperature diffusion anneals. The resulting EDM wire offers a faster cutting rate and a surface finish better than traditional wire electrodes. Other pros of the US patent 5945010-99 is achieved by the higher zinc content in the coating compared to the earlier US patent 5945010-97. This results in significantly lower volumetric heat of sublimation for the coating, which leads to more efficient flushing of wire, ensuring sufficient tenacity to survive the EDM erosion process. The tensile strength increases sharply with the formation of the beta phase. With the presence of alpha and beta phases in equal proportion, the tensile strength of brass peaks at a maximum value of 32% zinc content.[135] Considering these factors, patent US5808262 is meant to produce a spark erosion electrode. The core of this wire has relatively lower zinc alpha brass with an outer layer of highly rich zinc beta and gamma brass. This formation offers improved flashability of the electro-erosion process along with relatively higher tensile strength of the electrode core material.[136]

Patent number US2011/0290531A1 refers to a wire electrode (1,1′) for electric discharge cutting processes. The wire electrode (1,1′) has a core (2) made of a metal or metal alloy and a coating (3, 4; 3, 4, 5), at least one (3) of which constitutes a phase mixture of beta brass or beta prime brass and gamma brass, as shown in Figure 27. The beta or beta prime phase and the gamma phase are arranged sequentially in a fine-grained structure. The average size of these grains can be as high as 5 μm. In the preferred embodiment according to Figure 27(b), a core (2) is made of Cu–Zn20% with a coating layer (4) that adjoins the core. The core is primarily made of beta or beta prime brass alloyed with a zinc content of approximately 45 wt%. The coating layer (3) consists of a phase mixture of beta or beta prime brass and gamma brass with a mean zinc content of approximately 53 wt%. The major element of the top layer (5) is zinc oxide. This composition of materials yields a wire electrode (1′) of 750 N mm^{-2} tensile strength and electrical conductivity of approximately 17 m Ωmm^{-2}.[137]

Patent US8338735 has a brass core (1) coated with a gamma phase brass layer (2) with fragmented blocks (2a), between which the core (1) is exposed. The blocks (2a) have E2 thickness with a narrow distribution and they cover more than 50% of the core (1), as shown in Figure 28. This structure forms regular fragments in the coating to facilitate better finishing of the machined parts.[138]

US patent 5762726-98 is known for higher zinc content phases in the copper–zinc constructions. The gamma is a useful phase for EDM wire electrodes because it offers cutting

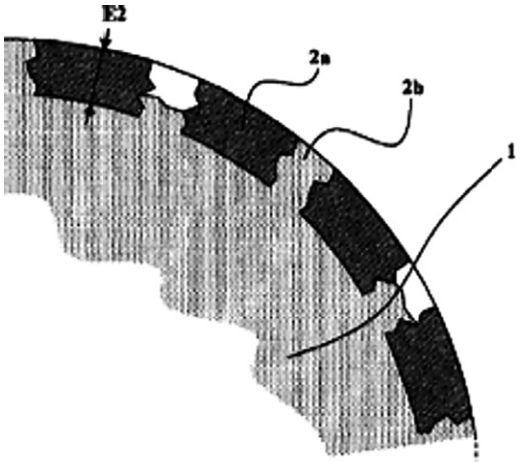

Figure 28 Large-scale diagrammatic view of cross-sectioned wire.[138]

performance superior to that of a wire electrode with a sheath layer over a pure beta phase. The cutting process is made more efficient with the aid of a pure gamma phase when compared to that of the beta phase. The gamma phase, which adds hard inert materials, is rarely produced in a traditional process like long-time diffusion. Therefore, a mixed structure with fractions of alpha, beta, and/or gamma phases is produced. Figure 29(a) shows the initial core of alpha brass and a sheath layer of zinc (eta zinc). Following heat treatment and the shortest possible holding time, another layer is formed between the core and sheath layer, which is termed the epsilon zinc layer (Figure 29(b)). After an increase in the annealing time and diffusion increase, the eta zinc layer transforms into an epsilon zinc layer (Figure 29(c)). It is evident in Figure 29(c) that during the annealing period, a thin gamma brass layer is intermediately formed between the core and epsilon zinc layer. The expansion of the gamma brass layer facilitates the diffusion process of the epsilon zinc layer into the gamma brass layer (Figure 29(d)). A thin layer of beta brass appears at a significantly lower growth rate between the regions of the gamma brass layer and the alpha brass core (Figure 29(e)). Figure 29(f) shows the period when the sheath layer changes to a gamma brass layer. The beta brass sheath layer is developed a little larger in the transitional region between the core and gamma brass sheath layer shown in Figure 29(e). Finally, Figure 29(f) illustrates the final processing state where the eta zinc layer is substantially decomposed and the expansion of the beta crystals results in a thin layer around the core. However, such wire electrodes are not viable in commercial manufacturing due to their failure to resist brittleness in these phases.[139]

There are two requirements in a machining process: speed the machining for a given current and ensure maximum usage of machining current for a given wire diameter. The EDM performance can be improved by using an electrode wire (1) made of copper or brass core (2) a beta brass sub-layer (3) and covered by a coating that combines a fractured gamma brass surface layer (4) (Figure 30). The advantage of beta brass is that it at least partially fills the fractures (5a) in the gamma phase region (5). The beta brass sub-layer may have a relatively smoother surface that facilitates better performance than does

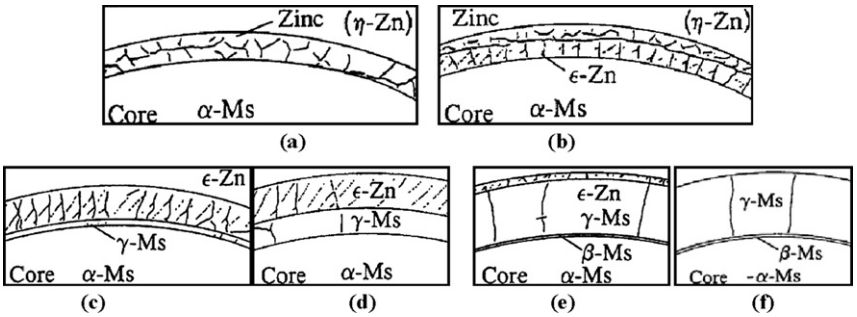

Figure 29 An enlarged representation of the detail of the sheath layer and the core.[139]

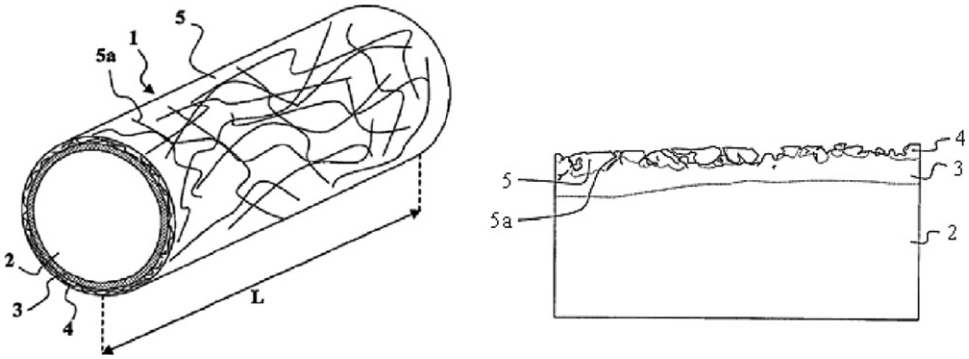

Figure 30 Schematic perspective view and a longitudinal section through an electrical discharge machining wire.[140]

an uneven sub-layer. The thickness of the fractured gamma brass layer is made less than 5% of the wire diameter to facilitate both higher speed and better finish of the machined workpiece.[140]

1.9.2.2.4.4 Epsilon phase wires

The lower melting point is known as one of the limitations of the epsilon phase when compared to beta or gamma phase coatings. However, the limitation is compensated by the higher zinc content in the epsilon phase, which matches the epsilon phase coating performance with that of beta phase coatings while being competitive with gamma phase coating performance. In general, coatings of the epsilon phase yield similar machining performance at a reduced production cost when compared to either beta or gamma phase coatings.[20]

US patent number 20070295695 reveals an EDM wire with a copper core, which is layered with continuous coating of porous epsilon phase brass. Graphite particles are used to fill the porous coating to enhance the performance of epsilon phase coating.[141]

The EDM wire of patent US8067689 consists of an outer layer of gamma phase brass followed by a continuous layer of single zinc or ductile epsilon phase brass. The continuous layer eliminates any discontinuities of the gamma phase and thus exposes a surface of homogeneous electrical properties to the workpiece (**Figure 31**). The epsilon phase brass coating is thinner than that filling the gaps between the gamma particles, which yield high performance with gamma coating. For the purpose of rough cuts, speed is more important than machining accuracy. **Figure 31(a)** shows a brass core (12) coated with a 10-μm-thick layer of zinc (15). The wire is heat-treated for 6 h at a temperature of 1700 °C in a nitrogen atmosphere. The heat-treated wire is shown in **Figure 31(b)**, which shows a coating of gamma phase brass (18) on the high brass core (12). The wire can be plated with a further layer of 10-μm-thick zinc (15), as shown in **Figure 31(c)**, because the nitrogen gas in the heat treatment has a nonoxidizing atmosphere. The brittle gamma phase forms fractured particles (19) in the event of cold drawing of the wire to its final diameter of 0.25 mm, as portrayed in **Figure 31(d)**. However, these particles are encapsulated by the zinc layer (16) on the high brass core (12) because the zinc layer is ductile enough to follow along these particles. The core substrate or its outer surface is also known to add copper content accordingly to the inventor. Therefore, several substrate metals have been considered for this wire design, such as pure copper, brass clad steel, copper-clad steel, brass, brass on copper, brass on copper-clad steel, and brass on brass.[142]

1.9.2.2.5 High tensile strength wires

The electric discharge during the machining process creates electrostatic and electromagnetic forces on the wire electrode. The machined area of the wire electrode is also subjected to a force opposite to the direction of the machining process. During the machining process, all these force factors including the wire vibration can deviate the wire position from its programmed position. This affects the quality and precision of the machining process.[143–146] The deviation of the wire position yields round corners instead of the desired sharp corners.[147] As a result, plain molybdenum or tungsten wires can form because of high tensile strength (>1900 MPa).[61,148] To address the high cost and poor flushability of wires, an improved

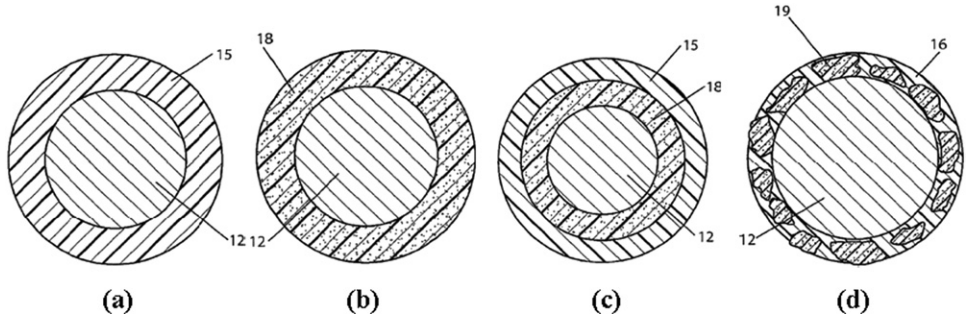

Figure 31 Cross-sectional view of wire.[142]

wire type was developed that is made of a high-strength pearlite steel wire with more than 0.06% carbon content and a layer of copper-free zinc or zinc alloy coating. This yields better precision and accuracy, even under a higher mechanical load.[20,119]

1.9.2.2.5.1 Molybdenum wire

Molybdenum wire is found in very specific applications. To achieve a decent load-carrying capacity in a thin wire, very high tensile strength is required. Moly wire is an excellent candidate in this regard, because it offers both high tensile strength and a high melting point at a diameter of 0.1 mm or less. Unfortunately, this wire suffers from low electrical conductivity and poor flushability. Furthermore, moly wire is very abrasive to power feeds and wire guides, very difficult to auto-thread, and very expensive to produce.[57,72]

1.9.2.2.5.2 Tungsten wire

Tungsten wire is often chosen as a cost-effective option over moly wires for a diameter of 0.05 mm or smaller. In addition, it offers a higher melting point and tensile strength than those of moly wire. Therefore, high-precision machining prefers tungsten wire to moly wire because it requires smaller inner radii within the range of 0.025–0.1 mm. These materials are preferable in high load-carrying capacity requirements, which are not feasible using brass and coated wires at such smaller diameter. However, tungsten and Moly wires are not suitable for thick work because of their numerous shortcomings such as high melting point, limited conductivity, low vapor pressure rating, and slow cutting tendency.[72,149]

1.9.2.2.5.3 MolyCarb wire

For requirements of small wire diameters, a composite wire known as MolyCarb offers competitive advantages. The flushability of moly wire is improved in this type of wire by its graphite and molybdenum oxide mixture coating.[57,150]

1.9.2.2.5.4 Steel core wires

The steel core wire uses a steel core and is typically known by trade names such as Compeed, MicroCut, and MacroCut. The steel core provides excellent tensile strength and ductility, and the intermediate copper layer provides conductivity in addition to a beta phase brass outer layer (**Figure 32**). Steel core wire shows significant resistance to interrupted cuts, breakage for tall workpieces, and poor flushing conditions without compromising exceptional machining performance. However, the steel core has several drawbacks such as straightness issues,

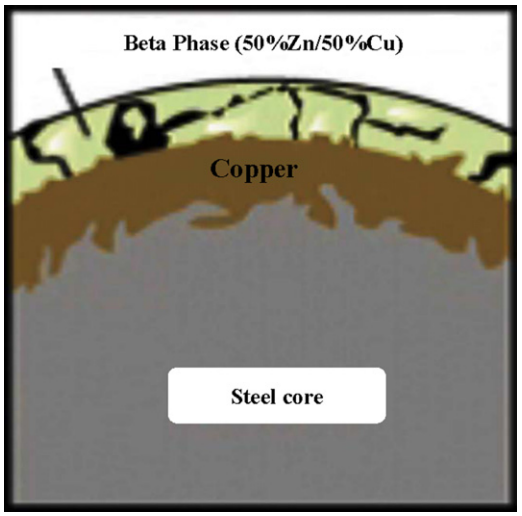

Figure 32 Steel core wire.[57]

high cost, possible damage to scrap choppers, and auto-threadability.[57,140,151]

US patent 4287404-1981 was designed to make the steel core wire effective in the machining process.[111] This invention includes steel core wire with a copper coating and then a coating of a material such as zinc, cadmium, tin, lead, antimony, bismuth, or alloys. This electrode offers good triggering of electrical discharge and reduces the probability of any short circuit. The outcome of this wire electrode is a machining speed higher than that of other conventional electrodes. In addition, Korean patent 10-1-0009194 and US patent US20080245773 offer a wire electrode for electrical discharge machining. These inventions include a steel core coated with copper or a copper–zinc alloy layer of CuZn10–CuZn50.[117] US patent US4686153-87 refers to an electrode wire with a steel core wire coated with conductive metals like copper, along with a surface coating layer of zinc. The average zinc content in the copper–zinc alloy coating is within 10–50 wt%.

The electrode wire (10) in **Figure 33** consists of a copper-clad steel wire (13) with a steel core (11) coated with uniform layers of copper (12) and copper–zinc alloy (14) 0.1–15 μm thick.[121] The wire electrode of US patent 4998552-91 includes a steel core wire with two layers: an inner layer of pure copper and an upper brass layer composed of 50 wt% zinc. The steel core is covered by pure or alloyed copper, which results in higher mechanical strength through a multilayer structure.[20]

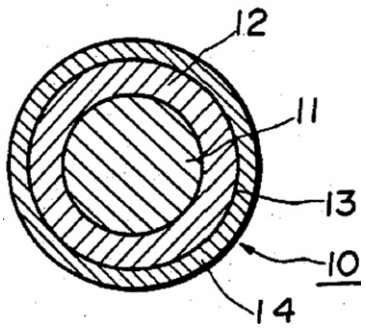

Figure 33 Sectional view of electrode wire.[123]

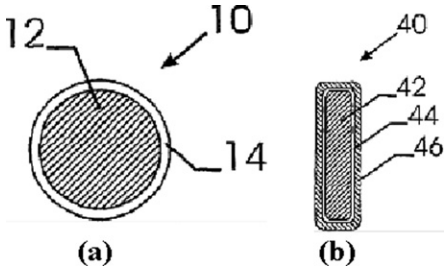

Figure 34 Round and flat electrical discharge machining wires.[152]

US patent 6875943-2005 refers to a high-strength pearlitic steel wire (10) characterized by more than 0.6% carbon and more than 3000 MPa tensile strength. The steel core (12) of the electrode is layered by a copper-free zinc or zinc alloy coating (14). The electrode is effective in applications requiring high-precision machining. Alternatively, a steel strip can be used as shown in **Figure 34(b)**. The wire of the circular cross-section, as shown in **Figure 34(a)**, should preferably have a diameter less than 0.35 mm and can be as low as 0.1, 0.07, or 0.03 mm. Wires with considerably low thickness such as 0.1, 0.05, or 0.02 mm are used as flat wires (40). The pearlitic steel core (42) contributes high strength, whereas the zinc or zinc alloy (Zn–Al alloy) coating (46) offers qualities like heat dissipation and machining functions. The coating with the zinc–aluminum alloy consists of 2 and 10% Al. A rare earth element such as La and/or Ce can be mixed in a proportion between 0.1 and 0.4%. An intermediate layer (44) made of aluminum or silver or alloy, or a nickel or nickel alloy, can be placed between the steel core and zinc or zinc alloy coating. This intermediate layer improves the electrical conductivity of the electrode. In one embodiment of the present invention, an additional layer is formed on the zinc or zinc alloy coating and one of the following materials is used to form this additional layer: graphite or metal oxides like ZnO, TiO_2, $A1_2O_3$, Cr_2O_3, ZrO_2, or Ag.[152]

1.9.2.2.6 Special wires

1.9.2.2.6.1 Abrasive-assisted wire

The EDM wire research currently focuses on achieving higher machining speed and surface integrity. In this regard, US patent 20100012628A1 presents a hybrid wire embedded with electrically nonconducting abrasives, as shown in **Figure 35**. In this process, two-body abrasion is used to improve material removal through electrical erosion. This results in a remarkable

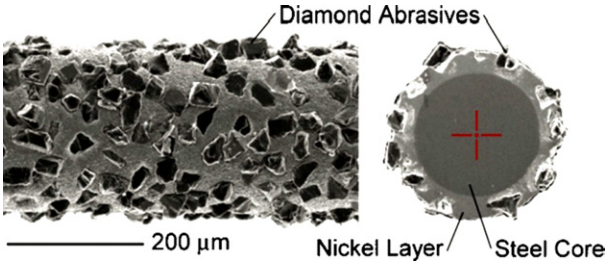

Figure 35 Surface and section of abrasive-assisted wire.[153,154]

improvement in removal rate and ensures better recast surface layer when compared to an equivalent WEDM process. There was negligible recast material present on the machined surfaces. A majority of this process is dedicated to machining steel. However, it may be useful in machining MMCs (such as polycrystalline diamond), which are usually hard to process with WEDM. The abrasion can negatively affect the machining performance, which makes such a process suitable for roughing sequences. Therefore, it is usually developed in a twin-wire machine tool. Although diamond wire can be effective in such work, wire with aluminum oxide abrasives can provide better performance at a lower cost.[153,154]

1.9.2.2.6.2 Hot dip galvanized wire

There are special cases of diffusion-annealed wires with less efficiency because of the nonuniform composition of zinc and alloy.[155] This led to the invention of US patent 20060138091, which involves the hot dip galvanization method. This method is effective for developing a uniform zinc coating on the wire surface.[156] During the first step, the wire goes under a surface-forming process. The coating formation is the next step, and then a second surface-forming process is performed. The final step involves homogeneous heat treatment. This type of wire can prevent harmful contaminants such as disposal of toxic gas and water that are common in traditional methods. In addition, developing a thicker zinc-coated layer eliminates the generation of waste powder and thus improves overall performance of the wire.[157]

1.9.2.2.6.3 Porous electrode wire

Prior studies revealed that the discharge property of diffusion-annealed wire electrodes is improved because of their porous surface infiltrated with graphite.[141] Continuous coating is maintained when the heat-treated wire is cold-drawn. The machining speed increases by at least 15% compared with the traditional zinc-coated wire because of rapid cooling of the wire in a cooling medium. The increased cooling ability is achieved due to the enlarged and porous surface morphology of the wire.[135]

Patent US6482535 refers to a porous EDM wire electrode as shown in **Figure 36**. This invention increases the surface area and inner part of the wire to offer a coated wire for enhanced machining speed. The rapid cooling of the wire is made possible by exposing the inner part to a cooling liquid. The following steps are adopted for this design purpose. First, a core metal with an initial diameter is chosen for a wire. Second, a second metal with a low vaporization point is chosen to perform hot dip galvanization of the core wire by passing it for

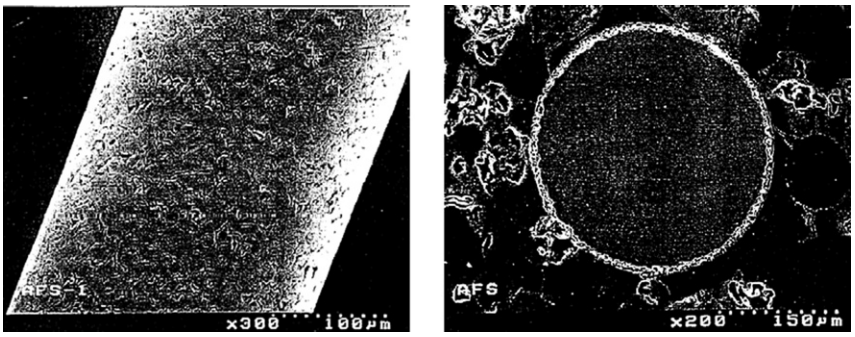

Figure 36 Illustration of the cross-section and surface of porous-coated wire.[103]

a specific time through the molten second metal. Third, an alloy coating by diffusion of both metals is developed, where the second metal is harder and with less elongation than the first metal. Finally, draw the wire with the alloy and coating layers to form a second diameter. This develops cracks in coating layers because of hardness and low elongation of the alloy layer. At this stage, copper or brass with 63–67 wt% copper and 33–37 wt% zinc contents can be alloyed with the first metal. In addition, metals like zinc, aluminum, or tin are viable options to be used as the second metal. The drawing procedure creates cracks in the alloy and coating layers, which characterize the porous nature of the wire.[158]

Similar to many other engineering practices, the selection of an optimal wire for a particular application would most likely be a trade-off for the properties mentioned. As an example, wires with high conductivity are usually low in tensile strength.

1.9.3 White Layer and Heat-Affected Zone

The temperature during electric discharge can go as high as 12 000 °C, which may lead to metallurgical changes in the workpiece surface during the WEDM process.[10] The dielectric fluid fails to remove some of the molten materials, which cool rapidly, and the heat conduction of the workpiece helps it stay hard on the surface. The annealed surface depth is directly determined by the spark energy of the machining process. The depth is reported approximately 50 µm for finish cutting and approximately 200 µm for high cutting rates.[16] In different spark erosion states, a recast layer (white layer) appears with many pockmarks, globules, and cracks of different sizes. Three types of recast layers have been reported. Type 1 represents a single layer less than 10 µm thick, without any distinct feature. Type 2 is an etchable single layer with a thickness of 10–20 µm. Type 3 consists of multiple overlapping hard layers with a thickness of 20 µm or more.[159]

Figure 37 shows the heat-stressed regions of AISI 1050 carbon steel (Figure 37(a)) and titanium alloy grade 5 (Ti6Al4V) materials (Figure 37(b)). Figure 37 illustrates that the heat-stressed regions consist of the white layer and the thermally affected zone.

The white layer forms at the temperature close to the melting point, which is not heated enough to be discharged and flushed away between the wire electrode and workpiece. This layer formation due to unejected and rapidly cooled molten materials during the WEDM process changes the metallurgical structure and properties of the surface layer. The solidified expelled particles may further deposit on the surface before they can be flushed out of the gap. The white layer is heavily contaminated with carbon, which turns it into a structure very different from the base material. The WEDM process expels the hydrocarbons from the electrode and dielectric fluid breakdown and creates extensive carbon particles that penetrate into the molten white layer.

The analysis of microstructure, topography, and composition of AISI 1050 carbon steel was conducted with the aid of scanning electron microscopy (SEM) coupled with energy-dispersive X-ray spectroscopy (EDX), as shown in Figure 38. Table 1 shows a comparative breakdown of the elements present in the AISI 1050 carbon steel base material prior to WEDM and after the white layer formation due to the WEDM. It is evident that there is a significantly high presence of carbon content after the WEDM process when compared to the base material before the WEDM. The heat-affected region lies beneath the white layer. Because this layer is thermally treated at a temperature below the melting point, it is relatively less affected due to the carbon infiltration of the white layer. This heat treatment below the melting point is absorbed by the heat-affected region without causing any alteration in the metallurgical structure of the parent material. Therefore, the WEDM process does not affect the parent material below the heat-affected region.

Figure 39 shows a very high prevalence of micro-cracking in the white layer. These micro-cracks may cause early failure of the material in the case where the white layer becomes too thick and not cleaned through finer finishes or polishing. Furthermore, the micro-cracks are responsible to reduce the corrosion and fatigue resistance of the product. Surface integrity is a major concern for the evaluation of the WEDM performance, and hence the WEDM process should aim to eliminate the formation of such white layers. The micro-cracks form due to the heat stress at the pulse on-time phase of the WEDM cycle. The intensity of micro-cracks is partially determined by the WEDM process, and the thickness of the white layer increases proportionately with the spark energy. The number and size of micro-cracks present in the cavity are also increased due to this process. The affected surface integrity due to the WEDM process can be controlled by the recent power supply technology. The parameters of the power supply that control the surface integrity are voltage, peak current, pulse on-time, pulse off-time, and pulse frequency. Efficient and

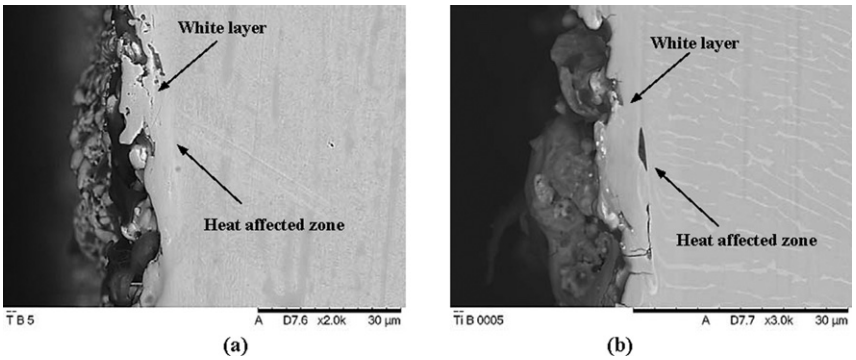

Figure 37 Thermally affected zone of (a) AISI 1050 carbon steel and (b) titanium alloy grade 5.

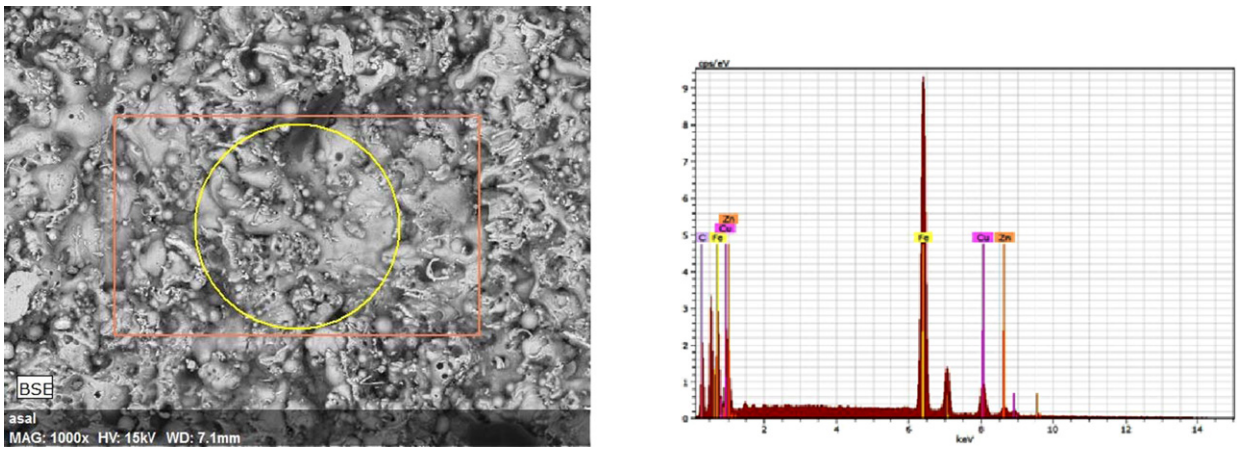

Figure 38 Energy-dispersive X-ray spectroscopy analysis of AISI 1050 carbon steel surface.

Table 1 Elemental analysis of AISI 1050 carbon steel surface before and after wire electrical discharge machining (WEDM)

Element	*C*	*Mn*	*P*	*S*	*Fe*	*Cu*	*Zn*
Before	0.54	0.69	0.03	0.04	98.7	–	–
After WEDM	14.8	–	–	–	63.5	15.8	5.9

balanced control of these power parameters can optimize the WEDM performance and maintain the surface integrity during the stages from roughing to the final finish.

It can be speculated that the intensity of spark energy during the WEDM discharge directly determines the thickness of the white layer and depth of the micro-cracks. The spark energy is gradually lowered from the roughing to the finishing state to reduce the white layer depth and crack formations.

1.9.4 Experimental Details

1.9.4.1 Experimental Design

The design of experiment (DOE) is one of the most powerful tools for experimental planning. It can be used as a great advantage to reduce experimental design changes and cost, as well as to increase design process speed by using statistical methods. The Taguchi method is most important DOE; it provides a simple and effective approach to determine the optimum process parameters. The Taguchi method applies an orthogonal array DOEs and selects a large number of control factors with a reduced number of experiments. In this array, the control factor matrix ensures a balanced contrast between the level and independent distribution among parameters. DOE can play an effective role in identifying impacts of many individual parameters on the system performance. The study of the effect of individual parameter can determine the most influential parameters for the performance measure.[160]

The Taguchi L18 orthogonal array is considered, which involves four machining parameters with three levels and one parameter with two levels, as shown in **Table 2**. Based on an initial investigation, the choice of these parameters is made within the range limit of a running machine without wire breakage.

1.9.4.2 Experimental Setup

A CNC Sodick AQ325L WEDM machine tool is used to conduct the experiment (**Figure 40**). Two different wire electrodes are used for machining titanium alloy grade 5 (Ti6Al4V) and AISI 1050 carbon steel under the machining conditions mentioned in **Table 2**. The characteristics of the two wire electrodes are listed in **Table 3**.

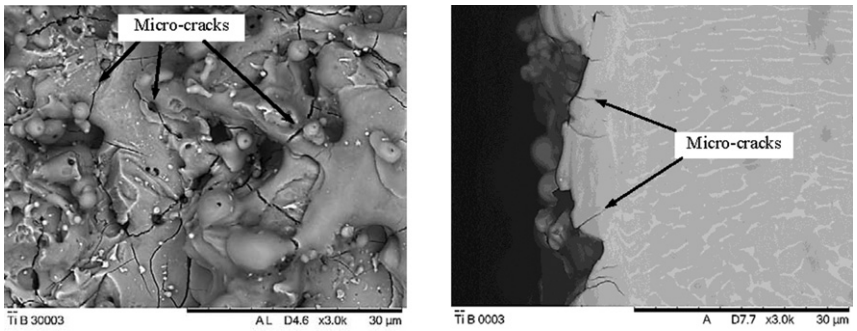

Figure 39 Scanning electron microscopy analysis of (a) Ti6Al4V surface and (b) cross-section illustrating micro-cracks in the white layer.

Table 2 Levels of machining parameters

Machining parameter	*Symbol*	*Units*	*Levels*		
			1	*2*	*3*
Peak current	IP	A	16	17	–
Pulse on-time	T_{on}	µs	0.2	0.3	0.4
Pulse off-time	T_{off}	µs	0.5	0.9	1.3
Wire speed	WS	m min^{-1}	2	4	6
Wire tension	WT	N	3.5	6	10.5

The machining parameters related to the power supply were taken into account to investigate their effect on WLT. These parameters were peak current (IP), pulse width (T_{on}), charging time (T_{off}), wire speed (WS), and wire tension (WT). The machining parameter levels (Table 2) were selected from prior studies, with the working range and levels of the WEDM process parameters following the one-factor-at-a-time method. The other machining parameters were kept constant (main voltage $V_o = 100$ V; spark gap voltage $V_d = 20$ V; flush pressure $= 14$ kgf cm^{-2}; and water resistivity $= 6 \times 10^4$ Ω cm) as recommended by the machine maker.

1.9.4.3 Samples Preparation

The workpiece materials used are titanium alloy grade 5 (Ti6Al4V) and AISI 1050 carbon steel with 100 mm × 100 mm × 20 mm dimensions, which were machined into 5 mm × 5 mm × 20 mm for each specimen. The chemical composition of titanium alloy and was produced by the EDX machine (Table 4) and AISI 1050 carbon steel (Table 1). The electrical resistivity and thermal conductivity of titanium alloy were 17.8×10^{-5} Ω cm and 6.7 W m^{-1} K^{-1}, respectively, and 1.63×10^{-5} Ω cm and 49.8 W m^{-1} K^{-1}, respectively, for AISI 1050 carbon steel.

1.9.4.3.1 Titanium alloy grade 5 (Ti6Al4V) preparation

The samples were ground using P240 (30 s), P320 (40 s), P400 (60 s), P600 (90 s), P800 (120 s), P1200 (180 s), P2500 (210 s), grit silicon carbide paper with a pressure of approximately 9 N, counter rotation of 400 rpm, and plenty of coolant water. Then, the samples were cleaned in ethanol at 30 °C for 15 min using an ultrasonic agitator between the steps. Then, the samples were polished using 9-, 6-, 3-, and 1-µm diamond suspension liquid under 6 N pressure with 7 min of counter rotation at 400 rpm. This was repeated until the surface become smooth (verified with optical microscope (OM) in interference contrast mode).

After polishing, 50 ml of oxide polishing suspension (OPS) with 10 ml H_2O_2 were used for final polishing with 400 rpm counter rotation for 5 min. This was repeated until the microstructure was visible, typically two or three times (checked with OM). Then, the sample surface was washed with dishwashing liquid and water, flushed with ethanol, and dried with a hair dryer. Finally, the samples were etched with Kroll's reagent 5–10 s. The samples were then cleaned in an ultrasonic agitator in acetone at 30 °C for 15 min. Then, samples were carefully rinsed, cleaned in distilled water, and dried to remove contaminants to acquire a uniform surface.

1.9.4.3.2 AISI 1050 carbon steel preparation

The samples were ground using 120 SiC abrasives for stock removal requirements. Once planarity and the area of interest are obtained, one of the standard procedures such as P220 (30 s), P360 (30 s), P800 (30 s), P1200 (60 s), P2400 (90 s), or P4000 (120 s) is applied using grit silicon carbide paper with pressure of approximately 10 N, counter rotation of 400 rpm, and plenty of coolant water. Then, the samples were cleaned in ethanol at 30 °C for 15 min using an ultrasonic agitator between the steps. Then, the samples were roughly polished using 6 and 3 µm diamond suspension liquid with pressure of 6 N, with 5 min of counter rotation at 400 rpm. It is repeated until the surface is smooth (checked with OM in interference contrast mode).

Finally, 0.05 µm alumina suspension liquid with pressure of 5 N was used for the final polishing at 400 rpm counter rotation for 5 min. It was repeated until the microstructure was distinctly visible (checked with OM). Then, the samples surface was washed with distilled water, flushed with ethanol, and dried with a hair dryer. The samples were then cleaned in an ultrasonic agitator in acetone at 30 °C for 15 min. Then, the samples were carefully rinsed, cleaned in ethanol, and dried to remove contaminants to acquire a uniform surface.

1.9.4.4 Surface Characterization

Microscopic surface examinations after each grinding and finishing step were performed using Olumpus BX 61 light OM.

1.9.5 Experimental Results and ANFIS Modeling

1.9.5.1 Experimental Results

The average WLT was calculated for three different measurements at three different places using an image-processing program (ImageJ). 36 Sets of data were used based on DOEs for building and training the ANFIS model, as shown in Table 5. Another four sets were used in a testing step after the training to verify the performance of estimating WLT values.

1.9.5.2 ANFIS Model Development

The neuro-fuzzy system gathers the benefits of fuzzy systems and offers an explicit and understandable representation of knowledge. However, the neural network involves implicit knowledge that is obtained through learning. The fusion of the concepts of fuzzy logic and neural networks may clarify cognitive uncertainties in manner similar to that of humans. The computational steps involved in the fuzzy-neural system are as follows. First, it builds a fuzzy-neuron based on the concept of biological neuronal morphologies, and then it applies a learning mechanism, as shown in Figure 41. This results in three steps in the fuzzy neural process[161,162]:

- Biological neuron-inspired construction of fuzzy neural models.
- Fuzziness introduced in neural network using synaptic connection models.
- Development of learning algorithms (algorithm to update the synaptic weights).

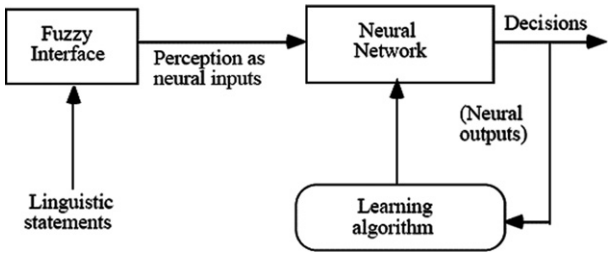

Figure 41 Fuzzy-neural system model.[161]

ANFIS was constructed on the MATLAB platform, and the training data set had 18 readings for each wire electrode, as listed in Table 5. ANFIS was trained using different membership functions. For each wire electrode, the ANFIS model was created using two membership functions for the peak current and three membership functions for other parameters (pulse on-time, pulse off-time, wire speed, and wire tension). The generalized bell-shaped membership functions (gbellmf) yields the minimum training error, which is chosen for training the ANFIS model in this study. The fuzzy rule architecture of the ANFIS involves 18 fuzzy rules produced by the input–output data set following the Sugeno fuzzy model. The training entails 50 cycles of learning using 18 performance measure values. The learning was conducted with an average error of 1.43×10^{-5} and 1.04×10^{-5} for brass and wire electrode with coating, respectively.

ANFIS uses five layers in the network to conduct several steps for fuzzy inference: (1) input parameters; (2) fuzzy set database layer; (3) fuzzy rule base construction; (4) decision-making; and (5) output defuzzification. For simple interpretation of each input variable, we considered two rules and two linguistic values, as shown in Figure 42.

Layer 1: This layer outputs the degree to which the given input conforms with the linguistic label associated with the node. The linguistic terms are represented using gbellmf because of the nonlinear relationship between the cutting parameters and machining performance (Figure 43(a)). A generalized bell MF is specified by three parameters (a, b, c), as shown in

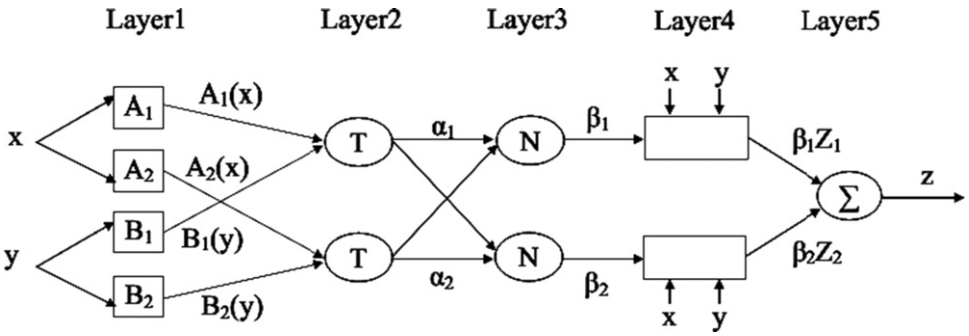

Figure 42 Adaptive neuro-fuzzy inference system architecture for a two-input Sugeno fuzzy model.[161]

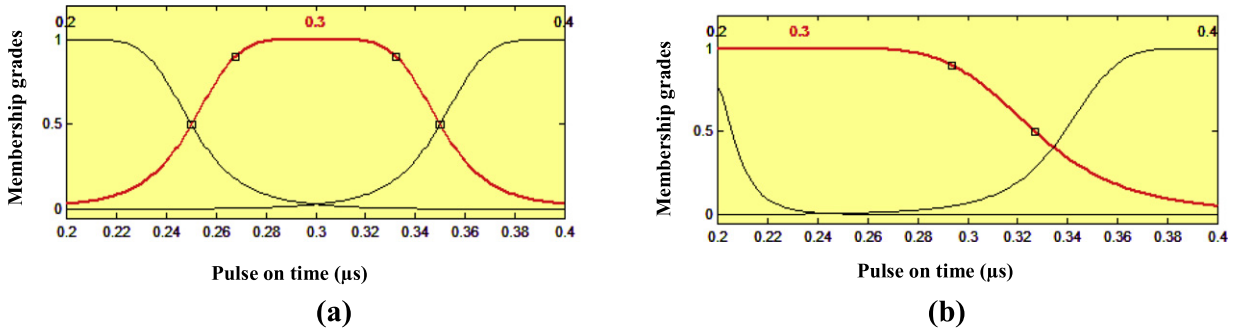

Figure 43 Initial and final membership function of pulse on-time: (a) initial membership function and (b) final membership function.

eqns [4] and [5]. Here, parameter b is usually positive and used to control the slope of the crossover point. Moreover, parameters a and c control the center and width of the MF.

$$A_i(x) = \frac{1}{1 + \left|\frac{x - c_{i1}}{a_{i1}}\right|^{2b_{i1}}} \quad [4]$$

$$B_i(y) = \frac{1}{1 + \left|\frac{y - c_{i2}}{a_{i2}}\right|^{2b_{i2}}} \quad [5]$$

Here (a_{i1}, a_{i2}, b_{i1}, b_{i2}, c_{i1}, c_{i2}) are the model parameters.

With the change in the parameter values, the bell-shaped functions differ consequently (Figure 43(b)). This results in

multiple forms of membership functions on linguistic labels A_i and B_i. The parameters of this layer are known as the principal parameters.

Layer 2: Each neuron in layer 2 estimates the strength of firing or activating the associated rule. The outputs from the top and bottom nodes are as follows:

$$\alpha_1 = A_1(x) \times B_1(y) = A_1(x) \wedge B_1(y) \quad [6]$$

$$\alpha_2 = A_2(x) \times B_2(y) = A_2(x) \wedge B_2(y) \quad [7]$$

The two nodes of this layer are labeled by T, because other t-norms are selected to model the logical and the operator. These nodes are termed as rule nodes.

Layer 3: Individual neurons of this layer estimate the normalization of the firing levels with respect to the sum of firing levels. The outputs of the top and bottom neurons are the normalized firing level of the first and second roles, respectively.

$$\beta_1 = \frac{\alpha_1}{\alpha_1 + \alpha_2} \quad [8]$$

$$\beta_2 = \frac{\alpha_2}{\alpha_1 + \alpha_2} \quad [9]$$

Layer 4: Each neuron of this layer estimates the product of the normalized firing levels with the outputs of the individual associated rule.

$$\beta_1 Z_1 = \beta_1(a_1 x + b_1 y) \quad [10]$$

$$\beta_2 Z_2 = \beta_2(a_2 x + b_2 y) \quad [11]$$

Layer 5: Neurons in this layer estimate the total system output by adding all incoming values.

$$Z = \beta_1 Z_1 + \beta_2 Z_2 \quad [12]$$

If a crisp training set $((x^k, y^k), k=1,\ldots, K)$ is known, then descent type methods can be used to train the parameters of the hybrid neural net. The error function for pattern k is given by:

$$E_k = (O^k - Z^k)^2 \quad [13]$$

where O^k is the desired output and Z^k is the estimated output by the neural network.

1.9.5.3 ANFIS Model Verification

Four random readings were considered in the testing data set. The measured WLT values versus predicted values from the ANFIS model are listed in **Table 6**. The plot of four measured WLT values versus predicted values from the ANFIS model is presented in **Figure 44**. This figure presents a comparison of the measured and predicted WLT of Ti6Al4V using brass and coated wire electrodes. There are also proper agreements between the experimental and model predicted values. This close agreement clearly shows that the ANFIS model is useful for predicting and optimizing the WLT under consideration.

To evaluate the fuzzy model, the percentage error E_i and average percentage error E_{av} defined in eqns [14] and [15], respectively, were used.

$$E_i = \frac{|T_m - T_p|}{T_m} \times 100 \quad [14]$$

$$E_{av} = \frac{1}{m}\sum_{i=1}^{m} E_i \quad [15]$$

Here, E_i represents the percentage error for the sample number i, T_m is the measured value, T_p is the predicted value, $i=1,2,3$ denotes the sample number, and E_{av} represents the average percentage error of m sample data.

The obtained average percentage errors are 6.07 and 7.18 for brass and coated wires, respectively. These low error values indicate that the ANFIS-predicted WLT results are almost similar to the actual measurements from the experiment. The error values suggest that the proposed model can predict and optimize the WLT satisfactorily.

1.9.6 ANFIS Modeling Results and Discussion

1.9.6.1 Effect of Electrical Parameters on WLT

This section introduces the effect of electrical parameters (pulse on-time, peak current, and pulse off-time) on the WLT of titanium alloy grade 5 (Ti6Al4V) using brass and coated wire electrodes. In addition, the effect of discharge energy and pulse frequency on the WLT was also introduced.

1.9.6.1.1 Brass wire electrode

Figure 45 introduces the effects of the electrical parameters on the WLT of Ti6Al4V based on the ANFIS models of brass wire electrode. **Figure 45** shows that pulse on-time, peak current, and pulse off-time have great effects on WLT, whereby the WLT increases with increasing pulse on-time and peak current but decreases with the increase of pulse off-time.

The same conclusion was obtained from the experimental work, as shown in **Table 7**. It introduces SEM micrographs at $\times 3000$ magnification for the WLT of Ti6Al4V at different pulse on times and peak currents using brass wire electrode. This micrograph verifies that the maximum of WLT is at the highest levels of peak current and pulse on-time. The minimum WLT occurs at the lowest values of pulse on-time and peak current. Increasing peak current and pulse on-time increase the spark energy, as shown in eqn [1]. Hence, the heat produced on the machined surface is increased further, resulting in a larger WLT on the workpiece. Moreover, **Figure 46** and **Table 5** show that during WEDM, the WLT of Ti6Al4V is 3 µm at 40 µJ spark energy and the WLT increases 3 µm linearly for each increase of 20 µJ spark energy at the same duty factor. In addition, the increase of pulse off-time decreases the WLT, as shown in **Figure 46**. This is because the increase of pulse off-time decreases the pulse frequency (eqn [2]). The increase in pulse frequency increases the heat generated on the workpiece surface; therefore, the WLT increases. The same conclusion was obtained from the experimental work, for which the WLT at a low level of pulse off-time ($T_{off}=0.5$ µm or $F=1\,250\,000$ HZ) is 20.23 µm (**Figure 47(a)**) and that at a high level of pulse off-time ($T_{off}=1.3$ µm or $F=625\,000$ HZ) equals 15.61 µm (**Figure 47(b)**). The smallest values of peak current and pulse on-time with the biggest values of pulse off-time appear to be the best choices to obtain a less thick white layer.

1.9.6.1.2 Coated wire electrode

Figure 48 introduces the effects of the electrical parameters on the WLT based on the ANFIS models of coated wire electrode. Figure 48 shows that peak current, pulse on-time, and pulse off-time have a significant impact on WLT. That is, the WLT increases with the increase of the peak current and pulse on-time but decreases with the increase of the pulse off-time.

The same conclusion was obtained from the experimental work, as shown in Table 8. Table 8 introduce SEM micrographs at $\times 3000$ magnification of the WLT at different peak current and pulse on-time using a coated wire electrode. This micrograph verifies that the maximum of WLT is at the highest levels of peak current and pulse on-time, and the least WLT is at the lowest values of pulse on-time and peak current. Moreover, Figure 49 and Table 5 show that during WEDM, a thin WLT of 2 μm at 40 μJ spark energy is produced, and the WLT increases 2 μm linearly for each increase of 20 μJ spark energy at the same duty factor. Moreover, the decrease of pulse frequency decreases the WLT, as shown in Figure 49. The same conclusion was obtained from the experimental work. Here, the WLT at a low level of pulse off-time ($T_{off}=0.5$ μm or $F=1\,250\,000$ HZ) is 11.48 μm (Figure 50(a)), and of high level of pulse off-time ($T_{off}=1.3$ μm or F=625 000 HZ) is equal 8.63 μm (Figure 50(b)). The smallest values of peak current and pulse on-time with the biggest values of pulse off-time appear to be the best choices to obtain a less thick white layer.

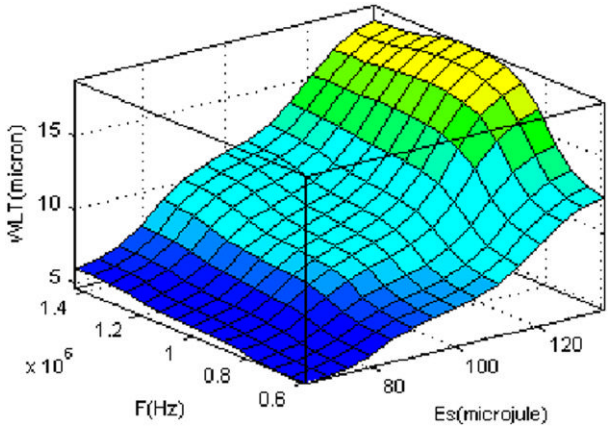

Figure 49 Adaptive neuro-fuzzy inference system model white layer thickness in relation to spark energy and pulse frequency of coated wire electrode.

1.9.6.2 Effect of Wire Electrode Parameters on WLT

This section shows the effects of the wire electrode parameters on the WLT of Ti6Al4V based on the ANFIS models of brass

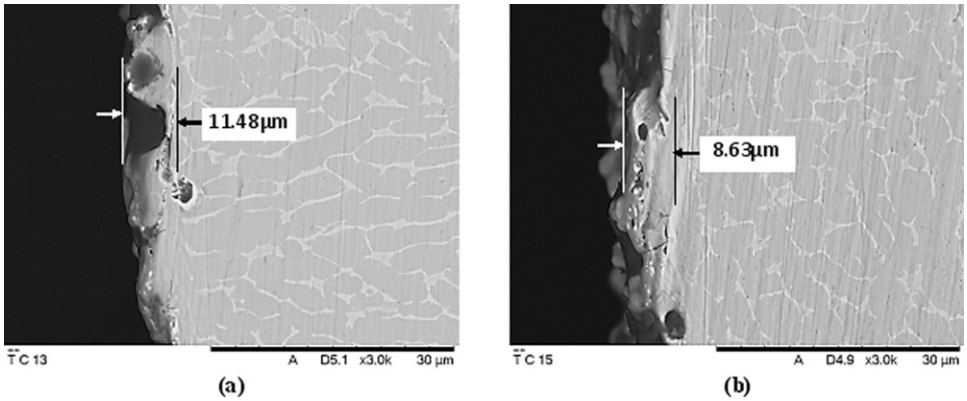

Figure 50 Scanning electron microscopy micrograph of the white layer thickness using coated wire electrode: (a) low level of pulse off-time and (b) high level of pulse off-time.

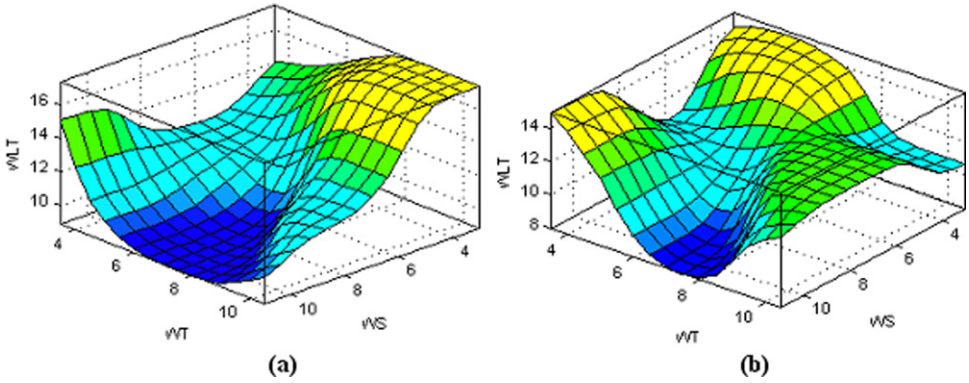

Figure 51 Adaptive neuro-fuzzy inference system model white layer thickness in relation to wire speed and tension parameters change: (a) using brass electrode and (b) using coated wire electrode.

and coated wire electrodes. Figure 51 shows that wire speed has a considerable effect on WLT, but wire tension has a minor effect on WLT. In both cases (brass and coated wires), the WLT decreases with the increase of the wire speed. This is because when the wire speed increases, fresh wire is introduced to the cutting zone, leading to stable cutting by preventing wire rupture. This type of electrode has a considerable effect on maintaining surface integrity. Figures 52(a) and 52(b) show the surface micrograph using brass and coated wire electrodes, respectively, at the same machining parameters. In addition, Figures 53(a) and 53(b) show the WLT using brass and coated wire electrodes, respectively, at the same machining parameters. It can be seen from Figure 52 that the surface finish using coated wire is better than using

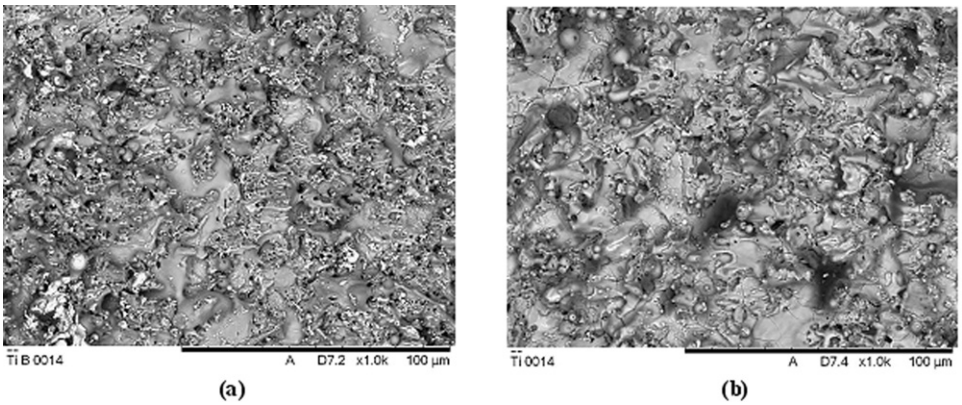

Figure 52 Scanning electron microscopy micrograph of Ti6Al4V surface using (a) brass wire and (b) coated wire electrode.

a brass wire electrode. Moreover, the WLT obtained using coated wire (**Figure 53(b)**) is smaller than that using brass wire (**Figure 53(a)**).

1.9.6.3 Effect of Workpiece Parameters on WLT

The thermal conductivity of the work metal plays an important role in the surface integrity of WEDM. Metals with high thermal conductivity will usually yield a smaller WLT and less micro-cracking than a lower conductive material. This is because of the higher energy dissipation over the surface of the higher conductive materials. From the experimental work, AISI 1050 carbon steel material has a thinner white layer with less cracks because of its high thermal conductivity and ductile nature when compared to titanium alloy grade 5 (Ti6Al4V), as shown in **Figures 54** and **55**. **Figures 54(a)** and **54(b)** introduce the WLT SEM micrograph of Ti6Al4V and AISI 1050 carbon steel, respectively, at the same machining conditions (IP = 17 A, T_{on} = 0.3 µs, T_{off} = 1.3 µs, WS = 7 m min^{-1}, WT = 3.5 N) using a brass wire electrode. The WLT of Ti6Al4V equals 15.61 µm, and that of AISI 1050 carbon steel equals 10.73 µm. **Figures 55(a)** and **55(b)** introduce the SEM micrograph of Ti6Al4V and AISI 1050 carbon steel surface, respectively, during the same machining conditions (IP = 16 A, T_{on} = 0.2 µs, T_{off} = 0.5 µs, WS = 3 mm min^{-1}, WT = 3.5 N) using a brass wire electrode. There are many more surface cracks in Ti6Al4V than in AISI 1050 carbon steel. In contrast, material with low thermal conductivity cannot act fast enough to dissipate the energy at the neighboring areas, as shown in **Figures 54** and **55**. This allows the spark energy to remain longer, resulting in a thicker white layer with more cracking.

1.9.7 Conclusions

This study investigates the effect of cutting parameters on the WLT of Ti6Al4V and AISI 1050 carbon steel workpieces using brass and coated wire electrodes. Based on these experimental investigations, the peak current, pulse on-time, pulse off-time, and workpiece material are the most influential parameters affecting the WLT formation. The wire speed has a considerable effect, but wire tension has a minor effect on the WLT. A successful empirical model is developed with the aid of ANFIS to predict the relationship between machining parameters (IP, T_{on}, T_{off}, WS, and WT) and the WLT. The training data set for the ANFIS model is built using 36 measured WLT values under different cutting conditions. Four values were used as testing data to verify the models where the average errors were 6.07% using brass wire and 7.18 using coated wire electrode. These results indicate that the ANFIS model with gbellmf is accurate and can be used to predict WLT in WEDM. The ANFIS model is found to be an efficient predictor because of its ability to capture complex nonlinearities and interactions. The ANFIS models settles the peak current, pulse on-time, and pulse off-time as the most influential parameters affecting the WLT. The wire tension and wire speed have minor effect on the WLT. The ANFIS models show that minimum WLT is achieved at the lowest levels of peak current and pulse width, and with the highest level of pulse off-time. In addition, the application of the ANFIS model in the analysis of results in WEDM reveals the following conclusions:

- Low pulse on-time (0.2 µs), low peak current (16 A), high pulse off-time (1.3 µs), high wire speed (11 m min^{-1}), and high wire tension (10.5 N) lead to a smaller WLT for the specific test range.
- By applying the proposed ANFIS, it appears that using a lower spark setting with higher pulse cycle settings will reduce the chip size and produce better flushing. This could lead to less WLT.
- At the same duty factor, the WLT of Ti6Al4V using brass wire equals 3 µm at 40 µJ spark energy and increases 3 µm linearly for each increase of 20 µJ spark energy. WLT using coated wire equals 2 µm at 40 µJ spark energy and increases 2 µm linearly for each increase of 20 µJ spark energy.
- Using a coated wire electrode is better than using brass wire for smaller WLT.
- High thermally conductive metals (AISI 1050 carbon steel) typically have a smaller WLT and less micro-cracking than those of a less conductive material (Ti6Al4V) in WEDM.

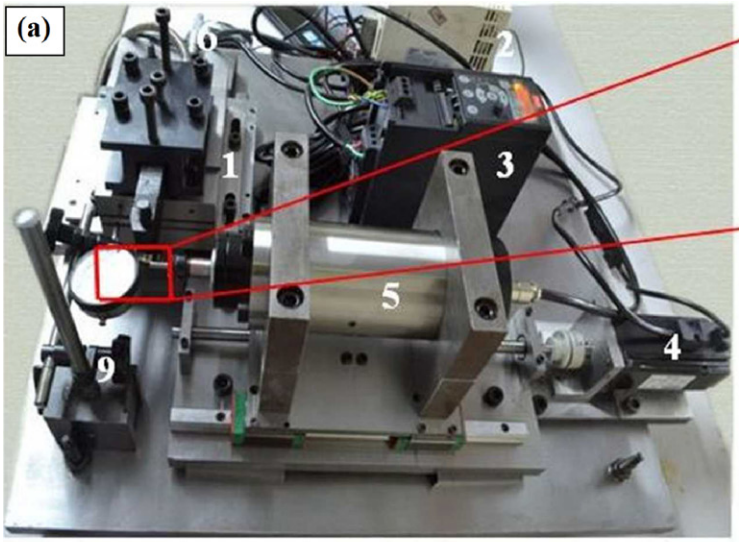
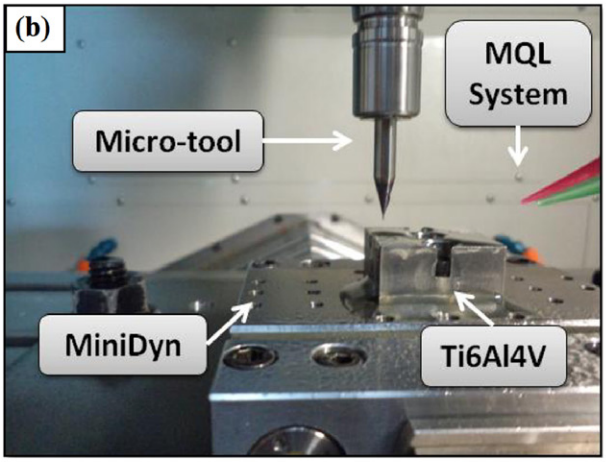
1.10.1 Introduction

According to the CRIP committee of physical and chemical processes, micro-machining is considered as one of the most fundamental technologies to manufacture and miniaturize products and parts with a dimension between 1 and 999 μm.[1] Miniaturized products and parts are mainly used in biotechnology, information technology, environmental, medical industries, electric devices, miniaturized machines, and so on.[2,3] With the recent advancements in Microelectro Mechanical System, micro-machining is being more and more popular day-by-day.[4] A lot of studies have already been done about the fabrication of functional micro-structure and component.[4,5] Basically, micromachining has been classified into three processes including conventional material removal processes, non-conventional material removal processes, and hybridized processes.

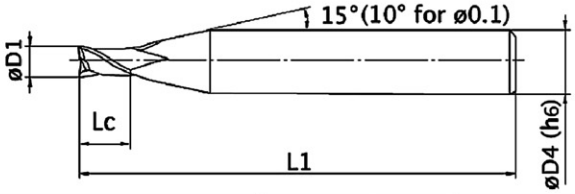


1.10.2 Material Removal Processes

1.10.2.1 Conventional Process



Mechanical force and energy are required for conventional material removal processes where shear force removes the material. Shear refers to simple machining process by physical contact between material and cutting tools.[6,7] Traditional material removal processes such as micro-turning, micro-milling, micro-drilling, and grinding use a single-point diamond cutter or very fine-grit-sized grinding wheels to produce machine parts. They can be used for machining of the most of the materials; for example, ferrous and non-ferrous metals, semiconductors, and plastics. The products with any shape such as flat surfaces, arbitral curvature, long shaft, and so on can be fabricated by conventional material removal processes.[8,9] Figure 1 presents the experimental setup for micro-turning, micro-milling, and micro-grinding.[10–13]



1.10.2.2 Nonconventional Process

In the nonconventional process, other sources of energy such as light energy, spark energy, vibration energy, electrolysis energy, energy beams (laser beam, electron beam, or ion beams), mechanical energy (based on erosion mechanism), etc., are used to remove the material.[7,14–16] Techniques based on energy beams (beam-based micromachining) or solid cutting tools (tool-based micromachining) can be used for micro-machining. There are some constraints due to poor control of 3D structures, low material removal rate (MRR) and low aspect ratio in the beam-based micro-machining by using the laser beam, ion beams, or electron beam. Furthermore, special facilities are required for these processes and the maximum achievable thickness is relatively small.[15,16] Also, due to its quasi-three-dimensional structure, there are some limitations in using photolithography on silicon substrates includes its low aspect ratio and limitation of the work material. High aspect ratio of three-dimensional submicron structures by very high form accuracy can be produced deep X-ray lithography using synchrotron radiation beam (LIGA) process and focused-ion beam machining process. While the special facilities are required for these processes and the

maximum thickness is relatively small.[15,16] Figure 2 illustrates the photographic view of the CNC-pulsed Nd:YAG laser machining system[17] and schematic diagram of experimental setup for laser micro-milling process,[18] cover plate laser beam machining (c-LBM),[19] laser induced plasma micro-machining,[20] focused ion beams (FIB) system,[21] and gas cluster ion beam irradiation system for precision machining.[22]

1.10.2.3 Hybridized Process

Hybridized processes are basically a combination of conventional material removal processes (like turning and milling) and non-conventional (such as electrical discharge machining (EDM), wire electrical discharge grinding (WEDG), and electrical discharge grinding (EDG)) to make microstructures with high accuracy. The hybrid material removal process can produce micro-components with almost all kinds of the material, such as metal, plastics, and semiconductors. It can be machined with no limitation of shape; for instance, flat surface, arbitrary curvatures, and long shaft that are needed for the moving parts and guiding structures.[23–26] The hybrid machine which includes microturning, micromilling, micro-EDM, wire electrical discharge machining (micro-WEDM), micro-WEDG, and on machine measurement equipment is shown in Figure 3.

1.10.3 EDM and Micro-EDM Processes

1.10.3.1 Electrical Discharge Machining

EDM is a nonconventional machining process that removes electrical conductive materials according to the thermal energy (melting and partial vaporization of the workpiece) produced by series of sparks occurring between the electrode and workpiece.[27–30] The EDM process is potentially useful for machining materials with various hardness, complex shapes, strength, temperature–resistant, fine surface finish, and accurate dimensions.[27–29,31–33]

Figure 4(a) illustrates that each spark occurs between the workpiece and the closest points of the electrode. The material is removed from both the electrode and workpiece by the spark, which results in an increase of the distance between the electrode and the workpiece at that point. This causes the next spark to occur at the next-closest points between the electrode and workpiece as shown in Figure 4(b). As also can be seen in Figures 4(a) and 4(b), the electrode and workpiece surfaces are quite rough. In fact, all surface finishes have irregular surfaces. Even though the surfaces have only very minute peaks and valleys, these very small changes of dimension allow the EDM spark to occur between the closest peaks.[34]

In EDM, the flow of electricity between the electrode and workpiece introduce the heat in the form of a spark. The main characteristic of the dielectric fluid is that it works as an electrical insulator, until enough voltage is applied to cause it to change into an electrical conductor. The dielectric fluid deionizes when the spark is turned off and the fluid returns to being an electrical insulator. For each spark, this change of the dielectric fluid from an insulator to a conductor, and vice versa occurs as shown in Figure 5.[34]

A small amount of the electrode and workpiece material is vaporized with each spark. The vaporized material is placed in the sparking gap between the workpiece and the electrode in the form of a cloud. The vaporized cloud solidifies when the spark is turned off. Each spark then produces a very tiny hollow sphere of material known as EDM chip (debris) made up of the electrode and workpiece material. Figure 5 illustrates the spark producing the vapor cloud, the cloud in suspension, cloud being cooled and forming into an EDM chip, and removing the chip by flowing dielectric.[34]

The EDM chip must be removed from the sparking area for efficient machining. This removal is performed by flowing dielectric fluid through the sparking gap. Part of the EDM chip is removed by the dielectric fluid and the remaining part solidifies on the electrode surface. As a result, each discharge produces a small crater on both workpiece and tool electrode.[35]

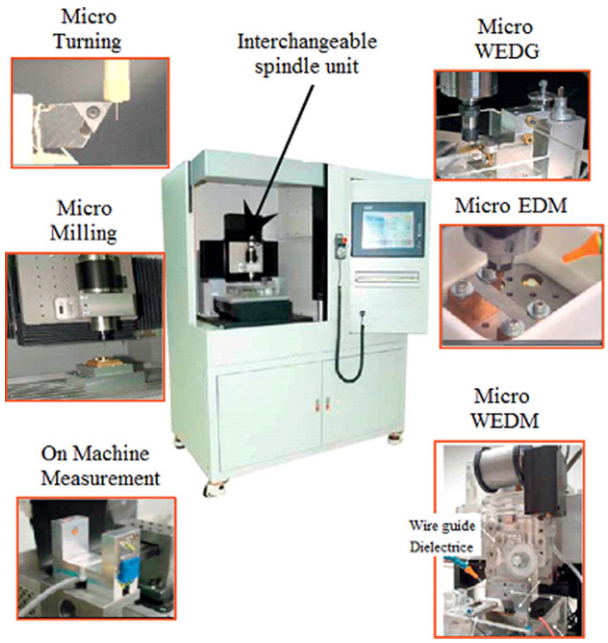

Figure 3 Hybrid machine for multi-processes of micromachining.[3]

1.10.3.2 Sparking and Gap Phenomena in EDM

Rajurkar *et al.* and Kunieda *et al.* reveal that the steps of gap phenomena include the formation of plasma in the dielectric, electrons and ions interaction, heat transfer and material removal by melting and vaporizing, solidified the melting and vaporizing material to debris (chip), flushing the debris, and another spark generation as schematically illustrated in Figures 6(a)–6(c).[36,37]

Figure 6(d) presents a schematic view of the discharge spot. The arc column diameter is considered to increase with the passage of time and equal to the diameter of the generated discharge crater. Electrode materials and dielectric liquid are evaporated, molecules are dissociated, and atoms are ionized, resulting in a rapid expansion of the bubble. As the expansion is confined by the viscosity and inertia of the dielectric fluids, the remaining inside pressure of the bubble gets extremely high level and the boundaries between the bubble and liquid get expanded with the several 10 m s^{-1} of velocity order. It is yet considered that the dielectric liquid has a significant role in the material removal process as the dynamics of the material removal in EDM depends on the high velocity and pressure development in the bubble.[36]

After the end of the discharge duration, ions and electrons are recombined and the dielectric breakdown strength is recovered. The evaporated atoms and molecules are solidified or

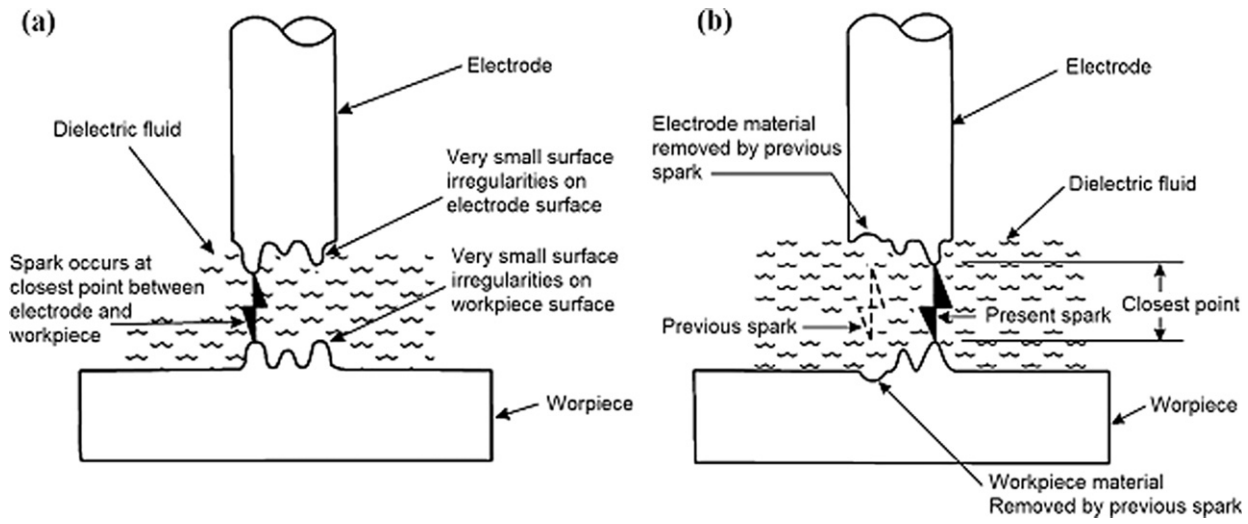

Figure 4 (a) Spark occurs between closest points. (b) Spark movement with a change of closest points.[34]

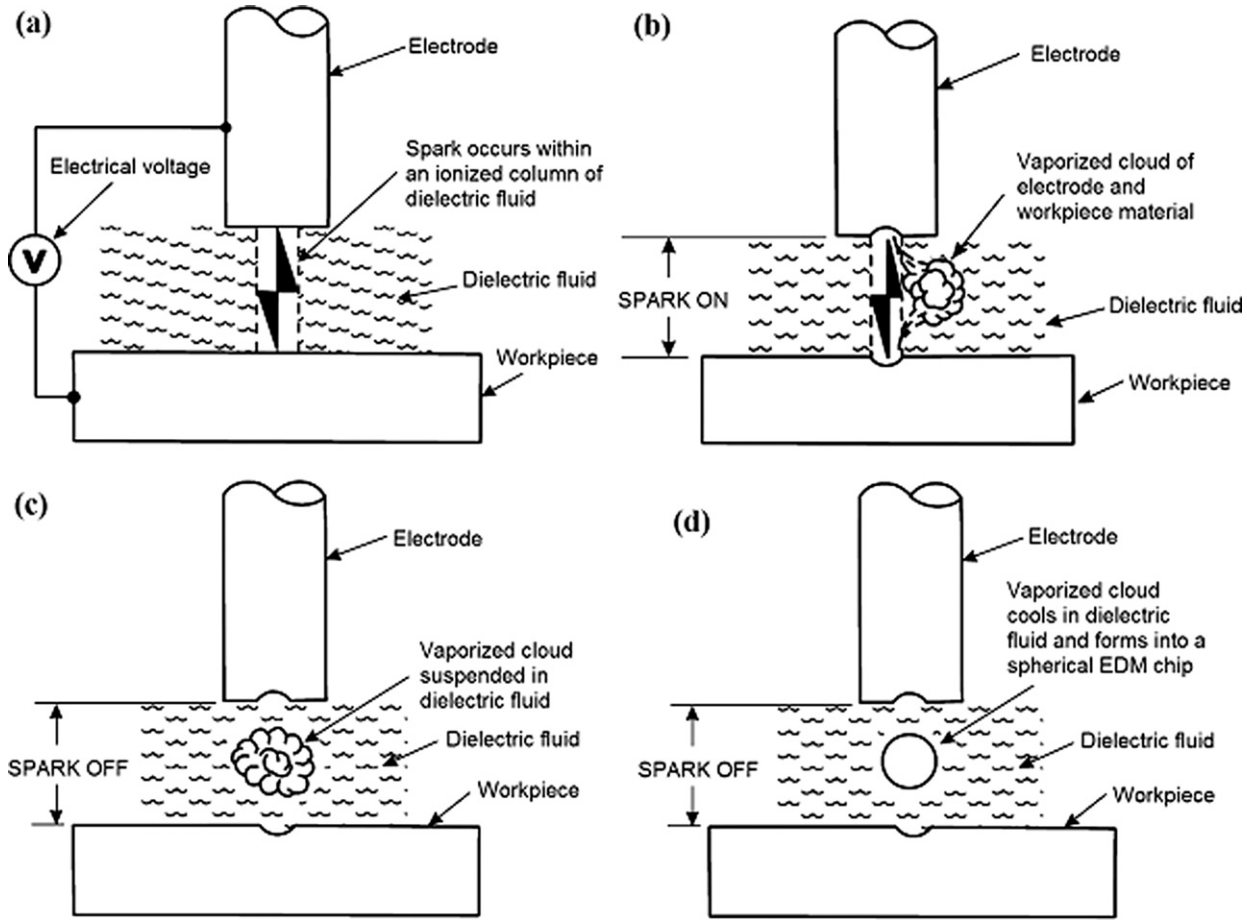

Figure 5 (a) Spark ON: electrode and workpiece material vaporized. (b) Spark OFF: vaporized cloud suspended in dielectric fluid. (c) Spark-OFF: vaporized cloud solidifies to form EDM chip (debris).[34] (d) Spark-OFF: remove the chip by flowing dielectric.

condensed to form debris particles or dielectric liquid, but gases such as hydrogen and methane which are generated by the dissociation of the working oil are left to form a bubble. Since pulse discharge occurs several thousand times or more per second, obviously the gap becomes filled with gas in typical EDM processes. Hundreds of debris particles are generated per single pulse discharge. Melted and evaporated materials are cooled by the dielectric liquid and solidified to form spherical debris particles. Thus, debris particles are removed from the gap with the dielectric liquid and not reattached on the workpiece and electrode surfaces. Furthermore, heat convection in the boundary layers of the dielectric liquid cools the workpiece and electrode surfaces, resulting in machining stability. Thus, the dielectric liquid plays another important role in flushing debris particles and cooling of the gap.[36]

1.10.3.3 Function and Types of Micro-EDM Process

Micro-EDM and EDM have same characteristics but only the size of electrode, discharge energy, and resolution of movement in axis are at the micron level in micro-EDM.[6] The principle functions of the micro-EDM process are micro-mold making, production of die and cavities, and complex three-dimensional shapes in the micron size.[38] In EDM and micro-EDM, no direct contact and negligible force between the workpiece and tool cause to elimination of deformation on the tool, chatter, mechanical stress, and vibration errors during machining.[6,39,40]

A micro-mold cavity has function in mass production of a microcomponent which can be produced by injection molding. Hard-to-machined materials are used for micro-injection that should be machined very accurately and complex shape in three-dimensional forms in the micron range.[3–5] Micro-EDM is one of the effective alternative machining processes that can be used successfully in the production of complicated three-dimensional models using very hard die materials.[3–5] Besides, it is also possible to use for very high-precision machining of the curved surface, slope surface, and thin-sheet materials that are difficult for machining.[1,6,39,41,42] Moreover, a conductive material with any hardness can be machined by micro-EDM without any force. So, micro-mold can be fabricated by using a very thin electrode with controlling of the EDM contour.[3–5]

According to Jahan *et al.*,[43] current micro-EDM technology schematic is shown in **Figure 7**, is used for manufacturing micro-features can be categorized into five different types are as follows:

- Die-sinking micro-EDM, where a microelectrode is used to fabricate its mirror image in the workpiece.

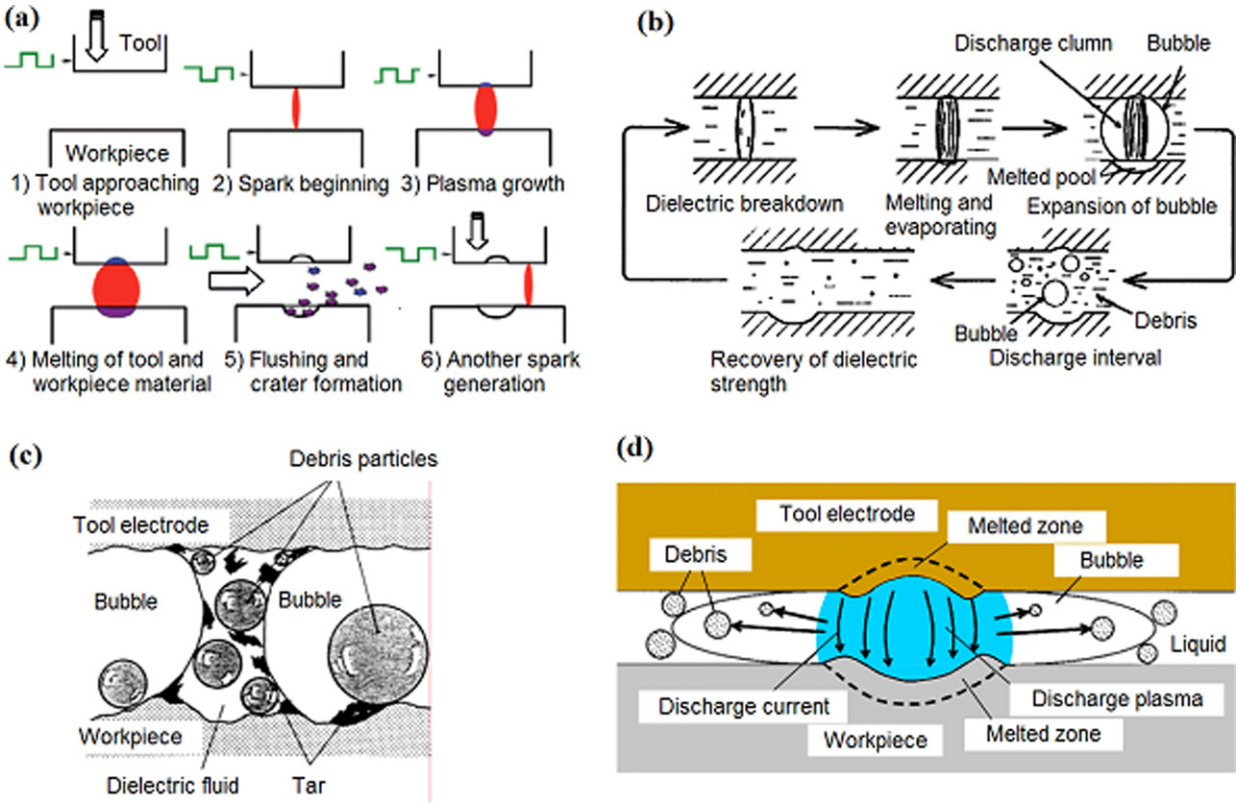

Figure 6 (a) EDM process mechanism (phenomena process).[37] (b) Model of EDM gap phenomena.[36] (c) Schematic view of discharge gap.[36] (d) Discharge phenomena in EDM gap.[36]

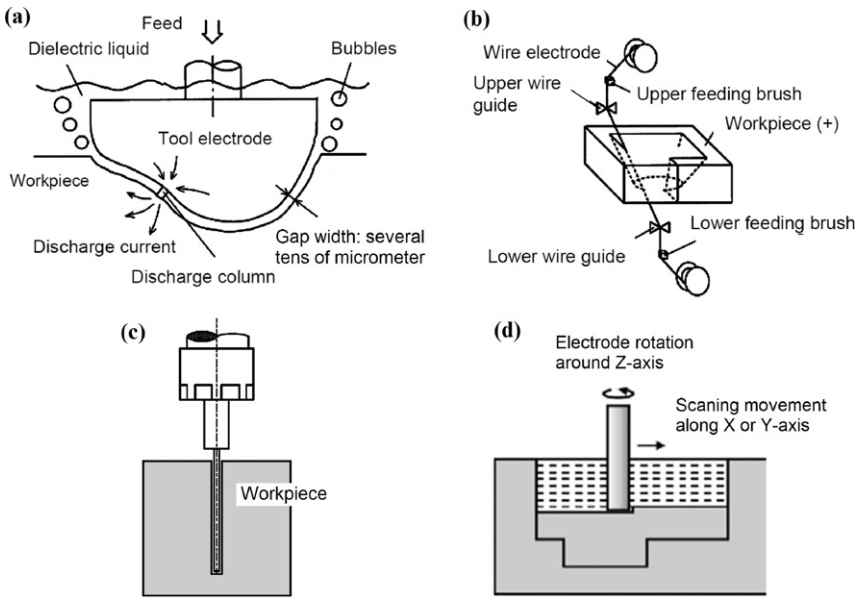

Figure 7 Schematic representation of (a) die-sinking micro-EDM,[36] (b) micro-WEDM,[36] (c) drilling micro-EDM,[5] and (d) milling micro-EDM[44] (all the tools used in different varieties of micro-EDM are in the range of 1–999 mm).[43]

- Micro-wire EDM, in which a wire of diameter less than 0.02 mm is employed to cut through a conductive workpiece.
- Micro-EDM drilling, where microelectrodes are used to 'drill' micro-holes in the workpiece.
- Micro-EDM milling, where microelectrodes are employed to produce 3D cavities by adopting a movement strategy similar to that in conventional milling.
- During micro-EDM, the micro-EDG process is employed to fabricate the microelectrodes on the micro-EDM machine

from a thicker electrode. Different setup and trajectory control of the electrode can be employed in this process included using a 'stationary block,' 'rotating disk,' 'wire EDG (WEDG),' etc.

1.10.3.4 Pulse Generators/Power Supply

Transistor-type pulse generator and resistance capacitance (RC) (relaxation-type) are the two major types of EDM power supply (Figure 8). Among these two types, *RC*-based power supply has gained extensive usage in micro-EDM. Moreover, transistor-type power supply has been employed for the power supply of the conventional EDM.[36,45–47]

1.10.3.4.1 Transistor-type pulse generator

A series of transistors and resistances are connected in parallel between the direct current power supply and the discharge gap in a transistor-type power supply as shown in Figure 8(a). The discharge current flow increases proportionately with the number of transistors switched on at the same time. The Field-effect transistor (FET) operates the gate control circuit by switching it ON or OFF. While generating a single pulse, the gap voltage is monitored to detect the discharge phenomena and the FET is turned OFF after the preset discharge duration.[45]

Transistor-type pulse generators can change the discharge current and the pulse duration based on the required machining characteristics. It provides a very uniform pulse shape resulting in much better control of surface roughness. The resistance across the circuit and the input voltage (*R* and *Vcc* in Figure 8(a)) control the discharge energy in every spark.[45] The smallest UR is obtained by increasing the resistance at around 60 V with voltage settings in transistor-type power supply. If the voltages get lower than 60 V, it will result in unstable discharges.[45–47] It is difficult to minimize the UR frequency because of micro-EDM is fundamentally a discontinuous material removal process but the UR could be minimized significantly by increasing the resistance. The transistor-type pulse generator controls the sparks using microcontroller (decision-making process of the electronics). The micro-controller sets pulse-ON time, pulse-OFF time, signal propagation delay, and the inherent delay of the power transistor. Very fast electronics are used in the setup as all those processes contribute more than few hundred nanoseconds.[36,45,48] This imposes a limit on the shortest pulse duration.[45] Jameson[34] stated that "spark energy is determined by the amount of electrical power contained in each spark, multiplied by the amount of time the electrical power is flowing." The equation for determining spark energy is:

$$E = V \cdot I_p . t_{ON} \quad [1]$$

where, V=voltage e, I_p=current of a single pulse, and t_{ON}=pulse-ON time.

1.10.3.4.2 RC-type pulse generator

Figure 8(b) shows schematic of basic circuit diagram for RC-type pulse generator. Discharge pulse duration in an RC- or relaxation type circuit is dominated by the capacitance of the capacitor and the inductance of the wire connecting the capacitor to the tool and workpiece[37,45,49] and the spark energy (discharge energy) is specified by the used capacitor. The charging and discharging cycle of the capacitor takes place repeatedly.

The capacitor (C) is charged during the charging cycle through the resistor (R) and discharged between the electrode and workpiece during the discharging cycle. The pulse energy (*E*) induced in the gap can be calculated by the following formula;[1,45,46] the gap voltage V_g is assumed to be constant during the discharge cycle.

$$E = 2CV_g(V - V_g) \quad [2]$$

In this equation, the discharge capacitance is denoted by *C* and *V* is the supplied DC voltage. The maximum discharge energy is produced when $V = 2V_g$. The value of maximum discharge energy is $0.5CV^2$, which is equal to the energy stored in the capacitor. In a real application, the RC-type pulse supply will have a stray capacitance between the electric feeders, tool electrode holder, and the work table and the tool electrode and the workpiece. Therefore, the modified form of the above equation is given below[45]:

$$E = 2(C1 + C2)V_g(V - V_g) \quad [3]$$

According to the eqn [3], the minimum achievable discharge energy per pulse is determined by the stray capacitance (*C*2) provided that the value of discharge capacitance (*C*1) is 0. Therefore, it is important to reduce the stray capacitance between the wire and the workpiece in order to decrease the spark energy. A minimum discharge energy is needed in the finishing (final stage of machining) or while machining features at the lower boundary of micro-machining domain.[3,45,49] It can easily produce pulses with high-peak current and short duration which cause to achieve required surface finish with efficient and accurate material removal. On a properly designed equipment, the stray capacitance could be kept as small as around 10–12 pF delivering 0.2-mA peak current and 30-ns wide pulse.[45,50]

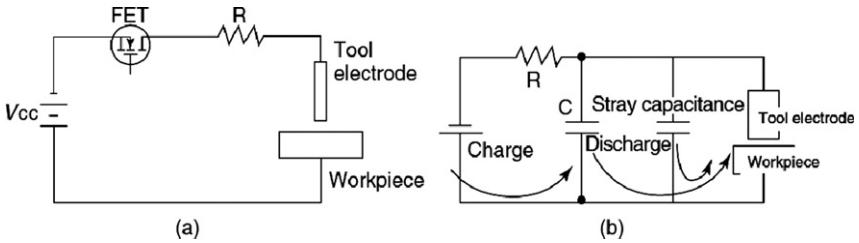

Figure 8 Schematic representation of basic circuit diagram of (a) transistor-type and (b) RC-type pulse generator.[45]

The discharge frequency (discharge repetition rate) depends on the charging time, that is determined by the circuit resistor (R) and this provides for an additional advantage of the RC power supply: when the capacitance is reduced, it also reduces the capacitor charging-up time following a first-order differential equation. The time taken for full charging-up of a capacitor can be calculated by $5 \times RC$ and while $R = 1\,k\Omega$ and $C = 10\,pF$, the full charging time of the capacitor is around 50 ns. Therefore, the value of 'R' should not be very low as arcing can occur instead of sparking and critical resistance that will prevent arcing is desirable.[45,51]

However, the use of RC pulse generator in machining usually results an extremely low MRR. This is due to the fact that the energy per spark is reduced significantly as it depends on the uncontrolled spontaneous discharge frequency bottlenecked by the required capacitor charging time. Moreover, it is difficult to obtain uniform surface finish as the discharge energy varies by depending on the stored electrical charge in the capacitor before dielectric breakdown. In addition, the workpiece can easily be thermally damaged, if the dielectric strength was not properly recovered after the previous discharge and the current continued to flow through the same plasma channel in the gap without charging the capacitor.[45,48]

The basic reason of still using RC-type power supply in micro-EDM is the fact that the charging time for a very small capacitor is much smaller, around few tens of nanoseconds, than the smallest duration of the OFF time that can be reliably achieved using a transistor-type power supply designed using available electronic components. Besides, a transistor power supply would occupy additional time around few tens of nanoseconds for the discharge current to be diminished to zero while an immediate active control of power supply is needed upon short circuit detection. Therefore, the existing high current may pass through the circuit in this additional time and causes damage to fine feature that will be machined in the workpiece.[45]

1.10.3.4.3 Pulse waveform and discharge energy

The pulse generator type determines the discharge energy and pulse shape for the micro-EDM. **Figures 9(a)** and **9(b)**, demonstrate the ideal voltage and current signals for transistor and RC-type pulse generator respectively. The spark energy (discharge energy) of a pulse generator is calculated by its electrical and discharge parameters. MRR, electrode wear ratio (EWR), and surface roughness increase with amplifying of discharge energy.[45] Though used pulse shape in micro-EDM is generally rectangular type, but generators using other pulse shapes have also been developed for various applications.[45,52] For instance, EWR decreased to very low values by initiating trapezoidal pulse shapes in micro-EDM.[45,53]

The open voltage is applied between the tool electrode and the workpiece when the transistors are switched on in the transistor-type pulse generator. But the discharge does not occur instantly. It occurs after the ignition delay time and a discharge current (I_p) is passed through the gap after the dielectric breakdown. The transistors are kept on by the gate control circuit during the discharge time, t_{on}, resulting in a uniform discharge crater size. The transistors are again switched on after the fixed discharge interval t_{off}, while the open voltage is applied between the electrodes.[34,36,45] Equation [1] can be used to calculate the discharge energy per single pulse.

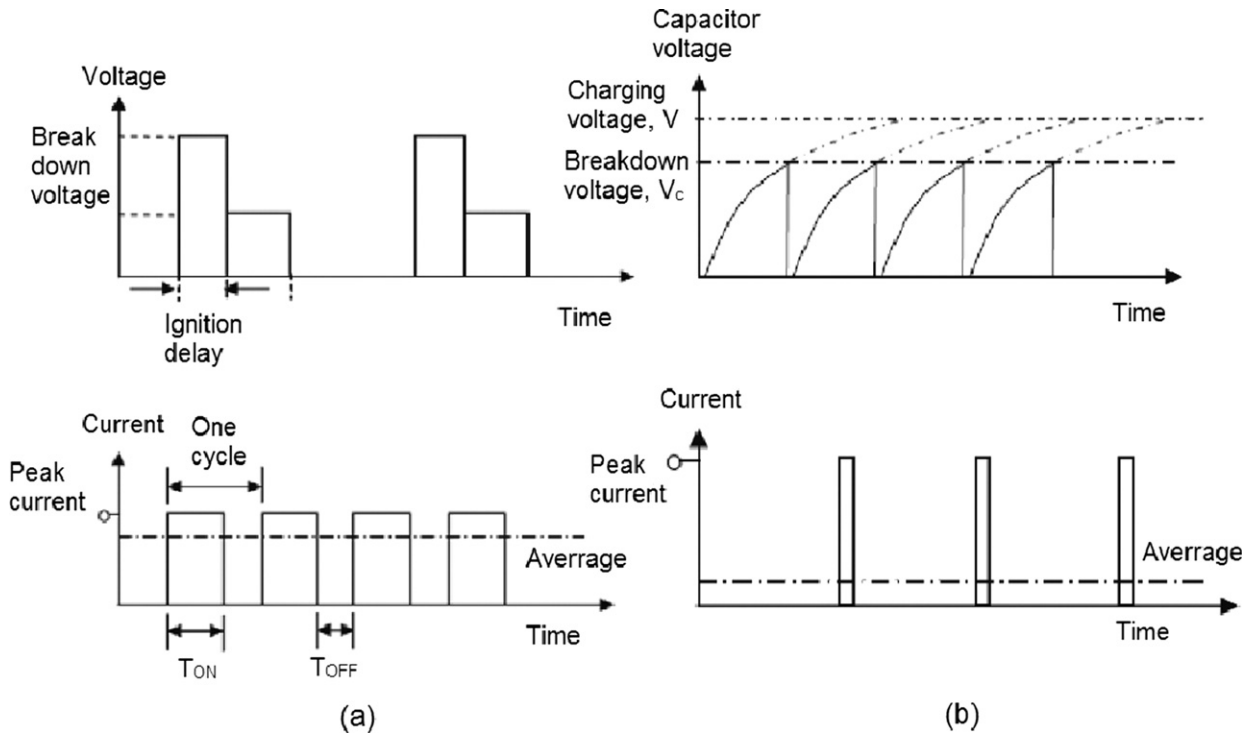

Figure 9 Ideal voltage–time (top) and current–time (bottom) characteristics curve/waveform for (a) transistor-type and (b) RC-type pulse generator.[45,54–58]

The capacitor charging time is considered as the pulse interval or pulse-OFF time, whereas the discharging time is assumed as the pulse-ON time in the RC pulse generator. One of the major characteristics of RC-type pulse generator is that the charging voltage is higher than the breakdown or discharging voltage (V). As a result, sometimes discharging starts before the capacitor is fully charged,[45,48] which generates nonuniform discharge energy. A simplified form of the discharge energy per single pulse, E, can be calculated by eqn [2] where $V=2V_g$

$$E=\frac{1}{2}CV^2 \quad [4]$$

where C is the capacitance used for machining and V is the discharge voltage.[45,59]

1.10.3.5 Electrode Material for EDM

Jameson[34] stated that "electrode materials for EDM must be electrically conductive. However, they should have features such as: high melting point, an ability to be easily machined and low cost." No single electrode material provides all of the desired features for any particular application. The following list of materials is intended as a guide to electrode materials commonly used for die-sinking machines.

1.10.3.5.1 Copper

As Jameson[34] stated "copper is readily available and normally specified as electrolytic-grade or tellurium-copper alloy." Electrolytic grade may be considered as pure copper. Tellurium copper is copper with the element tellurium added and it is equivalent in machinability to free-machining brass. Copper is difficult to grind but has good no-wear-machining characteristics. It is often used for RC power supply operations. Wang and Lin[60] stated that "copper was chosen as electrode for electrical discharge machining of copper tungsten." The physical properties of copper that used by Che Haron[61] are shown in Table 1.

Table 1 Physical properties of copper electrode[61]

Physical properties	*Value*
Electrical resistivity ($\mu\Omega$ cm^{-1})	1.96
Electrical conductivity compared with silver (%)	92
Thermal conductivity (W m K^{-1})	268–389
Melting point (°C)	1083
Specific heat (cal g^{-1} °C)	0.092
Specific gravity at 20 °C (g cm^{-3})	8.9
Coefficient of thermal expansion ($\times 10^{-6}$ °C^{-1})	6.6

1.10.3.5.2 Copper tungsten

Copper–tungsten (CuW) composite is a one kind of self-cooling which is highly resistant to heat corrosion. Phasing can be seen between tungsten and copper in the microstructure of CuW composites because of tungsten and copper have no solid solubility with each other.[62,63] Therefore, CuW composites can be considered as composite material and they are not alloys. CuW composites cannot be created through traditional metal-casting processes and are currently produced through powder metallurgy because of large dissimilation between the melting points of tungsten and copper. Powder metallurgy is gained by compacting pure tungsten powder in a mold (porous), then sintering it under high temperatures and infiltration of liquid copper.[64–66] CuW composites have a high-melting point, corrosion, and abrasion resistance, and act as good conductors for both current and heat.[60] CuW composites possess a very high-melting point with promising corrosion and abrasion resistance, and a good conductor of electricity and heat.[60] The Specification of copper tungsten is shown in Table 2.

Jameson[34] stated that "CuW is often used as an electrode for EDM of tungsten carbide." Lee and Li[68] used copper tungsten as an electrode during the machining of tungsten carbide. Moreover, Soni and Chakraverti[69] found that chemical composition of high-carbon high-chromium die steel (hardened) was changed during EDM machining with rotating copper tungsten (W80, Cu 20) electrode because of the material migration from the electrode. The result of this experiment showed that the migration of tungsten from the tool electrode to the workpiece was higher in blind holes machining rather than in through holes machining. The properties of electrode material are given in Table 3.[68]

1.10.3.5.3 Graphite

Lee and Li[68] used graphite as their electrode material to identify with the comparisons between others electrode in

Table 2 Specification of copper tungsten[67]

Code No.	*Chemical composition %*			*Mechanical properties*				
	Cu	*Impurity*	*W*	*Density (g cm^{-3})*	*Hardness (HB)*	*Resistivity (cm)*	*Conductivity IACS (%)*	*TRS (MPa)*

Melting point (°C)	3350
Electrical resistivity (μΩ cm^{-1})	1400
Hardness (HB)	10

their researches when machining tungsten carbide. The properties of graphite used in their study are given in **Table 4**. Graphite was found to have high effects on the MRR and on the surface roughness (Ra) when compared to copper and copper tungsten.

1.10.3.5.4 Brass

According to Jameson,[34] brass is readily available. The grade used is normally specified as free machining brass. It has a fairly good wear ratio when machining steel and a very high wear ratio when machining tungsten carbide. Brass is not normally recommended for use with RC-power supplies.

1.10.3.5.5 Copper graphite

Copper graphite is fine-gram graphite that is infiltrated with copper. It has the qualities of graphite, plus the electrical conductivity of copper.[34]

1.10.3.5.6 Zinc alloys

Zinc is rarely used except for coating. It is basically a crystalline metal with moderate ductility and strength. Followed by iron, aluminum, and copper, zinc is the fourth mostly used metal. Many wrought alloys of zinc are available with different alloying elements to improve the strength, ductility, and workability. There are two major group of zinc alloy available for casting. The first one is a standard casting alloy which basically contains zinc with less than 5% aluminum in a hypo-eutectic alloy. The second one is a newer group of hyper-eutectic zinc–aluminum alloys, containing up to 27% of aluminum. Both groups are primarily used in die casting.[70] Jameson reported that[34] zinc alloys may be adopted as an electrode material, but the wear characteristics are very poor.

1.10.3.5.7 Silver tungsten

Silver tungsten (AgW) is a kind of powder metal that combines the high conductivity of silver with the wear resistance of tungsten, to give an unmatched combination of low wear and fine surface finish for EDM applications with fine detail. AgW can be fabricated by the same process as CuW. AgW has some limited range of applications because of its high cost and limited availability.[71]

Table 5 Properties of WC–6%Co[75]

Nominal composition	*94WC–6Co*		
Grain size (in micron size)	*Fine*	*Medium*	*Coarse*
Hardness, HRA	92.5–93.1	91.7–92.2	90.5–91.5
Density, g cm^{-1}	15.0	15.0	15.0
Transverse strength, MPa	1790	2000	2210
Compressive strength, MPa	5930	5450	5170

CTE, ppm K^{-1}	4.3	4.3	4.3
CTE, ppm K^{-1}, at 1000 °C	5.9	5.4	5.6
Thermal conductivity, W m^{-1} K^{-1}	–	100	121

1.10.3.5.8 Tungsten

Tungsten (W) had been the electrode material of choice for certain limited EDM applications due to the combination of its high density, melting point, and tensile strength. Tungsten has poor electrical conductivity which causes to cut much slower than copper or brass. Also, tungsten is seldom used because of its high cost and very low machinability.[71]

1.10.3.5.9 Tungsten carbide–cobalt (WC–Co)

Tungsten carbide (WC) and its composite (WC–Co) are employed for producing cutting tools, dies, and other special tools and components owing to their high hardness, strength, wear, and corrosion resistance over a wide range of temperatures;[72,73] Also, they can be used as electrode for EDM.[3,74] **Table 5** illustrates the properties of WC–6%Co.

1.10.3.6 Electrode Material for Micro-EDM

The thermal property of the electrode materials has significant influence on the micro-EDM performance as micro-EDM is a thermal process. The electrode with higher heat conductivity has lower temperature on its surface when the heat fluxes from the arc column are equal.[36] Therefore, the materials with higher heat conductivity, melting point, and boiling point are appropriate as microelectrodes. The important properties of the electrode materials, which influence on the micro-EDM process, include melting and boiling temperatures, electrical and thermal conductivity, and specific heat.[54,55,57] **Table 6** demonstrates what kind of materials as microelectrode was used by previous researchers for machining of various materials.

According to Jahan *et al.*,[57] between AgW, CuW, and W electrodes for micro-EDM of WC, AgW electrode produces smoother and defect-free nanosurface with the lowest R_a and R_{max} among the three electrodes. Besides, a minimum amount of material migrates from the AgW electrode to the WC workpiece during the finishing micro-EDM. On the other hand, a CuW electrode achieves the highest MRR followed by AgW and W. In the case of electrode wear, the W electrode has the lowest wear followed by CuW and AgW.

Table 6 Materials of microelectrode for machining various workpieces

Materials of microelectrode	*Materials of workpiece*	*Reference*
Copper tungsten (CuW) Silver tungsten (AgW) Tungsten (W)	WC 10 wt.%Co	57
Tungsten carbide	A block of Uddeholm Stavax ESR tool steel	76
Brass	Nickel–titanium-based shape memory alloy (SMA) with 500 μm thickness	77
Tungsten carbide	Titanium alloy (Ti–6Al–4V)	78
Tungsten carbide	SiC microparticle suspended dielectric on machining Ti–6Al–4 V	79
Tungsten	Inconel 718 alloy	80
Tungsten	RB-SiC material composed of 6H–SiC grains (grain size 1 μm, 88% in volume) and a Si matrix (12% in volume)	81

1.10.3.7 Dielectric Medium in EDM

Basic characteristics required for dielectric used in EDM are high-dielectric strength and quick recovery after breakdown.[82] Sommer[83] stated that "dielectric fluid performs three important functions:

1. The fluid forms a dielectric barrier for the spark between the workpiece and the electrode.
2. The fluid cools the eroded particles between the workpiece and the electrode.
3. The pressurized fluid flushes out the eroded gap particles and removes the particles from the fluid by causing the fluid to pass through a filter system."

The selection of a dielectric fluid is subject to certain conditional as follows[84]:

1. It must be capable of being ionized at a consistence voltage so that its performance is predicted.
2. It must be able to deionizer so that it becomes an efficient insulator during his next build-up of the discharge.
3. There must be no dermatitis.
4. There should be no toxic fumes or excessive smoking.
5. The fluid should inhibit corrosion.
6. The flashpoint of the fluid should be high.
7. The fluid must have low viscosity.

1.10.3.7.1 Mineral oil

Mineral oil or liquid petroleum is a by-product in the distillation of petroleum.[85]

1.10.3.7.2 Kerosene

Kerosene was one of the first popular dielectric oils. Its primary benefit is that it has very low viscosity and flushes very well. Unfortunately, it has many drawbacks like low-flash point, high volatility, odor, and skin reactions. In the 'old days,' there were numerous EDM fires and explosions attributed to the use of kerosene.[85]

1.10.3.7.3 Mineral seal

The name mineral seal oil refers to the fact that it has been derived from sea seal blubber for using in signal lamps and light houses. Mineral seal oil is basically petroleum oil which has many industrial applications. For example, this oil was used as a dielectric fluid in EDM by a number of aerospace companies. In fact, it is listed as potential aerospace dielectric oil in recent times. Unfortunately, it contains some potentially carcinogenic elements, and its use is no longer recommended.[85]

1.10.3.7.4 Transformer oil

Transformer oil is another type of mineral oil-based product which was tailored to be used in EDM as dielectric. Earlier generations of transformer oil were compounded with PCBs. However, transformer oil is not currently being used in EDM.[85]

1.10.3.7.5 Water-based dielectrics

Water is a dielectric fluid which can be used as an alternative to hydrocarbon-based oils. This approach is important to promote a healthy and safe environment while using water in EDM machining. Contemporarily used hydrocarbon oils (i.e., kerosene) release toxic vapor (CO and CH_4) after being decomposed.[86] Research has been carried out over the last 25 years which involves the use of pure water and water with additives.[85,87] Leao and Pashby[88] reported that many works have already been carried out to evaluate the feasibility of adding organic additives such as ethylene glycol, polyethylene glycol 200, polyethylene glycol 400, polyethylene glycol 600, dextrose, and sucrose to improve the properties as well as performance of demonized water as dielectric.

1.10.3.7.6 Powder-mixed EDM

The working principle of powder-mixed EDM (PMEDM) is completely different from the contemporary EDM machining process.[89] An appropriate material in the powder form is mixed into the EDM dielectric. When a suitable voltage is applied, the spark gap filled up with powder particles and the gap distance setup between tool and the work piece increased. The powder particles get energized and act in a zigzag fashion as illustrated in **Figure 10**. These energized particles are accelerated by the supplied electric field and behave as electric conductors. The charged powder particles arrange themselves in clusters beneath the sparking area.[85] This chain formation of charged particles in the dielectric helps to bridge the gap between electrode and workpiece which is responsible for the early explosion. Thus, faster sparking (discharge) takes place and faster erosion from the workpiece surface occurs.[85,90] Adding aluminum powder in the dielectrice results in increased MRR and improved surface roughness during EDM.[27,91]

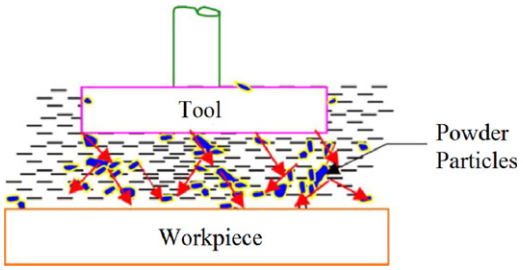

Figure 10 Principle of powder-mixed EDM.[92]

1.10.3.7.7 Dry EDM

In dry EDM, a thin-walled pipe works as tool electrode through which high-pressure gas or air is flown. The high-pressure gas flow to remove the debris from the gap and cools down the inter electrode gap. The technique was invented to decrease the pollution caused by the use of dielectric fluid which leads to production of vapors during machining and the cost to manage the waste.[93]

1.10.4 EDM and Micro-EDM Process Parameters

EDM parameters are categorized into two groups:

1. Electrical parameters:
   - Polarity of the electrode
   - Machining voltage
   - Current
   - Pulse-ON time (duration or pulse time)
   - Pulse-OFF time (non-load voltage or pause time)
   - Duty factor
   - Capacitor.
2. Non-electrical parameters:
   - Flushing pressure of dielectric
   - Rotating speed of the electrode.

The electrode polarity, machining voltage, current, pulse-ON time, pulse-OFF time, duty factor, flushing pressure of dielectric, and rotating speed of the electrode are the parameters are used in transistor-type pulse generator while the electrode polarity, machining voltage, capacitor, flushing pressure of dielectric, and rotating speed of the electrode are the parameters used in RC-type pulse generator. As mentioned before, RC-based power supply has gained extensive usage in micro-EDM.[36,45–47]

The electrode polarity: Electrical polarity of the electrode and workpiece determines the direction of flow for electrons and positive ions. Some EDM manufacturers describe electrode and workpiece polarity as standard and reverse. This description is not acceptable since not all manufacturers use the same polarity for standard and reverse. Because of this, most manufacturers have revised their electrode and workpiece polarity description to specify only electrode polarity as either negative or positive. It is understood, when using this description, that the workpiece is the opposite polarity of that specified for the electrode.[34]

The electrons usually are emitted from the cathode (negative polarity) and move toward the anode (positive polarity) during the micro-EDM process. After that, the metal ions are removed from the anode material due to the electrons which reach the anode surface strike the anode surface. Hence, more materials are removed from the anode's surface rather than the cathode's surface. This is the main reason for earning high MRR when the polarity of electrode is negative during micro-EDM of workpiece with positive polarity.[45]

Discharge voltage: Discharge voltage in the EDM process depends on the spark gap and breakdown dielectric strength. Before flowing electricity, the open gap voltage gets increased till the ionization path is created through the dielectric. As soon as the current starts to flow, the voltage decreases and stabilizes at the working gap level. The predetermined voltage sets the spark gap width between the leading edge of the electrode and workpiece. A higher voltage setting augments the gap, which improves the flushing conditions and helps to stabilize the cut. As the electric field strength improves, tool wear rate (TWR) of MRR and surface roughness amplifies with increasing the open-circuit voltage. However, the after machining effect of varying the open-circuit voltage on surface hardness has been found to be marginal.[52]

Peak current: Peak current is the amount of power used in discharge machining and the ampere (A) is its unit. The current is the most important machining parameter in EDM. During each pulse-ON time, the current amplifies until it reaches a preset level, which is expressed as the peak current, with the augmentation of the current, MRR and electrode wear increase and surface finish deteriorates.[39,52]

Pulse-ON time (duration or pulse time): Pulse-ON time is the time duration that the current is allowed to flow per cycle. Material removal is directly proportional to the amount of energy applied during this pulse-ON time. The spark energy (discharge energy) is controlled by the pulse-ON time and peak current.[94]

Pulse-OFF time (non-load voltage or pause time): Pulse-OFF time is the time duration between the sparks (pulse-ON time). Pulse-OFF time allows the molten material to solidify and to remove debris from the distance between electrode and workpiece (arc gap). This parameter is to affect the speed and the stability of the cut. Thus, using the too short pulse-OFF time causes the sparks to be unstable.[94]

Duty factor: Duty factor is calculated based on following equation.[95]

$$\text{Duty factor} = \frac{\text{Pulse-ON time}}{\text{Pulse-ON time} + \text{Pulse-OFF Time}} \times 100\% \quad [5]$$

Capacitor: The capacitor stores the electrical energy and discharges during the machining. When machining starts as soon as the dielectric breaks down, it discharges the charge stored in the capacitor.[96]

Flushing of dielectric fluid: The dielectric fluid is utilized to flush through the spark gap (the distance between electrode and workpiece) to remove debris (chip) during machining and to keep the dielectric temperature below its flash point.[52] The dielectric flushing during the sparking process has an effect on the EDM performance measures. The flushing during the roughing step influenced the MRR and EWR, while in the finishing step; it influenced the surface roughness. The flushing rate also affects the recast layer and crack density, which can be minimized by obtaining an optimal flushing rate. Moreover, the different properties of the dielectric fluid also play a vital role in flushing away the debris from the machining gap. MRR and

EWR are dependent on the conductivity, breakdown resistance, viscosity, flash point, and safety factors of the dielectric fluids.[52]

Rotating speed of the electrode: The tangential velocities of the electrode amplifies with increasing of the electrode rotating speed, which causes to the dielectric disturbance.[97] The augmentation of the dielectric flow speed helps to remove and flash out debris between the electrode and workpiece (the machined zone). Therefore, it causes to remove higher material from the workpiece.[74]

1.10.4.1 EDM Performance Measure (Machining Characteristics)

1.10.4.1.1 MRR

MRR is calculated based on the volume of material removed from the workpiece divided by machining time.[95]

$$\text{MRR} = \frac{\text{Volume of material removed from workpiece}}{\text{Time of machining}} = \frac{W_b - W_a}{t_m}(\text{g min}^{-1}) \quad [6]$$

where W_b is the weight of workpiece material before machining (g), W_a is the weight of workpiece material after machining (g), and t_m is the machining times (min).

1.10.4.1.2 EWR

EWR is calculated based on the percentage of volume of material removed from the electrode divided by the volume of material removed from the workpiece.[95]

$$EWR = \frac{T_b - T_a}{W_b - W_a} \times 100\% \quad [7]$$

where, T_b is the weight of electrode material before machining (g), T_a is the weight of electrode material after machining (g), W_b is the weight of workpiece material before machining (g), and W_a is the weight of workpiece material after machining (g). Figure 11 illustrates different kinds of electrode wear including: (1) corner wear, (2) end wear, (3) side wear, and (4) volumetric wear[34]:

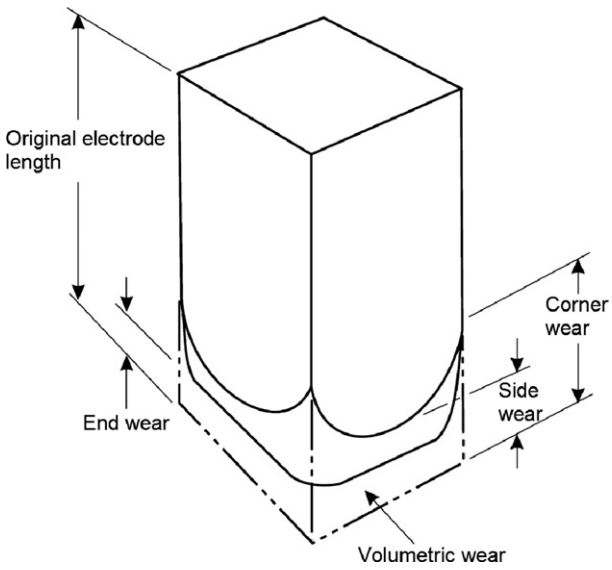

Figure 11 The different kinds of electrode wear.[34]

1.10.4.1.3 Surface roughness

The surface finish is controlled by the number of discharges per second, more often referred to as the frequency sparks. The greater amount of energy applied the greater amount of material removed. However, when greater amounts of current are used larger craters are eroded from the work, causing a rougher surface finish. To maintain increased metal-removal rates and at the same time improve the surface finish, it is necessary to increase the frequency of the discharges. Surface integrity involves the measures of surface roughness, heat affected zone, micro-hardness, micro-crack, residual stress, diffusion of tool material and carbon, and endurance limit.[98]

1.10.4.2 Micro-EDM Performance Measure (Machining Characteristics)

1.10.4.2.1 MRR

Micro-EDM produces the reverse-copied shape of the microelectrode in the workpiece. Figure 12 illustrates the relationship of the micro-hole shape with an microelectrode feed. It is possible the micro-holes shapes were not confirmed because of the microelectrode wear if the microelectrodes did not feed enough. In order to achieve the acceptable micro-holes shape, it is essential to feed the microelectrodes several times as long as the workpiece thickness.[40]

In fact, it is usual to measure the weight differences and convert them into volumes by the materials density. But, this method is inappropriate for micro-EDM as the removed materials is so small (about less than 10 ng) that it is difficult to measure it accurately. So, it is important to measure and calculate removed volume of materials directly.[40] The micro-hole is not an ideal cylindrical one but a tapered one because of the debris moving and the second discharge on the side of micro-hole.[96] MRR is calculated by following equation (the geometry is shown in Figure 13).[96]

$$\text{MRR} = \left\{\frac{\pi}{3}\left[r_{\text{Top}}^2 + r_{\text{Top}}\, r_{\text{Bottom}} + r_{\text{Bottom}}^2\right] \times h\right\} \div t \quad [8]$$

where, r_{Top} is the radius at the entrance side, r_{Bottom} is radius at exit side, h is the workpiece thickness, and t is the machining time to make a micro-hole at a particular setting.

1.10.4.2.2 EWR

Figure 14 demonstrates the different types of wear on the microelectrode. EWR refers to the ratio of amount of

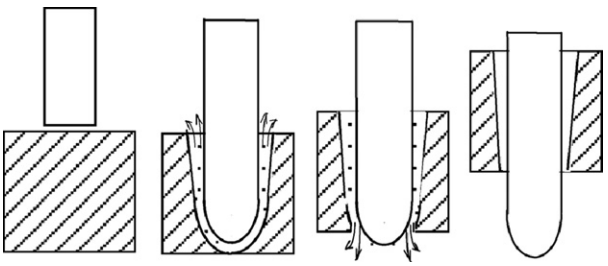

Figure 12 Influence of microelectrode feed on the shape of a micro-hole.[40]

microelectrode removal to the workpiece removal. There are four different methods to determine the EWR which include measuring weight, shape, microelectrode length, and total volume respectively. A popular one is by evaluating volumetric EWR. In fact, it is a usual method to measure the weight differences and then transfer them into the volumes by the density of materials. However, this method is not suitable to evaluate EWR for micro-EDM. As the weight change of the materials in micro-EDM is so small (about less than 10 ng) that it is difficult to determine it accurately. Therefore, it is necessary to directly measure and analyze removed volume.[40]

EWR is computed by following equations respectively.

$$\mathrm{EWR} = \frac{TW}{\mathrm{MRR}} \quad [9]$$

$$TW = \frac{\pi D^2 T}{4t} \quad [10]$$

where TW refers to the volumetric TWR, T refers to the frontal microelectrode wear (bottom wear), D refers to the microelectrode diameter, and t refers to the machining time to make a micro-hole at a particular setting.

The wear morphologies of the fabricated microelectrodes are illustrated in the **Figure 15** after machining micro-holes on the workpiece SUS304 with the same condition. It was reported that strong wear occurs on the corner areas especially for nickel (Ni), titanium (Ti), and iron (Fe) microelectrodes because of the low thermal conductivity. Aluminum microelectrode (Al) had the melting trace after machining of SUS304 and the bending was during machining of iron. Therefore, the very low melting point aluminum has to be taken into consideration. The results show that corner rounding of the microelectrodes is strongly correlated with heat and a great amount of heat stacked at the corner would cause strong wear off.[40]

Tsai and Masuzawa[40] by comparing the microelectrode wears of various materials in micro-EDM found that:

a. The microelectrode volumetric wear ratio gets lower for the microelectrode material with high boiling and melting point with high thermal conductivity. This is independent phenomena for different workpiece materials.
b. Microelectrode corner wear is related to heat diffusion. Therefore, corner rounding is more obvious when the thermal conductivity of the microelectrode remains low.
c. The boiling point of the microelectrode material takes a vital role in wear mechanism of micro-EDM, as high surface temperature and energy density are related to small discharge spot.

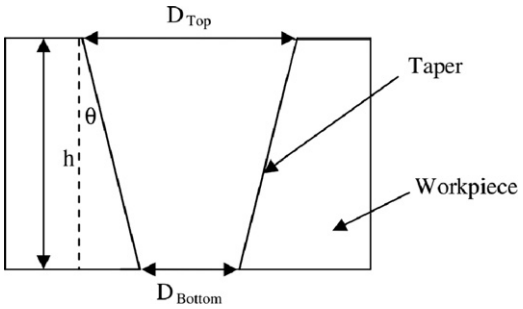

Figure 13 Overview of micro-hole.[96]

1.10.4.2.3 Overcut

The micro-holes overcut were calculated from the distance between the machined micro-holes diameter and the microelectrode diameter. Due to the taper shape of the microelectrode, the overcut was calculated from the average value of the micro-holes entrance and exit side. The overcut is calculated from the following equations (**Figure 13**)[96]:

$$O_c = \frac{D_h - D_t}{2} \quad [11]$$

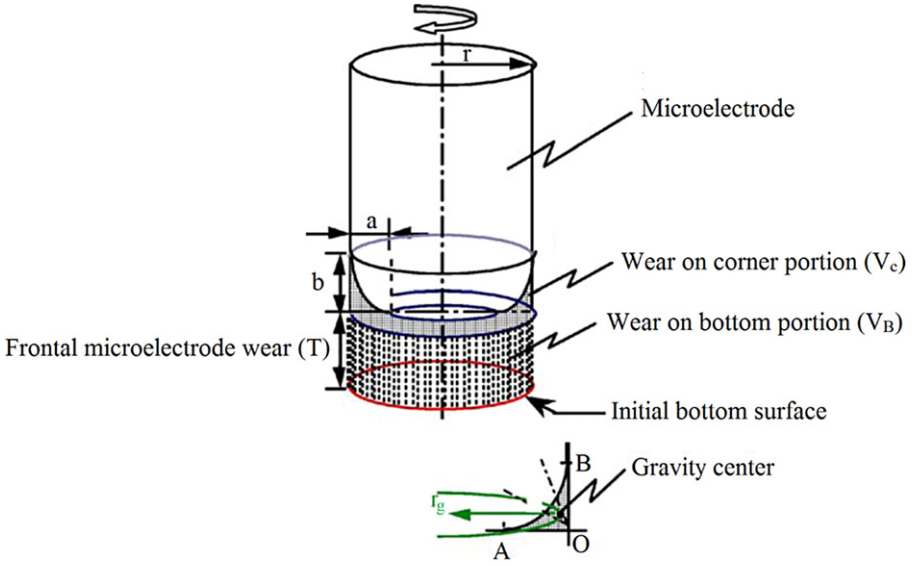

Figure 14 Wear of the microelectrode.[40]

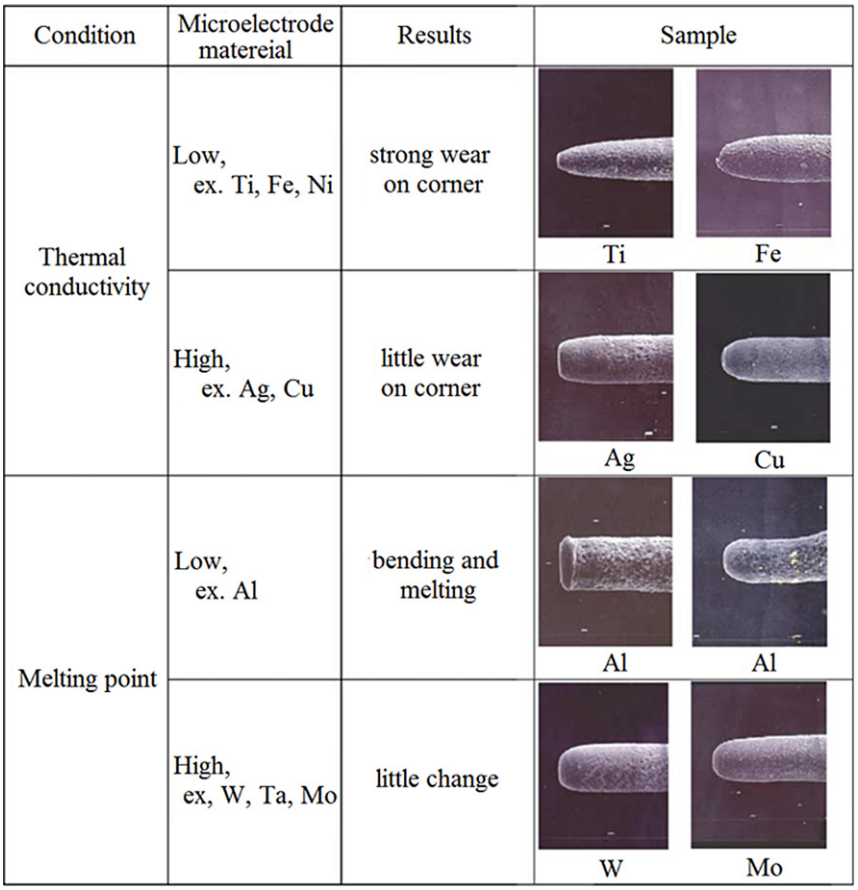

Figure 15 Microelectrode morphology with the thermal properties of materials.[40]

and

$$D_h = \frac{D_{Top} + D_{Bottom}}{2} \quad [12]$$

where O_c is overcut of the micro-holes, D_h is the average diameter of the micro-hole after machining, D_t is the diameter of the microelectrode, D_{Top} is the entrance diameter, and D_{Bottom} is the exit diameter of the micro-hole.

1.10.4.2.4 Surface integrity

Surface integrity involves two aspects: topography characteristics and surface layer characteristics. The topography characteristics are made up of surface roughness, waviness, errors of form, and flaws. The surface layer characteristics that can change through processing are: plastic deformation, residual stresses, heat affected zone, micro-cracks, micro-hardness, phase changes, and recrystallization.

1.10.4.3 Various Fabrication Processes of Microelectrode

Micro-EDM is one the most efficient technologies for fabricating micro-components between nonconventional machining technology. It can be machined ductile, brittle, or super hardened-materials with noncontact process; thus, there is little or almost no force between electrode and workpiece. For micro-EDM process. It is possible to achieve high-precision and high-quality machining with suitable parameters.[4]

It is possible to utilize a very thin and long microelectrode for machining, because of the noncontact nature of EDM. A micro-Milling cutter of down to 50 μm in diameter can be found in the market. However, the length of the tool is usually three to five times of its diameter. Micro-EDM can be used to machine tough die material which micro-Milling is not appropriate to machine them. Although micro-EDM has significant role in the field of micro-machining, EWR and low MRR are some of the disadvantages of micro-EDM. Changing the microelectrode or preparing longer microelectrode from the beginning or fabricating the microelectrode can compensate the wear of microelectrode. Change the microelectrode can reduce the accuracy to the change in setup or re-clamping of the microelectrode; hence, it is not recommended during machining.[4] Consequently, to avoid clamping error in micro-EDM process, microelectrode should be fabricated on the machine. By EDM process using a sacrificial microelectrode can be fabricated a cylindrical microelectrode from an microelectrode thicker than the required diameter.[4]

The fabrication processes of microelectrode are as follows:

1. WEDG
2. Rotating sacrificial disk
3. Stationary block electrical discharge grinding (BEDG)

4. Moving block electrical discharge grinding (MBEDG)
5. Self-drilled micro-hole
6. Revers EDM
7. Micro-turning process
8. Hybrid process.

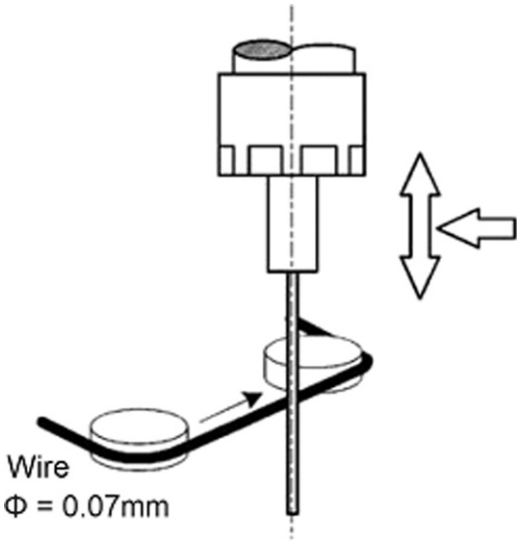

Figure 16 WEDG process.[5]

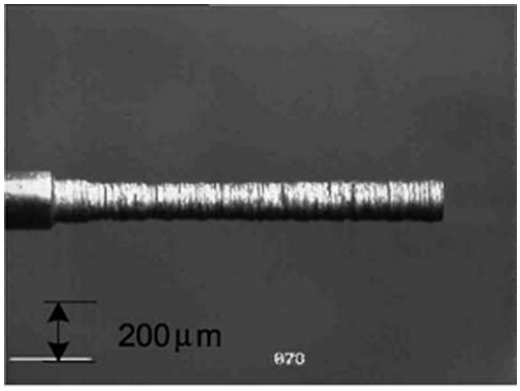

Figure 17 Microelectrode machined using running wire.[5]

1.10.4.3.1 WEDG

WEDG process is known as guided running wire, and it is a typically process for micro-EDM in Figure 16. Figure 17 illustrates typical surface condition of the microelectrode is fabricated by EDM using a running wire. This method is mainly used for micro-EDM machining. The dimensional change of the electrode is theoretically zero, because of using a fresh wire continuously. High-accuracy dimensional can be achieved in micro-EDM by this fact. However, the efficiency of the surface finishing in WEDG method is lower than the rotating electrode process. Because the running wire diameter is only 0.07 mm which is not enough to smoothly finish the machined surface the same as the rotating electrode method with 0.5 mm thickness. Therefore, the speed of the finish machining should be reduced to achieve better surface finishing by using this thin wire.[5] Figure 18 shows the schematic diagram of tangential-feed WEDG (TF-WEDG) compared with conventional radial-feed WEDG. WEDG can fabricate the microelectrode by employing a continuous wire electrode which is fed on a wire guide (Figure 18(a)).[99]

1.10.4.3.1.1 Radial-feed WEDG

Figure 18(b) shows the conventional radial-feed WEDG process. In this process, the microelectrode is positioned to align its central axis in the direction of the symmetry axis ON of wire guide, and during the WEDG method the microelectrode feeds along the radial direction of the guide, namely the direction of axis ON (Y axis). The removal resolution of the microelectrode (the minimum thickness to be removed from microelectrode) is in direct proportion to the motion resolution of Y axis, and the diameter error of machined microelectrode is twice of the positioning error of Y axis (given radial feed S_R, microelectrode diameter decrease Δd, and $\Delta d = 2S_R$). Thus, the alignment error (in X-axis direction) and the positioning error affects directly the machining accuracy of the microelectrode.[99]

1.10.4.3.1.2 TF-WEDG

The TF-WEDG process is proposed to reduce the effect of positioning error during fabricating the microelectrode in order to improve the accuracy.

1.10.4.3.1.2.1 Principle of TF-WEDG

The principle of proposed TF-WEDG method is presented in Figure 18(c). Here, the relative position of the microelectrode

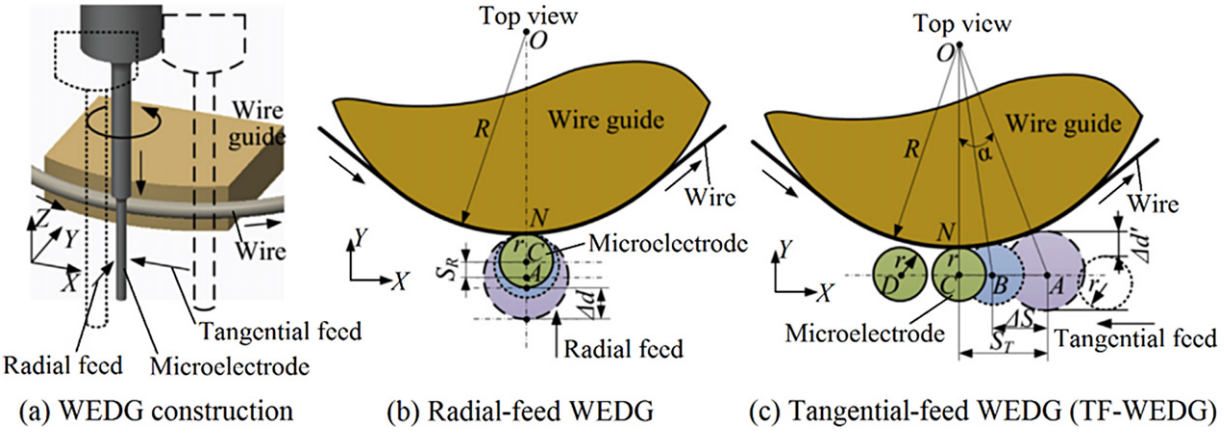

Figure 18 Comparison between radial-feed WEDG and TF-WEDG; (a) WEDG construction, (b) radial-feed WEDG, and (c) TF-WEDG.[99]

and the wire guide with the *Y*-axis is set fixed. During the WEDG process, the microelectrode moves along the tangential *X*-axis direction of the wire-guide arc. In this method for given tangential feed S_T and microelectrode diameter decrease $\Delta d'$, so that $\Delta d' \ll 2 \cdot S_T$ which is detailed in Section 1.10.2.2. Therefore, the removal resolution of the microelectrodes gets improved, and the diameter error of the machined microelectrode can be controlled easily by keeping it lower than the positioning error. Moreover, it is easy to repeatedly achieve a consistent diameter for a numbers of machined microelectrodes by TF-WEDG method by fixing *Y*-axis position and feeding to the position *D*.[99]

1.10.4.3.1.2.2 Analysis of TF-WEDG

Figure 18(c) shows the wire guide which is designed as an arc shape, therefore it properly fit with the wire of TF-WEDG. The microelectrode feeds from the position A to the position B and then to the position C. Therefore, the microelectrode diameter gets reduced during the feeding procedure to obtain a minimum diameter of the microelectrode at the position C. Here the radius of the wire guide and the machined radius of the microelectrode are denoted by *r* and *R* respectively and the distance between the position A and the position C is denoted by S_T. The microelectrodes diameter under different values of S_T can be calculated by using the following equation[99]:

$$d_A = 2(OA - R) = 2\left(\sqrt{(R+r)^2 + S_T^2} - R\right) \qquad [13]$$

The TF-WEDG experimental setup was performed by using wire guide with 1.3 mm radius (*R*). The relations between microelectrode diameter (d_A) and tangential-feed distance (S_T) is shown in **Figure 19** which is calculated by the eqn [13] for machining the microelectrode with diameter of 20, 40, 60, and 80 μm, respectively. As shown in **Figure 19**, when the distance S_T is equal to 120 μm, increments in diameters of four microelectrodes are from 10.72 to 10.96 μm while comparing with $S_T = 0$, and in fact the difference of the increments is only 0.24 μm (10.96 − 10.72 μm). In fact, the slopes of these four curves almost remain the same. Therefore, four conclusions can be drawn as follows: (1) without considering the machined microelectrode diameter, the removed diameter Δd of the microelectrode can be determined only if the distance ΔS is previously given (**Figure 18(c)**). (2) The distance Δd is much smaller than the tangential-feed distance ΔS and the removal resolution is significantly improved. (3) It is evident from **Figure 19** that, the slopes of the curves are gradually decreasing with the reduction in the distance S_T and the removal resolution is higher when the microelectrode is more closer to the symmetric axis of the machine wire guide. (4) It can be seen from the **Figure 18(a)** that the error effect of the horizontal alignment with respect to the wire guide orientation on the removal resolution can be ignored. For instance, if the experimental error is controlled < 5 μm, this could result in the error of microelectrode diameter being smaller than 0.04 μm.[99]

From the analysis mentioned above, it is possible to machine the microelectrode diameter precisely by using the high resolution of TF-WEDG and on-line measurement of the microelectrode diameters. At the position S_T of the micromachining process as shown in **Figure 19**, the required diameter can be machined by feeding the value of ΔS which is calculated by the eqn [13] after the diameter feedback of on-line measurement.[99]

The TF-WEDG method is performed into three steps as presented **Figure 20** in order to earn high-accuracy rate. S_T works as a variable value representing the distance between the microelectrode and the wire-guide axis OO′. $S_T > S1$ in the first step, therefore the axial error of the microelectrode is totally omitted by feeding a large pulse energy. At position A, the microelectrode's diameter is measured by the on-line measurement device and feed based on second step and its diameter is determined by the eqn [13]. $S1 > S_T > S2$ according to the second step (transition step), the microelectrode feeds from the position A to the position B and the calculated diameter is achieved by machining at this position. Then, its diameter is measured again to calculate the feed amount of the final step. $S_T = S3$ is the final step to feed the microelectrode from the position B to the position C, and hence the desired microelectrode is finally fabricated. The final step is a trimming process to obtain a precise diameter and surface. In the second and third steps, the negative polarity machining (the microelectrode with negative polarity) is used for higher material removal and better surface roughness. The microelectrode fabrication will follow this three steps procedure.[99]

In TF-WEDG method, the negative polarity machining increases the material removal from the microelectrode and decreases the surface roughness of the microelectrode. Therefore, it results in an obvious improvement of the surface quality of microelectrode as shown in **Figure 21**. The experimental investigation on the microelectrodes of Φ27 and Φ64 μm are presented in **Figures 22** and **23**, respectively. In the axial direction, the consistency accuracy for one microelectrode is less than 1 μm, and the repeating machining accuracy

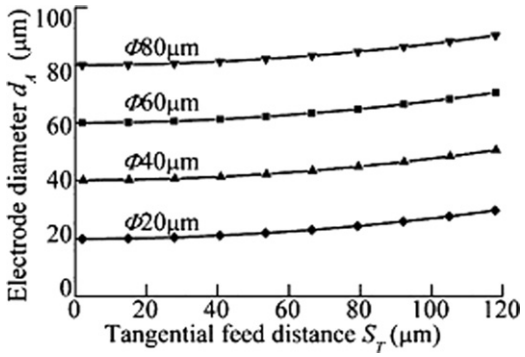

Figure 19 Error analysis of TF-WEDG.[99]

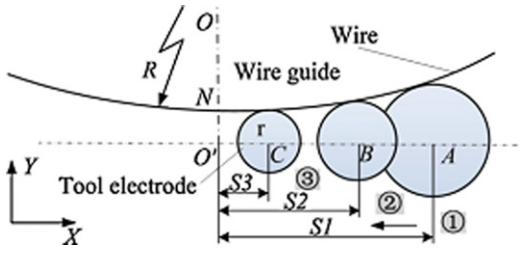

Figure 20 Three steps of TF-WEDG method.[99]

for several microelectrodes is less than 2 μm. The key factors that affect this repeating machining accuracy are the unit stability of WEDG, the geometric errors in the *X*-axis of horizontal straightness with respect to the linear positioning, and the error in the wire diameter.

1.10.4.3.1.3 Twin-wire EDM system

The WEDG technology invented by professor Masuzawa is used to fabricate the microelectrodes. This technology employs an RC pulse generator, which can maintain high accuracy throughout the whole machining process. However, WEDG method needs a lot of time to produce the microelectrodes because of using roughing and finishing steps. On the contrary, a twin-wire EDM system, which includes combined TrC and RC two pulse generators, can be used more efficiently to fabricate microelectrode as shown in **Figure 24**. This system offers only one step to fabricate the microelectrodes.[100]

The twin-wire EDM system works on two isolated wires which move on two v-shaped guides, as shown in **Figure 24**. In this system, two precisely machined copper wire electrodes create two separated pulse generators in one machine. The upper wire is connected a transistor pulse generator which is used for roughing step and another wire is connected an RC pulse generator which is used for finishing step. The transistor type pulse generators equipped with an additional large capacitor provides enough amount of spark energy (discharge energy) to obtain large MRR for roughing step. On the contrary, the RC pulse generator includes a smaller capacitor having reduced stray capacitance to achieve a very low amount

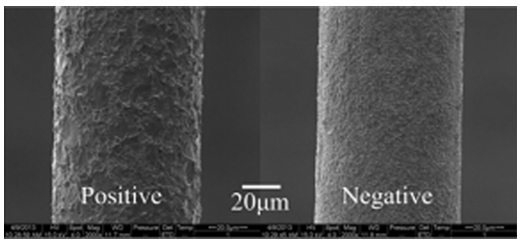

Figure 21 Roughness contrast of positive and negative polarity machining.[99]

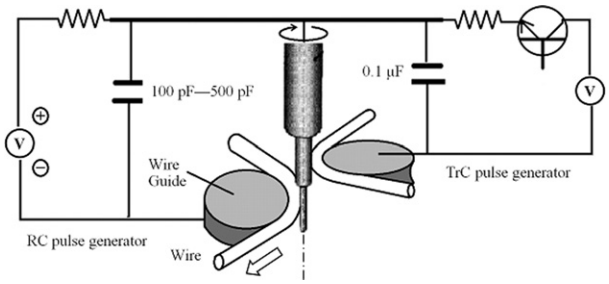

Figure 24 Twin-wire EDM system for the microelectrode fabrication.[100]

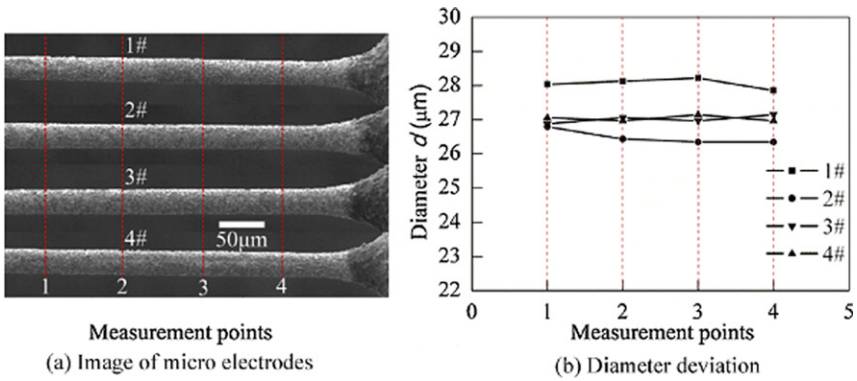

Figure 22 Experimental results of microelectrodes after finishing process (Φ27 μm): (a) image of microelectrodes and (b) diameter deviation.[99]

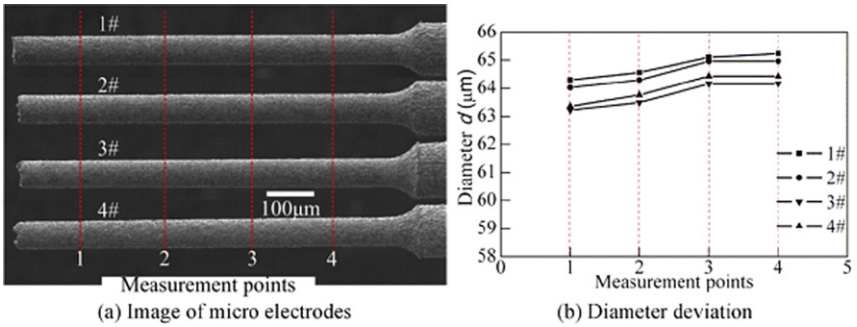

Figure 23 Experimental results of microelectrodes after finishing process (Φ 64 μm): (a) image of microelectrodes and (b) diameter deviation.[99]

of spark energy for finishing step. The lower stray capacitance and small amount of spark energy of an RC pulse generator have made it an essential discharge circuit for machining microelectrodes.[100] By using WEDG technology equipped with an RC pulse generator, it is possible to fabricate microelectrodes with diameters as small as 5 μm.[100,101]

As shown in **Figure 24**, the rod tool spindle at first feeds to the upper wire to shape the microelectrode roughly using a TrC (transistor electro-discharge circuit) electro pulse generator. When the feeding length crosses the gap between those two electrode wires, the twin-wire EDM machining system immediately starts the finish machining through the RC electro pulse generator simultaneously. Conventional EDM machining system that employs transistor type pulse generators required the pulse-ON time, pulse-OFF time, and a duty factor to achieve a high-precision machining. However, the finishing side of the twin-wire EDM machining system determines the accuracy of the microelectrodes without taking the transistor pulse generator into account. This system can produce the straight and thin microelectrodes by using high-precise position control. Fundamentally, twin-wire EDM system can fabricate the precision microelectrodes with various materials.[100]

1.10.4.3.1.4 Fabrication of microelectrode for batch production by WEDM

The micro-WEDM machine was used to manufacture the microelectrode array with high aspect ratio. The microelectrode is clamped on the spindle machine and gradually fed in downward direction against the wire which is moving toward horizontal direction. By this process, raw material of microelectrode (a small metal rod) can be machined to a microstructure array with micro-squared pillars. For producing mass micro-holes, an array of microelectrodes is needed to cut by performing the micro-WEDM process first. **Figure 25** shows the relative wire movement at some stages during the manufacturing. As shown in **Figure 25(a)**, the wire moves at an extremely slow speed from $-X$ to $+X$, while the microelectrode (workpiece) is also moving in downward direction. When all of the layers are machined completely, the workpiece is separated from the wire in the $+Z$ axis direction and then rotated around the Z axis at 90° angle for fabricating the other side as shown in **Figure 25(b)**. After that the fabricated microelectrode array is unclamped from the machine and is mounted directly above the stainless steel plate and then moved slowly toward the downward direction for producing the mass micro-holes array as shown in **Figure 25(c)**. Eventually, the mass micro-holes are machined by using the batch micro-EDM process (**Figure 25(d)**). Finally, the microelectrodes array gets shorter in length than the original one because of the consumption toward the longitudinal microelectrode direction.[102]

Figure 26 illustrates the machined microelectrodes array and also a single microelectrode in microphotograph with the total machining time of 130 and 33 min. These microelectrodes are all uniform and consistent on the tip and the middle. The heights of all the pillars are greater than 700 μm, hence providing a enough amount of compensation in the batch micro-EDM method. **Figure 27(a)** illustrates the results for a single hole as well as a hole array machining. As the fabricated microelectrodes array is not unclamped and reclamped, exceedingly excellent the micro-holes position are attained. **Figure 27(b)** illustrates the regular size of the partial hole.[102]

1.10.4.3.1.5 Compliant microelectrode arrays were fabricated by WEDM

The bending stiffness of the microelectrodes can be reduced by employing wire EDM process. This process has the ability to create real 2D geometries by selectively removing desired material in points that affect the lateral yielding. Flexure, tapered, and spring-like microelectrodes were designed using Pro/MECHANICA (finite element methods) to analyze their various features as shown in **Figure 28**.[103]

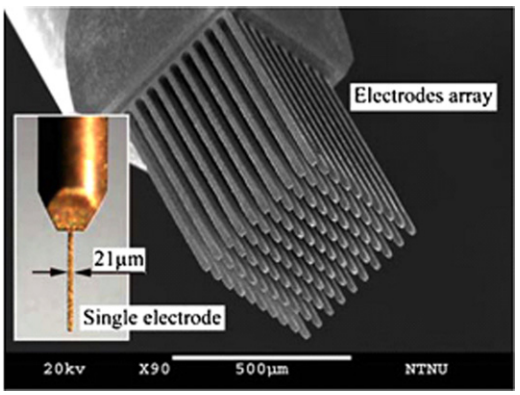

Figure 26 SEM microphotograph of the fabricated single electrode and electrode array.[102]

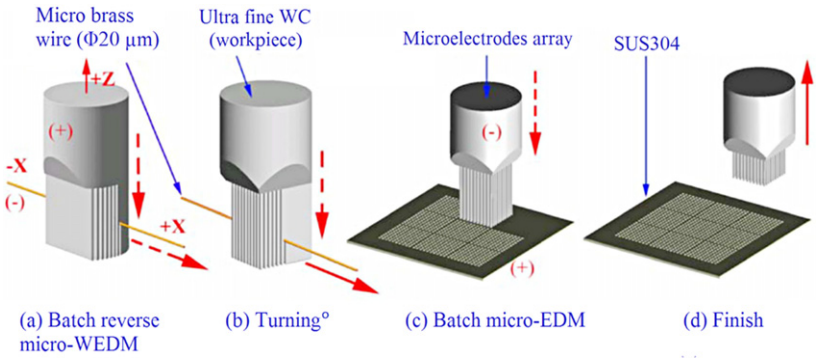

Figure 25 Batch production mode of mass micro-holes.[102]

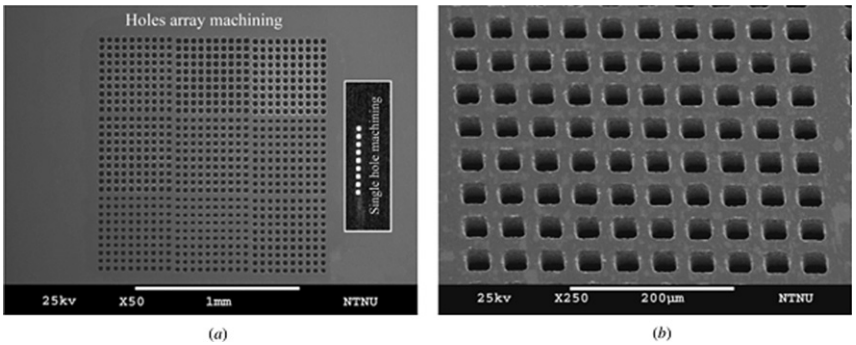

Figure 27 The fabricated micro-hole array (thickness: 30 μm): (a) fabricated single hole and hole array and (b) the partial magnification.[102]

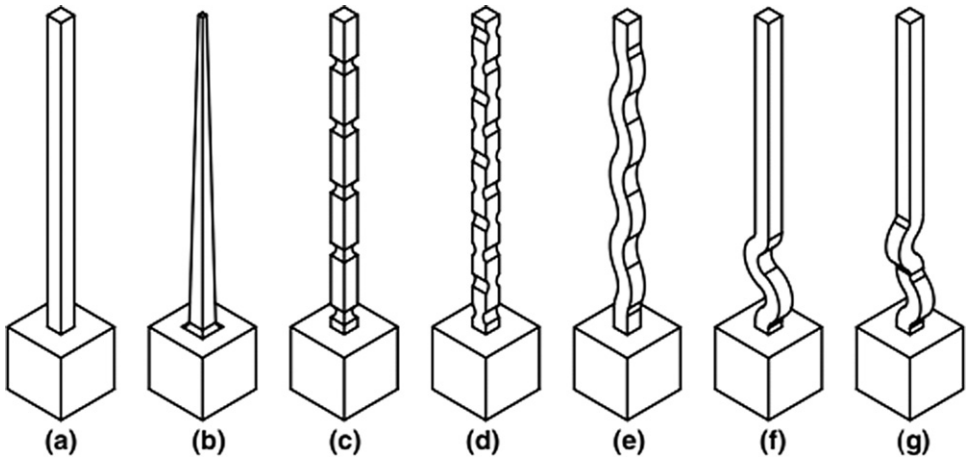

Figure 28 Different microelectrode geometries machined by μ-WEDM process includes: (a) straight, (b) tapered, (c) hour-glass flexures aligned on both sides, (d) hour-glass flexures shifted between both sides, (e) wavy, (f) spring in one horizontal direction, and (g) spring in both horizontal directions.[103]

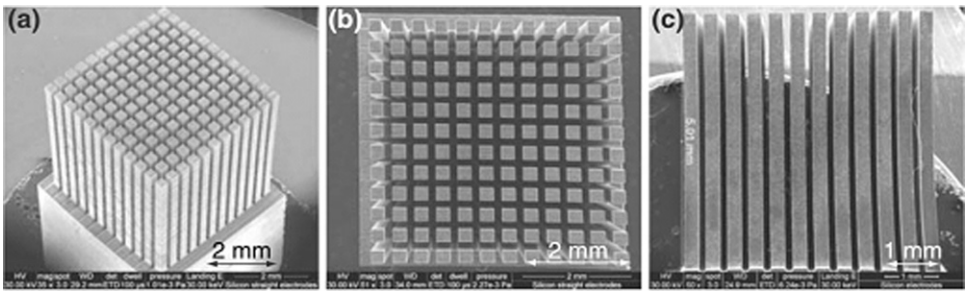

Figure 29 μ-WEDM fabricated straight microelectrode (a) 3D view, (b) top view, and (c) side view.[103]

A tapered microelectrode column with 0.1×0.1 mm tip reduces the bending stiffness by 5 times compared to the straight microelectrode as shown in Figures 28(a) and 28(b). On contrast, flexure feature microelectrodes with circular reliefs having a 0.05 mm depth in each 0.25 mm (Figures 28(c) and 28(d)), are more compliant than the contemporary straight microelectrode by a factor of 4. Besides, lateral rigidity of a straight microelectrode can also be reduced by creating curvatures on it. For instance, the torsional spring-type microelectrode shapes as shown in Figures 28(f) and 28(g) lowers the stiffness by roughly 15%.[103]

Microelectrode arrays of 144 microelectrodes were fabricated into single-crystal silicon blocks with $6 \times 6 \times 10$ mm size. The pitch between two microelectrodes was maintained at 400 μm with a 5 mm microelectrode length. The contemporary straight microelectrodes, shown in Figure 29 possess a 255×255 μm uniform cross section of and a cut achievable in three steps. A roughing step of cutting was accomplished in germanium first with a capacitance and voltage of 9.9 nF and 150 V respectively. This profiling cut made the outlines of the microelectrodes, roughly leaving 10 μm of material on all surfaces. These extended ridges were then retraced with a

capacitance and voltage 3.3 nF of and 150 V respectively. At the next step, the workpiece was rotated at 90° angle. For the other face, the rough cut was eliminated and the finish cut was employed instead. Around 8 h was needed for machining of the entire array.[103]

Similar machining processes were adopted for the microelectrode arrays illustrated in **Figure 30**, that show the μ-WEDM capability to properly trace the complex shapes found in **Figure 28**. The tapered-shaped microelectrode which is depicted in **Figure 30(a)** has a 95×94 μm tip dimension. On contrast, the flexure type microelectrode arrays in **Figures 30(b)** and **30(c)** are machined on square columns with a 250×250 μm cross section. The wavy microelectrode illustrated in **Figure 30(d)** as well as the microelectrodes with the base springs as shown in **Figures 30(e)** and **30(f)** are based on a 220×220 μm cross section for creating larger curvatures.[103]

The μ-WEDM method and subsequent etching were performed to manufacture an microelectrode array which has 144 microelectrodes with 5 mm length. To increase the lateral compliance, the microelectrodes were tapered and machined with a bidirectional spring at the base. After performing the μ-WEDM, the microelectrode array was etched for 1 min in HNO_3:CH_3COOH:HF followed by an another 1 min etching in HNO_3:HF. **Figure 31(a)** shows a SEM image of the microelectrode array and **Figure 31(b)** is a magnified image of the base geometry having a cross section of 100 μm. The two-directional curvatures of the base geometry act as torsional springs. **Figure 31(c)** shows an microelectrode tip that was etched to a very sharp point.[103]

Using μ-WEDM also allows variable the microelectrode lengths to a certain degree. **Figure 32** shows the microelectrode array was manufactured by first machining a v-groove into one side and cutting two chamfers in the other side. This resulted in an array whose tapered microelectrode lengths were from 5 to 9 mm.[103]

1.10.4.3.1.6 Fabrication of series-pattern micro-disk electrode

Schematic diagram of the essential parts of the micro-EDM working system are shown in **Figure 33**. A micro-EDM working system is composed of WEDG method and RC discharge circuit which are mounted on the XYZ stages with a nanometer range positioning accuracy. The stage accuracy this method is

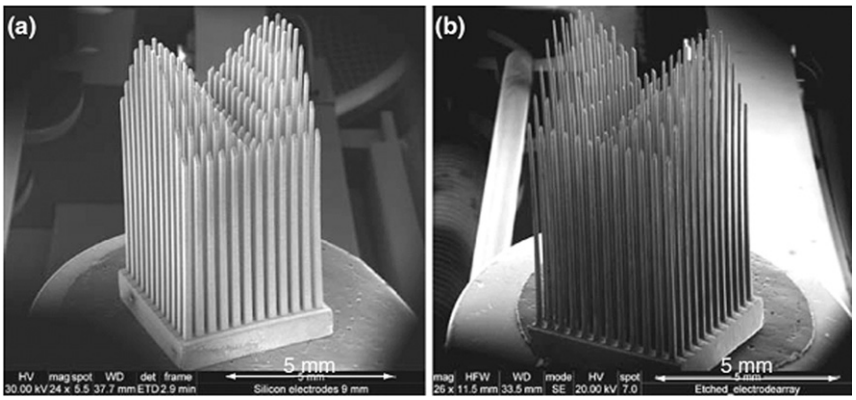

Figure 32 Variable length microelectrode array (a) after μ-WEDM and (b) after etching.[103]

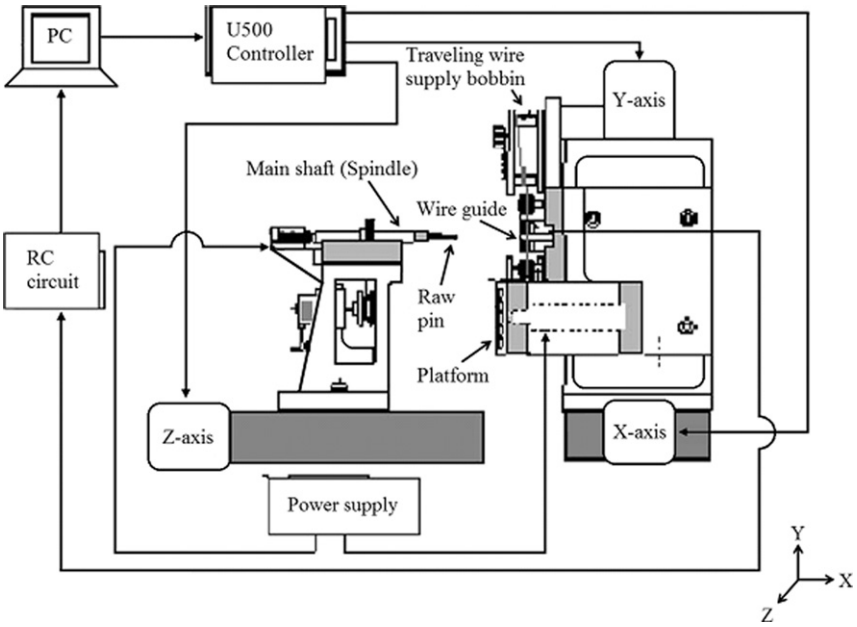

Figure 33 The micro-EDM system configuration.[104]

illustrated in Table 7. In the WEDG process, the tool electrode is basically a wire electrode which travels on a wire guide. By adjusting the discharge voltage and the capacitance at the improving RC discharge circuit, a moderate energy discharge can be obtained to make a micro-component. This method is a free-contact force machining process with a small sparking gap between electrodes.[104]

In the configuration of the micro-EDM working system, a main mandrel shaft is horizontally set on the bearing surface, which is known as horizontal micro-EDM working system. A raw pin can be clamped at the mandrel shaft by a capillary and a ceramic alignment sleeve. The raw pin can be horizontally rotated with the main shaft by means of a transmission motor. As illustrated in Figure 34, the machining can be performed through the sparking discharge between the pin and the wire traveling on the WEDG. The debris is effectively removed from the gap during the machining by gravitational force due to the horizontal position of the pin. U500 controller can control the relative position between the wire electrode and raw pin as shown in Figure 33.[104]

Table 7 Stage accuracy of the horizontal micro-EDM working system[104]

Travel range	*XYZ: 50 × 50 × 50 mm*
Incremental motion	XYZ: 0.1 μm
Velocity range	2–0.0005 mm min^{-1}
Velocity accuracy	±2% RMS
Pitch/yaw/roll	XYZ <20 lrad

The machining procedure of a single micro-disk can be extended into the fabrication of multiple micro-disks as illustrated in Figure 35. However, some factors influence the minimum interval between disks which should be specially noticed and discussed.[104]

Firstly, based on the fabrication procedures outlined, a raw pin can be fabricated into the tool electrode with the

micro-disk by the micro-EDM system illustrated in Figure 33. This tool electrode is rotated with the horizontal rotation on the main shaft by the means of a transmission motor, such tool electrode is called as micro-rotating disk electrode (MRDE).[104]

A polished work-piece plate is placed vertically on the XY table. Before the machining is performed, the positioning detection circuit is employed precisely to detect first position. Moreover, the positioning detection circuit maintains the relative original position between the work-piece surface and outermost MRDE. The MRDE can then be fed into the work-piece from the surface until it reaches the desired depth. A straight line with a micro-slit can thus be formed by means of moving the *Y*-stage which is carrying the workpiece, as schematically presented in Figure 36.[104]

1.10.4.3.2 Rotating sacrificial disk

Figure 37 illustrates the microelectrode fabrication process using a rotating sacrificial electrode. Electrical discharges have caused the erosion on the rotating electrode during the fabrication process. However, the erosion is almost uniformly distributed over the whole electrode perimeter during micro-EDM. The dimensional change of the rotating electrode is almost negligible in microelectrode fabrication by considering the diameter difference between the sacrificial electrode and microelectrode. Moreover, the rotating electrode with 0.5 mm thick provides the same effect as stationary electrode on the surface finish, since its wideness is sufficient to produce a smooth surface, as can be seen in Figure 38.[5]

1.10.4.3.3 Stationary BEDG

Stationary BEDG is the simplest ways to fabricate a micro-electrode. Figure 39 illustrates the fabricated microelectrode using BEDG process. This method can produce the micro-electrode with smooth surface. However, some taper is usually seen in the microelectrode shape and the accuracy is not as good as desired because of the wear occurs on block electrode

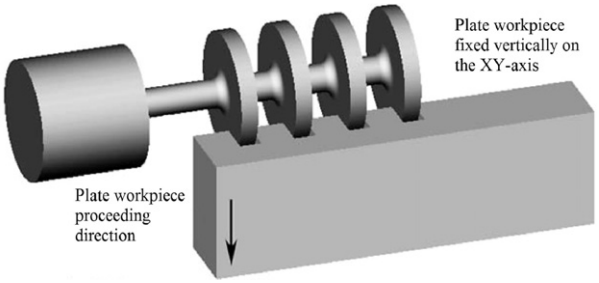

Figure 36 A schematic representation for cutting the micro-slit using the MRDE.[104]

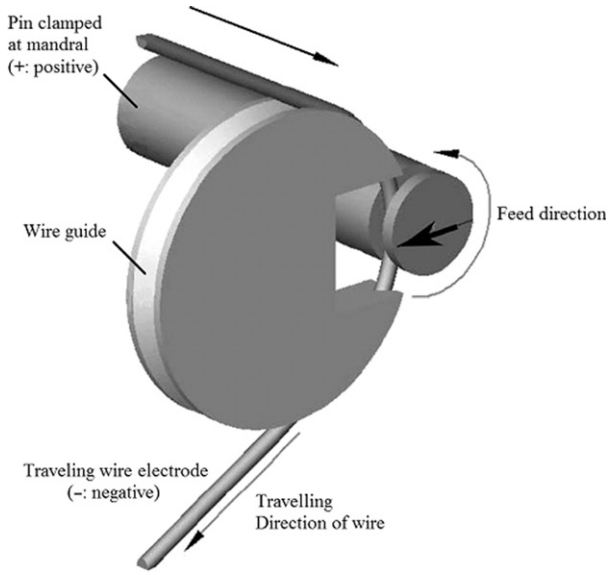

Figure 34 The micro-EDM system configuration.[104]

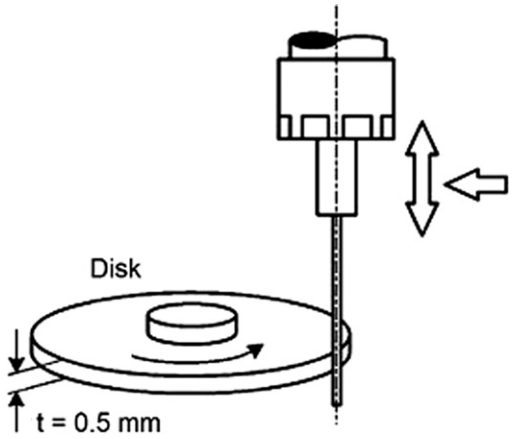

Figure 37 Rotating sacrificial disk.[5]

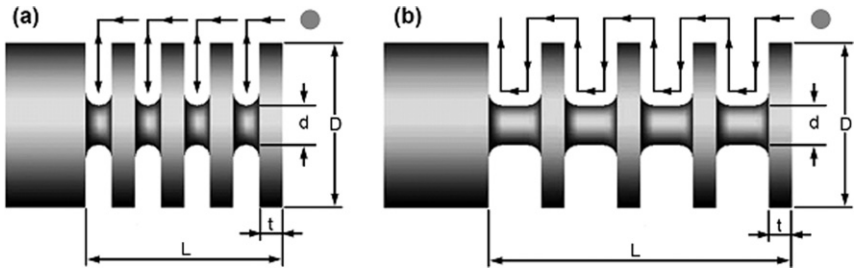

Figure 35 Schematic representation of the tracking path of wire to fabricate the series-pattern micro-disk for (a) a smaller interval or (b) a larger interval between disks.[104]

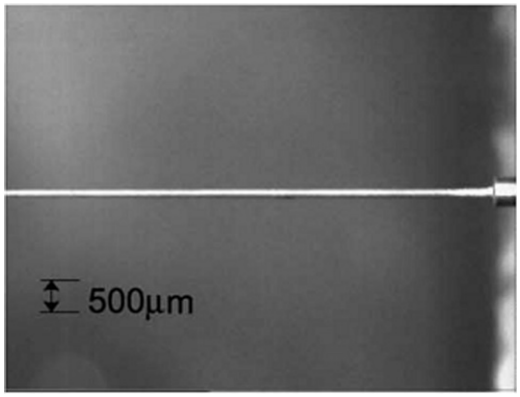

Figure 38 Fabricated microelectrode using rotating disk.[5]

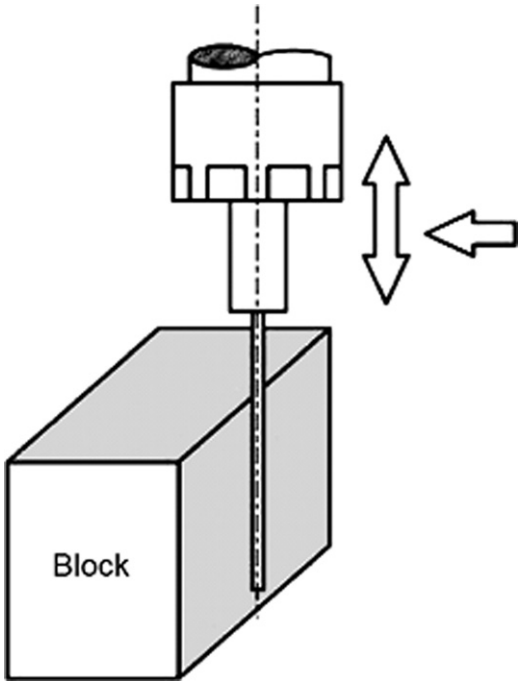

Figure 39 BEDG.[5]

as shown in Figure 40. Since the microelectrode feeds upward and downward during microelectrode fabrication, the lower (tip) portion has a greater chance to face the block electrode, and consequently is subjected to more discharges during the machining. Also, slight tilting of the block electrode toward the microelectrode does not shape to improve the tapered shape. Figures 40 and 41 show tapered and uneven diameter of microelectrode respectively. The block electrode is easy to setup but shape and dimensions of the microelectrode are not easy to control.[5]

1.10.4.3.4 MBEDG

Figure 42 shows the moving BEDG (MBEDG) which is combined the advantage of the rotating sacrificial disk and BEDG methods. Block electrode needs a very simple setup and the surface of the machined microelectrode is generally smooth. However, the precision of shape is not as improved as desired,

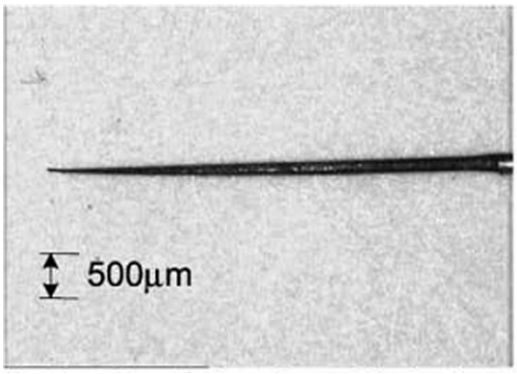

Figure 40 Tapered microelectrode is produced using BEDG.[5]

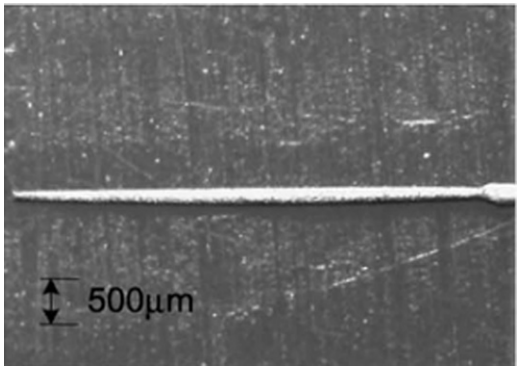

Figure 41 The microelectrode uneven diameter is machined using BEDG.[5]

and the microelectrode generally possesses a tapered shape as a result of the wear in the block electrode. In this fabrication process, the microelectrode in the *Z* axis controlled the EDM gap by the top surface of the block electrode. A relative feed between the microelectrode and the block electrode was employed longitudinally with the block electrode. During the Moving BEDG method, erosion occurred on the moving block electrode by the electrical discharges. However, the erosion occurred almost in a uniform manner over a very larger area of the block electrode. In addition, most of the sparks occurred between the un-machined part of the microelectrode and the top surface of the block electrode. Almost no spark occurs at the side surface of the microelectrode. This produced the not tapered microelectrode with very smooth surface and good accuracy in shape. However, there was difference in the produced microelectrode length which is smaller than the desired length always because of the created groove on the block electrode surface. The difference between the actual length and the desired length of the microelectrodes is almost negligible by considering the machined area between the microelectrode and block electrode.[4]

Figure 43(a) illustrates the CuW microelectrode with about 50 µm diameter and 3 mm length (aspect ratio = 60) was fabricated using BEDG. Figure 43(b) shows the improvement in taperness of the microelectrode which was produced using moving BEDG. Figures 44(a) and 44(b) illustrate the W microelectrodes which were fabricated using BEDG and moving BEDG methods respectively. It is clear that the moving

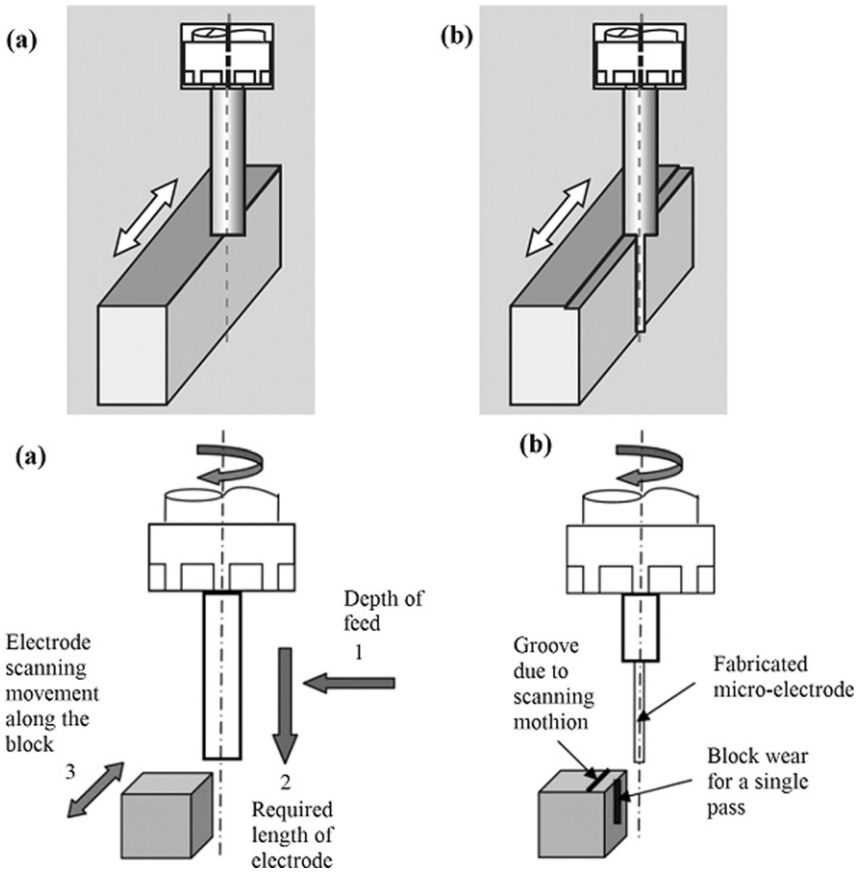

Figure 42 Moving BEDG method for on-machine microelectrode fabrication. (a) At the beginning of moving BEDG. (b) Groove create by erosion.[4,74]

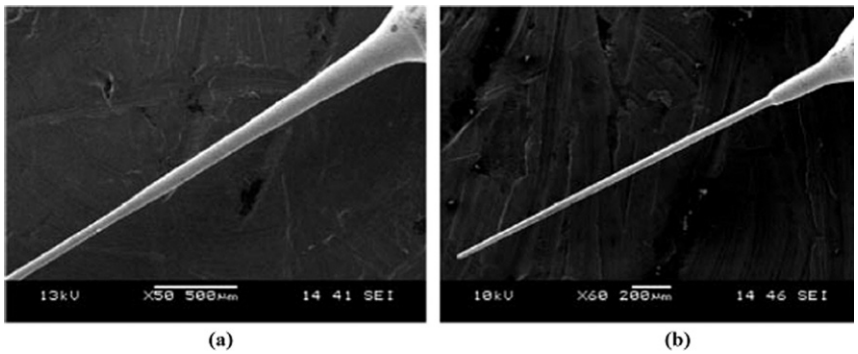

Figure 43 CuW microelectrode; (a) with 50 μm diameter and 3 mm length (aspect ratio = 60) was produced by the BEDG method, (b) with 40 μm diameter and 2 mm length (aspect ratio = 50) was produced by moving BEDG method.[74]

BEDG method can produce less tapered microelectrodes and provides a superior dimensional accuracy.[74]

1.10.4.3.5 Micro-turning process

The main problem that occurs during the micro-turning of the microelectrode is its deflection. Figure 45 illustrates the deflection of end portion of the microelectrode measured using a deflection sensor. Experiments revealed that the microelectrode is bending in normal (X) as well as tangential (Y) direction of the microelectrode contact region. Moreover, the microelectrode deflects toward the rake surface (top surface) of the cutting tool. It is very difficult to get straight microelectrodes below 100 μm diameter band in many cases. The microelectrode either gets broken or starts to wobble due to the excessive cutting force in radial direction on this microelectrode. Figure 46 demonstrates one of this kind of microelectrode which is machined by the conventional micro-turning process.[4]

Figure 47 shows the polycrystalline diamond (PCD) inserts with 100 μm tool nose radius (designed for finishing step or

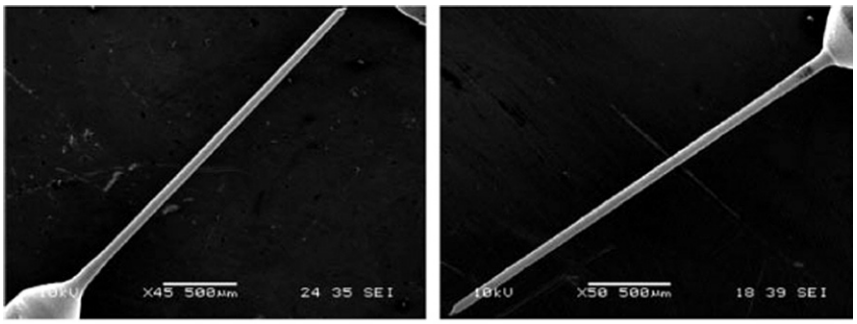

Figure 44 W microelectrode, (a) with 60 μm diameter and 3 mm length (aspect ratio = 50) was produced by the BEDG method, (b) with 40 μm diameter and 3 mm length (aspect ratio = 75) was produced by the moving BEDG method.[74]

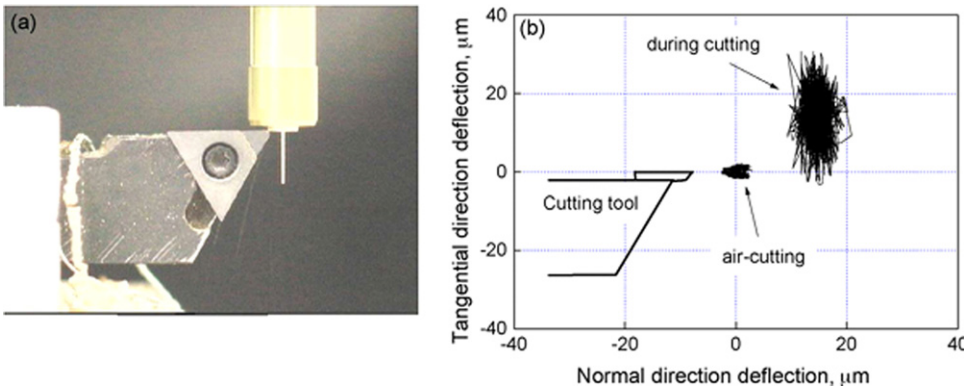

Figure 45 Microelectrode deflection during micro-turning.[4]

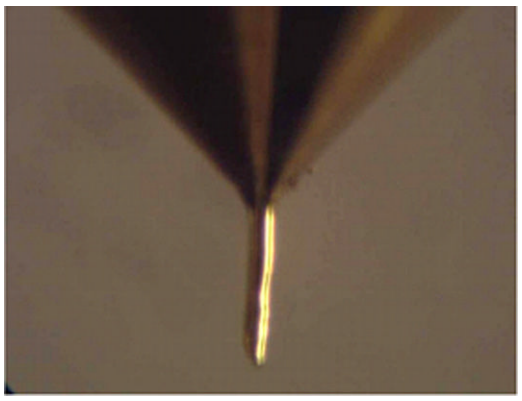

Figure 46 A 100 μm diameter microelectrode was machined by conventional micro-turning.[4]

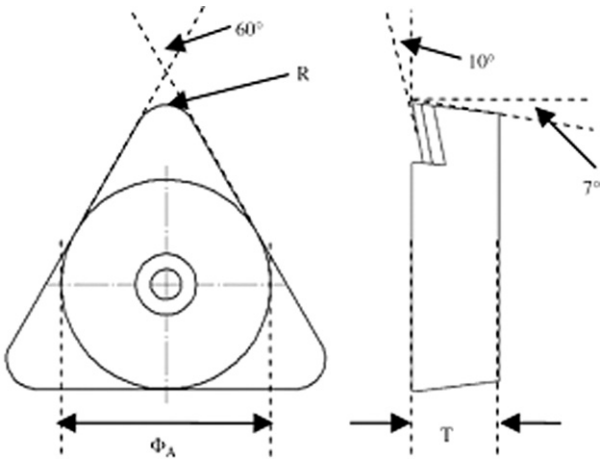

Figure 47 The tool geometry of commercially available PCD inserts for finishing step (light cutting).[4]

light cutting) was used for micro-Turning. This tool nose divides the cutting force on the microelectrode in to two different force components, F_x and F_y as shown in Figure 48(a). Basically the F_y cutting force component performs the actual cutting whereas the F_x component is responsible for the microelectrode deflection. Figure 48(b) illustrates the actual cutting with the commercially available PCD inserts under a tool scope.[4]

1.10.4.3.6 EDM of micro-rods by self-drilled holes

Figure 49 presents the working principle of the developed micro-EDM process. In this process, a rod electrode is rotated with negative polarity and fed into a plate electrode to create a hole. When the rod electrode is returned to its initial place, the axis gets off-centered from the hole center at a certain distance.

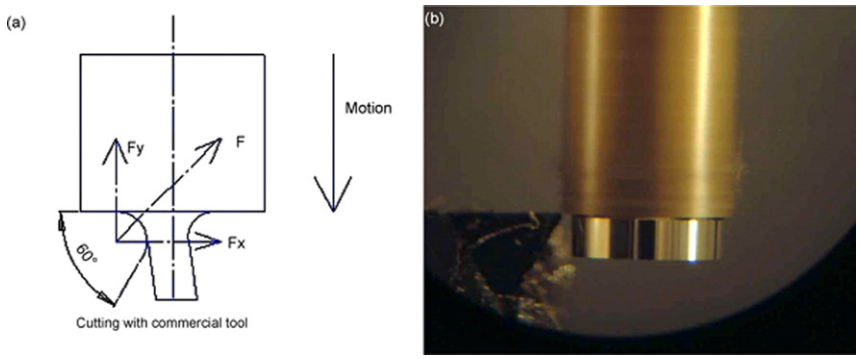

Figure 48 (a) Resolution of cutting forces and (b) actual cutting with the commercially available PCD inserts under a tool scope.[4]

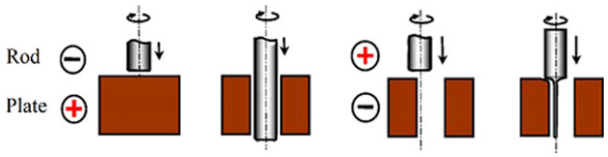

Figure 49 Principle of obtaining micro-rods by self-drilled holes.[105]

Then, the rod electrode polarity is reversed and the rod electrode is fed into the plate electrode either stationary or with rotation. The straight rod electrode (microelectrode) can be achieved if the wear does not occur at the outlet holes even though the inlet holes have already worn out. If the machining gaps between the hole and the electrode are determined before as illustrated in **Figure 50**, the rod electrode with any diameter can be fabricated. With traditional methods, it is essential to measure the machined rod electrode diameter and rectify the starting point of machining from the previous measured results. The benefits of this new process include no adjustment of the starting point is needed and accurate machining efficiency.[105]

Unlike reverse-EDM and WEDG, this process can produce the reference holes with the rod electrode, therefore no reference positioning of the tool electrode to the workpiece is needed. As a result, operation becomes easy and shorter. In addition, stable EDM is achieved because of the wide electrical discharge area compared with WEDG, and complicated shapes can be formed.[105]

Figure 51 shows the fabricated microelectrodes after various machining conditions. **Figure 52** illustrates microelectrodes fabricated by double forming is still taper.[99] **Figure 53** demonstrates the microelectrodes were fabricated by various holes for forming and holes obtained by EDM using these tools.

1.10.4.3.7 Reverse EDM

In micro-EDM, micro-holes, and micro-structures are fabricated by feeding a microelectrode machined by wire EDM or grinding process as illustrated in **Figure 54(a)**. Micro-EDM can be used for fabrication of the micro-holes and microelectrodes. For instance, some holes are fabricated on a metal plate by using EDM. After applying a positive voltage to a workpiece material for machining microelectrodes, the workpiece is fed down to the holes of the metal plate while being machined by EDM. However, the areas around the holes are not machined and remain, getting into a microelectrode at each hole as illustrated in **Figure 54(b)**. This machining process is generally called reverse EDM (REDM). Different microelectrodes shapes can be machined by REDM, which is difficult to fabricate using normal EDM.[106] **Figure 55** depicts examples of multiple microelectrodes and U-shape microelectrode which were fabricated by REDM.

1.10.4.3.8 Hybrid process

1.10.4.3.8.1 Micro-turning–micro-EDM hybrid machining process

As has been described before, all of the microelectrode fabrication processes have their own benefits and disadvantages. The disadvantage of the conventional micro-turning is the transferring the microelectrode to EDM machine. Moreover, rotating sacrificial disk, WEDG, BEDG, moving BEDG, and self-drilled holes are very difficult for automation and are always prone to error. In most cases, the operator is required to check the whole fabrication process and perform manual compensation to find the error. Besides, it takes more than few hours for the electrode fabrication process. For example, it takes about 3–4 h to fabricate a microelectrode with 15 μm diameter and 0.5 mm length using a commercially available 500 μm diameter tungsten electrode with by moving BEDG method. It is a well-known fact that tungsten electrode has negligible wear against stainless steel and 100 holes could be machined on 50 μm thick SUS-304 plate with this microelectrode. A new hybrid machining method for micro-turning can be employed to machine very fine microelectrodes and nearly eliminates all the disadvantages of microelectrode fabrication methods which used micro-EDM machine.[4]

Figure 56 shows the process of turning-EDM hybrid machining. In this type of machining process, EDM is carried by using a microelectrode. Therefore, an electrode of certain length is machined using the micro-turning process. Elimination of clamping error and minimizing the electrode deflection is possible in hybrid machining process, which results in the significant improvement in machining accuracy. When variable diameters of microelectrode are required, turning can significantly save the microelectrode preparation time as compared to the EDM processes. Nonrotational cylindrical micro-components such as key slot or flat bar can also be fabricated using hybrid machining technology with the help of EDM process followed by turning.[4]

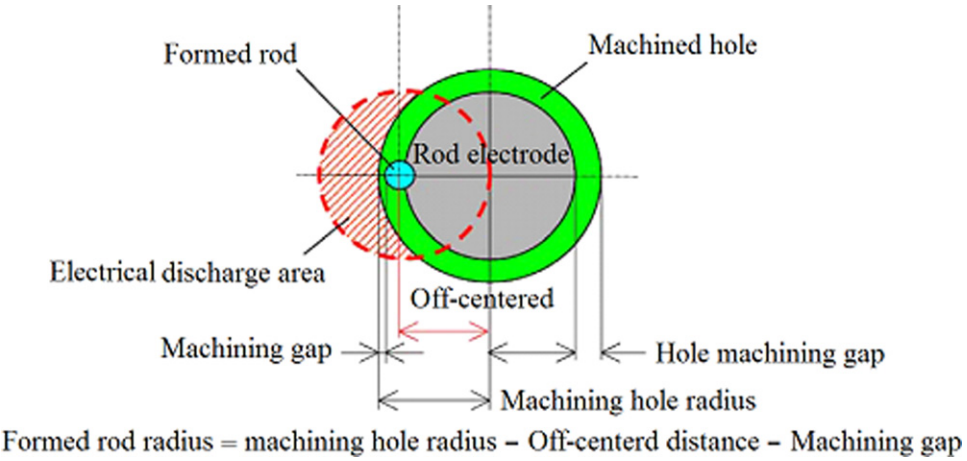

Figure 50 Off-centering concept chart.[105]

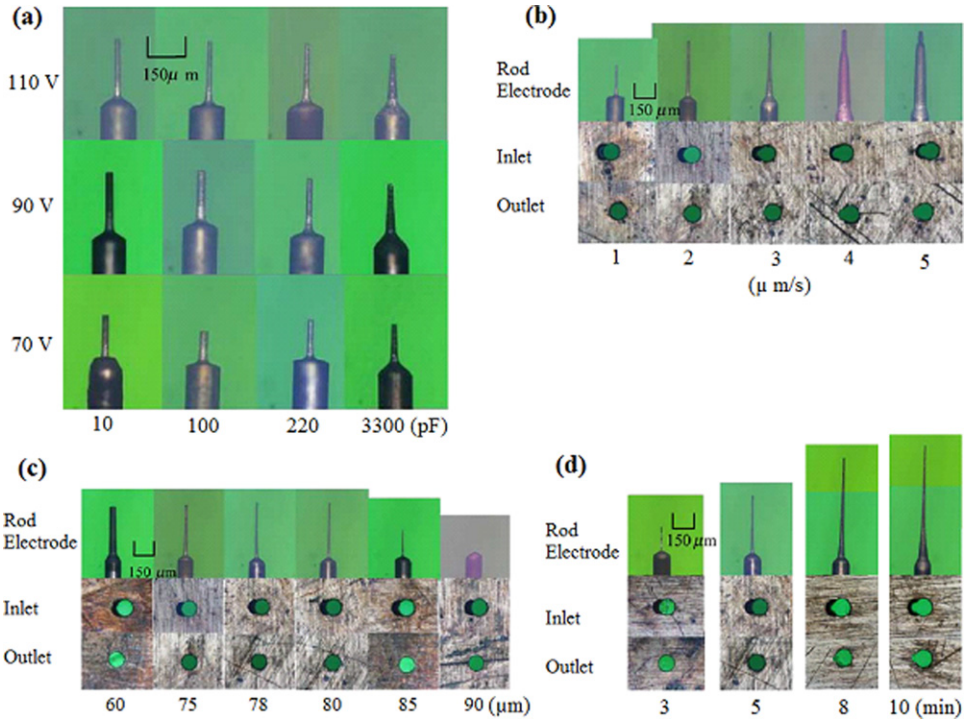

Figure 51 Microelectrodes obtained by (a) varying discharge energy (1 μm s^{-1}, 75 μm, and 5 min), (b) varying feed speed (110 V, 100 pF, 75 μm, and 5 min, (c) off-centering (110 V, 3300 pF, 2 μm s^{-1}, and 5 min, and (d) varying machining time (110 V, 3300 pF, 2 μm s^{-1}, and 78 μm).[105]

As described before, it is always very difficult by microturning to achieve straight microelectrode below 100 μm diameter and in a lot of cases, the microelectrode is either broken or starts to wobble due to excessive radial cutting force on this microelectrode. A commercially available PCD insert can be modified to achieve a very sharp cutting edge which would reduce the F_x component of the cutting force significantly (Figure 57) and thus this makes it possible to achieve straight microelectrode with much smaller diameter.[4] Figure 57 Illustrates the resolution of cutting forces in F_x and F_y components in commercial tool (on the left). Modified tool can reduce the F_x component of cutting force significantly due to sharp cutting edge (on the right).[3]

An approach has been developed to manufacture an ultrasharp-edged tool from the commercially available PCD insert using micro-EDM. A rotating electrode is mounted on the spindle and used to perform micro-EDM (EDG) on the PCD tool edge to produce a very sharp edge.[4] This is illustrated in Figure 58. Table 8 shows the parameters that were used during the tool tip fabrication. Figure 59 shows the

commercially available PCD insert (a) and the modified PCD tool (b). The modified PCD tool has less than 5 mm tool nose radius.

In Figure 60, a microelectrode and the EDG-edged tool used for machining the microelectrode under a tool scope is observed.[4] This has stretched the possibility of micro-turning to an extreme. This method illustrates much improvement on the machining time compared to rotating sacrificial disk, WEDG, BEDG, moving BEDG, and self-drilled holes which takes few hours to fabricate as mentioned earlier. In addition, this method does not require much operator intervention and can mostly be automated due to the less chances of error. Two millimeter long microelectrodes with less than 20 μm diameter have been fabricated very easily. The fabrication process for a 2.0 mm long microelectrode takes less than 10 min.[4] Figure 61(a) shows a microelectrode with 22 μm diameter was produced by micro-turning process and after drilling about 10 holes on 100 μm thick SUS-304 plate.[4] Figure 61(b) demonstrates a graphite microelectrode of 0.5 mm long and 19 μm in diameter that is similarly produced.[3]

1.10.4.3.8.2 Self-drilled holes–TF-WEDG hybrid machining process

Figure 62 shows the hybrid process of self-drilled holes and TF-WEDG holes for the complementary benefits of high efficiency and accuracy. First, the tool electrode with negative polarity drills holes on the plate electrode. Then tool electrode is returned to its initial position and the axis gets off-centered from the hole center at a certain distance. Next, tool electrode polarity changes to the positive and is fed into the plate electrode with rotation in order to machine the microelectrode (rod electrode). The microelectrode is fabricated with dimension close to the desired diameter in the rough machining condition. Finally, TF-WEDG method with the on-line measurement is used to fabricate the accurate microelectrode.[99] A charge coupled device (CCD) is utilized for the on-line measurement.

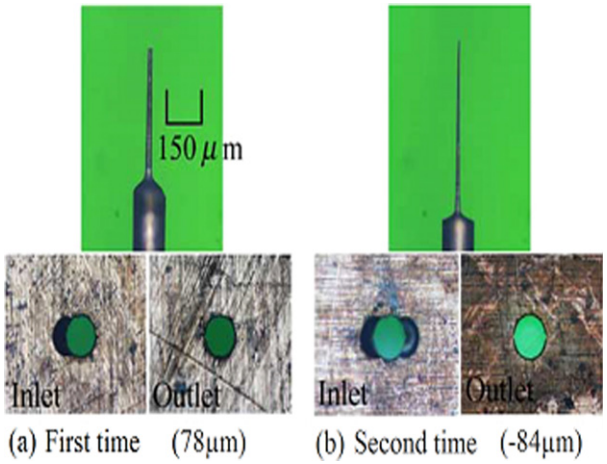

Figure 52 Image of microelectrodes obtained by double forming (110 V, 100 pF, 2 μm s^{-1}, and 5 min): (a) first time (78 μm) and (b) second time (− 84 μm).[105]

1.10.4.3.8.3 Continuous machining process of array micro-holes

To gain high consistency accuracy of array micro-holes and to avoid the negative effects of low rigidity of long microelectrode, a continuous machining process is presented according to the TF-WEDG method. **Figure 63** demonstrates the continuous machining process of array micro-holes. After the implement of the self-drilled holes process (**Figure 62**), the microelectrode is machined with a larger diameter D and an

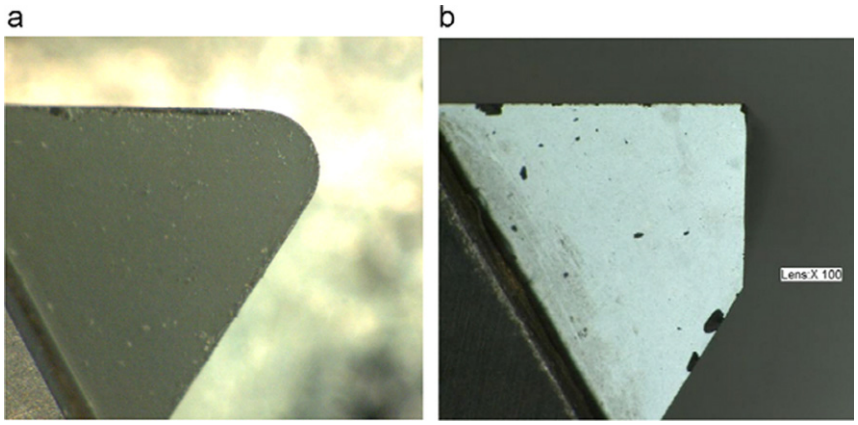

Figure 59 (a) Commercial tool and (b) modified PCD tool.[3]

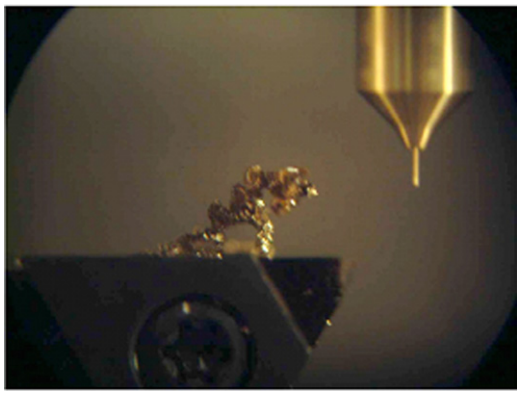

Figure 60 The 2 mm long microelectrode fabricated using modified PCD tool and observed under tool scope.[4]

effective length L. The diameter D guarantees the rigidity of the electrode with the length L. As shown in Figure 63(a), firstly the microelectrode with the desired diameter d and proper aspect ratio of length $L1$ is machined by TF-WEDG. The aspect ratio guarantees enough rigidity of the microelectrode. The desired aspect ratio between d and $L1$ guarantees enough rigidity of the microelectrode. Secondly, the microelectrode is utilized for micro-hole EDM drilling (Figure 63(b)). The microelectrode becomes shorter (wear length ΔL) after micro-EDM drilling the expected number of holes because of electrode wear during micro-EDM. When the microelectrode becomes too short after micro-hole EDM drilling (Figure 63(c)). The remained part of the microelectrode with diameter D is re-machined by TF-WEDG to produce again the microelectrode with diameter d and length $L1$. The procedures are repeated (Figures 63(a)–63(c)) are repeatedly performed until all designed holes are produced (Figure 63(d)). Array micro-holes can be produced by the circulation process.[99]

Based on the continuous machining process, 5×5 array micro-holes were produced through 5 times microelectrodes machining by TF-WEDG and 5 times micro-hole machining with 5 micro-holes each time. The consistency accuracy of micro-holes is evaluated by measuring the magnified images of 25 micro-holes. The experimental results of the micro-holes and the used microelectrodes are presented in Figures 64(a) and 64(b) respectively. The results revealed that the consistency accuracy of 25 micro-holes of $\Phi 73\ \mu m$ is ± 1.1 m, and the drilling time of single micro-hole is 1 min 10 s on the 200 μm thick stainless steel plate.[99]

1.10.4.3.8.4 LIGA–micro-EDM hybrid machining process

The flow of the LIGA process is shown in Figure 65. The LIGA process (step 1–5) which was developed by the University of Wisconsin at Madison[107] fabricates the electroplated electrodes for the micro-EDM. The electrodes that are produced on a silicon substrate are basically negative-type microstructures with ultrafine designs. An electroplated metal plate is used to form many microelectrodes. In the step 5, the metal plate that has the electrodes is released from the substrate as step 5 as the negative-type electrodes are self-supporting. The electrode position in the metal plate is very accurate as photolithographic methods are used for electrode fabrication.[108]

Step 6 shows a positive type of patterned structure is fabricated by feeding the WC–Co workpiece into one of the electrodes using micro-EDM. During this step the shape of the electrode is deformed due its wear. To achieve a uniform cross section along the workpiece length, the electrode has to be replaced before its deformation takes place throughout the thickness. Such deformed electrodes can be replaced with a new electrode by X-Y position between the workpiece and each of the electrodes. This can be done with a high precision as the accurate position of the electrodes as in the step 7. A patterned microstructure with high aspect ratio is achieved after repeating the machining and replacing process.[108]

In the LIGA method an array of nickel electrodes with a negative type gear pattern with 200 μm outside diameter was machined as illustrated in Figure 66. The height of the structure is 300 μm. The primary shape of the nickel electrode is illustrated on the left side of Figure 67. It is deformed by metal wear as illustrated on the right side of Figure 67. Deformation occurs when the WC–Co workpiece with 300 μm diameter is fed to the electrode about 400 μm by using micro-EDM. Though the length of the EDMed structure is confined to the amount of feed depth in single machining, much larger height can be fabricated be repeating the machining and replacing the worn electrode with a new one at X-Y position.[108]

Figure 68 illustrates a positive-type WC–Co microstructure having a 1 mm length fabricated by using three different electrodes of the serial micro-EDM. However, much higher aspect ratio

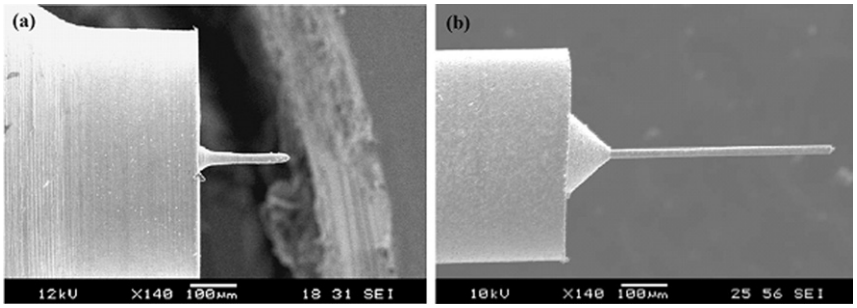

Figure 61 (a) A 22 μm brass electrode fabricated by micro-turning process and used for machining 10 micro-holes on 100 μm thick stainless steel plate, showing some wear.[3,4] (b) A 19 μm graphite micro-microelectrode of 0.5 mm length fabricated by micro-turning process.[3]

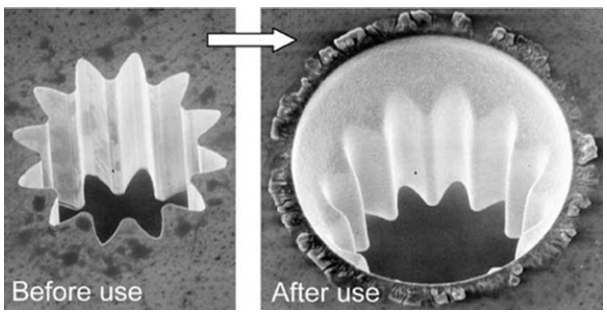

Figure 67 Initial shape of patterned negative-type electrode and deformed one after use.[108]

structure with over 1 mm length can be fabricated by increasing the replacement cycles. The variation in the outside diameter of the 1 mm long structure along its length is measured and the result is illustrated in Figure 69. The provided graph depicts this particular gear length varies by an amount of about 4 μm in the outside diameter along its length. The results illustrate this process has capability to produce high aspect ratio microstructures from various bulk materials as well as WC–Co.[108]

1.10.5 Prospective on Process Selection

A micro-mold cavity is needed, when the mass production of various micro-components is involved.[5] Micro-holes are required in micro-dies and micro-molds.[109] Moreover, hard materials are used for micro-injection-mold, which requires

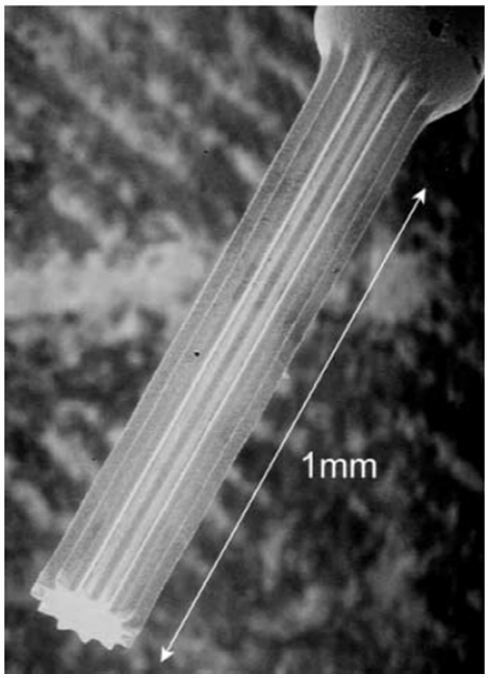

Figure 68 1 mm long WC–Co microstructure with gear pattern produce by micro-EDM.[108]

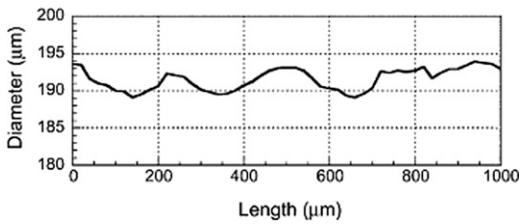

Figure 69 Variation of outside diameter of 1 mm long gear in Figure 68.[108]

very accurate machining of complex and three dimensional shapes in micron range.[5]

Tungsten carbide (WC) and composite of tungsten carbide (WC–Co) are employed for producing cutting tools, dies, other special tools and components owing to high hardness, strength, wear and corrosion resistance of WC and WC-Co over a wide range of temperatures;[72,73] therefore, machining of WC plays a

remarkable roles in recent trend of manufacturing.[110] EDM and electro-chemical machining (ECM) are the only feasible processes for the modern machining of WC–Co.[73] Investigation of Watson and Freer[111] revealed that due to a resistant oxide layer generation on the surface, MRR is very slow during ECM of WC–Co. In fact, more the percentage of cobalt in the alloy increases, the amount of MRR decreases more with it. Singh[112] reported that, the EDM machining process is more suitable for the machining of carbides and other refractory materials.

In the EDM process, conductive materials are removed according to the thermal energy (melting and partial vaporization of the workpiece) produced by series of sparks occurring between the electrode and electrical workpiece.[113] EDM is a useful process in industry for machining conductive materials with accurate dimensions regardless of hardness, strength, and toughness.[114,115] Adding aluminum powder to the dielectric leads to increased MRR and improved surface roughness during EDM.[27,91] The chain formation among powder particles in the dielectric helps bridge the gap between electrode and workpiece that can cause an early explosion. Therefore, faster sparking within discharge and faster erosion of the workpiece surface take place.[90] Micro-EDM and EDM have the same characteristics, with the only differences being the electrode size, discharge energy, and axis movement resolution at the micron level in micro-EDM.[6] Micro-mold making, production of dies and cavities, and producing of the complex three-dimensional shapes at the micro-level are the major functions of micro-EDM.[38] In EDM and micro-EDM, no direct contact and negligible force between the workpiece and tool cause the elimination of tool deformation, chatter, mechanical stress, and vibration errors during machining.[6,39,40] Therefore, micro-EDM is one of the most effective methods of machining of ECM (WC).[43,57]

Jahan *et al.*[57] used AgW, CuW, and W microelectrodes for machining of WC-10wt.%Co. The highest MRR was obtained with the CuW electrode. Also, Jameson[34] stated that "copper tungsten is often used for machining of tungsten carbide." Electrode polarity produces a re-sticky effect during EDM of tungsten carbide.[116] It was reported that the WC workpiece surface does not have any re-sticky regions after finishing with positive electrode polarity in the EDM process.[116] On the other hand, negative electrode polarity for micro-EDM of WC is more suitable as it provides higher MRR, lower electrode wear, better surface roughness, and controlled performance.[117] Jahan *et al.*[43,55] investigated the micro-EDM parameters effects on WC (micro-hole quality) using a transistor and RC-type pulse generator. The results indicated that micro-EDM performance relies on the discharge energy. It has been reported that controlling the performance of RC-type micro-EDM is easier as the electrical discharge energy is determined by voltage and capacitance only. In RC-type micro-EDM, Jahan *et al.*[55,57] used voltage and capacitance (capacitor) as parameters during micro-EDM of WC–10%Co and 0.6% others. Moreover, in transistor-type micro-EDM, they applied voltage, resistance, pulse-ON time, pulse-OFF time,[55,117] and electrode rotational speed[117] as parameters during micro-EDM of WC–10%Co and 0.6% others.[55,117]

The thermal stress during EDM of tungsten carbide creates micro-cracks on the machined surface, as tungsten carbide has low thermal conductivity and brittleness.[118–124] This is especially true during EDM of WC–Co composite, since WC and Co are two quite different phases.[121] Micro-cracks and micropores on the machined surface severely deteriorate the service life, reliability, and machining precision of tungsten carbide tool or mold.[122] Suitable machining parameters during EDM of WC reduce the damage caused by the micro-cracks on the machined surface.[122] It has also been reported that the EDM process has no effect on the microstructure of the bulk workpiece material (WC). This means that EDM causes damage only on the machined surface (surface layer) within a certain depth.[121] Hence, a complimentary finishing operation might become necessary to remove micro-cracks on the machined surface and to produce good surface quality when utilizing the EDM process.[73] On the other hand, the depth of the damaged layer and the average length, width, and number of micro-cracks reportedly increase with increasing current and pulse-ON time.[121] The micro-cracks are more visible when the spark energy (electrical discharge energy) is set to a higher level. Moreover, the machined surface becomes smoother as the spark energy is set at a lower level.[121,122]

Moreover, micro-EDM possess a significant place in the field of micromachining. Because of its non-contact nature, a very long and thin electrodes can be used in micro-EDM.[5] Main disadvantages of micro-EDM are EWR and low MRR. Electrode wear can be balanced by changing the microelectrode, preparing a longer microelectrode from the earlier stage or manufacturing the microelectrode *in situ* for further machining.[4] Also, changing the microelectrode during machining causes decreased accuracy due to changing the setup or microelectrode re-clamping. Thus, An on-machine microelectrode fabrication can eliminate clamping error in the micro-EDM process.[4]

The microelectrode production procedures explained have a number of benefits. For one, the BEDG method setup is simple and the rotating sacrificial disk can be used to fabricate microelectrodes with smooth surface.[5] The block electrode can fabricate cylindrical, triangular, or square microelectrodes at low cost.[125] Moreover, the moving BEDG process has all the advantages of the rotating sacrificial disk and BEDG method. Therefore, moving BEDG can be utilized to manufacture non-tapered cylindrical or non-cylindrical microelectrodes with smooth surface and accurate shapes at low cost using a simple setup.[3,4]

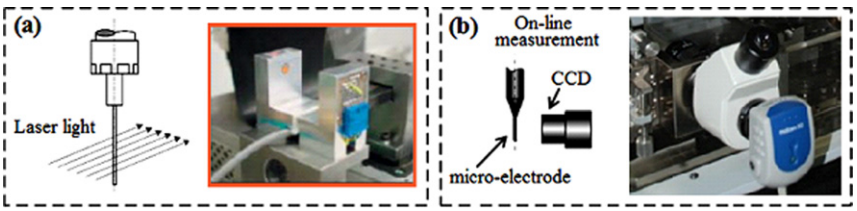

Figure 70 Online measurement (a) Laser light[3–5] and (b) charge coupled device.[99]

Nonetheless, the microelectrode fabrication procedures addressed have some disadvantages as well. For instance, deflection occurs during thin microelectrode fabrication with the micro-turning process.[4] Also, the microelectrode produced with a micro-turning machine needs to be transferred and clamped to the micro-EDM or EDM machine. The fabricated microelectrode cannot be aligned on the micro-EDM or EDM machine, which causes reduced accuracy. The self-drilling hole method usually produces tapered microelectrodes.[99] In addition, tapered or uneven microelectrode diameters are produced with the BEDG process.[5] The rotating sacrificial disk method produces microelectrodes with better surface roughness than the WEDG (guided running wire) process.[5] Moreover, WEDG requires special equipment and high investment. Rotating sacrificial disk setup is relatively complicated. Hybrid machining requires special equipment and high investment. It can be easily outsourced through other workshop. Using a rotating sacrificial disk involves a rather complex setup.[3] Hybrid machining requires special equipment and high investment. Besides, it cannot be easily obtained from all workshops.

Figure 71 AG40L Sodick electrical discharge machine.

Moreover, on-machine measurement is needed to achieve the desired and accurate microelectrode because of estimation of the microelectrode diameter is very difficult. Thus, optical measurement and CCD were applied for the microelectrode measurements, as shown in Figure 70.[3–5,99]

In this research, EDM machine is used instead of micro-EDM and hybrid machines, because the EDM machine is cheaper and more widely available in workshops. CuW is selected as microelectrode to produce the micro-holes in WC–16%Co. There is less information about the effects of micro-EDM parameters (voltage, current, pulse-ON time,

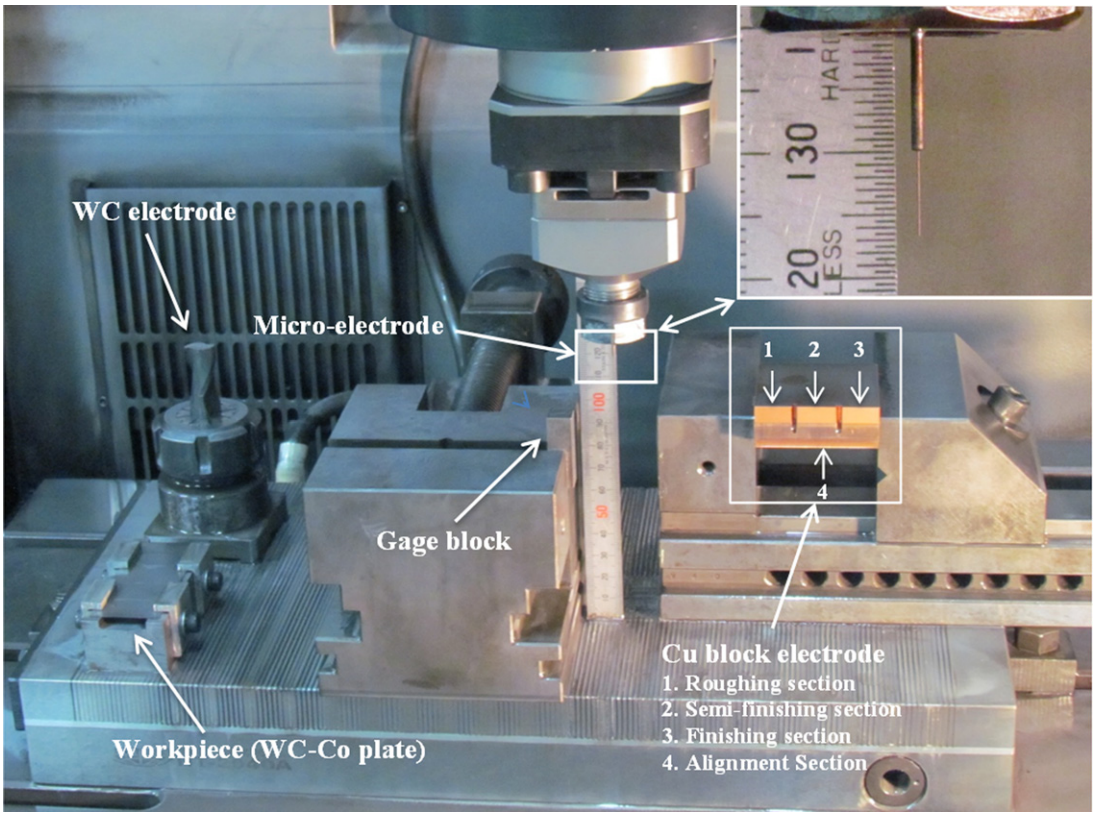

Figure 72 Experimental setup design for the on-machine fabrication and measurement techniques of microelectrodes and micro-EDM drilling.

pulse-OFF time, rotating speed, and capacitor) on micro-EDM drilling of WC–16%Co using an ordinary EDM machine. This research is carried out to investigate the effects of micro-EDM parameters on MRR, EWR, surface roughness, micro-cracks, migration of material to the workpiece, and overcut during micro-EDM drilling of WC–Co using an EDM machine.

1.10.6 Methodology

1.10.6.1 Experimental Setup

In this research, an AG40L Sodick electrical discharge machine was used to replace the micro-EDM machine, as shown in **Figure 71**. This EDM machine has 0.0001 mm (0.1 μm) movement resolution on each axis and the amount of discharge energy can be controlled toward lower energy. **Figure 72** shows the experimental setup for fabricating microelectrodes and measuring microelectrodes diameter, electrode wear, and micro-holes EDM drilling. CuW material (30%Cu + 70%W) with 1 mm diameter was selected as the raw material for the microelectrode and WC–16%Co (HS-US16 plate with 0.331 mm thickness) was chosen as the workpiece. **Tables 9** and **10** illustrate the properties of the CuW electrode and WC–16%Co. The copper block electrode was used to manufacture the microelectrodes as shown in **Figure 72**.[60] A WC electrode was utilized to dress the tapered microelectrode after micro-holes EDM drilling in order to produce a straight electrode.[96] The polarity of the microelectrode during fabrication and electrode dressing was positive, while negative polarity

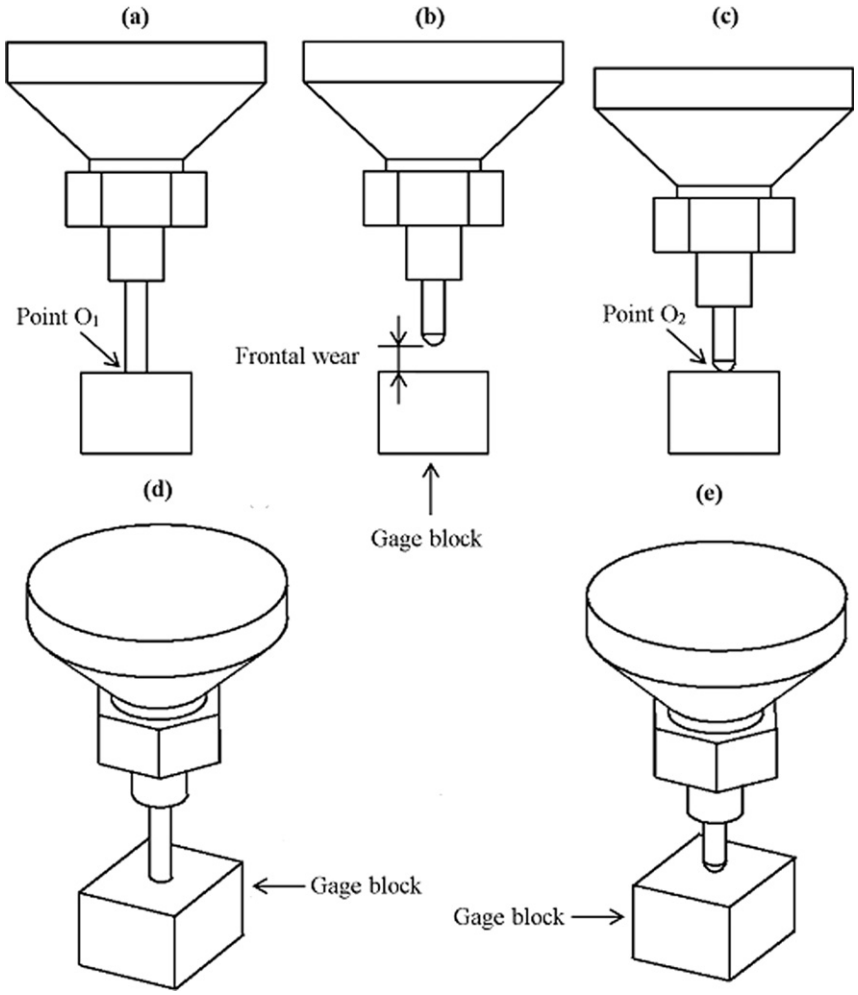

Figure 73 Measuring frontal wear of microelectrode (a) microelectrode before micro-hole EDM drilling touches gage block, (b) microelectrode after micro-hole EDM drilling, (c) microelectrode after micro-hole EDM drilling touches gage block, (d) 3D shape of section a, and (e) 3D shape of section c.

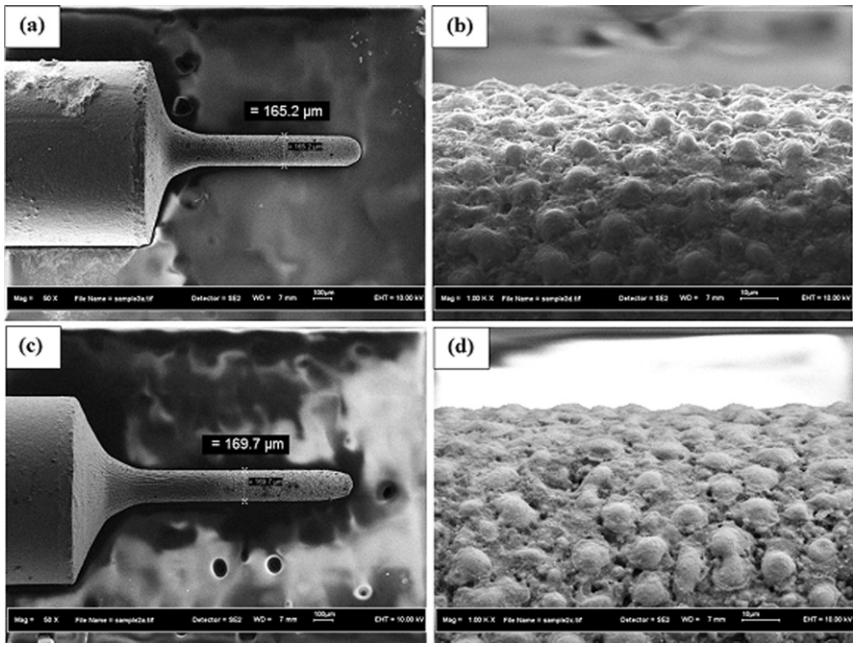

Figure 74 (a) Microelectrodes with 165.2 μm diameter. (b) Surface of microelectrodes with 165.2 μm diameter. (c) Microelectrodes with 169.7 μm diameter. (d) Surface of microelectrodes with 165.2 μm diameter.

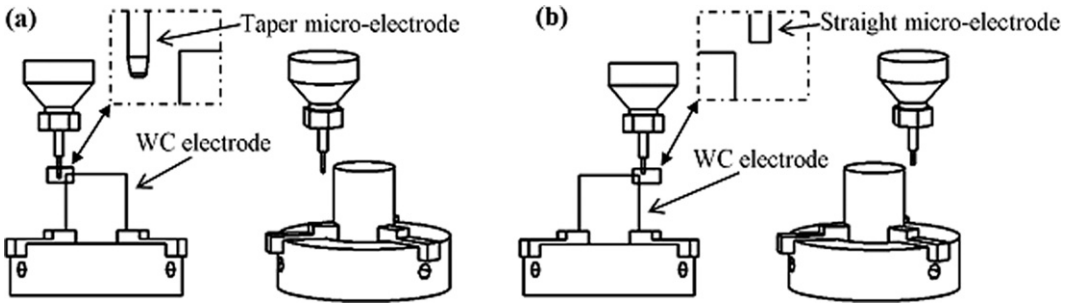

Figure 75 Dressing process. (a) Taper part of microelectrode after machining micro-hole and before dressing process. (b) Straight microelectrode after dressing process.

helped produce the micro-holes.[96] Oil-based dielectric fluid mixed with aluminum powder (PGM WHITE 3) at 1.5 g l^{-1}[126] was also used as it is recommended by Sodick company[126] and the excitation of the aluminum powder in dielectric can help increase MRR and improve the surface quality during EDM.[27,91] A 10 mm thick gage block was used to measure the frontal wear of the microelectrode. The gage block and copper block electrode were aligned with a dial test indicator with 2 μm accuracy.

The frontal electrode wear was measured in the steps shown in Figure 73 and eqn [14]. First, the microelectrode touches the top surface of the gage block at point O_1 before micro-hole EDM drilling (Figures 73(a) and 73(d)), then it will be touch again the top surface of the gage block O_2 after machining the micro-hole (Figures 73(c) and 73(e)). The difference between these positions shows frontal electrode wear (Figure 73(b)).

$$\text{Front wear} = |O_2 - O_1| \qquad [14]$$

1.10.6.2 Micro-EDM of WC–Co

Two CuW microelectrodes with 165.2 and 169.7 μm diameter and around 6.8 mm initial lengths (Figure 74) were utilized for producing micro-holes. These two electrodes were fabricated on-machine by moving BEDG process as described in our previous paper[127] and carried out according to the experimental setup shown in Figure 72. As described before, the polarity of the microelectrode during fabrication and electrode dressing was positive while negative polarity was used for producing micro-hole. Through holes were produced on WC–16%Co plate with 0.331 mm thickness. After micro-EDM drilling of every hole, the microelectrode becomes tapered. The dressing process serves to remove the taper of the microelectrode and produce a straight microelectrode for the next micro-hole EDM drilling based on Figure 75 and using setup shown in Figure 72. Voltage, current, pulse-ON time, pulse-OFF time, rotating speed, and capacitor were adopted as the

parameters to analyze MRR, EWR, surface roughness, microcrack, migration of material to the workpiece, and over cut during micro-EDM drilling of WC–Co using EDM machine. MRR, EWR, and overcut were calculated by following eqns [8, 9, and 11], respectively (the geometry is shown in **Figure 13** and **Figure 73**).[96] **Table 11** demonstrates the machining parameter levels and symbols.

The experiments were designed with 2^{6-2}_{IV} fractional factorial design and 3 center points consisting of 19 runs including 16 ($=2^{6-2}$) and 3 center points. These (resolution IV designs) are designs in which no main effect is aliased with any other main effect or with any two-factor interactions, but two-factor interactions are aliased with each other. The factorial effects defining contrast are I=ABEF=ACDF=BCDE. The alias relationships are as follows:

A=BEF=CDF
B=AEF=CDE
C=ADF=BDE
D=ACF=BCE
E=ABF=BCD
F=ABE=ACD
AB=EF
AC=DF
AD=CF
AE=BF
AF=BE=CD
BC=DE
BD=CE
ABC=ADE=BDF=CEF
ABD=ACE=BCF=DEF

The three-, four-, five-, and six-factor interactions are considered errors. Therefore, the aliased of two-factor interactions are important in this case.

1.10.7 Results and Discussions

1.10.7.1 Analysis of Results on Micro-EDM of WC–Co

Table 12 shows the experimental design and results. Moreover, **Figure 76** demonstrates the effects of the micro-EDM parameters on the holes' diameters and shapes. As can be seen in **Figure 76**, various machining parameters produced microholes with different diameters and shapes. The micro-hole's diameters depend on microelectrode's diameter, overcut, and electrode wear.

1.10.7.1.1 Overcut

Figure 77 illustrates the amount of overcut in various machining conditions. It is clear that overcut varied from 0.0155 to 0.039225 mm. Most of the overcut at different parameter values was around 0.025 mm and below. The minimum overcuts were achieved during machining hole 6 (0.0155 mm) (90 V voltage, 0.4 A current, 5 μs pulse-ON time, 1 μs pulse-OFF time, 20 rpm rotating speed, and without capacitor) and hole 5 (0.015775 mm) (50 V voltage, 0.4 A current, 5 μs pulse-ON time, 9 μs pulse-OFF time, and without spindle rotation and capacitor). The maximum overcut was reached when machining hole 1 (0.039225 mm) (50 V voltage, 0.4 A current, 1 μs pulse-ON time, 9 μs pulse-OFF time, 20 rpm rotating speed, and 0.1 μF capacitor).

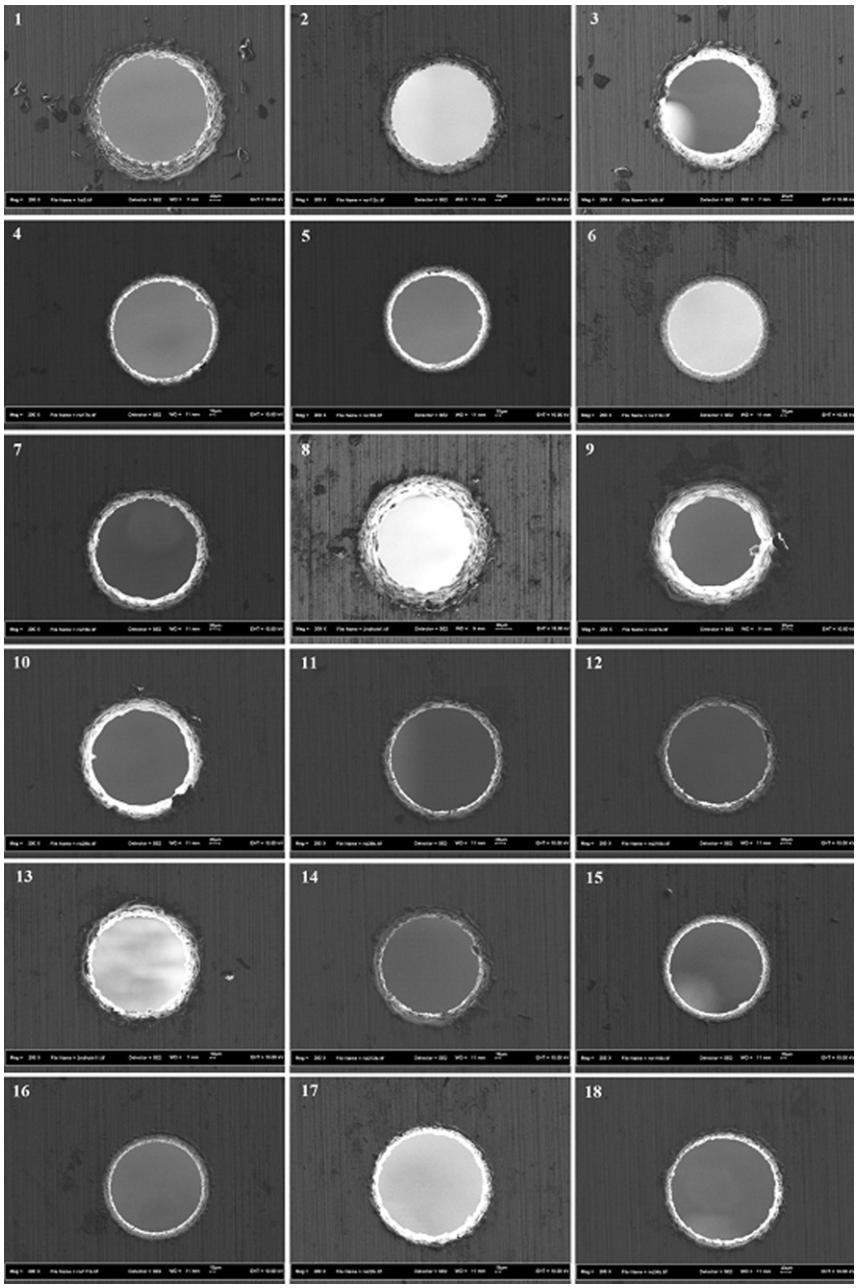

Figure 76 Micro-holes.

In the micro-EDM process, the micro-hole is very small and low amounts of energy for material removal causes to produce small overcut. So the chips cannot be removed easily from the sparking gap (between the microelectrode and workpiece) inside the micro-hole. The remaining chips inside the micro-hole are passed on to the workpiece by the spark electricity force. The remaining chips are re-machined with spark energy into smaller than normal amounts of removed material from the workpiece material, as described in Figure 78. This leads to inefficient EDM. The smaller chips can be removed more easily. Also, the chips collected in the sparking gap create unstable servo operation, which further deteriorates machining efficiency due to the electrode-to-workpiece voltage variation with the free movement of chips. The machine's servo system advances and holds the position or retracts the electrode from the workpiece by comparing the electrode-to-workpiece voltage to a reference voltage. The electrode moves forward and reverses, increasing the chip movement on the surface.[34]

1.10.7.1.2 MRR and EWR

Design-Expert software was used to analyze the experimental outcomes for MRR and EWR. Analysis of variance (ANOVA) was conducted to test the significance of the models, individual

model terms and lack-of-fit. Square root transformation was applied on the MRR response for ANOVA validation, while EWR did not require any transformation.

Tables 13 and 14 demonstrate the ANOVA tables for MRR and EWR. If the 'Prob > F' value is less than 0.05, it is significant.[95] In this research, A, B, C, E, F, AB, and AF were

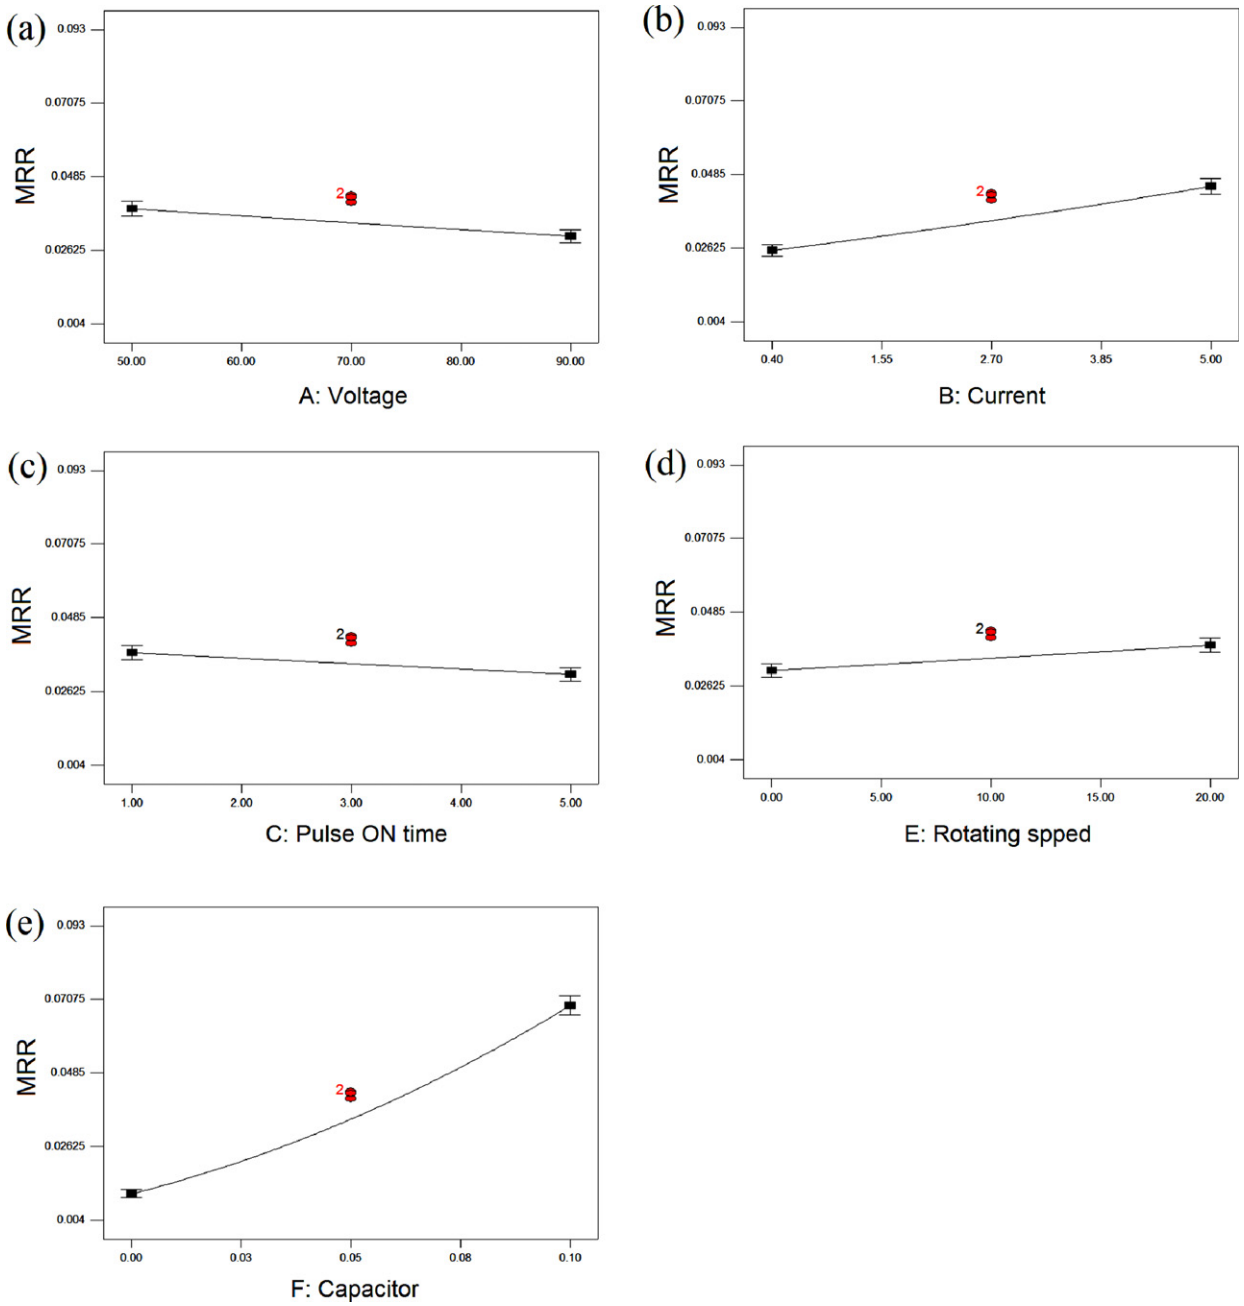

Figure 80 Response graphs for MRR vs. (a) voltage, (b) current, (c) pulse-ON time, (d) rotating speed, and (e) capacitor.

significant model terms for MRR response. Moreover, B and F were the most significant factors. But AB, EF, AF, BE, and CD were possibly significant due to aliase. The ANOVA table results for EWR response depict that B, C, D, AC, AD, and AE were significant. In addition, C was the most significant factor, while AC, DF, AD, CF, AE, and BF were possibly significant.

Insignificant lack-of-fit is desirable for MRR and EWR responses. The outcomes for both MRR and EWR illustrate that an R-Squared value approaching one is desirable. In addition, there were minor differences between Adj. R-Squared and Pred. R-Squared, meaning that the models had acceptable transaction between the input and output parameters. Furthermore, Adeq. Precision greater than four is desirable, as it measures the signal-to-noise ratio.[95]

Residuals must have normal distribution and constant variance. Figure 79 depicts that a normal probability plot of residuals mapped the residuals versus the predicted response for MRR and EWR after the square root transformation was performed only on MRR. Figures 79(a) and 79(c) reveal small departures from the straight line in the normal probability plot of residuals for MRR and EWR, which are common.

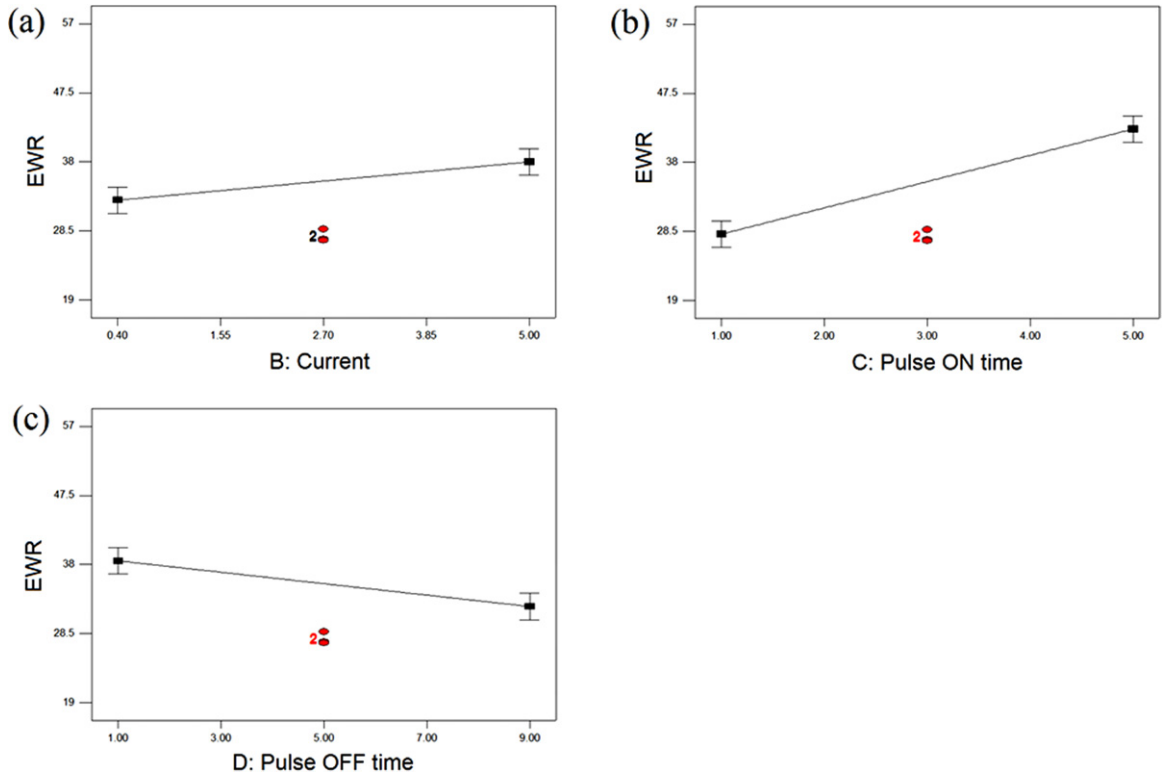

Figure 81 Response graphs for EWR vs. (a) current, (b) pulse-ON time, and (c) pulse-OFF time.

Figures 79(b) and 79(d) depict unusual scatter and patterns. Based on these plots, it can be concluded that the residuals had normal distribution and constant variance after using the square root transformation to analyze and model MRR response.

Figure 80 illustrates the response graph for MRR. According to Figure 80, MRR increased with amplifying current, rotating speed and capacitor, and decreasing voltage and pulse-ON time. The current and capacitor were the most significant factors; however, the effect of the capacitor was greater than the current. The voltage controls the discharge gap between the microelectrode and workpiece, and increasing the voltage increases the discharge gap.[128] Suitable voltage according to current, pulse-ON time, pulse-OFF time, capacitor, and rotating speed results in improved MRR. Figure 80(a) demonstrates that the amount of MRR decreased with voltage greater than 50 V because the discharge gap was larger than the suitable range[95] for low amounts of energy in micro-EDM (current (0.4–5 A), pulse-ON time (1–5 μs), and capacitor (0–0.1 μF) are low). Based on Figure 80(b), MRR increased with current amplification due to the rising amount of heat and energy transmitted to the workpiece for melting and vaporization. Figure 80(c) shows the effect of pulse-ON time on MRR. Sparks occurred during pulse-ON time. Increasing pulse-ON time causes an increase in the amount of energy.[34] During long pulse-ON time, sparks initially take place between the microelectrode and workpiece, after which some of the sparks take place between the microelectrode and chip and some between the microelectrode and workpiece owing to the difficulty in removing chips between the microelectrode and workpiece. The occurring sparks between the microelectrode and chips cause the chip size to decrease. Thus, machining efficiency is reduced.[34] Another reason for the further decrease in machining efficiency is that chips collected inside the micro-hole produced unstable servo operation. As a result, MRR deteriorated with increasing pulse-ON time (Figure 80(c)). Figure 80(d) shows that MRR improved by amplifying the rotating speed, because higher rotating speed helped remove chips from the distance between the workpiece and microelectrode. Figure 80(e) shows that the capacitor was the most significant factor on MRR. MRR increased with increasing capacitor due to the amplified electrical discharge energy transmitted to the workpiece.

Figure 81 illustrates the EWR response graph. Figures 81(a) and 81(b) show that EWR increased with increasing current and pulse-ON time due to the rising amount of heat and energy transmitted to the workpiece for melting and vaporizing that caused microelectrode melting or vaporizing as well.[34] Another reason for the EWR amplification with pulse-ON time is that in micro-EDM, the micro-hole is very small and the low amount of energy for removing material causes overcut, as described in Section 1.10.7.1.1. Hence, the chips cannot be easily removed inside the hole between the microelectrode and workpiece. Some of the sparks took place between these chip and microelectrode that caused to augment wear of the microelectrode.[34] Moreover, the collection of chips inside the micro-hole produces unstable servo operation, which further decreases machining efficiency and increases EWR.[34] During

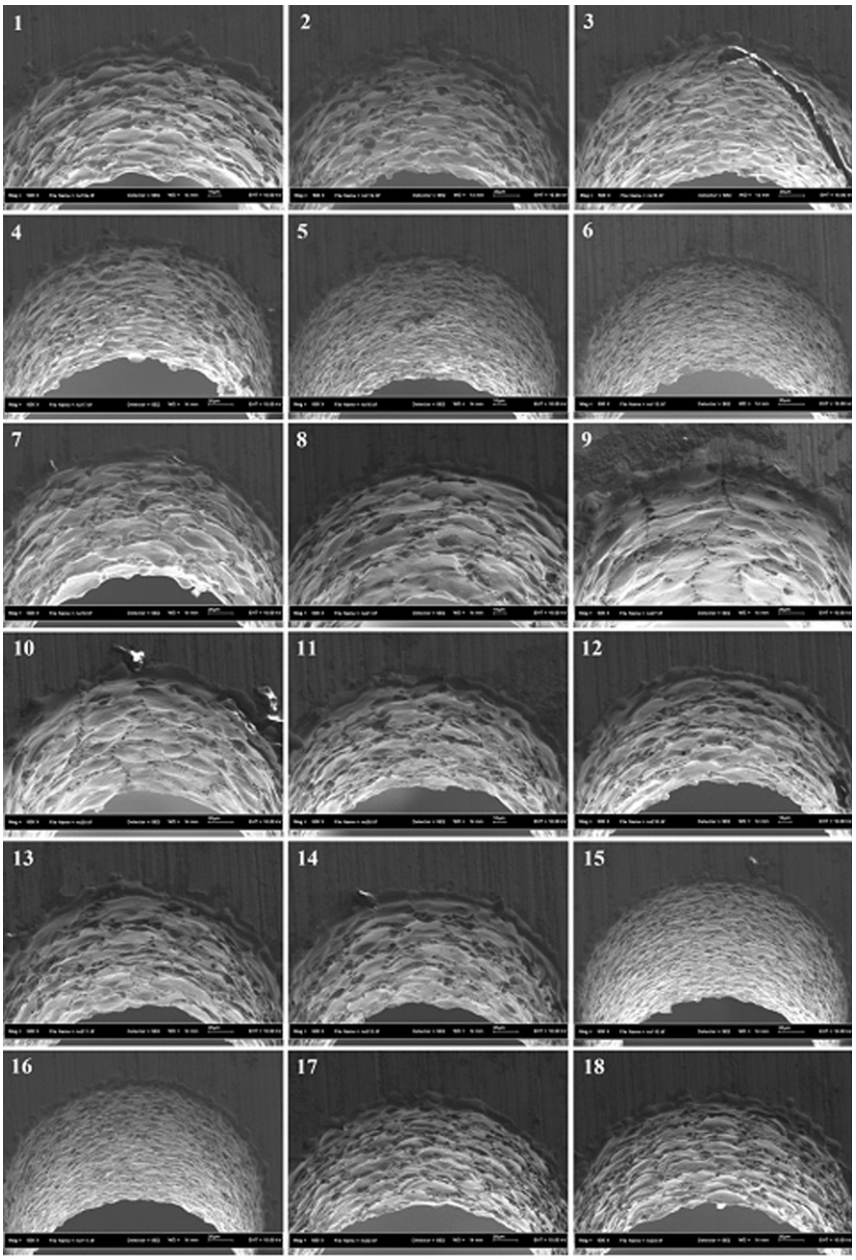

Figure 82 Comparison of surface quality at the rim of the micro-holes at deferent conditions.

pulse-OFF time, sparks did not occur, so melted and vaporized material solidified to the EDM chips, allowing the chips to be removed from the distance between the microelectrode and workpiece. Increasing pulse-OFF time caused more chips to be removed from the distance between the microelectrode and workpiece. This decreased the amount of sparks that occurred between the microelectrode and chips and increased the amount of sparks between the microelectrode and workpiece. Thus, EWR was reduced by increasing pulse-OFF time (Figure 81(c)). Based on Figure 81, the effect of pulse-ON time on EWR seemed more significant than the other parameters.

1.10.7.1.3 Surface roughness

Figure 82 demonstrates FESEM images presenting the surface quality at the rim (wall) of the micro-holes attained in WC–16%Co composite in different EDM conditions. These pictures were taken by rotating the WC–Co plate inside the FESEM. It was found that there are direct relationships between the micro-hole surface finish, burr-like recast layer at the top surface and MRR, based on observations in Figure 82 and Table 12 surface roughness enhanced by decreasing the MRR, but it deteriorated by increasing the MRR. The amount of burr-like recast layer at the top surface decreased when the surface roughness enhanced. It can be concluded that the surface

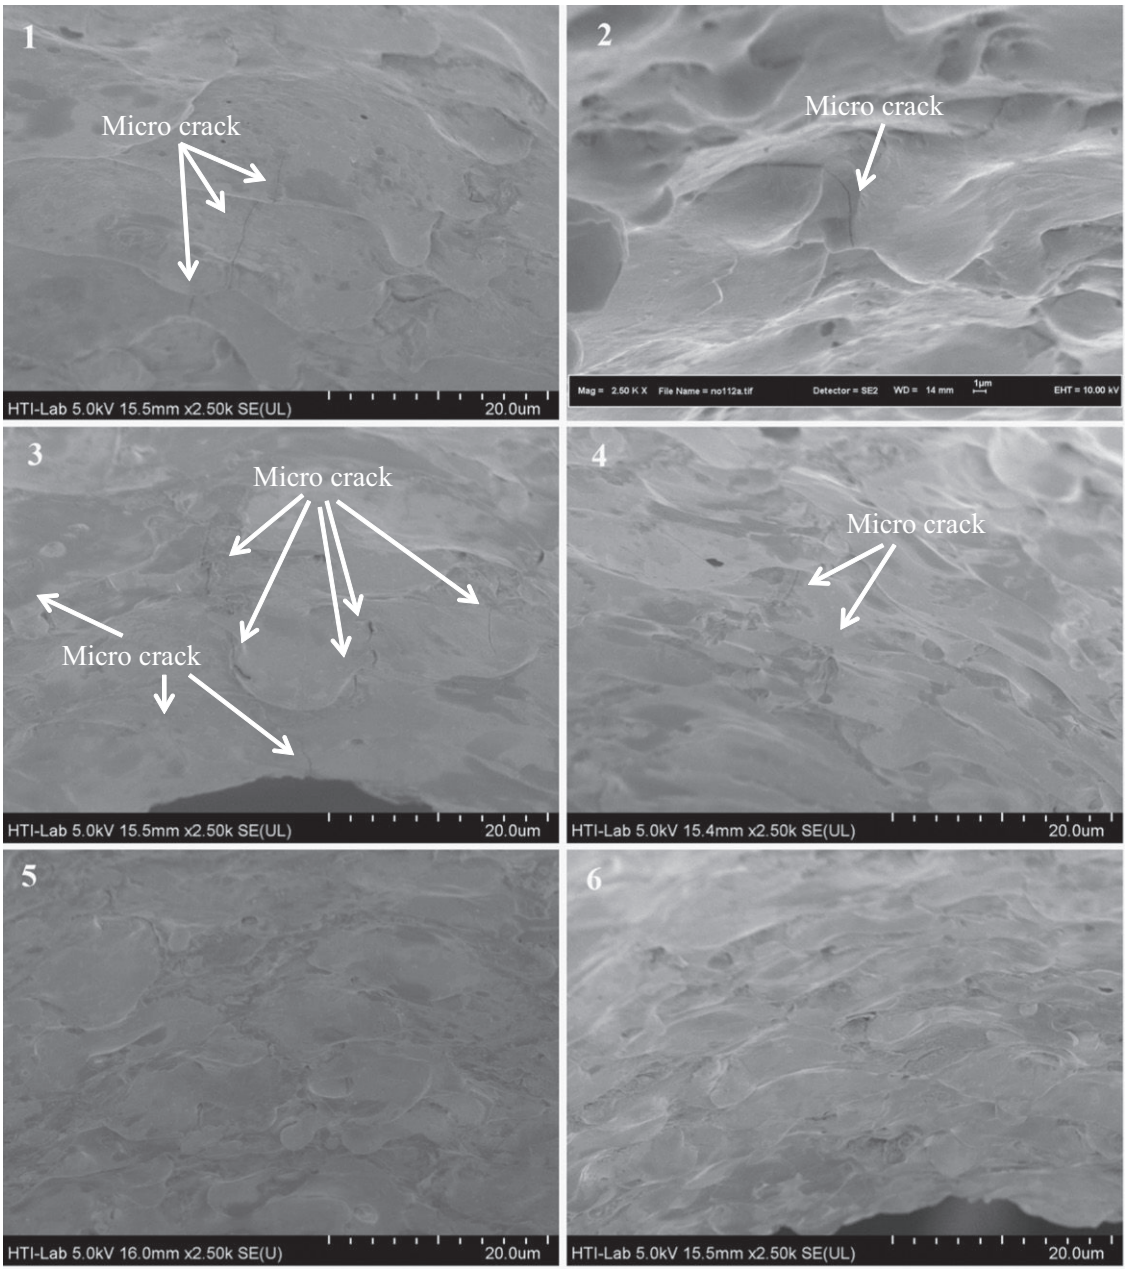

Figure 83 Micro-cracks at various machining conditions (holes 1–18).

roughness improved and the burr-like recast layer at the top surface decreased with decreasing current, rotating speed, and capacitor and increasing voltage and pulse-ON time because of decreasing MRR. Current and capacitor were the most significant factors; however, the effect of the capacitor was more prominent than current.

1.10.7.1.4 Micro-crack

The electrical discharge energy increases with the amplification of voltage, current, pulse-ON time, and capacitor, while pulse-OFF time and rotating speed have no effect on the electrical discharge energy according to the formula for calculating electrical energy ($E=VI_{\mathrm{p}}t_{\mathrm{on}}$[34] and $E=(1/2)CV^2$ [45,59]). Moreover, the voltage controls the discharge gap between electrode and workpiece. Increasing the voltage will increase the discharge gap.[95] Suitable voltage according to current, pulse-ON time, pulse-OFF time, rotating speed, and capacitor results in better MRR and helps the thermal energy reach the workpiece. When current and pulse-ON time are high, MRR increase with amplifying voltage up to a desired value due to the increased discharge gap and because the chips and debris can easily be removed from this area. Subsequently, the amount of MRR decreases with voltage above the desired value because the discharge gap is larger than the suitable range and less energy reaches the workpiece.[95]

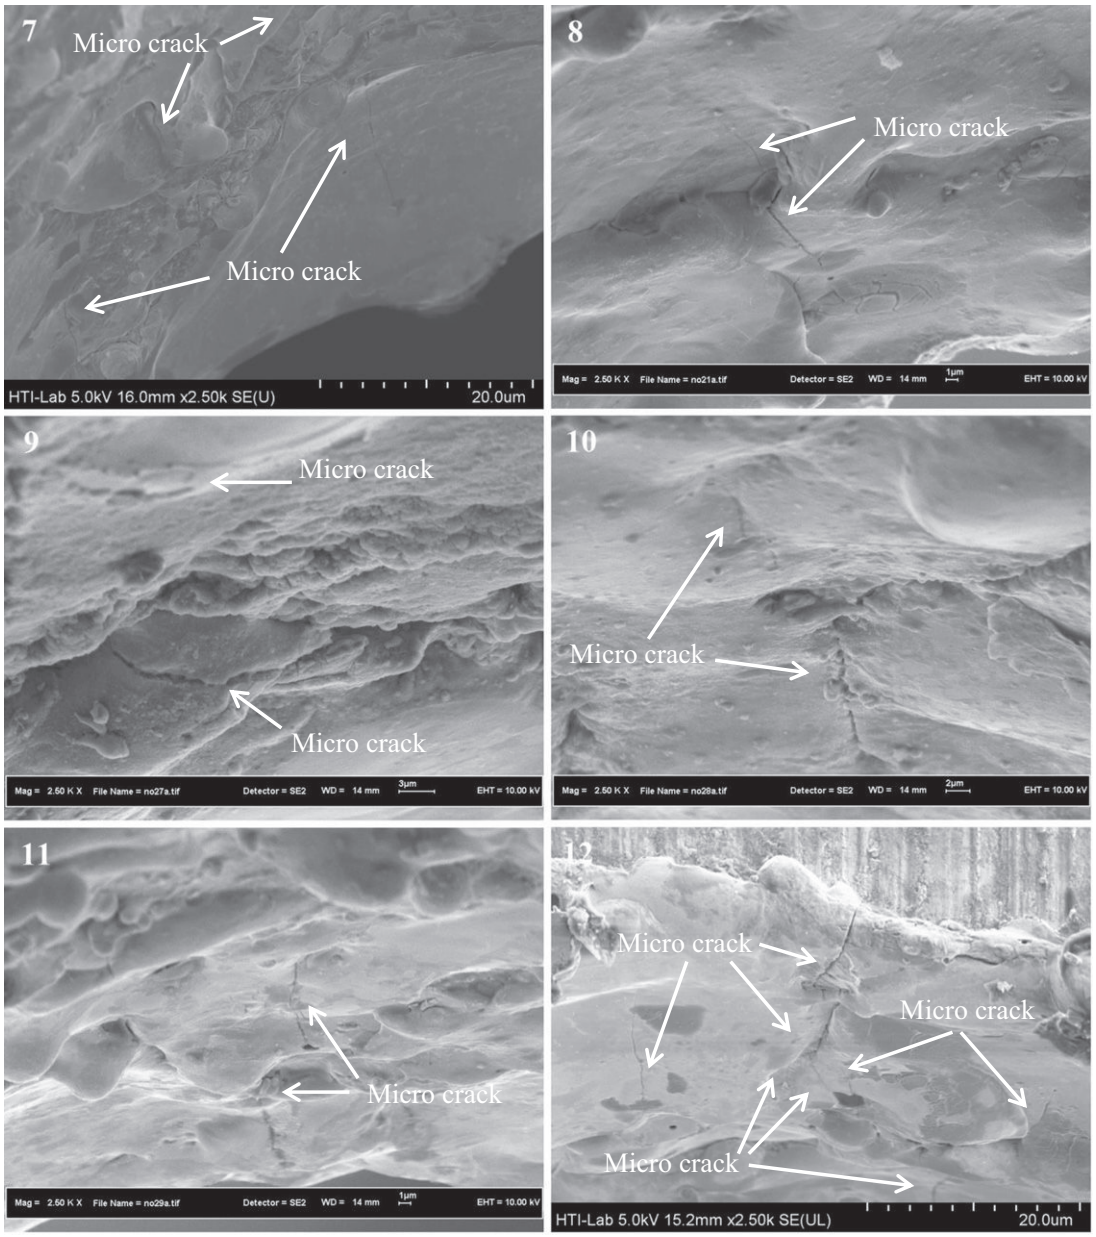

Figure 83 (Continued)

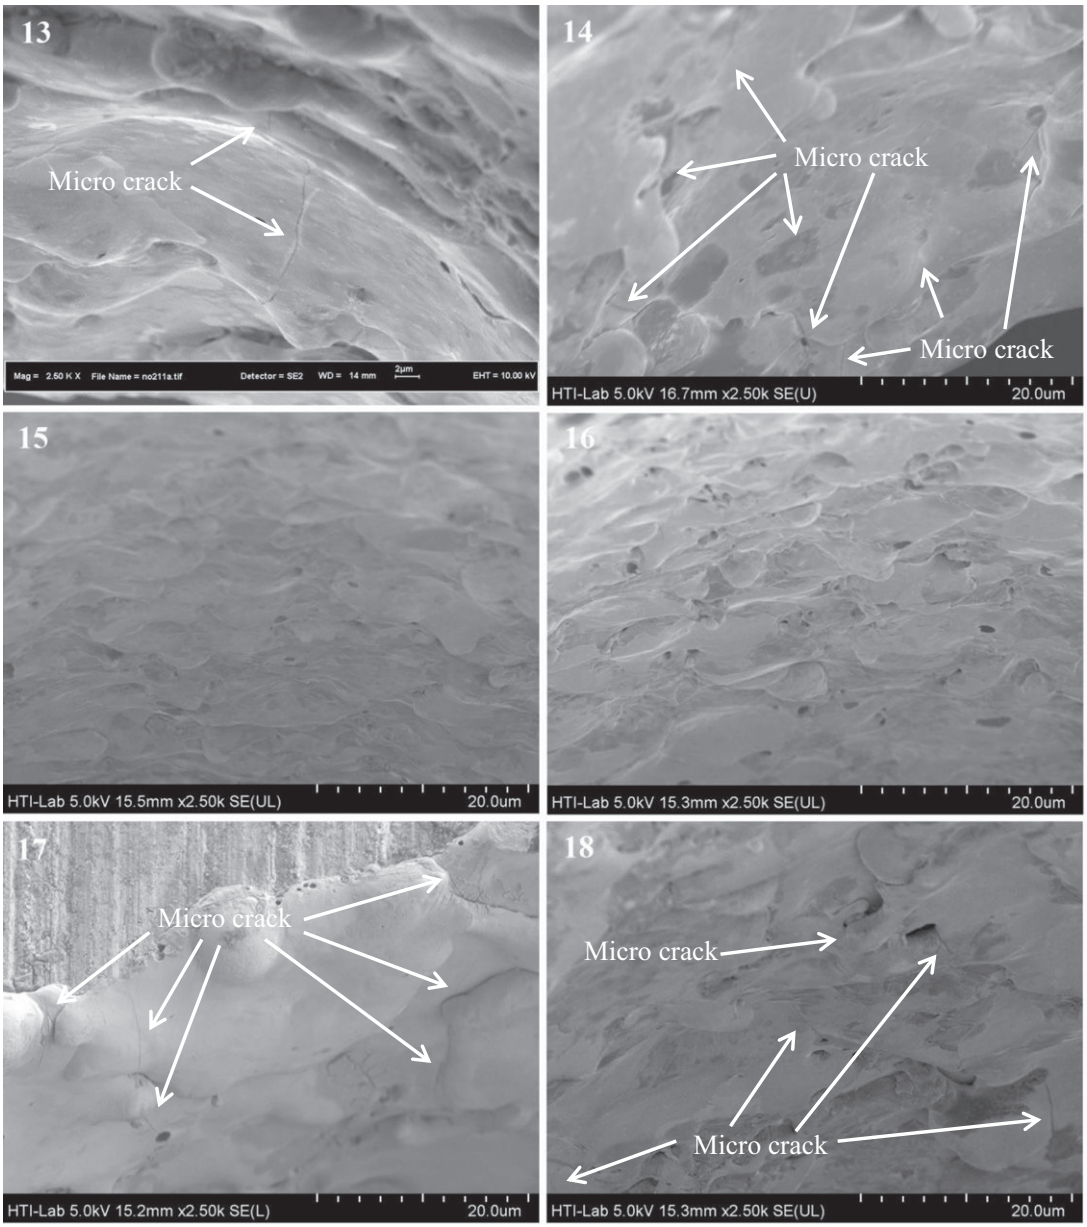
FESES served for taking pictures with 2500 magnification. Figure 83 shows that the amounts of micro-cracks were on the surface in different machining conditions for holes 1–16. Figure 83 demonstrates that pulse-OFF time and rotating speed had no effect on the amount of micro-cracks, because they had no effect on electrical discharge energy. It is clear that the amounts of micro-cracks on holes 5, 6, 15, and 16 were less than on other holes. Larger pictures of these holes (at the end of Figure 83) show the distribution of micro-cracks. Comparing low pulse-ON time (holes 15 and 16) with high pulse-ON time (5 and 6) indicates that pulse-ON time had less effect on changing the amount of micro-cracks because the deference between low and high pulse-ON time (1 and 5 μs) is short. Analyzing low voltage (holes 1 and 3) and high voltage (holes 2 and 4) depicts that voltage was one of the most significant factors on the amount of micro-cracks. Investigating low current (holes 15 and 16) and high current (holes 3 and 4) demonstrates that current was another significant factor affecting the amount of micro-cracks. Studying low capacitor (holes 15 and 16) and high capacitor (holes 1 and 2) represents that the capacitor was another factor determining the amount of micro-cracks. Evidently, the highest amount of micro-cracks appeared in hole 7 (low voltage, low current, high current, high pulse-ON time, and high capacitor), hole 12 (low voltage, low current, high pulse-ON time, and high capacitor), and hole 14 (low voltage, high current, low pulse-ON time, and high capacitor). The least micro-cracks appeared on hole 15 at 90 V voltage, 0.4 A current, 1 μs pulse-ON time,



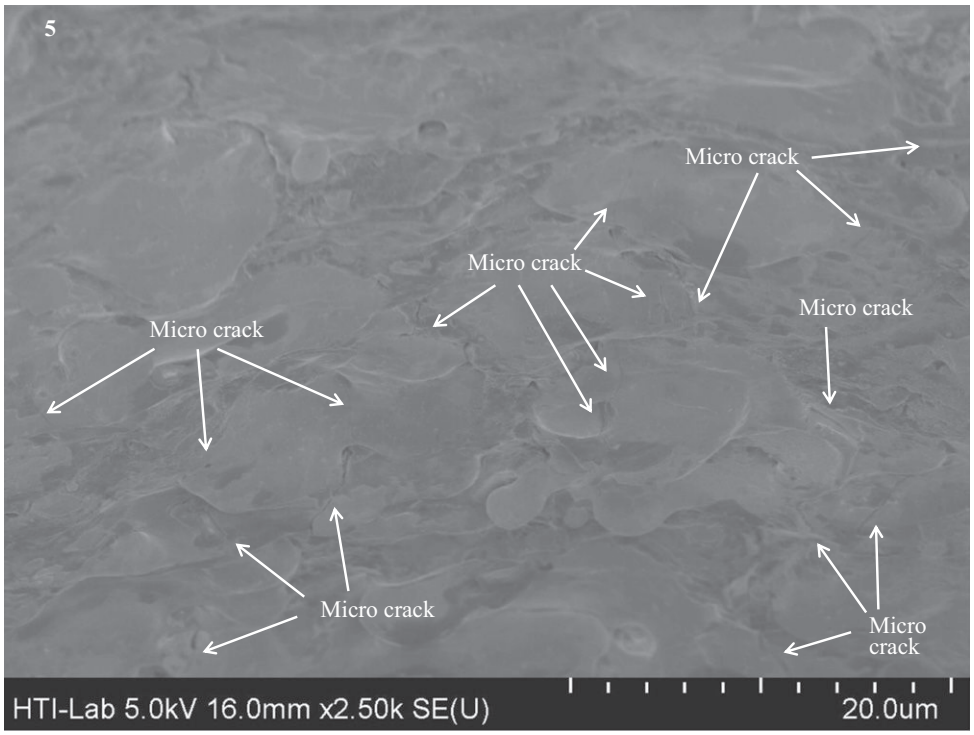


Figure 83 (Continued)

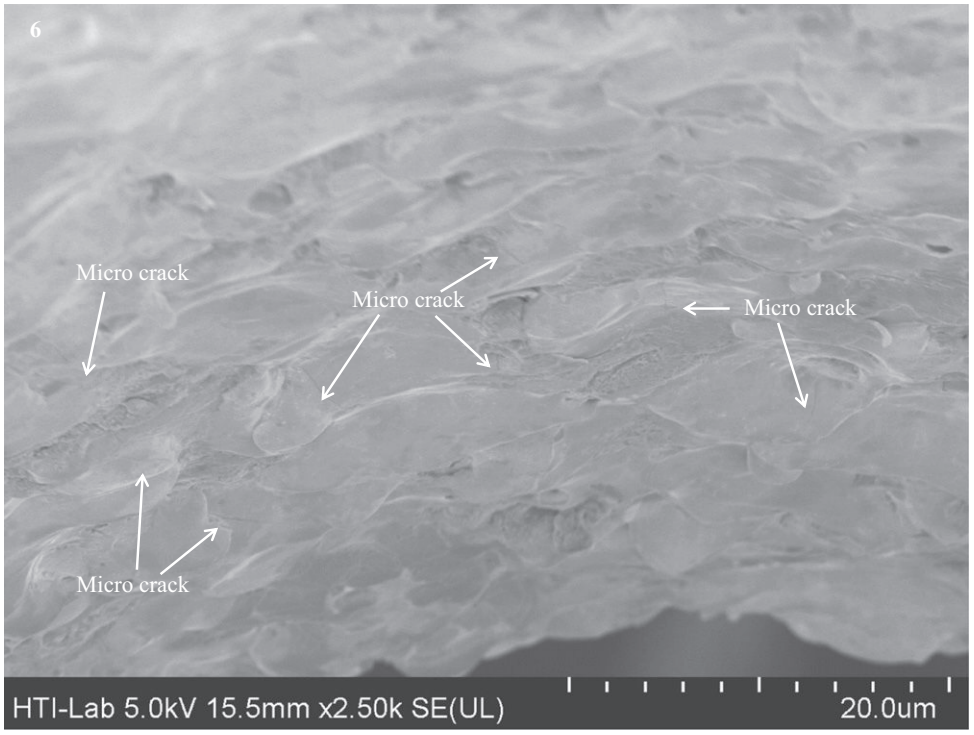

9 μs pulse-OFF time, 20 rpm rotating speed, and 0 μF capacitor. It is clearly observed that more micro-cracks formed when the current, pulse-ON time, and capacitor were at high levels, due to high electrical discharge energy and low thermal conductivity and brittleness of the cemented tungsten carbide. Besides, the amount of micro-cracks decreased when current, pulse-ON time, and capacitor were adjusted to low levels. As described before, the MRR diminished by increasing the voltage because the voltage increases to the more suitable current range of 0.4–5 A, pulse-ON time range of 1–5 μs, pulse-OFF time range of 1–9 μs, rotating speed range of 0–20 rpm and capacitor range of 0–0.1 μF.[95] This caused the workpiece to receive less energy at the high level voltage. It can be concluded that voltage, current, pulse-ON time, and capacitor were the most significant factors contributing to the amount of micro-cracks. The effects of voltage, current, and capacitor were greater than pulse-ON time according to these machining parameter levels.

1.10.7.1.5 Material migration

EDX spectrum analysis was performed to analyze the elemental composition of the raw material and recast layer at the wall of the holes. Figure 84 shows the EDX spectrum analysis of the raw material surface and recast layer at the wall of hole 11 as an example. Moreover, Figure 85 demonstrates the elemental composition and percentage of each element for the material and the entire hole's wall. As seen in Figure 85, W, Co, C, and O elements were present in the workpiece's raw

material, while W, Co, C, O, and Al W elements were present in the recast layer at the wall of the micro-holes. Al was added to the recast layer at the wall of the micro-holes, because aluminum powder was used in the dielectric and aluminum migrated to the machined surface and recast layer. The amount of C and O in the recast layer increased when oil-based dielectric was used. On the other hand, the amount of W and Co decreased due to increasing C and O. Moreover, the percentage of W decreased sharply. The lowest percentage of W, approximately the lowest percentage of Co and the highest percentage of C appeared in the recast layer at the wall of hole 9. As a result, it is suggested to use powder with greater elemental composition similarity to the workpiece in the dielectric.

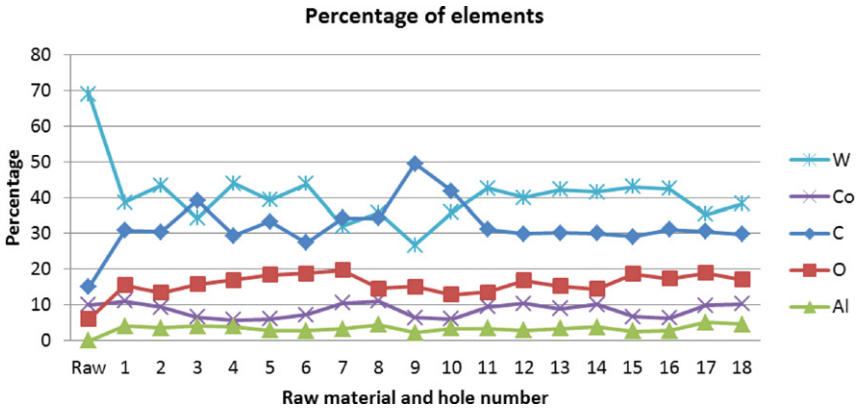

Figure 85 Percentage of elements.

1.10.8 Conclusions

This work describes EDM and micro-EDM comprehensively and compares the types of pulse generators, electrodes and methods for calculating MRR, EWR, overcut, and surface roughness for these methods. Various fabrication and measurement processes of microelectrode are explained as well. Moreover, this research work was carried out to characterize the effects of micro-EDM drilling of WC–16%Co with a CuW microelectrode by using EDM machine. The results show that:

- Various machining conditions produced different amounts of overcut.
- ANOVA analysis illustrated that MRR increased with amplifying current, rotating speed and capacitor, and decreasing voltage and pulse-ON time. The current and capacitor were the most significant factors, but the effect of the capacitor was greater than current. It can be concluded that the capacitor had the greatest impact on improving MRR. Moreover, EWR increased by increasing current and pulse-ON time and decreasing pulse-OFF time. The effect of pulse-ON time on EWR was more prominent than other parameters.
- It was found there were direct relationships between the surface finish of micro-holes, burr-like recast layer at the top surfaces and MRR. It can be concluded that surface roughness enhanced and the amount of burr-like recast layer at the top surfaces decreased with decreasing current, rotating speed and capacitor, and increasing voltage and pulse-ON time. The current and capacitor were the most significant factors; however, the effect of the capacitor was greater than current.
- Pulse-OFF time and rotating speed had no effect on the amount of micro-cracks due to the insignificant effect on electrical discharge energy. On the other hand, the electrical discharge energy depends on the voltage, current, pulse-ON time, and capacitor. It can be concluded that amount of the micro-cracks decrease with increasing voltage and decreasing current, pulse-ON time and capacitor. The voltage, current, pulse-ON time, and capacitor were significant factors contributing to the amount of micro-cracks. However, the effects of voltage, current, and capacitor were stronger than pulse-ON time.
- Al was added to the recast layer at the wall of the micro-holes, and because aluminum powder was used in the dielectric, aluminum migrated to the machined surface and recast layer. The amount of C and O in the recast layer increased because oil-based dielectric was used. As a result, it is suggested to use powder that is more similar in terms of elemental composition to the workpiece in dielectric. Finally, various machining conditions produced different amounts of overcut.
- In conclusion, EDM can be used confidently for producing micro-holes.

1.11.1 Introduction

Micromachining is an advanced technology that enables micro components with dimensions in the range of 1–500 μm to be fabricated using micro fabrication techniques. Micromachined components are important for the advancement of micro/nano electromechanical systems (MEMS/NEMS), microelectronics such as semiconductor devices and integrated circuit technology and nanotechnology.[1–3] Different manufacturing processes such as Lithographie Galvanoformung Abformung (LIGA), micromachining of silicon and similar semiconducting materials, and tool based micromachining are the applications of micromachining that are used to fabricate small precision components and micro structured parts.[4]

In modern manufacturing industries, the product miniaturization becomes significantly important due to demanding market trend for a more compact device with ever increasing features. The field of application of conventional mechanical machining processes has been extended to micromachining after a significant technological effort worldwide. These processes have been enhanced for small series and single piece production due to their flexibility and effectiveness concerning the producible geometries, material spectrum, removal rates, and achievable surface topographies.[4,5] However, scaling down of parameters or process modeling from macroscale to micromachining cannot be simply applied due to size effect, workpiece material inhomogeneity, minimum chip thickness, cutting forces, brittle and ductile mode machining, surface quality, and lack of suitable microcutting tools.[5]

The size effect in traditional machining occurs due to the relative dimensions of uncut chip thickness and tool edge radius. An undesirable ploughing of workpiece material rather than chip shearing happens when these dimensions are approximately the same. Microstructure of workpiece material can also have major influence on the cutting mechanism. The workpiece materials behave homogeneously and isotropically

in macromachining but then act differently in micromachining. In homogeneity, microstructural defects, grain size, grain boundaries, inclusions, local hardness, and elastic recovery all contribute to the complexity of micro/nano machining. Micromachining processes are influenced by the ratio of the depth of cut to the cutting edge radius which determines how chip is formed, and quality of the machined surface. Although low cutting forces in some micromachining processes, such as diamond turning, can reduce tool deflection and tool wear, delay tool failure, and narrow the workpiece tolerance limits[5]; such relative low cutting forces, however, can be detrimental in other processes such as microdrilling and micromilling when the resulting high stresses can lead to catastrophic breakage of fragile microcutting tools.

Size effect must also be considered for nontraditional micromachining processes. Tiny electrodes for electrical discharge micromachining may not last due to repeating high energy sparks, or may be deflected due to flow of dielectric fluid. Similarly, when the size of an electrode for electrochemical micromachining (ECM) is comparable with the workpiece grain size, then the resulting material removal rate (MRR) would be different from grain to grain and contributes to poor surface quality. This chapter provides background information for readers to (1) understand the fundamentals of traditional and nontraditional micromachining and (2) present key challenges and advantages for each technique.

1.11.2 Tool Based Micromachining

Micromachining with mechanical cutting tool also known as tool based micromachining is capable of producing high profile accuracy, surface finish quality, and acceptable subsurface integrity at a reasonable cost. It is the primary choices amongst various manufacturing processes in fabricating micro components.[6,7] However, unreliable tool life and early tool failure are the most common problems when employing micro tools for micromachining applications. Many contributions have been made toward the development and investigation of microtools.[8] Examples of the tool based micromachining are discussed in the following subsections.

1.11.2.1 Micromilling

Micromilling is a type of micromachining with mechanical cutting tool that is capable of fabricating microfeatures (Figure 1) with high-accuracy and high-surface quality at a reasonable cost. It is known as a microcutting method which removes workpiece material by mechanical forces via chip shearing or brittle breakage. Most of the workpiece materials, either metals or plastics, can be machined by micromilling with the exception of very hard and brittle materials.[6,9] Although micromilling technique can be similar to conventional macromilling technique including the kinematics process,[10–12] the cutting and surface generation mechanisms involved in the process do change when it comes to micromilling operation. It is due to the different cutting mechanics brought by the scaling relationship between the tool geometry, workpiece microstructure, and cutting geometry.[12] The ratio of feed per tooth to tool edge radius for micromilling is much

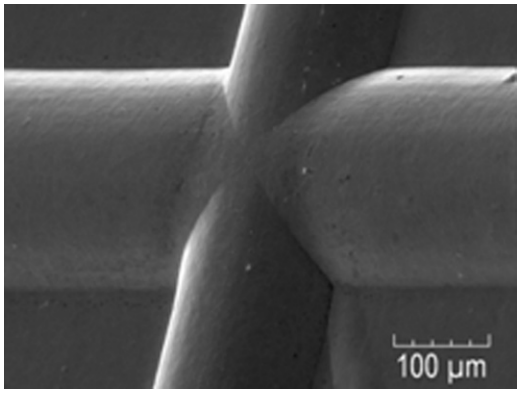

Figure 1 SEM image of milled and polished microchannels on 316L stainless steel.

larger compared to the conventional macromilling in order to maintain productivity. The stresses on a tiny microtool are substantially higher compared to those on a macrotool, and they can effectively shorten the tool life of fragile microtools.[10,11] This technique is related with sudden tool failure because of its highly unpredictable cutting action, and the wear in the tool is not obvious.[13–17] In micromilling, the chip formation depends on the minimum chip thickness and chip does not constantly form whenever the tool and work material is engaged.[13–16,18] The size effect and ploughing forces are vital for surface integrity and force generation in micromilling when chip load is small compared to the cutting edge radius.[16,18,19] Two of the main issues of micromilled structure are discussed in the following subsections.

1.11.2.1.1 Surface roughness

Surface roughness R_a is commonly used to indicate the level of surface roughness. In order to get good surface finish and high accuracy in micromilling operation, it is essential to cut at a low-chip load. This feed per tooth and the cutting depth should be maintained less than 1 μm, if machining tolerance is desired to be less than 1 μm. An important ploughing phenomenon will emerge when the ratio of chip load and tool edge radius is less than a critical value.[17,19–21] Chip load is the most influential factor that affects surface roughness since surface roughness deteriorates with the increase of chip load.[22] However, due to dynamic behavior (low vibration), surface roughness decreases when high feed and depth of cut are used.[23] A micromilled surface roughness reduces with chip load until embedded built-up-edges (BUEs) become significant.[24]

1.11.2.1.2 Vibration

Vibration is frequently caused by the dynamic forces in machines due to lack of a rigid setup, or rotation of imbalanced, misaligned, or worn machine components. A repeating force is capable in producing small resonance which is initiated by the motion of the machine components. This mild repetition is the beginning of the vibration that can lead to brisk and severe damage. Vibration can affect the stability of the machining operation, reduce the dimensional accuracy, deteriorate the surface roughness, and also limit the productivity of machining operation. In order to limit the cutting stability, tool breakage, and machine tool damage, forced and

self-excited vibrations can be used.[25–27] Vibration adversely affects the surface roughness of the machined components and the tool life of micromilling. A higher feed rate enables vibration which eventually has resulted in poor surface quality.[28] Contradictory results are reported when a vibration is rapidly increased when chip loads increases from 0.2 to 0.4 μm per tooth, but vibration decrease rapidly when chip load increases from 1.2 to 1.6 μm per tooth.[23] The difference trends, perhaps, are due to the different natural frequency of each machining system and rigidity of specific set up.[20,25]

1.11.2.2 Microdrilling

Microdrilling has the potential to achieve superior roundness, smoother surfaces, and better lead times. Although similar to macroscale drilling, microdrilling poses a greater challenge than macrodrilling in many aspects:

- A slight lateral skidding motion during initial penetration into the workpiece can bend and fracture a long microdrill.
- Heat dissipation and chip removal from deep microholes is a major issue.
- The process parameters for microdrilling cannot be extrapolated from macrodrilling data.
- Both drill edge sharpness and crystalline orientation of workpiece grains affect microdrill performance.

Microdrill failure is caused by gradual wear of cutting edge or too high-cutting temperature. However, majority of the failure is due to excessive cutting force at the tip of the tool causing it to fail suddenly by brittle fracture.[29] Drill life can be randomly distributed from 1–100 holes depending on different approaches.[30] Monitoring of drilling force and torque is a challenge due to their small magnitudes; perhaps this is the reason why a correlation between drill wear and drilling force is yet to be established. Drill wandering is minimized by predrilling to form a pilot hole,[31] or by changing drilling parameters depending on drilling thrust force and torque.[32] Wandering of a microdrill could be improved by lowering the ratio of drilling speed and feed rate at the beginning. This ratio then can be increased after the tool penetrates below the surface; however, both thrust force and torque increase with drilling depth for continuous drilling due to accumulation of chips in a hole. Peck-drilling helps clearing chips from the bottom of a deep hole, but this practice increases cycle time and slows down the production rate.

Some investigators study microdrilling at low rotational speeds in the range 45–6000 rpm, but most researchers utilize rigid machines with high rotational speeds in the range 50 000–150 000 rpm to achieve a reasonable surface cutting speeds on a microdrill. Process parameters and tool geometries are examined from both analytical and experimental approaches to study microdrilling and its size effect. Chip load should be small enough for low thrust force and torque, but is high enough compared to the drill edge sharpness so that ploughing and work hardening below the workpiece surface can be minimized.[32] A high-drilling speed increases the tool chip temperature, softens the material, and decreases thrust force. However, a very high-drilling speed facilitates BUE formation contrary to macrodrilling practice. Using oil mist for minimum quantity lubrication (MQL) provides the best approach

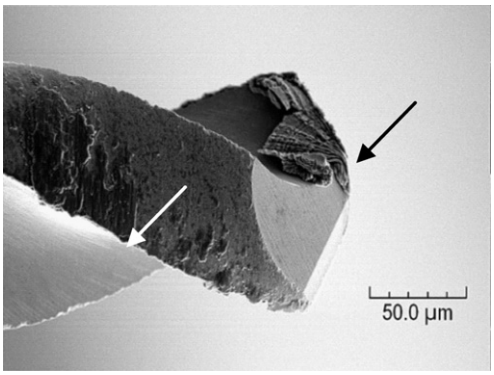

Figure 2 Titanium built-up edges (at arrows) on a microdrill. Speed 14 m min^{-1}, 0.05 μm chipload.

since it reduces drilling force, torque, and cutting temperature. The drilling temperature is lowest when MQL is applied internally through a drill in macrodrilling. When applying MQL externally in microdriling, the temperature is highest for uncoated drill and is lower but about the same for microdrills with different coatings.

Kudla[33] compared different microdrill geometries (twist drill, spade drill, and D-shape drill) to study the behavior of microdrills in bending, compression and torsion under static and dynamic conditions. Buckling of a drill is possible since a microdrill is long and slender. In the beginning when a drill engages to a workpiece surface, it is supported in a shallow spot and its condition is like that of a pin-ended strut. After drilling deeper into a hole, the boundary condition for buckling changes from pin-end to built-in end condition. Buckling load of 6.2–33.7 N is expected for a 0.5 mm twist drill based on Euler formula for column buckling. A high speed steel (HSS) drill deforms more than a carbide drill before fracture. An Ø200 μm HSS drill can be twisted 90° before failure but a carbide drill fails about 28° in a torsion test. Twist drill outperforms the spade drill and D-shape drills since the former would take a higher torque and greater angle of twist to fail. The author also measured both torque and thrust force when drilling various ferrous alloys to confirm the failure mechanisms of microdrills.

Built-up-edges are the main concern in microdrilling (Figure 2). These BUEs worsen hole quality while shortening drill life since a lubricant cannot penetrate to the drill/chip interface in high-aspect-ratio drilling of microsize holes. The problem can be solved with progressive peck drilling in MQL.[34] Thin TiAlN coated microdrills can minimize BUEs, reduce drill wandering 115%, and decrease diametric variation from 0.11% per mm for uncoated drills to 0.003% per mm for coated drills.

1.11.2.3 MQL

MQL is gaining acceptance in metal processing industries because of overall cost saving while enhancing part quality. Conflicting information in published literature on how MQL effect machining probably due to different setting of MQL parameters in each study. The objective of this chapter is to present required conditions of MQL setup for effective machining in high-speed machining.

Marksberry and Jawahir[35] turned high strength low alloy steel (equivalent to SAE 070Y) at 3.2 mm depth, 4 m s^{-1} speed, and 0.3 mm per rev feed in MQL using straight oil, water soluble, semi synthetic, and synthetic fluids. Minimum tool wear was obtained when machining at the highest volumetric flow rate of 160 mL h^{-1}. They found that the synthetic fluid improved tool life by 402% while the straight oil improved 102% over dry machining. When applying vegetable oil mist particles of 3.7 μm to mill Ti 6Al 4 V at 0.67 m s^{-1}, Sun *et al.*[36] reported that MQL improved tool life 800% over dry milling, while flood coolant improved 50% over dry milling. The total cutting force magnitude reduced from 417 N in dry milling to 344 N for milling with flood coolant, and then further reduced to 115 N when machining with MQL. Cutting tools under MQL conditions resulted in the least flank wear when the coolant rate was as low as 6 mL h^{-1}. However, it was postulated that the oil droplets could not reach and wet the cutting edge of a tool moving at a speed within 1.6–2.1 m s^{-1} (96–126 m min^{-1}).[37] In another study, Park *et al.*[38] proposed an imaging technique to reconstruct microdroplet profiles. The authors measured the accumulative mass of Coolube 2210 oil at different distances from a nozzle at nozzle air pressure of 14–55 kPa (2–8 psi). Although very fine droplets were formed at higher air pressure, the accumulative mass was 50% less at 300 mm away from the nozzle. The study stated that the average airborne microdroplet diameter of 10 μm and recommended a working distance less than 50 mm.

The application of MQL is particularly beneficial at high cutting speeds or high rotational speed in micromilling.[39,40] Tool flank wear was reduced ~50% when MQL was used. Poor wetting of emulsion coolant on a cutting tool was due to the slower coolant flowing speed (6.4 m s^{-1}) as compared to the higher cutting speed of the tool (15 m s^{-1}). The much higher speed of air after leaving a nozzle (120 m s^{-1}) allowed MQL microdroplets to reach and efficiently lubricate the cutting tool. However, Rahman *et al.*[41] concluded that MQL was effective at cutting speed lower than 75 m min^{-1}, but it provided no significant effect at cutting speeds above 125 m min^{-1}.

Tool failure mechanisms were studied by Liao *et al.*[42] when they milled NAK80 hardened steel at 150–250 m min^{-1}. Water-soluble flood coolant at 1200 L h^{-1} was applied while MQL was set at 10 mL h^{-1} and 450 kPa air pressure. The study concluded that flood cooling caused thermal crack on tools, while MQL reduced the tool temperature when cutting at 250 m min^{-1}. The surface finish, a 50% improvement compared to that after flood cooling, was due to delay chip welding on cutting tool when wetting with MQL.

Characterization of microdroplet flow in air was presented by Diakodimitris *et al.*[43] The study combined particle image velocimetry (PIV), particle dynamics analysis (PDA), and computational fluid dynamics (CFD) to analyze MQL microdroplets in an air jet. An asymmetric profile of velocity field was found: air flowed at higher speed above the nozzle axis, and the difference of 60 m s^{-1} was observed. The maximum speed location was 4 mm above the nozzle axis and 40 mm away from the nozzle when the air mass flowrate was set to 6.2×10^{-4} kg s^{-1}. When considering different combinations of air mass flow rates (5–6.2×10^{-4} kg s^{-1}) and oil mass flow rates (1.66–2.92×10^{-4} kg s^{-1}), the maximum velocity of microdroplets along the nozzle axis was measured about ~27 m s^{-1} (1620 m min^{-1}) at a distance 40 mm away from the nozzle. In another finite element analysis of air flow near a cutting tool in orthogonal machining, Kamata *et al.*[44] simulated high speed machining in the range 2–5 m s^{-1} (120–300 m min^{-1}) and concluded that high air speed at 300 m s^{-1} can provide an effective mist supply of 15% at 1 mm away from the cutting edge. Although cutting speed reduced the effective mist supply ~2%, this reduction was made up with increasing mist supply due to a low pressure zone at the flank face. This low pressure zone was formed by the suction of boundary layer around a moving workpiece in addition to the dropping of air pressure when flowing into a narrow channel between the flank face and workpiece surface.

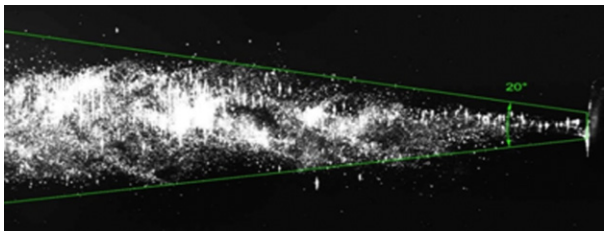

Figure 3 Micromist flow in front of a nozzle by particle image velocimetry. Coolube 2210, 483 kPa (70 psi) input air pressure, nozzle speed 154 m s^{-1}, 8 strokes min^{-1}.

Literature review indicates that when the supply of MQL is inadequate, the lubrication and cooling effect diminishes and degrades machinability. Li *et al.*[45] concluded that the droplet size and its velocity must be in the optimal range so it can acquire an adequate momentum to reach and wet the surface of moving tool and workpiece. Air speed in front of a nozzle can be as high as 10 000 m min^{-1}. A high nozzle speed produces small droplets in front of the coaxial nozzle as shown in Figure 3. The droplets then coalesce to form larger droplets 3–11 μm depending on the exiting air speed. The system can produce nozzle air speed more than 10 000 m min^{-1} for effective high speed machining. The distance between tool and workpiece should be less than 50 mm and the tool size should be less than 17 mm. Multiple nozzles should be used for a larger cutting tool.

1.11.2.4 Ductile Regime Machining

The concept of ductile-regime machining has been investigated since 1960s for amorphous brittle materials such as glasses. Silicon, germanium, and glasses have become strategic materials that are widely used to fabricate intricate components in microelectronics, optical, defense industries, and recently as micro optical-electrical-mechanical systems. Silicon and other brittle materials are known for their low machinability unless they are machined in the ductile-regime conditions. When utilized at the optimal machining conditions, only minimum effort is required for the subsequent etching, grinding, or polishing to remove the damaged subsurface. The mechanism of ductile-regime machining has been studied by many researchers. Using fracture mechanics approach, it can be shown that there is a threshold below which ductile regime prevailed.

A shallow depth of cut, therefore, would energetically promote plastic flow rather than brittle fracture in the substrate and the chips. Table 1 enlisted properties of some brittle materials and their experimental critical depths of cut.

$$d_c = \frac{\text{plastic flow energy}}{\text{fracture energy}} = A\left(\frac{E}{H}\right)\left(\frac{K_c}{H}\right)^2 \quad [1]$$

where,

d_c: critical depth of cut (m, in)
A: constant
E: Young modulus (Pa, psi)
K_C: surface fracture toughness (Pa $m^{0.5}$, psi $in^{0.5}$)
H: surface microhardness (Pa, psi)

The constant A in eqn [1] varies in the range 0.1–0.6 due to measuring uncertainty of surface toughness K_c, elastic modulus E, and microhardness H in a testing environment. These properties depend on crystalline orientation of the materials, surface conditions, and tool geometry.

The critical resolved shear stress, on a crystalline plane due to the cutting action, is directly proportional to the Schmid factor cos ϕ cos λ, where ϕ and λ are the orientations of the slip plane and slip direction. An ideal ductile mode machining would happen when the cutting shear stress is parallel to both the slip plane and the slip direction, otherwise a pseudo ductile mode with micro cleavages occurs. True ductile-regime machining happens only along certain crystalline orientation, but brittle machining occurs at other crystalline orientation. This explains why micromachining a crystalline specimen at the same speed, depth of cut, and coolant produces ductile machined surfaces in one direction (Figure 4) but brittle machined surfaces on others.

Cutting fluid changes the surface properties of materials (Kc, E, and H) and affects conditions for ductile regime micromachining. When micromachining the (100) germanium using a single crystalline diamond (SCD) tool, the critical depth of cut changes from 0.13 μm with distilled water as cutting fluid to 0.29 μm in dry machining.

Tool geometry also affects the results. Ploughing and fracture of material occurs when depth of cut is less than approximately half of the tool cutting edge radius. Tool with negative top rake angle is usually utilized since a negative rake causes compressive zone in the workpiece ahead and below the tool and suppresses microcrack formation.

Table 1 Selected properties of some brittle materials

Materials	*Young modulus (GPa)*	*Fracture toughness (MPa $m^{0.5}$)*	*Knoop hardness (GPa)*	*Critical depth of cut (μm)*
α-Al_2O_3	275–393	3.85–5.90	19.6–20.1	1.0
SiC	382–475	2.50–3.50	24.5–25.0	0.2
Silicon	168	0.6	10	0.5

1.11.2.5 Tooling

Success of micromachining depends on tool quality and precision of a machine tool. Machine spindle runout, tool concentricity and tool positioning accuracy must be in the neighborhood of 1/100 of drill diameter or less for successful operation. Tolerance stack up for spindle runout, tool eccentricity, and wandering of a microdrill cause cyclic bending of a tool that lead to catastrophic failure. At a low rotating speed, the displacement of a spindle can be monitored with a sensitive mechanical indicator. However, this option is not applicable for machines that operates at few thousands rpm or above. Other noncontact techniques using capacitance, magnetism, or light would be more appropriate. An example of spindle runout measurement is shown below. A laser beam is pointed on a rotating precision plug gage. The spindle displacement is then recorded on a computer for further analysis

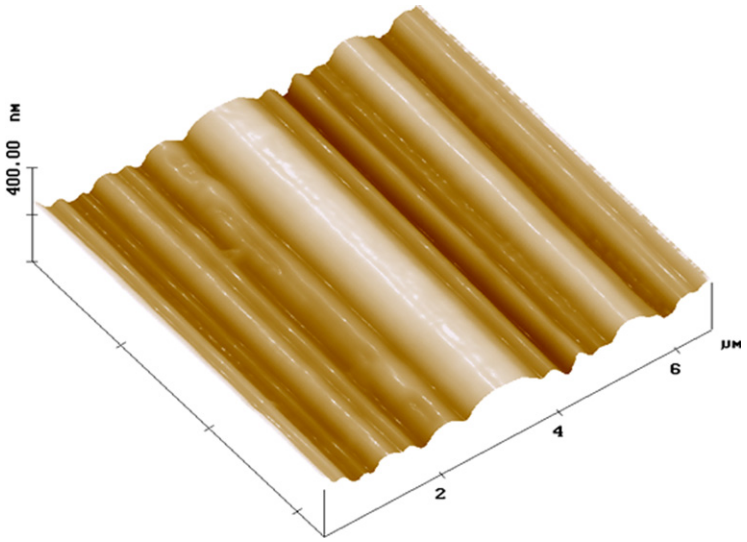

Figure 4 Perfect ductile regime machining of (001) plane of silicon along [$\bar{1}$10] direction. Speed 75 m min^{-1}, feed 2.5 μm rev^{-1}; depth 0.5 μm; SCD tool (5°, 0°, 0°, 5°, 5°, 30°, 0°, 0.5 mm,10–40 nm).

and display in either frequency or time domain. Commercial laser systems can provide displacement reading to ± 0.1 μm resolution or even lower. Figure 5 below shows the frequency spectrum during micromilling. As expected, we have two dominating peaks: one from the spindle frequency of 466.3 Hz when rotating at 27 238 rpm, and one from tool passing frequency of 932.6 Hz from a two-flute micromill.

Tool stiffness and tool edge sharpness are crucial to micromachining success. It is relatively easy to have a rigid turning or facing microtool, but it is requires careful planning to maintain rigidity of a micromill or a microdrill. Geometries of macroscale and microscale drilling/milling tools are the same: tool diameter, number of cutting flutes, point included angle for microdrill, helix angle, web thickness, clearance angle, flute length, shank diameter, and overall length. A careful selection of microtools must consider the intended machined features and highest possible tool stiffness. The two most important geometries that affect the microtool stiffness are the tool diameter and flute length assuming the number of flutes have been chosen. It can be shown that the torsional stiffness of a mill/drill is proportional to (tool diameter)^4 and (flute length)$^{-2}$. For a specific mill/drill tool dimension, we must adjust the milling/drilling strategy accordingly to avoid tool breakage.

The tool edge radius is critical in micromachining. Figure 6 shows two scenarios for a same microcutting tools with edge radius r. The tool can be either a turning, facing, or boring microtool that linearly engages a workpiece material at a certain depth of cut. A similar tool can move in a circular path as a microdrill or micromill, and engages a workpiece at a certain chip load (feed per tooth). If the depth of cut (or chip load) is too shallow, the tool simply plows the material and pushes

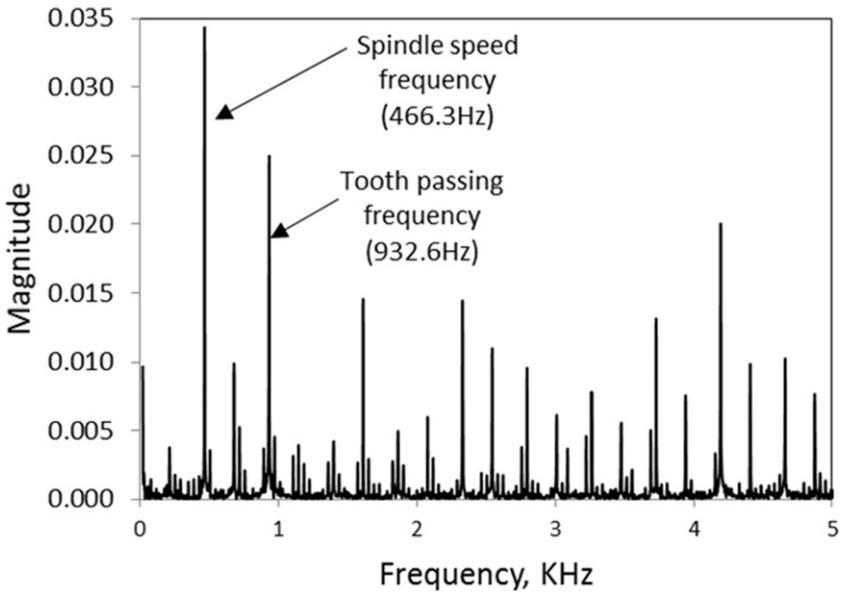

Figure 5 Frequency spectrum of tool and spindle runout. Milling CP Titanium, Ball End Mill ϕ0.152 mm, spindle speed 27 238 rpm, feed rate 2.7 mm min^{-1}, depth of cut 76 μm, MQL.[46]

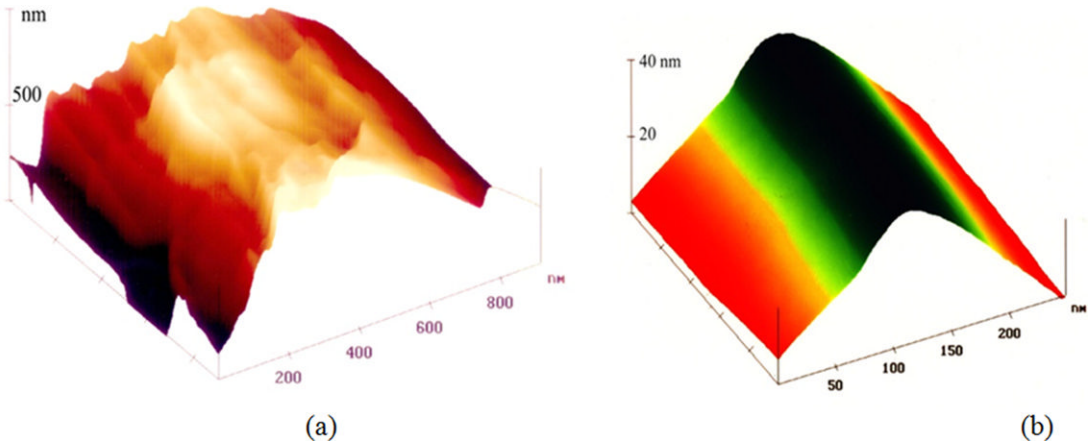

Figure 6 Tool edge measurement by scanning probe microscopy (a) new polycrystalline diamond tool with 750 nm edge radius, and (b) new single crystalline diamond tool with 10 nm edge radius. Note the different vertical and horizontal scales.

it away elastically. This elastic material layer just springs back after the tool passing by. If the depth of cut (or chip load) is substantial, then a chip is formed and a new machined surface is generated.

Typical fine grain carbide tools are first sintered from submicron carbide particles in a cobalt matrix, and then ground and lapped to final geometry. Optimal edge radii of 1–4 μm are typically designed for sintered tools to balance edge sharpness and edge strength. Only SCD tools can be ground and lapped to edge radii within nanometer range.

The threshold depth has been investigated theoretically and verified experimentally by many researchers. It varies from 5–40% of the tool edge radius depending on the workpiece material and original rake angles. A depth of cut or chip load, therefore, can be conservatively set to be 50% of the tool edge radius. When machining below this threshold, a microtool just rubs the surface and deforms it elastically during the first pass. When machining with depth of cut below the critical level, the material is plowed with negative effective rake angle. This results in high cutting force, high specific energy, fast tool wear, rough surface finish, and significant burrs. In subsequent passes when the cumulative depth is above the critical depth of cut, then a tool can remove materials as chips and the cycle repeats.

It is crucial to verify the tool edge radius before deciding on cutting parameters. Measuring of tool edge radius, however, is not trivial. A tool edge radius can be estimated from a scanning electron microscopic picture when the cutting edge is parallel to the electron beam, or scanning probe microscopic picture using a probe to scan the neighborhood of a cutting edge, or by scanning the edge on an optical microscope profiler in different views to reconstruct a 3D image of an tool edge before finding its radius.

Having the right microtool is essential for micromachining. A microtool that successfully drills through holes on a plastic printed circuit board does not necessarily be able to drill deep blind holes on titanium alloys. Understand the requirement and select the right microtool for each condition would save time, money, and frustration.

It has been theoretically derived and experimentally proven that the smaller is the chip, then the higher is the stress to remove it. Microcutting tools, therefore, have to be designed for higher stress with extreme geometrical constraints. When depth of cut is smaller than the average grain size of a workpiece, each grain generates different stress on a cutting edge and eventually fatigues the tool.

Microtools as small as 25 μm are commercially available. Common tool materials are HSS, cermet, carbide, cubic boron nitride (CBN), polycrystalline diamond (PCD), and SCD. The HSS is commonly not used in micromachining of metal since it does not have required hardness and strength to resist plastic deformation. A SCD tool is available for microturning, but not for microdrilling or micromilling. Carbide and cermet, having properties between HSS and diamond, are most suitable for microcutting tools. They are sintered from random abrasive grains in either cobalt or nickel binder with a small addition of molybdenum or chromium. A higher binder content increases the tool toughness and crack resistance, but reduces the tool bulk hardness. Having ultrafine grain (submicron size) abrasives in a lesser amount of binder is the optimal solution since a tool with a submicron carbide grains can maintain a high hardness while improving its crack resistance against chattering, interrupted cut, or cyclic deflection due to spindle runout.

Microtool failure modes include shearing, chipping, and wear. To minimize shearing and catastrophic tool failure, a tool should be made from a high hardness substrate and its geometry would be suitable for micromachining, i.e., large included angle and sharp cutting edge. A tool with smaller than minimum included angle will be deformed and fractured in service.

Coating of microtool is still a technical challenge due to conflicting constraints for tool performance. Chemical or physical vapor deposition (CVD or PVD) techniques have been developed to coat cutting tools with mono/multiple layers of intermetallic or ceramic compounds (**Table 2**). Criteria for acceptable tool coating are numerous: uniformity, high hardness, high toughness, low friction, high wear resistance, surface smoothness, high chemical/diffusion resistance, and high temperature stability at a reasonable cost. Although a coating thickness of 2–4 μm (79–118 μin) is acceptable for a macrotool, coating thickness on a microtool should be thinner to minimize fracture and peeling of the coating. Both CVD and PVD processes not only add the coating thickness to an edge radius, but they also increase the radius due to extra coating at a sharp corner. This is unfortunate since the thicker coating reduces the tool sharpness by enlarging the tool edge radius and causes an unfavorable plowing effect with negative effective rake angle. An uncoated microtool might perform satisfactorily, but the same machining parameter can be devastating to an over-coated microtool. A thin coating less than 1.5 μm following by an edge sharpening process would improve the tool performance, however, at the expense of higher tool cost. Published data indicate that micrograin carbide tools with 1.5 μm-TiN coating is the best for micromilling of H13 tool steel hardened to 45 HRc.

Table 2 Commercial coating for microtools

Coating	*Structure*	*Hardness (GPa)*	*Coefficient of friction*	*Coating (μm)*	*Coating (°C)*
TiN	Monolayer	24	0.55	1–5	600
TiCN	Gradient	37	0.20	1–4	400
TiAlCN	Gradient	28	0.30	1–4	500
TiAlN	Multilayer	28	0.60	1–4	700
AlTiN	Gradient	38	0.70	1–3	900
ZrN	Monolayer	20	0.40	1–4	550

1.11.3 Silicon Micromachining

Silicon micromachining technique is used to fabricate micromechanical structures in silicon using micromachining processes. Gears and spiral springs with dimensions of 50–200 μm are examples for movable structures that are successfully fabricated using this method.[47] Two crucial types of silicon micromachining processes are bulk micromachining and surface micromachining.[48] Although the following discussion is limited to silicon, the process can be applied to other semiconducting materials with subtle modifications.

1.11.3.1 Bulk Micromachining

Bulk micromachining (Figure 7(a)) is a process where a bulk of materials such as silicon and glass is shaped by treatment with either orientation dependent or orientation independent etchants. In bulk micromachining, structures are produced inside a substrate. It is widely used to fabricate 'undercut' structures like membranes, beams, holes, grooves, and other microfeatures.[49–51] Due to the inherent process limitation, bonding methods are used to join thin and two-dimensional components into a complex three-dimensional (3D) and thicker structure. The most common bulk micromachining are wet and dry etching.[49,52,53] These techniques can be distinguished based on the phase of the reactants. Wet etchant refers to the aqueous chemical phase while dry etchants refers to the vapor and plasma phases.[51]

Wet etching (Figure 7(b)) bases on the immersion of workpiece in an aggressive liquid solution. It is a process where isotropic or anisotropic etchant can be adopted, while doping or etch stop methods are used to control machining depth in silicon wafers. Wet etching is commonly used for silicon and glass.[49,52] The geometries of etched features are isotropic if the etching rate is uniform in all directions, and anisotropic if the etching rates depend on the material crystalline orientations. The nature of the chemical reactions, the diffusion of reactants and products, and shapes of the masks

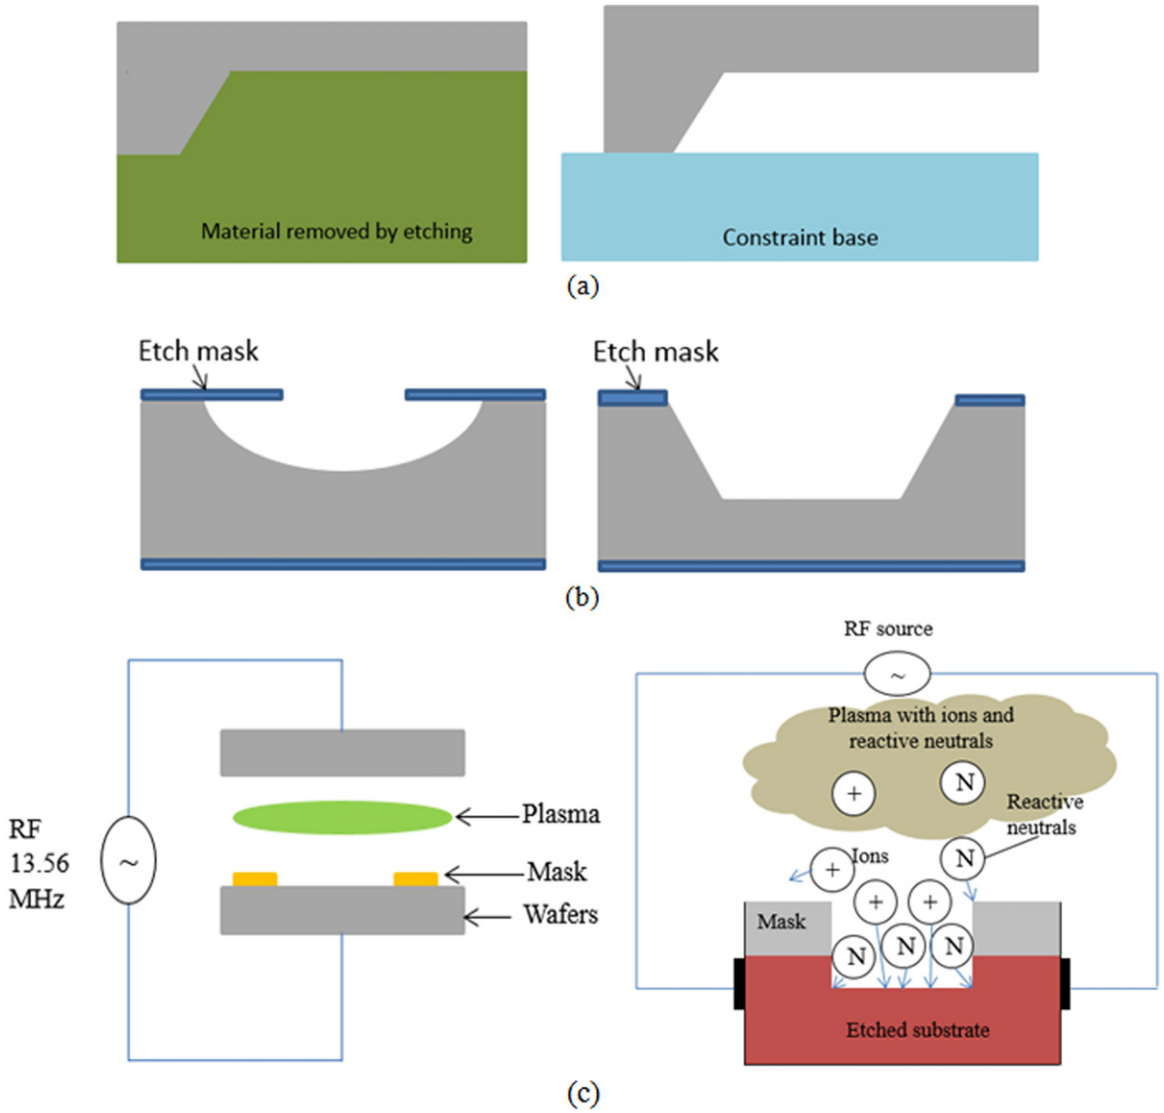

Figure 7 (a) Bulk micromachining, (b) isotopic (left), anisotropic (right) wet etching, and (c) deep RIE.

used to define the etched regions are among the factors that defines the shapes and productivity of final products.[51,54]

As for dry etching, there are a few different processes involve such as physical, chemical, and combinations of physical and chemical etch processes. Sputtering and ion milling are the examples for the physical processes while reactive ion etching (RIE), deep RIE (Figure 7(c)) and reactive ion beam etching are examples of physical and chemical synergy. While wet etching uses unique chemicals for specific material, dry etching can be applied on a variety of metals, ceramics, and plastics. Dry etching is applied in a controlled chamber where ions are accelerated to scan specific areas and remove affected atoms. This process is more expensive compared to the wet etching due to slower MRR, but it is the preferred choice when high-aspect-ratio vertical structures or thin layer machining must be obtained.[49,52]

1.11.3.2 Surface Micromachining

Surface micromachining is a process that relies on deposition of structural thin films on a sacrificial layer. It can produce smaller components compared to those from bulk micromachining. When the sacrificial layer is etched away, an undercut and freely suspended or a movable micromechanical structures are produced.[49,55] The common sacrificial layers are inorganic materials such as silica (SiO_2) and organic polymers such as polymethyl methacrylate (PMMA); acidic etchants such as hydrofluoric acid (HF) are common etching solutions.[56] This procedure typically includes (Figure 8(a)):

- Growing a sacrificial layer and patterning it on a silicon substrate,
- Depositing a structural material by either physical or chemical depositing techniques on top of the sacrificial layer,
- Shaping the this structural materials by appropriate lithography or etching techniques,
- Removing the sacrificial layer by a suitable etchant leaving behind the desired microstructures.

One of the advantages of this process is that the final structural and spacer features can be as small as 10 μm. A surfaced micromachined device (1) has smaller footprint than the that of bulk micromachining devices, (2) can be designed with tighter tolerance compared to the bulk micromachining devices, and (3) is easier to integrate into electronic microstructures. However, the main disadvantage of this technique is the vulnerability of surface microstructures when handling and integrating during manufacturing.[58] An example of microsystem with components fabricated by surface micromachining is shown in Figure 8(b).

1.11.4 Energy Beam Micromachining

Energy beam refers to collection of energetic particles such as photons, ions, or electron. A beam can be scanned or focused for desired material removal process.

1.11.4.1 Laser Micromachining

Light Amplification by Stimulated Emission of Radiation (LASER) is used for metal cutting since 1965. Laser light is collimated, coherent, and monochromatic; and because of its high power density, it can be used to process metals, ceramics, polymers, and even composites. Machining using laser is mainly due to the thermal action where rapid rise in temperature in a limited area caused the irradiation of substrate material by Yttrium Aluminum Garnet (YAG) laser or CO_2

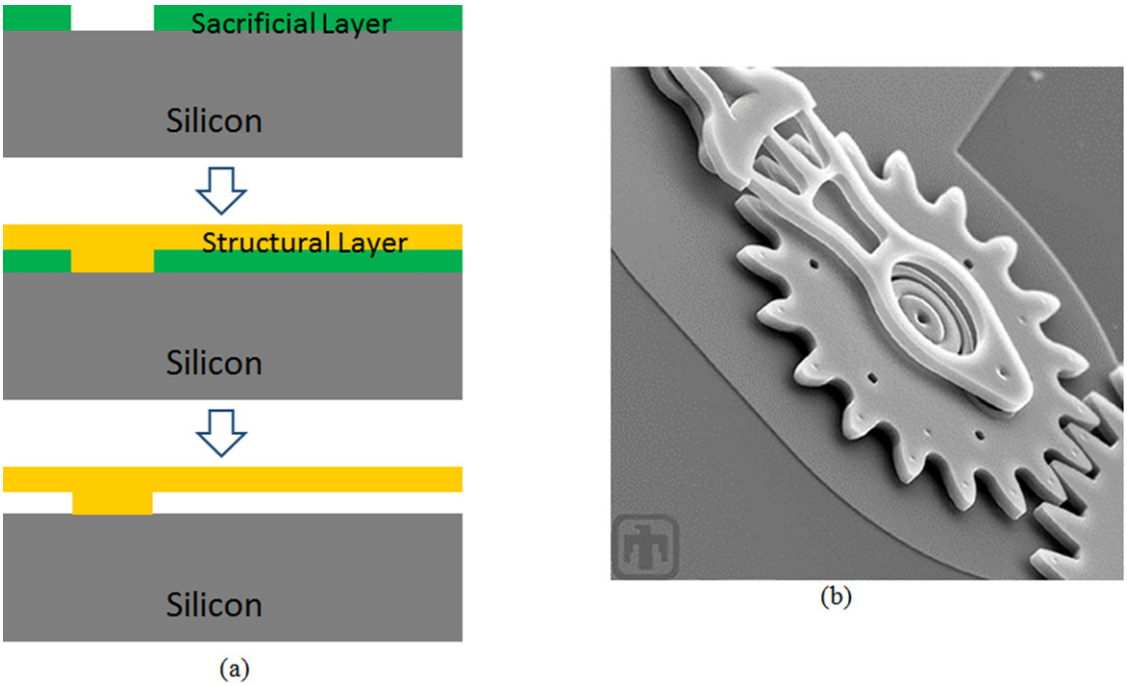

Figure 8 (a) Basic surface micromachining process and (b) An example of microsystem.[57]

laser. With the advances of laser in the recent years, it is also used for microdrilling, micromilling, and other microsurgery. Excimer laser, nanosecond laser and femtosecond laser are the example of many lasers that are used in micromachining. A simplified view of laser machining and an example of microdrilling (marking) are shown in Figure 9.

A short-pulse laser is capable of generating light pulses that last only a few micro/nano/femto-seconds. Short pulse machining process is so rapid that there is little time for heat to diffuse away from the focal spot. It directly changes solid matter into plasma and results not HAZ, microcracks, shock wave, delamination, recast layer, and damage to adjacent structures. This short-pulse laser generally performs micromachining with high accuracy and resolution. Micromachining quality depends on the amount of heat deposited in the workpiece and the amount of heat that is left behind in the material can cause damage. The main advantages of short-pulse laser are as follows:

- The laser energy does not have time to leak away from the micromachining spot.
- Huge amount of energy deposits so fast that the material is forced into a state of plasma which expands away from the material and taking away almost all the heat.
- Very low damage such as microcracks, resolidification of debris.
- The interaction of ultrashort laser pulses with matter is highly reproducible, shot-after-shot.

Laser assisted machining (LAM) is a machining operation that uses laser as a heat source with the beam focused on the surface of the workpiece and immediately in front of a cutting tool. Ductile deformation occurs during the cutting process when the heats soften the surface layer. The power requirement depends on the material and the nature of the machining operation. It is capable of cutting non-reflective materials. Minimum burr and little heat affected zone, resulting from a precise cut with high speed are among the advantages of the LAM process. Moreover, it has the ability to reduce cutting force and lower dynamic forces, producing less segmented chip generation, resulting in a smoother surface finish. Nevertheless, the drawback of this machining operation is that it requires high energy, involves high cost, and must be conducted in special conditions.[59]

1.11.4.2 Focused Ion Beam Micromachining

Focused ion beam (FIB) is a micro/nano machining technique that can produce miniaturized 3D features to form a mold for subsequent replication process. Combination of FIB micromachining and micromolding is an alternative to LIGA process for low aspect ratio component and flexibility when using software-generated masks. A FIB system can be an invaluable tool for micromachining electronic components (IC repair, modification, etc.), failure analysis by microsectioning and secondary ion mass spectrometry (SIMS), and fabrication of non-silicon microcomponents for MEMS (microgear, microneedle, microchannel, micromilling tool, etc.). Two main categories of FIB micromachining are sputtering and deposition.[7,60–62]

1.11.4.2.1 Deposition

Other than FIB sputtering, FIB is the catalyst for depositing materials on the surface of the substrate (Figure 10(a)). In example of deposition a tungsten thin film, a precursor gas such as tungsten hexacarbonyl is used in the FIB system. An injector of precursor needle is directly positioned near the substrate. Upon interacting with incoming ions of a FIB, the gas molecules are decomposed into a thin tungsten layer on top of the machining surface while releasing a volatile compound which is exhausted into a vacuum system.[63] Such FIB deposition is commonly used in microelectronic failure analysis or micro structural modification.[64]

1.11.4.2.2 Sputtering

The FIB sputtering is a technique for maskless micro fabrication where incident ions transfer momentum to the substrate and release atoms through cascades of collisions (Figure 10(b)). There are two types of FIB sputtering which are dry etching/sputtering and gas assisted etching (GAE). The GAE is known for its very complex phenomenon since the material removal is occurred due to the chemical action of the gas, the physical action of energetic ion, and the combination action of the gas and energetic ions. As for the dry sputtering or more commonly known as sputtering for FIB micromachining has become more crucial compared to GAE because it is

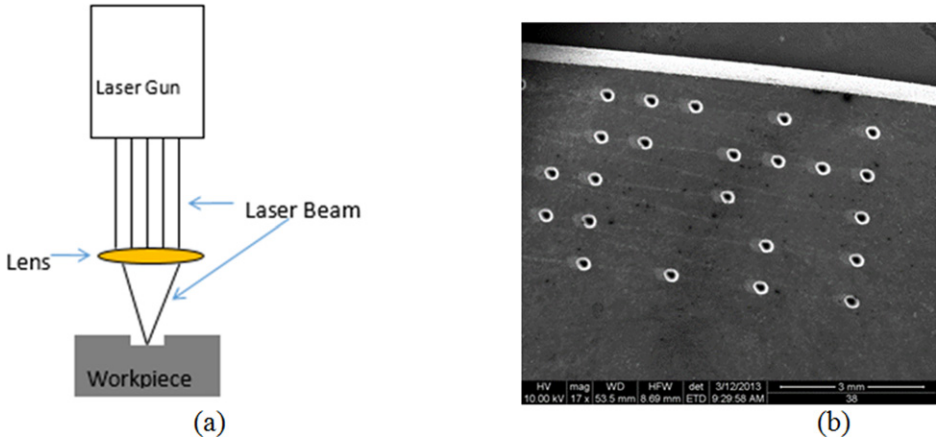

Figure 9 (a) Schemtic diagram of laser machining and (b) Femto laser marking on a turbine component.

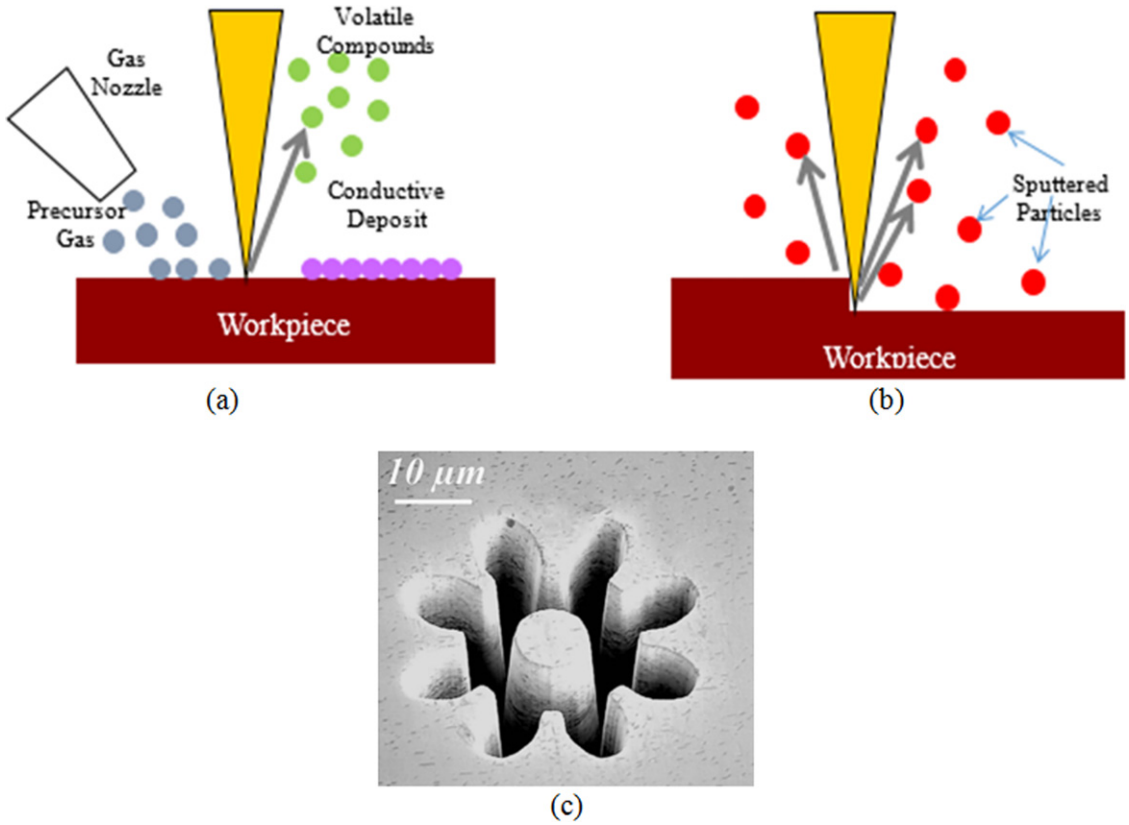

Figure 10 Schematic diagram of (a) FIB assisted deposition, (b) FIB sputtering, and (c) a micromold fabricated by FIB micromachining.

widely used for application in micro/nano engineering and various microscopic techniques.[7] A metallic mold with micromold cavity fabricated by FIB sputtering is shown in Figure 10(c).

1.11.4.3 Electron Beam Micromachining

The principle of electron beam machining (EBM) is similar to that of ion beam machining. Both techniques utilize energetic particles to strike a target so that a substrate is machined or a layer is deposited in presence of an assisted gas. Both techniques, either focused ion beam or focused electron beam, are sometimes cost prohibitive due to the high cost of equipment and maintenance while a small workpiece must be enclosed in vacuum.

The smaller size of electrons makes electron easier to manipulate, but less effective in machining compared to an ion beam. The low momentum of an electron would transfer its kinetic energy to thermal energy for material removal by melting and evaporating rather than sputtering. A small electron would scatter and bounce among substrate atoms and generate a larger heat affected zone, therefore, a microhole drilled by electron beam is typically deep but not precise. Holes with diameters in the range 50–1000 μm can be drilled through 10 mm plates at an astonishing rate of 3000 holes s^{-1}.[65] An electron beam with 1.1 nm spot size drills a much larger hole ~100 nm on a silicon nitrate membrane due to the scattered electrons.[66]

1.11.5 Electrical Discharged Micromachining

The nontraditional electrical discharge machining (EDM) process is commonly used in mold-and-die manufacturing industries due to its capability in removal of difficult-to-cut and brittle conductive materials.[67–69] It is one of the machining alternatives used in fabricating microparts with low cost and less time consuming compared to FIB, LIGA, and other lithography based techniques.[70] It is also used in aerospace and automotive industry as well as in making surgical components.[71] The workpiece machined by EDM depends on the thermal conductivity, electrical conductivity, and melting points of the materials.[72–74] The noncontact nature of the process with nearly force free machining allows soft electrode materials to machine a very hard, fragile, or thin workpiece.[75–77] The inherent noncontact nature of EDM, therefore, minimizes mechanical stresses, chatter, and vibration problems during machining[78]; however, other issues may emerge due to cyclic pumping pressure of dielectric fluids on an electrode and a workpiece.

A workpiece can be either positive or negative relative to the electrode. A negative workpiece would have higher material rate but rougher surface, but a positive workpiece causes high wear rate on the negative electrode. Polarity is a vital factor in this machining operation as electrical sparks are produced between the workpiece and electrode.[74] In this process electrical spark is created by electrical energy and materials are removed by thermal energy of the spark.[79] The series of electrical sparks or

discharges occur rapidly in a short span of time within a constant spark gap between the electrode and workpiece material. The nature of the sparks is repetitive and discrete. The tool and the workpiece are immersed in a dielectric medium, such as kerosene, deionised water, pure water, or any other suitable dielectric fluid.[68,80–82] The gap between the electrode and workpiece are small enough to produce voltage that ionizes the dielectric fluid.[74]

Micro-EDM follows the similar principle of macro EDM technology. But, there are some differences between these two machining in terms of circuitry. A macro EDM system commonly uses resistance capacitance relaxation (RC-relaxation) circuit meanwhile a micro-EDM system utilizes RC-pulse circuit. The RC-pulse circuit type produces a lower MRR due to its very small discharging energy. Micro-EDM is useful to manufacture component less than 1 mm with high precision and high accuracy.[83–86]

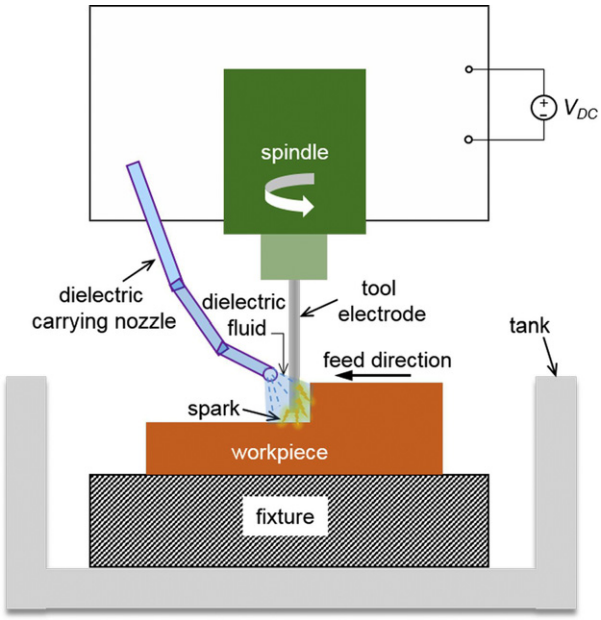

Figure 11 Schematic diagram of a 3-axis micro ED micromilling.[87]

1.11.5.1 Electrical Discharged Micromilling

Electrical discharge (ED) micromilling is a branch of the micro-EDM. It has the specialty in fabricating microfeatures with complex 3D geometries. It is an effective way to fabricate complex contour micromold and microtool for hot embossing. The mechanism of ED micromilling is same as the micro-EDM where the material is eroded by noncontact thermoelectrical process. Typical ED micromilling utilizes 5-axis system to move a rotating electrode into a workpiece. The electrode movement is controlled numerically in order to achieve the desired shape and accuracy of the micro parts.[9,87] The schematic diagram of the micro ED milling operation is shown in Figure 11.

1.11.5.2 Micro Wire EDM

Micro wire EDM (micro-WEDM) technique is a micro version of macro wire EDM. Still, sometimes the macro WEDM is 'stretched' to fabricate microcomponents because of high demand of microparts and less availability of miniaturized machine tools. This process uses thin wire (typically 100 μm) as an electrode to cut the workpiece into desired shapes which is controlled by a computer numerical control (CNC) system. Micro-WEDM (Figure 12(a)) is a machining process that can fabricate microfeatures with nanometric surface finish and submicron accuracy. A gear machined by micro-WEDM is shown in Figure 12(b). The surface quality would get worse with ripples, cracks, and recast layer if higher electrical energy is used. Besides, the debris that is not washed away can cause a short circuit and results in poor surface finish. However, regarding the surface finish, further investigation should be done since the fabricated microparts are usually used as a mold to replicate polymer microstructures.[7,88]

1.11.5.3 Micro-EDM of Nonconductive Ceramics

Ceramic materials are commonly used in many applications such as machine tools, molds and dies, vehicle systems, electronic devices, semiconductor systems, and in biomedical field. This is due to their material properties which include:

400–1465 MPa strength,[89,90]
1000–2500 Hv Vickers hardness,[90]
900–1200 MPa bending strength,[91–93]
2050–2720 °C melting temperature,[94,95]
High chemical inertness,[96–98]
Biocompatibility of some ceramics,[84]
Excellent dielectric strength,[68]
Outstanding corrosion resistance,[68] and
Good wear resistance.[96–98]

Aluminum oxide, also known as alumina (Al_2O_3) and zirconium dioxide, also known as zirconia (ZrO_2) are commonly used as advanced technical ceramic materials. Yet these materials are difficult to machine due to high brittleness, hardness, and nonelectrical conductivity.[68,84,94,96–99] In addition to conductive material, nonconductive materials can also be machined using the EDM. Examples of the latter includes:

Oxides[59]: Zirconia (ZrO_2)[68,75,91,92,100] and Alumina (Al_2O_3).[96,101,102]

Non-oxides[59]: Sialon ceramic or Silicon Nitride (Si_3N_4)[79,103,104] and Boron Carbide (B_4C).[105]

Composites[59]: Siliconised Silicon Carbide (SiSiC)[78,105] and Cobalt-bonded Tungsten Carbide (WC–Co).[105]

The common method used to process zirconia is laser scanning followed by milling process to enlarge the shape of the framework and finally ends with sintering to full density for two hours at 1350 °C.[106,107] Materials with a minimum electrical conductivity of 0.1 S cm^{-1} can be processed using EDM. So, conductive materials are capable to undergo this process.[91,92,108] But, the main problem occurs when EDM'ing ceramic materials with electrical conductivity between 0.01 and 3.333×10^{-3} S cm^{-1} (electrical resistivity between 100 and 300 Ωcm).[105] Besides, these materials are hard to shape by cutting techniques or laser ablation due to their material characteristics. Currently they are roughly shaped with diamond tools and then polishing with diamond suspensions; these approaches are time consuming and costly, however.[91,92,96,103]

Despite of above problems, ceramics have been machined with EDM since these materials are difficult to machine using other techniques.[67,79,104,109] Since the ceramics need to be conductive for EDM'ing, one solution is to (1) create a composite with dopants such as titanium nitride (TiN) or tungsten carbide (WC) onto the ceramic, (2) create a conductive compound by embedding the ceramic particles in a metal matrix, or (3) apply ultrasonic assisted spark erosion. The ultrasonic energy can assist in creating spark erosion and lead to crack formation that causes spalling. Nonetheless, the main disadvantage of these methods is that the ceramic's properties are affected. Moreover, material removal of ceramics during the spark erosion is different from metal erosion. This is due to difference in melting, evaporation, spalling, oxidation, and decomposition mechanism.[73,91,92,99] Thus, to avoid this problem, nonconductive ceramics have been successfully machined by EDM using the assisting electrode method (AEM) with some process modifications.[68,101,110–112]

1.11.5.3.1 Assisting electrode

In this method, a conductive layer is applied on top of the nonconductive ceramic in order to produce sparks between the workpiece and the electrode. Assisting electrode (AE) can be metal plates, foils or meshes as long as they are mechanically fixed on the ceramic surface.[68,91,92,96,99,110,113] During the erosion process, AE will be eroded. High temperature that occurs around the dielectric fluid will degenerate the polymer chains and creates carbon elements from decomposed polymer chains. These carbon elements, with combination of conductive debris cover the ceramic surface in order to sustain the conductivity during the erosion process. The spark erosion process for nonconductive ceramic is shown in **Figure 13**. Hence, oil based dielectric fluid such as kerosene is suggested to be used in order to continue the process after the conductive layer has relapse.[68,91,92,101,102,114]

Carbon can also be added into the dielectric fluid in order to support the formation of conductive debris. The thermal load of the discharged spark penetrates the ceramic which leads to stresses that stimulates cracks. Therefore, the ceramic is removed by spalling process which is explained in subsection of mechanism of material removal.[92] A study on EDM of high purity nonconductive ZrO_2 was investigated using two different types of adhesive foils as AE. Adhesive copper foil, known to have excellent thermal conductivity, gives optimum values for MRR, electrode wear rate, and surface roughness.[68] In another study, ceramic specimens were coated via doctor knife and screen printing with thickness of 800 and 30 μm respectively. Both techniques are suitable for machining process, yet screen printing technique is more favorable for thinner layer and better accuracy.[92]

1.11.5.3.2 Dielectric fluid

Closed flushing system and workpiece vibration unit can be added to die sinking micro-EDM to enhance the process. The flushing system varied by modifying the vibration frequency. The vibration frequencies used were in the range of 50–1000 Hz at 1–10 μm amplitudes in feed direction onto the workpiece. It is recommended that silver-based varnish as AE with vibration frequency of 440 Hz in carbon hydride based

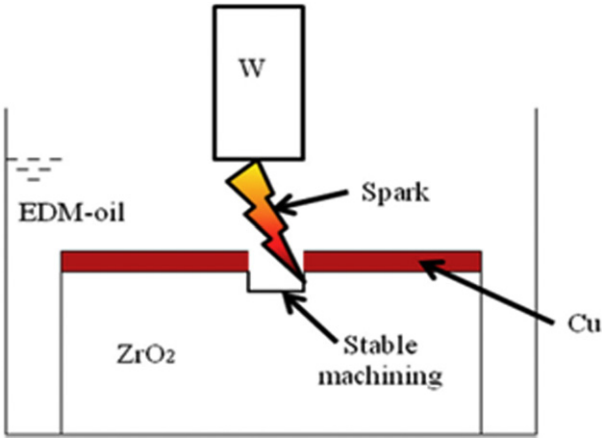

Figure 13 Principle of spark erosion in EDM with copper (Cu) as assisting electrode on nonconductive zirconia ceramic with tungsten (W) electrode.[99]

(IME-82) fluid can reach a stable process.[67] Ultrasonic vibration enables successful micro-EDM of nonconductive ZrO_2 ceramic. The machining was done using silver varnish as the AE with the thickness of 20 μm. The proposed experimental setup was completed by adding a peristaltic pump for flushing and filtering of the medium independent from the main dielectric circulation. Besides that, an active workpiece clamping unit with low-frequency vibration up to 1000 Hz at an amplitude of 20 μm peak to peak was added. The result showed that micro-EDM process with direct vibration gives higher aspect ratio structures with improved process speed. The direct ultrasonic vibration enabled the machining of complex structures with very high aspect ratios.[75] Micro-EDM of ZrO_2 with tungsten electrode and EDM-3 synthetic oil as the dielectric fluid was done in another study. Selection of AE, polarity, feed rate, and flushing type are the major factors that were considered in the process development of this machining process. The results showed that stable machining operation can be achieved with copper adhesive as AE, positive workpiece polarity, 3 μm s^{-1} feed rate, and workpiece submerged in dielectric fluid with one-way circulation.[99]

1.11.5.3.3 Mechanism of material removal

MRR has become one of the main concerns to remove bulk of the materials. Many researchers have attempted to develop empirical models to estimate MRR. The MRR depends on the amount of pulsed current in each discharge, frequency of the discharge, electrode material, workpiece material, polarity, and dielectric flushing condition.[74,115,116]

The MRR is low when the workpiece is connected to positive polarity. This is explained by the tendency of the dissociated carbon elements in dielectric fluid to remain at anode and formed a recast layer.[117] However, in order to obtain high MRR in ceramic, high power should be provided and the workpiece should be positive polarity.[59,96,99,118] This is preferred since more carbon elements are generated, forming a conductive layer that covered the ceramic surface during the EDM process.[99,118] Therefore, MRR is determined by the electrode and workpiece material, current density, and pulse length.[119]

There is a research done on ED-milling whereby the AE was stored in a bobbin and was continuously fed toward the electrode along the surface of the insulating Al_2O_3 ceramic workpiece using the actuating wheel. MRR of the insulating Al_2O_3 ceramic depended on the polarity, the rotational speed, and addition of suitable chemical additives in dielectric fluid. MRR was high when the electrode was positive with high rotational speed. The speed enhanced the flow velocity of the dielectric fluid at the discharge gap and led AE closer to the workpiece surface. The stability and electrical discharge energy acting on the workpiece surface increased and improved the MRR. Water-based emulsion was suggested to be used as the dielectric fluid since there was no production of harmful gases and the equipment was not corroded.[97,98] Since the ceramic took the longest machining time, the machining conditions were highly unstable. The shortest machining time and more stable machining conditions were found for ZrO_2 ceramic. The MRR increased when the thickness of AE was increased. Moreover, ceramics with low thermal conductivity give higher MRR values.[95]

Flushing system and rotation of the electrode are two factors crucial in machining of nonconductive ceramics. It showed that machining rate of nonconductive ceramics decreased without the utilization of flushing system or rotation of electrode. Both of these factors affected the machining rate at high discharge current.[73] Different dielectric fluids have different properties, which play important role in flushing away the debris from the machining gap. The breakdown resistance, conductivity, viscosity, flash point, health, and safety factors of dielectric fluids can all affect the MRR and the tool wear. Rotating electrode can provide an effective gap flushing technique and sparking efficiency that helps in improving the MRR and tool wear.[78] Still, with the increasing of the speed, the centrifugal force will be generated, causing more debris to escape from the machining zone.[117]

Different types of electrodes give different machining effects on the ceramic surface. A research proved this by using Cu, graphite (Poco EDM-3), and copper-infiltrated-graphite (Poco EDM-C3) as electrodes. Conductive layer was formed on the EDMed surface of alumina by all of the electrodes. The thickness of the conductive layer plays a vital role in EDM process since it has the ability to affect the MRR results. Thicker conductive layer give rise to a better MRR results. Semi-sintered electrode material can generate thicker conductive layer such as EDM-C3 and EDM-3.[101]

Another study on micro-EDM of insulating silicon nitride (Si_3N_4) using three different electrodes; Cu, copper tungsten (CuW), and silver tungsten (AgW) were carried out. MRR depends on the dielectric fluid breakdown which is usually initiated by low voltage and also by the electrical and thermal properties of the materials. Based on the investigation, Cu had the higher electrode wear rate than AgW and the later had the highest breakdown voltage compared to Cu since tungsten (W) has higher atomic mass and hardness. High melting and evaporation point together with high thermal conductivity are the basic requirements in choosing an electrode material. Electrode wear rate is also verified to be inversely proportional to melting point of electrode material.[79] Mechanisms of material removal occurring in nonconductive ceramics by EDM process are briefly explained below:

Melting and evaporation. Thermal removal of ceramic is induced by melting of the coated conductive layer. **Figure 14** shows the topography of droplets left on the micro-EDMed surface which probably indicates melting and evaporation. The droplets depend on the material properties such as melting point and thermal conductivity. Micro-cracks can form on the machined surface since ceramics have lower resistance against tensile stresses. This mechanism happens at the central region of the discharge where materials are removed depending on the ceramic material.[120,77,96]

Spalling. Small volumes of material from the base material are dropped out due to the surrounding micro-cracks generated during EDM (**Figure 15**). The formation of micro-cracks depends on the material properties such as thermal conductivity, melting point, and fracture toughness.[68,120] This process happens when large amount of energy is directly discharged into the discharge gap during machining process. The ceramic will encourage the formation of a steep-temperature gradient and high-thermal stress level at the interaction point. If the level of the thermal stress exceeds the maximum tensile

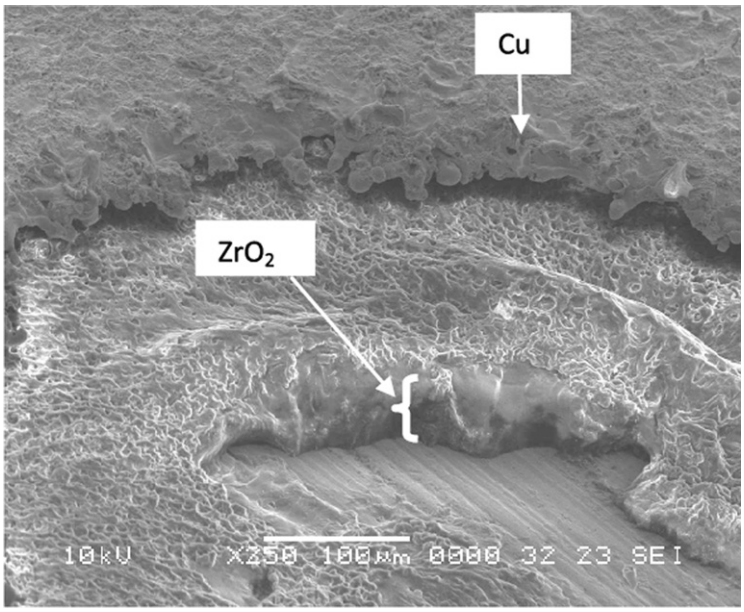

Figure 14 Melting and evaporation at the machined area of zirconia by micro-EDM using EDM-3 synthetic oil as dielectric fluid.

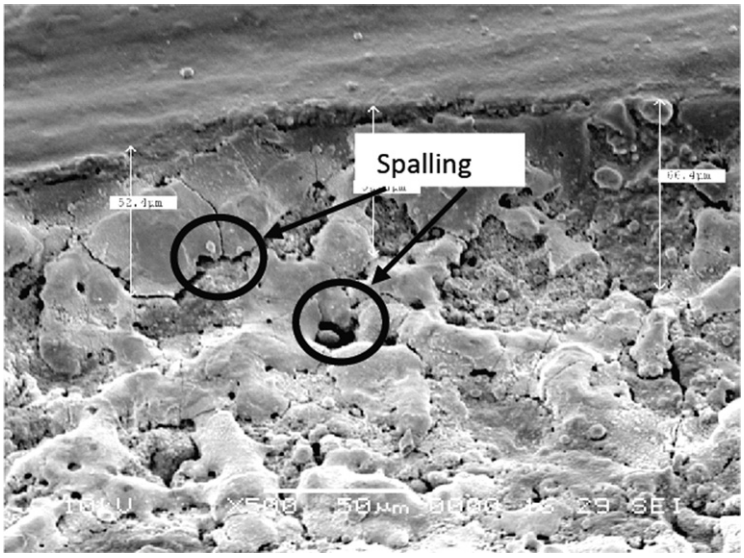

Figure 15 Spalling at the machined area of zirconia by micro-EDM using EDM-3 synthetic oil as dielectric fluid.

strength of the ceramic, it will lead to cracks and removal of the material by spalling.[96,99]

Oxidation and decomposition. After the spalling mechanism, oxidation and decomposition occur due to the thermal energy of the EDM process. **Figure 16** shows formation of foamy and porous layer on the surface of Si_3N_4–TiN, machined by WEDM in de-ionized water. This structure is caused by generation of many gas bubbles during the machining process. The visible bubbles and smell of ammonia are symptoms of oxidation and decomposition mechanism. This mechanism generates a large amount of gas, leading the porous structure of the machined surface as well as increase in MRR. On the contrary, if the machining is performed in oil, the formed droplets and craters produce a smoother recast layer with better machining surface.[120] Even though EDM is capable of machining complex shape with high precision and accuracy, it generates unwanted recast layer and HAZ.[121] Normally three layers are identified on top of the machined surface. The top surface layer is formed with spherical molten metal and electrode material. The next layer is the recast layer forming by resoludified materials, or white layer, and lastly the HAZ or annealed layer (**Figure 17**).[78] The EDM'ed surface is subjected to a very sharp temperature gradient during the machining, and resulting a high thermal residual stresses. Electrode material, dielectric fluid, and discharge condition are factors that can affect the profile of the temperature gradient. Since some of the molten metal cannot be excluded; it will be quenched rapidly by dielectric fluid, forming a recast

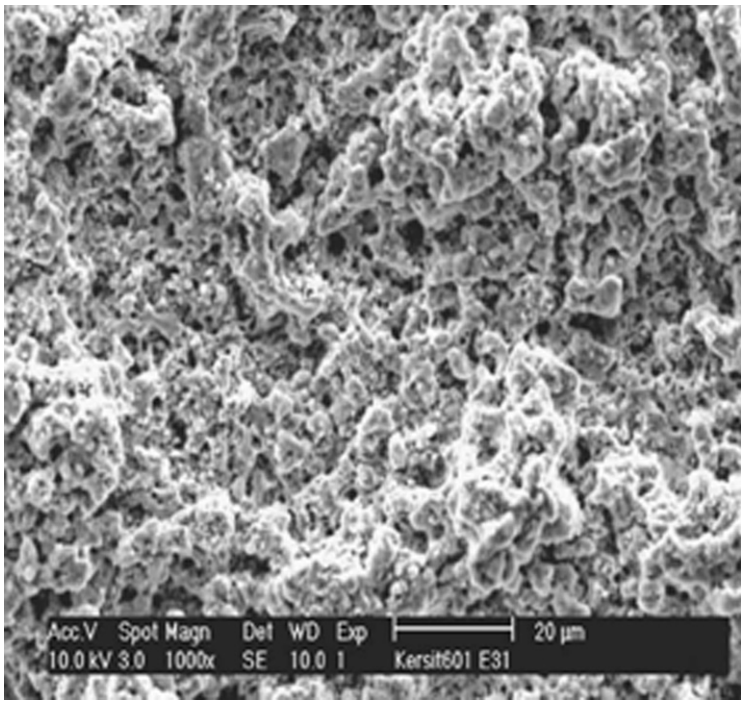

Figure 16 Topography of Si_3N_4–TiN by wire EDM in deionized water.[120]

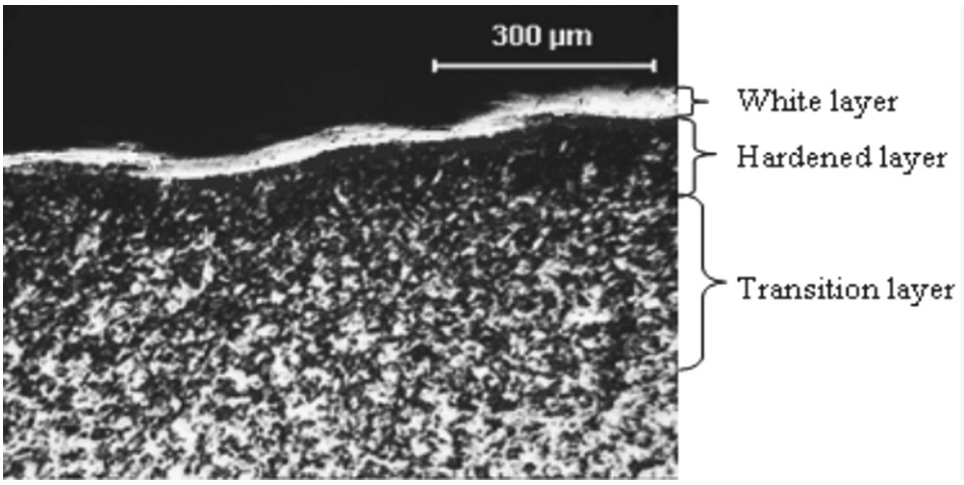

Figure 17 Layers produced on EDMed surface.[129]

layer.[78,114,122,123] Usually, the recast layer consists of craters, micro-cracks, bubbles, and high tensile residual stresses (Figure 18). This can cause deterioration of the surface finish, reduce wear resistance, cause premature part failure, stress cracking, and shorten the part's fine surface finish.[121,122,124–126] Surface quality such as tensile stress, strain, intensity, stiffness, and residual stress can also be affected by the formation of the recast layer.[114,127,128]

1.11.5.3.4 Recast layer

High microhardness of EDMed surface is reported due to the migration of carbon from the oil dielectric fluid to the workpiece surface and formation of recast layer with hard iron carbides. Frequency, polarity, pulse shape, machining gap, and dielectric fluid temperature affect the concentration of these carbides on surface layer of the workpiece. Besides that, recast layer and crack density are also influenced by the flushing rate. Yet, they can be minimized by using the optimal flushing rate.[78] Recast layer created in EDM process has different properties depending on the electrical energy that consist of voltage, current, time of pulse, and pulse interval. The electrode and dielectric fluid properties have a significant role in determining the surface layer properties. Chemical changes on the surface of the workpiece occur due to reactions with the dielectric fluid and the wear of the electrode. It is observed that when electrode is made of Cu in the combination of other

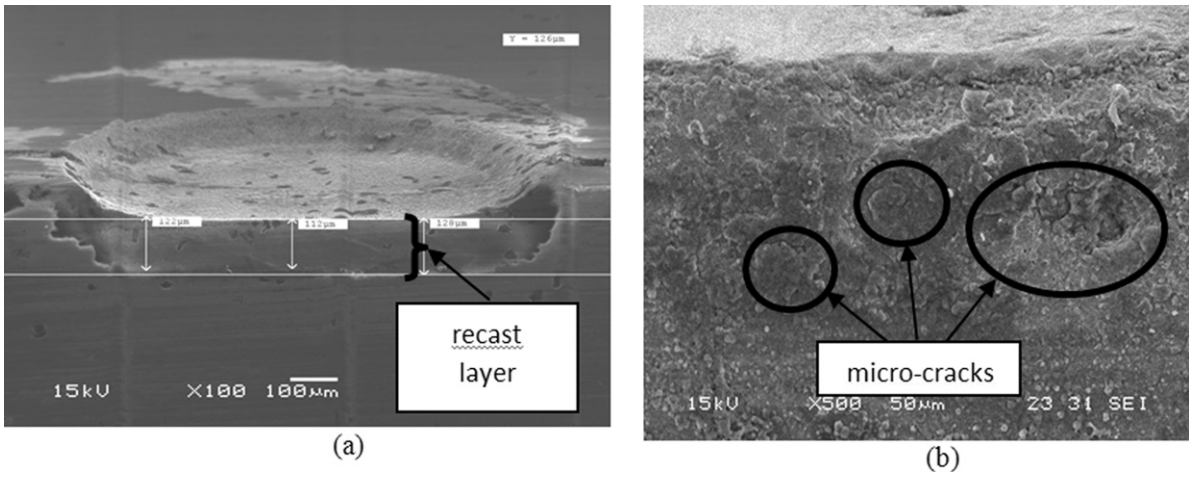

Figure 18 SEM images of (a) recast layer for machined area of zirconia due to micro-EDM and (b) micro-cracks for machined area of zirconia due to micro-EDM.

material for steel workpieces, the average Cu concentration was about 10% with diffusion up to 20 µm. The carbon percentage also increases because of the reactions with carbonic dielectric.[130,131]

Cracks are observed in the recast layer. During the cooling process, melted materials are being contracted rapidly and cracks are formed when the stress on the surface exceeds the material's ultimate tensile strength. It is seen that cracking increased with the increase of pulse energy and the crack density was inversely proportional to the thermal conductivity of the workpiece material. Surface crack intensity increased rapidly with the increase of carbon within the recast layer.[132] Peak current and pulse-on duration have been found as the influential parameters on EDMed surface integrity. Mathematical models were formulated based on the response surface methodology for correlating the influences of peak current and pulse-on time on surface integrity of M2 Die Steel after EDM process. The optimal parametric combinations were found for minimum surface roughness, recast layer thickness, and surface crack density. At peak current, 3.5 A and pulse-on duration, 20 µs, all the three criteria of surface integrity were found to be minimum.[133,122]

Influence of machining parameters on EDM of steels shows that the thickness of the recast layer varied with the change of current, duty factor, and pulse on time. Recast layer thickness increases with the increase in current due to the availability of more power for altering the metallurgical composition of the parent material. Similar results were seen when the duty factor is increased. In contrast, recast layer thickness decreased with the increase of pulse-on-time, contributed by the fact that less amount of heat is generated on the surface of the workpiece during the machining process.[122] Powder mixed dielectric has positive effect on the reduction of white-layer thickness. The effects of titanium carbide (TiC) and Al_2O_3 powder in kerosene on the EDM'ed surface shows that the recast layer thickness and the cracks increase with the increase of current. Higher layer thickness was observed when Al_2O_3 powder was used instead of TiC powder. However, when utilizing TiC powder, higher hardness was found than that of Al_2O_3 powder, besides the increase in electrode material and carbon depositions on the workpiece surface.[134]

1.11.6 ECM

1.11.6.1 Micromachining

ECM is another material removing technique for any conductive material. This anodic dissolution process uses direct current (DC), or pulsed DC, and electrochemical reaction to remove material in micro or nanoscales. Since the process is independent of the workpiece mechanical properties and can maintain the electrode dimension, it is suitable for machining, polishing, or forming intricate features on die and mold for subsequent mass replication, or shaping the difficult to be machined alloys for applications in aerospace, chemical, oil and gas, or medical industries.

While complicated contour of a macrocomponent can be formed by moving a specially shaped electrode on a controlled path, micro patterns can be fabricated using though-mask ECM technique. Rosset and Landolt[135] experimented with through-mask ECM on 304 stainless steel and Phynox cobalt alloy. A 6M $NaNO_3$ electrolyte was used with DC current density between 0.5 and 15 A cm^{-2}. The undercut underneath a mask was measured to be a linear function with feature depth. The undercut to depth ratio (etch factor) was 0.7 and proximity effect was experimentally found. The highest MRR was for the area with the lowest density of mask opening. This proximity effect was reduced and more uniform etching was obtained by integrating a thin cathodic layer on an insulating mask. Although minimum undercut was obtained, the elliptical profile of etched feature was far from an ideal anisotropic profile with straight walls and flat bottom.

An ECM simulation using moving boundary numerical technique was reported.[136] The study investigated shape evolution of a thin metal film sandwiched between a photoresist mask and an insulating support. Diffusion controlled ion transport prevailed in this case and the profile started as an ellipsoid then approached shape of a hemisphere for a round opening or hemicylinder for a slot opening on the mask. Mass transfer mechanism dominated in a very thin resist opening. With a resist thickness of 8% of an opening, the etched profile varied along the center to underneath a mask and the deepest

part was found near the mask edge due to the highest current distribution location. The etch factor varied from 1.45–1.8 depending on the mask opening. Experimental data for 304 stainless steel etched with a DC current density of 3 A cm^{-2} agreed with the simulation data. Similar semi spherical profiles were reported when ECM of titanium in NaBr, HF solutions, or mixture of H_2SO_4 and methanol solution using DC voltages in the range 2–8 V.[137]

Few researchers used high-frequency pulsed DC instead of DC current to investigate the ECM profiles. Kenney and Hwang[138] modeled an ECM cell as RC circuit to study the current response and distribution when using ultrashort pulses (50 ns on-time, 450 ns off-time). The polarization voltage was constant under the electrode, but then tapered away from the edge as predicted due to the exponential decay as seen in the Tafel equation. Assuming a Ø10 μm cylindrical tool advancing into the workpiece, an electrolyte with resistivity of 70 Ωcm, and a substrate double layer capacity of 10 μF cm^{-2}, the simulated hole profile was flat at the bottom, but with tapered side walls and rounded corners at the entrance and bottom. Pulsed DC was also applied to form micro arrays on 304 stainless steel.[139] Square pulses (50–500 kHz, 50% duty cycles) were applied to the system to produce currents in the range 100–400 mA. The cylindrical electrode was surrounded and submerged in a column of electrolyte (30 g L^{-1} or 0.35 M $NaNO_3$) flowing at a constant flow rate of 143 mL min^{-1}. The undercut (under a mask) was significant below the electrode center, but its magnitude reduced linearly and practically none at a distance of three electrode radius away. Kozak *et al.*[140] applied ultrashort pulses of 0.005 ms–5 ns (0.2 MHz–0.2 GHz) on tool steel and 440 stainless steel under 10% $NaNO_3$ electrolyte. Profiles of ECM micro slots, holes, grooves were affected not only by the electrical parameters but also the flow direction of electrolyte. Since the profile slope was proportional to current density of the electrode, a low voltage (resulting in low current and current density) and small electrode gap were recommended for sharper profiles. Similar results were also experimentally verified, i.e., high-frequency ECM improved the profile shapes and surface finish but at lower MRRs.[141,142]

1.11.6.2 Micro/Nano Polishing

The ECM process can be modified to polish a surface. Such electrochemical polishing (ECP) technique was demonstrated to effectively polish channels that were micromilled on 316L and titanium plates. Mirror-like microchannels were resulted from polishing in an alcohol-based electrolyte at two-level current densities. The differences in crystalline orientations, etching rates on each grain, and impurities in grain boundaries contributed to variance in surface finish data; the average surface finish of polished specimens was about 300 nm on a large polycrystalline surface, and few nanometers within a single grain.[143] **Figure 19** below shows the grain boundary between two adjacent titanium grains after ECP. It is obvious that the polishing rate depends on crystalline orientation on each grain.

1.11.6.3 Deburring

Deburring is another application of ECM. Consider a string of burr along the edge of a machined surface, a burr is modeled as an absolute sine wave. The total volume of burr can be shown to be:

$$V_L = \frac{bL}{D}\frac{\pi h^2}{2}\int_0^{P/2}\sin^2\left(\frac{2\pi x}{P}\right)dx \qquad [2]$$

where

V_L: burr volume along a length L,
b: number of burrs under the tool,
D: electrode diameter,
h: maximum burr height,
P: burr period.

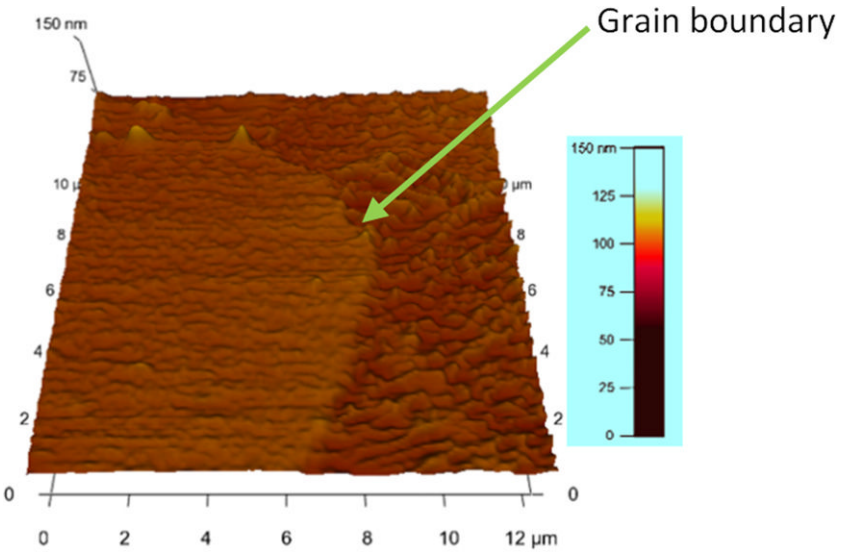

Figure 19 Atomic force microscopic image of adjacent polished titanium grains. 12 × 12 μm area, surface finish 42 nm R_{rms} across grains, and 1–10 nm R_{rms} within a grain.[143]

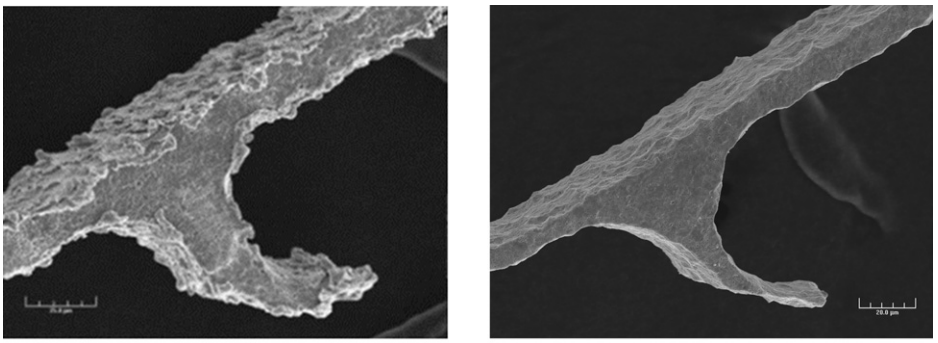

Figure 20 Copper alloy microcomponent (a) after EDM and before ECM, and (b) after ECM deburring using 0.5 mm diameter electrode, 50 KHz, and sodium based electrolyte.

The ECM process removes a volume of material in a single pulse according to Faraday's and Ohm's laws:

$$V_u = \int_0^{\tau} \frac{CEA\mathrm{d}t}{gr} \quad [3]$$

$$C = \frac{100}{F\sum_i \left(\frac{x_i z_i}{A_i}\right) \frac{100}{\sum_i \left(\frac{x_i}{\rho_i}\right)}} \quad [4]$$

where

V_u: volume of burr removed by a single pulse,
F: Faraday's constant = 96,500 C mol $^{-1}$,
E: voltage,
A: electrode area,
A_i : atomic weight of element i,
t: time,
g: interelectrode gap,
r: electrolyte resistivity,
x_i: element percentage,
ρ_i: density of element i,
τ: pulse on-time.

MRR for each pulse is simply:

$$MRR = \frac{V_u}{\tau} \quad [5]$$

Polishing time can be estimated by calculating the number of pulses and pulse frequency. The number of pulses to remove burrs along a distance L is:

$$N = \frac{V_L}{V_u} \quad [6]$$

Figure 20 compares a micropart before and after deburring by ECM. In fact, ECM is the only technique that can effectively remove burrs on micropart. It would be a challenge, however, when the part has internal burr that cannot be accessed with an electrode.

1.11.7 Summary

Micromachining techniques play an important role in product miniaturization. This chapter presents common micromachining techniques for semiconducting materials (bulk and surface micromachining) and for engineering materials (traditional and nontraditional micromachining).

The bulk micromachining can produce structures inside a substrate while surface micromachining can fabricate structural thin films on a sacrificial layer for semiconducting industry.

The tool based traditional processes (micromilling and microdrilling) and nontraditional processes (micro EDM, micro ECM, ion/electron/laser beam), degenerated from macroscale machining processes, are more popular to produce microcomponents in aerospace, transportation, oil & gas, and medical industries. The combination of these techniques not only allows fabrication of a single component, but also fabrication of microtools, microscale mold/die for mass producing of other microcomponents.

Although micromachining methods have been developed, a rapid implementation of micromanufacturing techniques, however, is hindered by lack of metrology and assembling techniques to effectively provide feedback to the fabrication line.

1.12.1 Introduction

Laser machining processes are the demanding focus areas of the materials and manufacturing disciplines. Lasers are considered to be the advanced material processing tools filling the gap in the advanced manufacturing systems because of their precision, low cost, localized processing, and high speed of operation. In laser machining applications, a laser beam is used as a heat source increasing temperature rapidly to the melting and evaporation temperature of the substrate material. Since the arrangements of the optical setting for the laser beam are very precise, the localized heating can be controlled easily. With recent advancement in laser technology and computations power, laser machining application has become almost an integral part of the aerospace, power, electronics, and sheet metal forming industries. However, in laser machining operations, the physical processes are complicated and they require deep understanding of process to secure improved end product quality.

Laser machining can be categorized into two groups based on the type of processing associated with the machining such as drilling, cutting, welding, alloying, and others. The laser processing can be involved with pre or posttreatment operations such as duplex treatment for coatings and scribing after coatings. In laser processing, material removal from the irradiated substrate material is critical to define the machining operation. For example, in laser drilling and cutting processes material removal from the irradiated region is essential to complete machining operation. On the other hand, laser-induced bending and laser annealing processes, control melting takes over the mass removal from the irradiated surface. However, laser welding falls in between these categories. Material removal is essential for deep penetration welding while control melting is necessary for thin substrate welding. In general, material removal and melting processes are involved with high intensity laser irradiation. Interaction of high intensity laser beam with solid surfaces results in evaporation at the surface. If the laser beam diameter at the irradiated surface is smaller than the thickness of the workpiece and the peak intensity is the highest at the irradiated spot center, one dimensional analysis for the surface evaporation becomes possible. In this case, the assumption of energy balance at the surface yields the steady analysis of the heating process, which provides useful information on temperature rise and the recession front velocity. On the other hand, the transient analysis gives detailed information on temperature raise in the irradiated region.

 doi:10.1016/B978-0-12-803581-8.09157-8

In machining applications, laser–workpiece interaction is involved with phase change at the irradiated surface; in which case, the substrate material undergoes a solid heating, melting, and subsequent evaporation at the surface. In the case of high intensity heating with short pulse durations, irradiated surface solid heating and melting takes place in a short duration and evaporation becomes the main phase change process at the surface. In addition, latent heat of melting is much smaller than enthalpy of evaporation, evaporation can be considered to be the major phase change mechanism at the irradiated surface. Allowance of existing of a vaporizing front requires that the temperature gradient at the surface be positive. Phase change process at the surface can be modeled analytically after considering the equilibrium heating situation at which the Fourier heating law is applicable. Laser-induced evaporation process is examined for different laser pulse types and they are given under the appropriate headings.

In order to optimize the laser machining process and reduce the experimental time and cost, the model studies receive considerable attention. In addition, the model studies give insight into the physical processes that take place during the heating process and being easier to accomplish as compared to experimental studies. The measurement of physical properties during laser–workpiece interaction is difficult and costly since, the process is involved with high temperature, short duration, and localized heating. From the modeling point of view, the laser machining can be classified into two categories: (1) laser conduction limited heating and (2) laser nonconduction limited heating. In the laser conduction limited heating situation, substrate surface is heated up to the melting temperature of the substrate material; in this case, substrate remains in the solid state during the process. One of the laser conduction limited applications is the laser quenching of the surfaces. In the laser nonconduction limited heating situation, substrate surface undergoes a phase change during the processing, i.e., melting and subsequent evaporation is resulted. The laser drilling, cutting, and welding are typical examples of laser nonconduction limited heating situation.

Laser drilling, cutting, welding, bending, and surface treatment processes have made significant headway into the well-established area of sheet metal industry. This is due to its low operational cost and high precision. When a high intensity laser is directed onto a metal surface, heating, melting, and evaporation of the substance occur, therefore, conduction, phase change, and convection processes are resulted. To enhance understanding of laser–workpiece interaction mechanism, the study into laser-induced heating and subsequent material removal initiating the laser drilling process is necessary. In industrial application of laser machining, the quality of machined parts is the important factor. The quality of the laser machined parts can be judged by geometric features of the machined sections such as internal form, taper, striations, dross attachments, and heat-affected zone. Consequently, the levels of the machining parameters resulting in geometries with small asperities, such as less taper, parallel-sided walls, small out of flatness, without forming striations, are needed to be identified. The laser and workpiece material parameters affecting the laser machining include laser output energy, pulse length and frequency, focus setting of focusing lens, ambient pressure, scanning speed, and workpiece thickness. The optimum performance in laser machining depends on the proper selection of these factors. However, with many variables and incomplete information of the relationship between them, a statistical method is fruitful to design an experiment and analyze the results accordingly. In addition, factorial experimental design methods are more secure basis and make the identification of controlling factors and interactions possible with reasonable accuracy.

In this chapter, in-depth understanding of laser machining processes, advantages, and limitations of the process parameters are to be presented. The main focus of laser machining is to cover the laser drilling, cutting, welding, and bending processes. Each of the processes is treated under the appropriate subheadings and the findings discussed in line with the previous studies.[1–7]

1.12.2 Laser Drilling

One of the important laser applications is the laser drilling. Laser drilling involves with solid heating, phase change (melting and subsequent evaporation), plasma formation, and vapor/melt ejection from the irradiated region. In laser drilling, laser pulses with millisecond pulse lengths are favorable because of the melt ejection from the irradiated surface. As the laser pulse reduces, melt ejection replaces with the surface evaporation and ablation. This is the case when the required drilled hole size becomes small and hole depth is shallow. In the present section, laser drilling into steel sheet is to be presented in line with the previous study.[1–3]

In laser drilling process one of the concerns is to reduce the drilling duration and minimize the geometric defects associated with the hole geometry. This situation was investigated by Yilbas.[9] He demonstrated that the increasing laser energy and locating the focus position slightly above the workpiece surface increased the mean hole diameter. Taneko *et al.*[8] examined laser hole drilling into electronic components and the findings revealed that the use of high peak pulsed CO_2 laser improved the drilling quality. The parametric analysis based on the statistical assessment of laser drilled hole quality was carried out by Yilbas.[9] He showed that main effects of laser drilling parameters and their interactions had significant effects on the hole geometry. A comprehensive study for the beam waist position and the hole formation in laser drilling process was introduced by Yilbas and Sami.[10] They demonstrated that altering the beam waist position resulted in converging and diverging hole walls for negative and positive positions, respectively. Furthermore, Yilbas[11] investigated the laser hole drilling into various metals. He showed that the parameter, almost for all cases, the most affecting parameter was the workpiece thickness.

In laser hole drilling process, thermal analysis provides useful information on the physical insight into the process. Since the heating is involved with melting and evaporation, the heat transfer analysis employing a phase change process in the region irradiated by a laser beam needs to be considered. However, when the laser–workpiece interaction time is comparable to the heating time of the substrate material (10 ps), the nonequilibrium energy transport dominates the heating process. The Fourier heating model over-estimates the lattice site temperature rise during the short interaction period. On

the other hand, as the duration of heating extends to nanoseconds or milliseconds, the equilibrium energy transport occurs inside the metallic substrates during the heating period. Consequently, the Fourier heating model becomes appropriate to describe the physical process that takes place during the nanosecond heating durations.

In most of the laser drilling applications, the laser beam power intensity can be approximated to a Gaussian profile. Therefore, in the analysis, a Gaussian power intensity distribution of a laser beam with its spot center at the center of the coordinate system is considered. This gives rise to an axisymmetric heating of the substrate material. As the temperature reaches the phase change temperatures of the substrate material during the heating process, the phase change is considered i.e., melting and subsequent evaporation of solid substrate should be introduced in the governing equation of heat transport with appropriate boundary conditions. During the solid heating (prior to the phase change), the conduction heating of the solid substrate with insulated boundary condition at the surface can be considered. This consideration minimizes the complication involved with the analysis. Therefore, the transient heat transfer equation for a solid substrate irradiated by a laser beam with a Gaussian intensity profile can be written as:

$$\rho_s Cp_s \frac{\partial T}{\partial t} = k_s \frac{\partial^2 T}{\partial z^2} + \frac{k_s}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right) + I_o(1-r_f)\delta \exp(-\delta z)\exp\left(-\frac{r^2}{a^2}\right) \quad [1]$$

where, I_o, δ, r_f, and 'a' are the laser peak power intensity, absorption coefficient, reflectivity, and the Gaussian parameter, respectively. The initial condition is:

At time $t \to 0$ $T(r,z,0) = T_o$ (specified)

The boundary conditions are

$$z = \infty \to T(r,\infty,t) = T_o$$
$$r = \infty \to T(\infty,z,t) = T_o$$
$$r = 0 \to \frac{\partial T(0,z,t)}{\partial r} = 0$$
$$z = 0 \to \frac{\partial T(r,0,t)}{\partial z} = 0$$

During the phase change process, it is assumed that the substrate material has single melting and boiling temperatures, i.e., when the substrate material reaches the melting or evaporation temperatures, the phase change takes place at a constant temperature. To describe the energy transfer during a phase change process, an energy or enthalpy methods can be used. In the case of enthalpy method, the governing equation of energy transport can be written in terms of enthalpy equation. Moreover, once the phase change occurs, a mushy zone (partially solid and partially liquid or partially liquid and partially vapor) is generated across the region where the phase change takes place. Consequently, when formulating the phase change problem, consideration is given for the generation of a mushy zone. In this case, during the phase change process, temperature of the substrate material remains same, but it's enthalpy changes. In order to formulate the problem the following approach is introduced, namely the energy method. Consider a differential element in a substrate material, which is subjected to a melting process and let x_m be the mass fraction of liquid present in the element, then the energy content ΔU of the differential element with volume ΔV at melting temperature T_m can be written as:

$$\Delta U = \rho_m \Delta V[x_m(L_m + Cp_m(T_m - T_{ref})) + Cp_s(1-x_m)(T_m - T_{ref})] \quad [2]$$

where

$$x_m = \frac{m_m}{m_m + m_s}$$

T_{ref}, x_m, m_m, m_s are reference temperature for enthalpy, quality of liquid, mass of liquid, and mass of solid in the element, respectively. After assuming specific heat of melt is the same as solid at melting temperature ($Cp_s = Cp_m$ at $T = T_m$), then above equation reduces to:

$$\Delta U = \rho_m \Delta V[x_m L_m + Cp_m(T_m - T_{ref})] \quad [3]$$

For a unit volume, it reduces to:

$$\frac{\Delta U}{\Delta V} = \Delta u = \rho_m\left[x_m L_m + Cp_m(T_m - T_{ref})\right] \quad [4]$$

Differentiation with time yields:

$$\frac{\partial u}{\partial t} = \rho_m L_m \frac{\partial x_m}{\partial t} \quad [5]$$

since $Cp_m(T_m - T_{ref})$ is constant.

Substituting eqn [5] into eqn [1] gives the energy equation for the differential element subjected to a phase change process:

$$\rho_m L_m \frac{\partial x}{\partial t} = k_m \frac{\partial^2 T}{\partial z^2} + \frac{k_m}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right) + I_o(1-r_f)\delta \exp(-\delta z)\exp\left(-\frac{r^2}{a^2}\right) \quad [6]$$

Equation [6] is applicable for the differential elements (cells defined by nodes in the substrate material) when temperature becomes the same as the melting temperature of the substrate material ($T = T_m$) and $x_m \le 1$, i.e., a mushy zone. Consequently, temperature of the cells with $0 \le x_m \le 1$ is set to the melting temperature ($T = T_m$). When the value of x_m exits 1 ($x_m > 1$) eqn [6] is not applicable for the differential element under consideration. In this case, eqn [1] is used to determine the temperature rise in the liquid heating with the liquid thermal properties employed, i.e., the liquid heating initiates and continues until the boiling point is reached.

When the boiling point is reached, the mushy zone consideration needs to be implemented. In this case, eqn [6] can be modified for a differential element, which is subjected to boiling, i.e.:

$$\rho_b L_b \frac{\partial x}{\partial t} = k_b \frac{\partial^2 T}{\partial z^2} + \frac{k_b}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right) + I_o(1-r_f)\delta \exp(-\delta z)\exp\left(-\frac{r^2}{a^2}\right) \quad [7]$$

Equation [7] is applicable for the range $T=T_b$ and $0\le x_b\le 1$ in the mushy zone (partially liquid partially vapor zone). Consequently, temperature of the cells with $0\le x_b\le 1$ is set to boiling temperature ($T=T_b$). It should be noted that x_m is replaced with x_b, which represents the fraction of vapor phase in the differential element.

The boundary condition at the evaporating surface is introduced in relation to eqn [7]. In this case, the temperature along the evaporated surface is kept at boiling temperature, i.e., the cells in the evaporated region are kept at boiling temperature, i.e.:

$$z=z_b\rightarrow T(r,z_b,t)=T_b$$

where z_b represents the axial location at the evaporated surface.

Equations [6] and [7] determine the relative position of solid–liquid and liquid–vapor interface in the substrate material. The liquid–vapor interface determines the shape and size of cavity generated after the evaporation process.

Equations [1], [6], and [7] can be made nondimensional through introducing the following dimensionless parameters:

$$r^*=r\delta : z^*=z\delta : a^*=a\delta; t^*=\alpha_i\delta^2 t : T^*=\frac{Tk_o\delta}{I_o}$$

where k_o represents the thermal conductivity at standard temperature. After introducing the dimensionless parameters, eqns [1], [6], and [7] yield:

$$\frac{\partial T^*}{\partial t^*}=\frac{\partial^2 T^*}{\partial z^{*2}}+\frac{\partial}{\partial r^*}\left(r^*\frac{\partial T^*}{\partial r^*}\right)+\exp(-z^*)\,\exp\left(-\frac{r^{*2}}{a^{*2}}\right) \quad [8]$$

$$\frac{\alpha_m\delta\rho_m L_m}{I_o}\frac{\partial x_m}{\partial t^*}=\frac{\partial^2 T^*}{\partial z^{*2}}+\frac{\partial}{\partial r^*}\left(r^*\frac{\partial T^*}{\partial r^*}\right)+\exp(-z^*)\,\exp\left(-\frac{r^{*2}}{a^{*2}}\right) \quad [9]$$

$$\frac{\alpha_b\delta\rho_b L_b}{I_o}\frac{\partial x_b}{\partial t^*}=\frac{\partial^2 T^*}{\partial z^2}+\frac{\partial}{\partial r^*}\left(r^*\frac{\partial T^*}{\partial r^*}\right)+\exp(-z^*)\,\exp\left(-\frac{r^{*2}}{a^{*2}}\right) \quad [10]$$

The initial and boundary conditions for eqns [8]–[10] are also nondimensionalized in a similar fashion.

Temperature distribution inside the substrate material is obtained solving the eqns [8]–[10] with the appropriate temperature ranges and boundary conditions.

1.12.2.1 Experimental Method

An Nd: YAG laser delivering energies in between 10–21 J within 1.48 ms pulses was used to irradiate the workpiece while nominal focal length of 51 mm lens was used to focus the laser beam on to the workpiece surface. The mode of laser beam was TEM_{00} and small variation in temporal distribution of the laser power intensity was observed after the each pulses. A vacuum cell was designed and was built to locate the workpiece and regulate the assisting ambient gas pressure during drilling. The optical microscopy and scanning electron microscopes are used to assess the geometry of the hole.

1.12.2.2 Hole Quality Assessment

The affecting parameters considered are laser output energy, focus setting of focusing lens, pressure of drilling ambient, and the workpiece thickness. The hole quality is assessed on the basis of rating the relevant features of the hole geometry. In this case, the hole geometry with minimum geometrical imperfections has received the highest score in the ranking scheme. A statistical analysis based on factorial design is introduced to determine the most effective parameters and level of their effects, i.e., factorial analysis for the quality assessment of the hole geometry.

1.12.2.2.1 Evaluation of hole geometric features

A schematic view of a typical laser drilled hole cross-section is shown in **Figure 1**. The hole geometry was described on the basis of seven features and judged overall by assigning to each feature a mark scored out of weighted maxima, and summing these scores. The features of the hole geometry and the marking scheme are listed below:

Resolidified material: Marks are assigned out of 10 according to the fraction of resolidified material to hole size, i.e., a score of 10 represents no solidification around the hole and 1 corresponds to resolidified material almost block the hole.
Taper: The taper angle, as shown in **Figure 1**, is measured without considering the inlet and exit cone angles. A mark of 0 indicates taper of 90° and 4 corresponds to a parallel-sided hole.
Barreling: The marks are assigned in between 0–4. A mark of 4 represents a straight hole while 0 indicates an even hole.
Inlet cone angle: It is measured as ratio of cone angle to 180°. A mark of 1 indicates no inlet cone and 0 corresponds to a cone angle of 180°.
Exit cone angle: In general, the exit cone is small in size and difficult to measure with accuracy. Therefore, marks are given through visual inspection and mark of 1 indicates no exit cone while 0 represents a large cone angle.

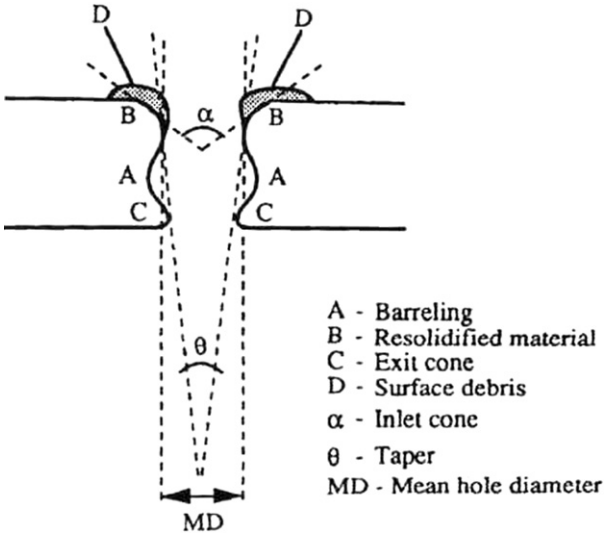

Figure 1 A schematic view of hole drilled.

Surface debris: This is assessed according to the amount of material resolidified at the surface of the workpiece near to the hole circumference. A mark of 1 is given with no or very small amount of surface debris and mark of 0 is assigned with large amount of surface debris.
Mean hole diameter: The mean hole diameter is measured under the microscope and the maximum value of mean hole diameter among all holes is considered and a mark of 3 is assigned. The minimum hole diameter is given a mark of 1.
Overall quality: The overall quality of the drilled hole is obtained summing the all marks assigned each hole feature, i.e.:

$$q = \mathrm{Re} + Ta + Ba + Ec + Ic + Sd \quad [11]$$

where q, Re, Ta, Ba, Ec, Ic, and Sd are marks of overall quality, resolidification, taper, barreling, exit cone, inlet cone, and surface debris, respectively. Moreover, for blank holes a mark of 3 is subtracted from the overall quality.

1.12.2.2.2 Factorial analysis

The qualitative and quantitative analyses are carried out. Four factors at four levels are considered, which are given in **Table 1**. The results and discussion related to the factorial analysis are given under the appropriate headings.

1.12.2.2.2.1 Qualitative analysis

The mathematical expression representing the factorial design can be expressed as:

$$X_{i,j,k,l} = P_i - F_j - E_k - T_l - P_iF_j - P_iE_k - P_iT_l - F_jE_k - F_jT_l - E_kT_l - P_iE_kF_j - P_iE_kT_l - F_jE_kT_l - \varepsilon_{ijkl} \quad [12]$$

where X_{ijkl} is the response (value given to the hole features), P_i, F_j, E_k, T_k are the main effects of pressure, focus settings, laser output energy, and workpiece thickness, P_iF_j, P_jE_k, P_iT_l, F_jE_k, F_jT_l, E_kT_l, $P_iE_kF_j$, $P_iE_kT_l$, $F_jE_kT_l$ are the first and second order interactions of selected factors, and ε_{ijkl} is the random error in the experiment provided that i, j, k, l represent the levels of pressure, focus settings, laser output energy, and thickness respectively. It should be noted that:

$$P_ixF_j = F_jxP_i$$
$$P_ixF_jxE_k = F_jxP_ixE_k$$

The above argument is valid for all the other interactions.

To calculate the main effects of each factor and the effects of interaction, it is necessary to determine the mean corrected sum of squares of response at all levels of factors. However, the mathematical arrangements of qualitative analysis are not given here, but it is referred to Ref.[12]

Table 1 Parameters and their levels employed in the experiment

Pressure (mm Hg)	*Focus setting (mm)*	*Laser output energy (J)*	*Thickness (mm)*
150	50	15	0.6
250	50.5	17	0.8
350	51	19	1.0
760	51.5	21	1.2

The significance of the effect of factors and interactions is tested by making the initial hypothesis that the mean squares of the effects or interactions are from the same populations as the error mean square, which is that all the mean squares are on a comparable basis with respect to error variance. It should be noted that the mean squares of effects and interactions are linear functions of observation. Since there are no repeats, the remainder mean square are representing the higher order interactions being used as an estimate of the error variance to test the significance of the effects calculated by means of the *F*-test.[12] The mean square of the effects is determined by dividing the corrected sum of squares by an appropriate number of degrees of freedom. In this case the variance ratio is:

$$F_{r,s} = \frac{\text{Mean sum of squares}}{\text{Error mean sum of squares}} \quad [13]$$

where r and s are the degrees of freedom of the mean sum of squares and the error mean sum of squares, respectively.

If the calculated variance ratio of any effect exists in the value in the *F*-test table[12] at corresponding r and s degrees of freedom, the effect is significant at that level.

1.12.2.2.2.2 Quantitative analysis

A quantitative factor is a factor for which the levels may be represented in terms of continuous points. The effect of such a factor is a mathematical function of the levels of the factor. This can be written in a polynomial form[12] as:

$$X = a_o\gamma + a_1\gamma^2 + a_2\gamma^3 + \ldots\ldots\ldots\ldots + a_n\gamma^{n+1} \quad [14]$$

where X is the response, γ is the level of factor, and n is the number of levels selected. The coefficients in the polynomial equation are estimated by the least square technique. Since four levels were selected, the values of the orthogonal coefficients are given in **Table 2** where η and γ are the sum of squares of the coefficients and a scale factor, respectively. The actual values of the constants in the orthogonal form of the polynomial are derived from $\Sigma\beta'X$, $\Sigma\gamma'X$, $\Sigma\delta'X$ multiplying the corresponding quantity of η/γ.[12] However, during the calculations of the variances, it is convenient to drop the multiplier γ/η, which is needed only to be introduced when the actual numerical values of the constants are required.

1.12.3 Laser Cutting Process

High power lasers are widely used to cut and shape the sheet metals with desired sizes. However, laser cutting process requires proper selection of cutting parameters such that the process parameters are adjusted and tuned to provide the quality of cut desired. However, this consumes considerable

Table 2 Orthogonal coefficients of polynomial equations

	Y_1	Y_2	Y_3	Y_4	η	γ
Linear	−3	−1	1	3	20	2
Quad.	1	−1	−1	1	4	1
Cubic	−1	3	−3	1	20	10/3

amount of time and effort, and still the optimal cutting parameters may not be found. If a different substance is used for cutting, all these parameters may require readjustment. This has been recognized as a major shortcoming, and this problem of optimized process planning is currently been addressed.[13] Deficiencies in the cutting quality may be related to the slow process drifts and disturbances. The main reasons for this drift to occur may include velocity fluctuations, variation in power and spatial intensity distribution, and optical integrity perturbations. The formation of striations has received considerable attention, since it is closely related to the laser cutting quality.[13–15] Explanations given on striation are, in general, quantitative and some little work has been carried out on classification of striation patterns. In the model introduced by Schuocker,[16] an attempt was made to calculate the striation frequency, but the predictions are limited in its use for characterizing and predicting surface roughness or a striation depth, which is considered as an important parameter in judging the laser cut quality. However, the results predicted for striation frequency agreed well with the experimental data. Study into striation process was also carried out by Olsen.[17] Some explanation of striation and prediction of striation frequency was given in his study.

The preceding sections thermal analysis of laser cutting process and the quality assessment of cut sections are presented. The formulations and the findings are discussed in line with the previous studies.[4–6]

1.12.3.1 Experimental Method

The experiment was carried out to investigate the affecting parameters on the kerf width size during CO_2 laser cutting of mild steel. A CO_2 laser delivering a nominal output power of 2000 W was used. Oxygen as assisting gas was introduced coaxially with the laser beam through a nozzle. The oxygen pressure was set to 200 kPa.

After completion of the cutting process, the widths of resulting cut were measured and SEM microphotography of the cut surfaces was carried out. To measure the striation depths and widths, the surface roughness measurement was carried out using a Bendix stylus instrument.

1.12.3.1.1 Thermal analysis

The energy balance due to absorption of the incident beam results in localized heating in the region of the substrate surface. In laser beam cutting process, some fraction of the beam is reflected and transmitted, and the rest of the beam intensity is absorbed by the substance. Since the heating situation is slow, the consideration of the Fourier law is appropriate to formulate the thermal analysis in the heated region. In this case, a moving heat source supplied along the z axis and the source travels along the x axis at a velocity u, the energy equation can be written as:

$$U\frac{\partial T}{\partial x}+\frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}+\frac{\partial^2 T}{\partial z^2}=2\lambda\frac{\partial T}{\partial t} \qquad [15]$$

After assuming no heat convection at the surface, then the boundary conditions yield:

$$\frac{\partial T}{\partial x}=0 \quad \text{as} \quad x=\pm\infty$$
$$\frac{\partial T}{\partial y}=0 \quad \text{as} \quad y=\pm\infty$$

This may be rearranged with the source at the origin by making the transformation $\xi=x-Ut$ for the wave front travel in the positive x direction and $2\lambda=1/\alpha$ is used for convenience. On substitution gives:

$$\frac{\partial^2 T}{\partial \xi^2}+\frac{\partial^2 T}{\partial y^2}+\frac{\partial^2 T}{\partial z^2}=-2\lambda u\frac{\partial T}{\partial \xi}+2\lambda\frac{\partial T}{\partial t} \qquad [16]$$

If the solid is of sufficient length, the temperature distribution around the heat source becomes constant, i.e., $\partial T/\partial t=0$. Therefore:

$$\frac{\partial^2 T}{\partial \xi^2}+\frac{\partial^2 T}{\partial y^2}+\frac{\partial^2 T}{\partial z^2}=-2\lambda U\frac{\partial T}{\partial \xi} \qquad [17]$$

The solution of eqn [17] is straight forward[18] and it gives the solution of the temperature distribution in an infinite solid due to continuous line source of q (energy per unit length) is:

$$T=\frac{q}{2\pi kD}e^{\frac{ux}{2\alpha}}K_o\left(\frac{Ur}{2\alpha}\right) \qquad [18]$$

where r is the radial distance to the point being considered (satisfying $r^2=x^2+y^2$), k is the thermal conductivity, D is the thickness of the workpiece, and K_o is the modified Bessel function of second kind zero order. When laser heating is considered the heat flux per unit time becomes:

$$q_{laser}=(1-R_f)I_o \qquad [19]$$

where R_f is the surface reflectivity and I_o is the laser incident power intensity.

In the case of a gas assisted laser cutting process the contribution of exothermic chemical reactions to the heat transfer taking place at the liquid surface may be written as:[15]

$$q_{chem}=\rho_e u_e C_{H_c}\Delta I\left\{1+\left[\frac{C_{H_d}}{C_{H_c}}-1\right]\frac{h_c}{\Delta I}-\frac{B_3}{\Delta I}\right\} \qquad [20]$$

where

$$\Delta I=(I_f)_e-(I_f)_g+h_c$$

and $[(I_f)_e-(I_f)_g]$ is the enthalpy change at the interface due to the assisting gas and h_c is the total chemical reaction enthalpy which is defined as:

$$h_c=\sum_{i\neq E}(h_i)_g[(C_i)_g-(1+B_2)(C_i)_g]+(h_E)_g[B_2-(1+B_2)(C_E)_g] \qquad [21]$$

where B_2 and B_3 are:

$$B_2=B_3\frac{C_{H_c}}{C_{H_d}}$$

and

$$B_3 = \frac{(\rho u)_g}{\rho_e u_e C_{H_c}}$$

Equation [18] gives the heat transfer to the liquid metal due to chemical reactions and mass transfer occurring at the assisted gas–liquid interface when a reacting turbulent flow occurs over the liquid molten metal. The total heat flux available at the surface becomes:

$$q_{tot} = q_{laser} + q_{chem} \quad [22]$$

When the temperature of the surface reaches the melting temperature, melting isotherm develops at the surface, then the temperature of the melting isotherm can be obtained by rearranging eqn [16], i.e.:

$$T_m = \frac{q_{tot}}{4\pi kD} e^{\frac{ux}{2\alpha}} K_o\left(\frac{ur}{2\alpha}\right) \quad [23]$$

Introducing dimensionless coordinates as:

$$X = \frac{ux}{2\alpha}; \quad R = \frac{ur}{2\alpha}$$

Equation [23] yields:

$$T_m = \frac{q_{tot}}{2\pi kD} e^{X} K_o(R) \quad [24]$$

To determine the maximum melt width, rearrangement of eqn [20] is necessary. Using the previously introduced technique,[19] the resulting $X = \frac{ux}{2\alpha}$ for the maximum melt width becomes:

$$X = \frac{RK_o[R]}{K_1[R]} \quad [25]$$

where

$$K_o[R] = \frac{2\pi kDT_m}{q_{tot}} e^{\left[-\frac{RK_o(R)}{K_1(R)}\right]}$$

and $K_1[R]$ is the modified Bessel function of second kind first order.

Solution of eqn [25] gives the values of R for the cut width. Consequently, the maximum melt width ($Y_{\max}$) can be found from:

$$Y_{\max} = RSin\phi \quad [26]$$

where

$$\phi = Cos^{-1}\left[\frac{K_o(R)}{K_1(R)}\right]$$

To determine the area ratio of the total melted area to focused spot area, a geometric description of the focused spot and melted area should be considered (**Figure 2**). Assume that the maximum width of the melting isotherm lies outside of the focused spot. The total area of the focused spot removed is the shaded zone in **Figure 2**, which may be expressed as:

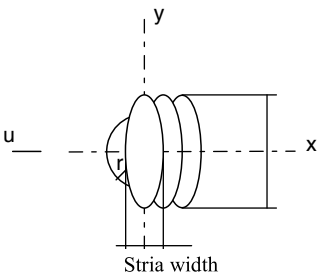

Figure 2 Laser cutting situation and stria width.

$$S_{tot} = S_1 + S_2 = r^2\phi + \frac{r^2 Sin\phi}{2} + 2\int_{X_1}^{X_2} Y\,dx \quad [27]$$

where

$$X_2 = \ln\left\{\frac{2\pi kDT_m}{q_{tot}} K_o[R]\right\}$$

and

$$\phi = Cos^{-1}\left(\frac{X_2}{r}\right)$$

Since,

$$Y = \sqrt{R^2 - X^2} = \left\{R^2 - \ln\left[\frac{2\pi kDT_m}{q_{tot}} K_o[R]\right]^2\right\}^{1/2} \quad [28]$$

and

$$dX = \frac{K_1[R]}{K_o[R]} dR$$

After rearranging eqn [28], it yields:

$$S = \frac{\phi}{\pi} - \frac{Sin2\phi}{2\pi} + \frac{2}{\pi r^2}\int_{X_1}^{r}\left\{R^2 - \left[\frac{2\pi kDT_m}{q_{tot}} K_o[R]\right]^2\right\}^{1/2} \frac{K_1[R]}{K_o[R]} dR \quad [29]$$

Consider **Figure 2**, the melted area may be approximated as an elliptic shape. Therefore, the striation width (w_k) can be calculated from:

$$w_k = \frac{S_{tot}}{2\pi\gamma_{\max}} \quad [30]$$

Consider the speed of melting isotherms penetrating into the workpiece; in this case assuming attainment of steady state at the surface and omitting the surface evaporation, the penetration speed can be written as:

$$v = \frac{q_{tot}}{\rho(L + CpT_m)} \quad [31]$$

The cutting parameters including nondimensional maximum cut width, area ratio, striation width, and penetration speed can be computed incorporating appropriate thermophysical properties of the workpiece.

1.12.3.2 Lump Parameter Analysis for Kerf Size

The overall energy balance in laser cutting process was simplified through introducing lumped parameter technique by Kar *et al.*[20] The simple scaling law states that the relationship is existed among the laser energy absorbed in a unit depth, convection, and conduction contributions of heat transfer and phase change. This yields the relation:[20]

$$\frac{P}{d} = \frac{vw_k + A_3\sqrt{vw_k}}{A_o} \quad [32]$$

where:

$$A_o = \frac{A}{a_o};\ A_3 = \frac{1}{a_o}\frac{(w_k + 2wk(T_mT_o))}{2\sqrt{\alpha w w_k}} \quad \text{and} \quad a_a = \rho[Cp(T_m - T_o) + L_m + \beta L_b]$$

The term 'A_o' is related to energy transfer rate to the workpiece at the surface during laser–workpiece interaction. 'A' is the effective energy coupling factor at the workpiece surface, and 'A_3' is related to energy loss due to conduction in the solid. β is the fraction of evaporation contribution at the workpiece surface.

Using the scale law, the kerf width can be written in a simplified form for a circular laser beam with a beam waist size of w as:[20]

$$w_k = \frac{1}{v}\frac{\left[2.51\sqrt{\frac{\alpha}{w}}\frac{2A\eta_u}{k(T_m - T_o)}P\sqrt{v}\right]}{\left[1 + 3.08\times 10^8 \frac{A_o}{A_3\sqrt{f}}\frac{\rho\rho_g\sigma^2\alpha}{M_w P_g f\sqrt{w}}P\sqrt{v}\right]} \quad [33]$$

where 'f' is the fraction of the pressure drop in the kerf, σ is the molecular diameter (Angstrom unit), M_w is the molecular weight (gr mol^{-1} unit) of the assisting gas, P_g and ρ_g are the pressure and density of the assisting gas, and η_u is the superheating factor in the melt pool.

Equation [33] is used to determine the kerf width while energy coupling factor (A), laser power (P), and cutting speed (v) are considered as variables in eqn [33]. The material properties in the computations are given in **Table 3**.

Table 3 Properties of the workpiece used in the computations

Properties	*Values*	*Units*
Boiling temperature	3133	K
Density of assisting gas	1.97	Kg m^{-3}
Density of workpiece	7880	Kg m^{-3}
Fraction of evaporation contribution ($0<\beta<1$)	0.1	–

1.12.3.3 Cut Quality Assessment

The cut quality assessment is based on the factorial analysis. The analyses pertinent to cut quality assessment are given under the appropriate subheadings.

1.12.3.3.1 Evaluation of cut quality

The cut quality may successfully be evaluated in terms of waviness, flatness (**Figure 3**), and metallurgical changes at cut surface and overall quality provided that the assessment for the cut quality is based on the international standards for thermal cuts (DIN2310). Height of waviness and flatness were measured with a reading microscope in mm units while elemental analysis at the cut edge was carried out using EDS technique. To determine the overall quality of cut, scores are assigned to waviness, flatness, and metallurgical changes. The scoring scheme includes:

1. Waviness (D): $D\leq30$ μm score of 3; $30\leq D\leq60$ μm score of 2; $D\geq60$ μm score of 1 are assigned.
2. Flatness (F): $F\leq20$ μm score of 3; $20\leq F\leq40$ μm score of 2; $F\geq40$ μm score of 1 are assigned.
3. Metallurgical changes (Mm): When no degradation and/or degradation of less than 1% is resulted in any element at the cut surface a score of 1 is assigned or/else a score of 0 is assigned.

The overall quality is then defined as:

$$Q_{\text{overall}} = D + F + Mm \quad [34]$$

1.12.3.3.2 Factorial analysis

To determine the significance levels of the cutting parameters a statistical analysis was carried out. To analyze the effect of laser cutting parameters on the resulting cut quality (measurable variables of waviness, flatness, metallurgical changes at cut surface, and overall quality), it was necessary to design an experiment in such a way that the influence of each parameter

could be examined individually and an interaction. This required a complete factorial design in which selected factors are varied at appropriately selected levels. It should be noted that in qualitative analysis, main effects are zero order effects, i.e., independent of each other. However, first order interactions demonstrate that the effects of the interacted factors on observation are dependent on each other.[12]

The factors affecting the cut quality may include cutting speed, assisting gas pressure, workpiece thickness, and laser pulsing frequency. An *F*-test was conducted to identify the significant effects of the parameters and their interactions on the various observations describing the cut quality. The terms most significant, very significant, and significant refer to minimum correlation levels of 0.99, 0.99 to 0.95, and 0.95 to 0.90 of the factors, respectively.

1.12.4 Laser Bending

One of the laser machining applications can be considered as the laser bending. The bending process differs slightly from the laser welding such that laser forming requires shallow depth of phase change at the surface while laser welding requires deep penetration of the laser beam into the substrate material. From the heating point of view, the irradiated surface undergoes solid heating and melting following the solidification for the forming process. Since laser heating and phase change process is almost rapid, the high cooling rates is resulted during the solidification of the melted regions. This causes attainment of high temperature gradients across the irradiated zone while increasing the thermal strain in this region. Depending on the magnitude and the nature of the residual stress generated, compressive or tensile, bending of irradiated substrate takes place toward or opposite to the irradiated surface of the workpiece. Since the laser heating and cooling processes are rapid, the size of the heat affected zone becomes narrow, which in turn provides advantages of the local treatment by a laser beam. In some cases, the formation of high residual stress results in crack formations in the bended region while limiting the practical use of the bended parts.

Jamil and Sheikh[21] studied laser bending of sheet metals and effect of laser beam geometries on the bending angles. They demonstrated that temperature dependent properties of the sheet metal were more crucial than the laser beam geometry in terms of the resulting bending angles. The simulation study for laser bending angle of sheet metals was carried out by Peng and Hongwei.[22] They showed that dimensional analysis was an effective method for predicting the bending angle accurately. The laser bending of preloaded sheet metals was investigated by Yanjin *et al.*[23] They indicated that the bending angle of the sheet metal increased considerably with the increased of the preloading. Laser bending of sheet metals was examined by Shichun and Jinsong.[24] They demonstrated that there was significant influence of the sheet thickness on the bending angle. Laser bending of circular sheet metal was examined by Nadeem and Na.[25] They introduced the scheme to achieve the geometrical transition from rectangular to ring shapes via laser controlled heating. The residual stresses development in laser bending of stainless steel sheet metal was studied by Gheorghies *et al.*[26] They indicated that the effect of multiple scans was difficult to simulate due to the complications involved when incorporating the material annealing during forming. Laser forming and bending processes were investigated by Yongxiang *et al.*[27] They demonstrated that a continuous decrease in bending angle from concave to convex took place with increasing workpiece thickness.

In this section, some aspects of laser bending are to be provided and the findings are discussed in line with the previous study.[28]

1.12.4.1 Experimental

The CO_2 laser (LC-ALPHAIII) delivering nominal output power of 2 kW is used to irradiate the workpiece surface. The nominal focal length of the focusing lens is 127 mm. Nitrogen assisting gas emerging from the conical nozzle and coaxially with the laser beam is used. The use of nitrogen as an assisting gas is due to its cost and higher specific heat capacity as compared to that of argon. The laser treatment conditions are given in **Table 4**.

The workpiece used is AISI 304 steel sheet at 1 mm in thicknesses. The morphological changes at the kerf surfaces were examined using Jeol 6460 electron microscopy. The XRD analysis was carried out incorporating Bruker D8 Advanced XRD unit with having Cu–Kα radiation. A typical setting of XRD was 40 kV and 30 mA. The parabolically-shaped Göbel Mirror was used in Bruker D8 Advanced, which provided the highly-parallel X-ray beams. The parallel beams from it removed the traditional limitations of the Bragg–Brentano geometry for powder diffraction and thin film investigations.

1.12.4.2 Mathematical Analysis

Laser heating situation is involved with a moving volumetric heat source scanning the workpiece surface as depicted in **Figure 4**.

In the numerical solution, the user subroutine DFLUX in ABAQUS[14] is used to introduce the volume flux described by eqn [1]. The subroutine first calculates the position of the laser beam according to the scanning time, *t*, and then computes the heat flux, *Q*, at each integration point. The Gauss parameter '*a*' is taken as 0.0003 m and velocity of 10 cm s^{-1} is used in line with the experimental conditions.

In the thermal analysis, the solid body heat conduction and phase change with temperature-dependent conductivity, internal energy (including latent heat effects), and convection and radiation boundary conditions are considered. The Fourier heat transfer equation for the laser heating process can be written as:

$$\rho \frac{DE}{Dt} = (\nabla(k\nabla T)) \qquad [35]$$

where E is the energy gain of the substrate material, ρ is the material density, and k is the thermal conductivity. In the case of a moving heat source along x-axis of the sheet with a constant velocity U, energy gain of the substrate material yields:

$$\rho \frac{DE}{Dt} = \rho \frac{\partial E}{\partial t} + \rho U \frac{\partial E}{\partial x} \qquad [36]$$

Table 4 Laser processing conditions used in the experiment

Welding speed (cm s^{-1})	*Peak power (W)*	*Laser peak intensity $\times 10^{12}$ (W m^{-2})*	*Frequency (Hz)*	*Nozzle gap (mm)*	*Nozzle diameter (mm)*	*Focus setting (mm)*	*N_2 gas pressure (kPa)*
10	2000	2.7	1500	1.5	1.5	127	600

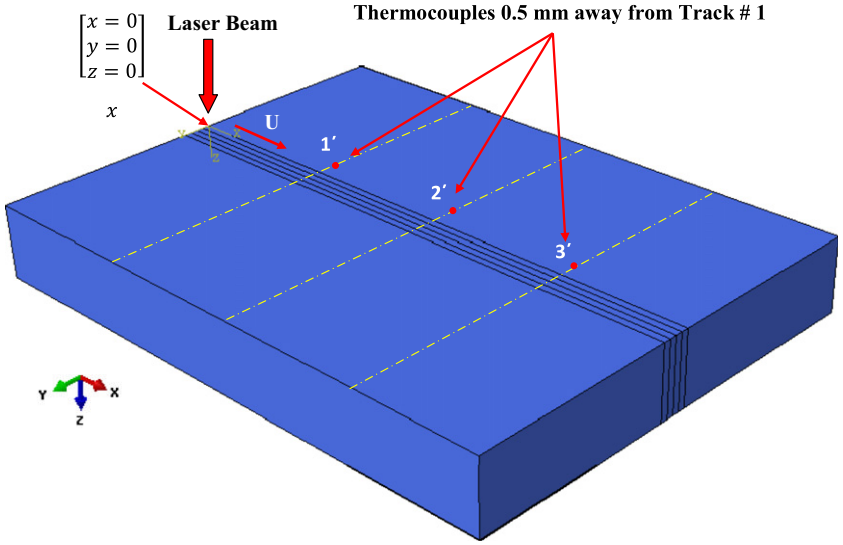

Figure 4 Schematic view of laser heating situation and the coordinate system.

or

$$\rho\frac{\mathrm{D}E}{\mathrm{D}t}=\rho\frac{\partial(C_pT)}{\partial t}+\rho U\frac{\partial(C_pT)}{\partial x} \quad [37]$$

Combining eqns [1] and [3] yields:

$$\rho\frac{\partial(C_pT)}{\partial t}=(\nabla(k\nabla T))+\rho U\frac{\partial(C_pT)}{\partial x} \quad [38]$$

where C_p is the specific heat. To analyze the phase change problem, the enthalpy method is used.[29] The specific heat is associated with the internal energy gain of the substrate material. However, the internal energy gain during the phase change is associated with the latent heat of fusion, which is given separately in terms of solidus and liquidus temperatures (**Table 5**) and the total internal energy associated with the phase change, called the latent heat. Since the primary interest is the stress field developed in the cutting section, the flow field generated in the liquid phase at the kerf surface during the laser cutting process is omitted.

The convective and radiation boundary conditions are considered at the free surface of the workpiece. Therefore, the corresponding boundary conditions are:

At the irradiated surface:

$$\frac{\partial T}{\partial z}=-\frac{I_{\max}}{k}(1-r_f)e^{\left(-\frac{x^2+y^2}{a^2}\right)}+\frac{h_f}{k}(T_s-T_{amb})+\frac{\varepsilon\sigma}{k}(T_s^4-T_{amb}^4) \quad [39]$$

where, $I_{\max}$ is laser power peak density, a is the Gaussian parameter, r_f is the surface reflectivity, x, y, and z are the axes, and $h_f=3000\ \mathrm{W\ m^{-2}\ K}$[30] is the forced convection heat transfer coefficient due to the assisting gas.

At the rear side of the surface:

$$\frac{\partial T}{\partial y}=\frac{h}{k}(T_s-T_{amb})+\frac{\varepsilon\sigma}{k}(T_s^4-T_{amb}^4) \quad \text{and}$$

$$\frac{\partial T}{\partial z}=\frac{h}{k}(T_s-T_{amb})+\frac{\varepsilon\sigma}{k}(T_s^4-T_{amb}^4) \quad [40]$$

where $h=20\ \mathrm{W\ m^{-2}}$ is the heat transfer coefficient due to natural convection, and T_s and T_{amb} are the surface and ambient temperatures, respectively, ε is the emissivity ($\varepsilon=0.9$ is considered), σ is the Stefan–Boltzmann constant ($\sigma=5.67\times10^{-8}\ \mathrm{W\ m^{-2}\ K^4}$). Initially (prior to laser heating), the substrate material is assumed to be at constant ambient temperature, i.e., $T=T_{amb}$, which is considered as constant ($T_{amb}=300$ K).

Equation [38] is solved numerically with the appropriate boundary conditions to predict the temperature field in the substrate material and the properties used in the simulations are given in **Table 5**.[31]

The thermal model consisted of two steps. The first step, which lasts 0.409 s, simulates the response of the sheet under a moving laser heat flux along five tracks each of length 8 mm. The distance between the centers of the spots during any two adjoining tracks were kept as 0.1 mm which resulted in an overlapping ration of 60%. The second step, which lasts for 300 s, simulated the continuous cooling in the model. Cooling was allowed to continue until the sheet reaches the initial temperature (room temperature). The temperature–time

Table 5 Properties used in the simulations

Temperature (K)	*Thermal conductivity ($W\,m^{-1}\,K^{-1}$)*	*Specific heat ($J\,kg^{-1}\,K^{-1}$)*	*Modulus of elasticity, $E \times 10^{11}$ (Pa)*	*Expansion coefficient $\times 10^{-5}$ ($1\,K^{-1}$)*

Density = 8030 kg m^{-3}; Latent heat = 300 000 J kg^{-1}; Solidus temperature = 1673 K; Liquidus temperature = 1728 K; Poisson's ratio = 0.3; Strength coefficient = 1.4 GPa and $n = 0.44$.

history resulting from the thermal analysis is used as input to the thermal stress analysis.

Solidification involves small strain, so the assumption of small strain is adopted in this work. The thermal strains which dominate thermo-mechanical behavior during solidification are on the order of only a few percent as confirmed by several previous solidification models.[32] In the stress analysis, displacements are stored at the nodal positions as a solution variable, and loads are defined as prescribed displacements and forces. Employing the interpolation functions, it is possible to calculate the strain and stress increments at any point within the element using the compatibility and constitutive equations. ABAQUS[29] transforms the mechanical equilibrium equations into a set of simultaneous equations, such that the nodal displacements and forces are related to each other through the elemental stiffness matrix. However, ABAQUS uses a temperature-dependent total thermal strain coefficient, $\alpha'(T)$. It is considered that the thermal stress field is almost zero (hydrodynamic pressures are present only) in the molten surface. The solid and liquid interface in the kerf vicinity remains at a solidus temperature, and the elastic module reduces at elevated temperatures, which is given in **Table 5**. The material is modeled as a von Mises elastic-plastic material with isotropic hardening. To account for the effects of material melting and resolidification and annealing the ABAQUS command *ANNEAL TEMPERATURE was used. This command causes a point in the material to lose its hardening history by setting the equivalent plastic strain at that point to zero if it exceeds a certain temperature. The annealing temperature used was 1728 K. To avoid computational difficulty, the yielding stress is limited to its value at the annealing temperature.

The mesh is generated after the identification of the critical regions in the geometry. The critical regions are considered as the regions where high temperature gradient and strain occur during the laser multitrack scanning (5 tracks in the present case). These regions are the material volumes around the laser beam path and the heat-affected zone. These regions are estimated experimentally from the bended samples which found to extend in a zone of width equal to about five times of the laser beam diameter. A refined mesh is selected in this region in order to capture the temperature and stress fields with high resolution. In addition, the convergence tests are carried out to ensure the mesh density independency of the predictions.

Sequentially coupled thermo-mechanical analysis is used to describe the laser bending analysis, which means that deformations during bending depend on temperatures but temperatures are independent of deformation. Therefore, the thermal analysis is first solved to obtain the temperature field throughout the specimen as a function of time which is then provided as an input for the stress analysis, to determine the thermal stress fields in the laser irradiated section. Continuum, three-dimensional 6-node linear heat transfer elements (DC3D6) are used in the thermal analysis whereas for stress analysis, three-dimensional 6-node linear stress elements (C3D6) are used. The mesh comprises of 33 520 elements and 23 991 nodes.

1.12.5 Results and Discussions

Laser machining process in general, involves with multiphysics and can be categorized in many different ways. However, main focus are of research in laser machining and extends to include drilling, cutting, bending, and welding. In this chapter, laser drilling and quality assessment is given in line with the previous studies,[28] laser cutting of thin metal sheets and quality assessments is provided in line with the previous studies, and laser bending of steel sheet is explored in line with the previous studies.[28] The findings and discussions are given according to the appropriate subheadings.

1.12.5.1 Laser Drilling

Laser drilling is one of the important applications of the laser machining. The findings of the temperature distribution and statistical analysis are discussed according to the previous studies.[1–3] The nondimensional temperature profiles are predicted for variable properties, which are given in **Table 6** while the pulse parameters employed in the temperature simulations are given **Table 7**.

Figure 5 shows the contour plot of dimensionless temperature profiles inside the substrate material while **Figure 6** shows dimensionless temperature distribution inside the substrate material along the z-axis at different heating periods. Temperature profiles terminate at some depth below the surface depending on the heating period, e.g., for $t^* = 3.05$, the corresponding depth is $z^* = 7.5$. This is because of the cavity formation after the evaporation process. Thus, the depth of cavity depends on the heating duration. Moreover, two regions

in the temperature profiles are evident because of the phase change process. In the first region, a solid heating occurs $T^* < 0.07$, while liquid phase heating is dominant in the second region ($0.07 < T^* < 0.126$). The depth of cavity exceeds the absorption depth of the substrate material for the heating periods shown in Figure 6. Consequently, energy transport due to diffusion dominates the heat transfer process during the heating periods considered. The slope of the liquid heating changes sharply after the initiation of melting process, i.e., in the region of the melt the slope of temperature curves changes sharply. This is because of the mushy zone introduced in the analysis, i.e., some of the substrate material is partially melted at constant temperature. Since the laser input intensity is high and the interaction duration is short, the size of the mushy zone is small.

1.12.5.1.1 Qualitative analysis

Table 8 gives the *F*-test results for the parameters pressure (P), focus settings (F), laser output energy (E), and workpiece thickness (T). The discussion for the test results are given under the headings relevant to the geometric features of the hole drilled.

Resolidified material: The main effect of pressure is significant, the first order interactions of pressure–thickness is most significant, pressure–focus setting and pressure–thickness are significant, and second order interaction of pressure–focus setting-energy is significant. This indicates that the ambient pressure has a significant effect on the resolidified material. In this case, reducing ambient pressure generates a pressure differential across the evaporated front and its surroundings. Consequently, the material removal rate increases from the cavity in the initial stage of the hole formation. Once the hole is drilled in the workpiece, the pressure in the cavity drops considerably. Despite the low pressure in the cavity, the low ambient pressure results in molten metal to drag toward the hole inlet. The molten metal, then, solidifies as soon as the laser pulse ceases. Therefore, the molten metal forms the resolidification at the hole exit. The first order interaction between the pressure-thickness has most significant effect on the resolidified material.

Taper: The main effects of all the parameters are found to be most significant for taper, except energy, which has only significant effect on taper. Almost all the first order interactions have most significant effect on taper while the second order interaction of pressure–focus setting–thickness has significant effect on taper. Therefore, taper increases as ambient pressure reduces, in which case the rate of mass removal from the cavity increases. In addition, the focus setting and thickness have similar effect on the taper. In this case, energy available at the workpiece surface varies as the focus setting changes. This influences the energy coupling at the workpiece surface. Therefore, the pressure generated due to superheating of liquid becomes considerably high, which in turn accelerates the mass removal from the cavity and enhances the liquid surface propagation into the workpiece. Consequently, high rate of material removal from the workpiece results in large taper. The first order interaction indicates that the coupling effects of pressure and thickness, pressure and focus setting, and thickness and focus setting are significant. Therefore, the formation of taper depends on the individual parameters as well as their interactions.

Inlet cone angle: Focus setting and thickness are found to be most significant parameters while pressure and energy are significant parameters in the case of inlet cone angle. Inlet cone angle is, in general, related to focus setting since the larger beam waist at the workpiece surface generates large inlet cone angles. The pressure inside the cavity before the through hole formation is also important. The pressure in the cavity increases as thickness of the workpiece increases. In addition, the differential pressure across the evaporating front and its surroundings increases due to subatmospheric ambient conditions, i.e., the mass removed from the cavity erodes thermally the exiting section of the cavity, which in turn results in large inlet cone angle. Therefore, the coupling effect of pressure and focus setting influences the inlet cone angle formation considerably.

Barreling: The focus setting and thickness have most significant effect on the barreling. The main effects of pressure and energy are found to be significant. Barreling defines the how parallel-sided the hole drilled. Thickness and focus setting contributions are more than pressure and energy contributions for barreling formation. This suggests that formation of parallel-sided hole is related to the pressure rise inside the cavity before through hole formation rather than the mass removal rate, i.e., the regulated mass removal rate results in improved barreling than the fast rate of mass removal. The first order interaction between pressure and focus setting shows that there exists a coupling effect of these parameters on barreling as the combinations of focus settings and pressure vary.

Exit cone: The focus setting and thickness have the most significant effect while pressure and energy have significant

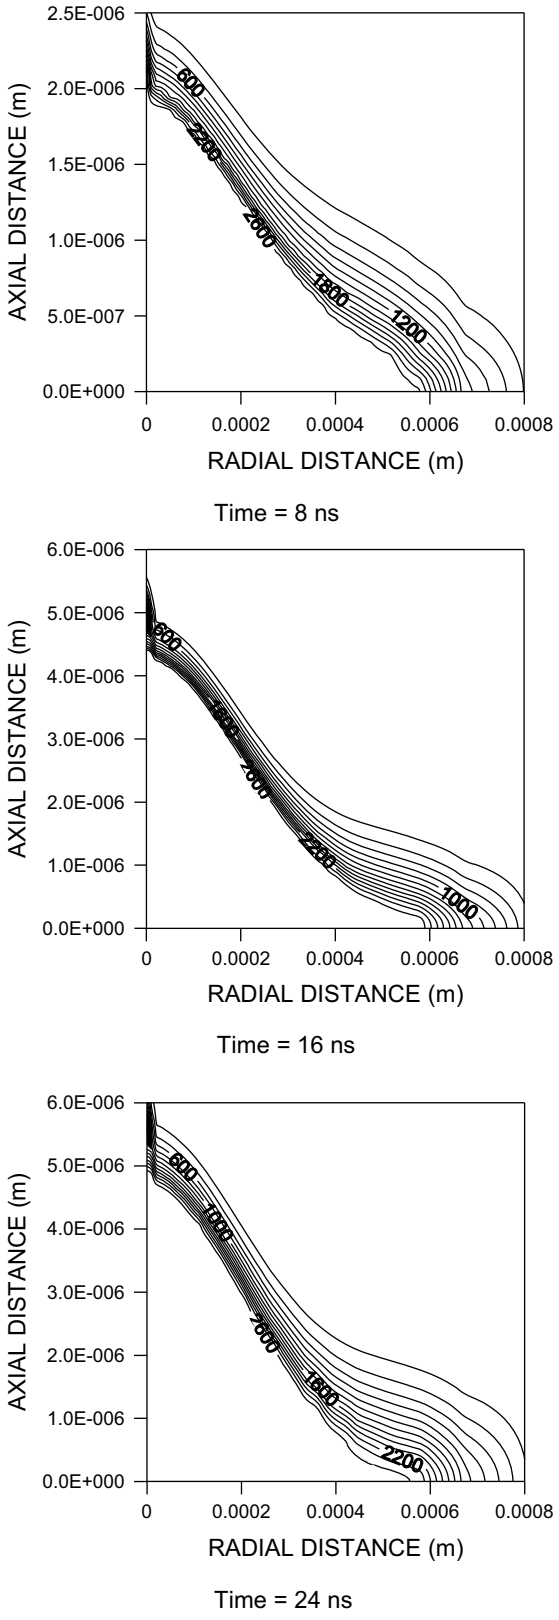

Figure 5 Contour plots of temperature at different heating periods.

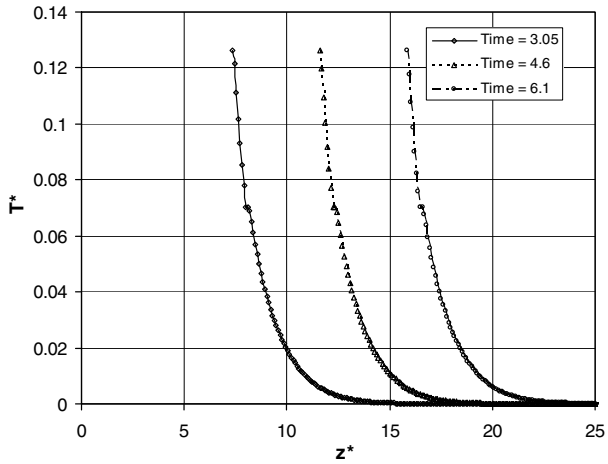

Figure 6 Variation in dimensionless temperature along dimensionless axial distance at different heating periods.

effect on the exit cone. The first order interactions of focus setting–thickness, and focus setting–energy are the most significant. This finding indicates that thickness, focus setting, and energy have significant contribution to the exit cone formation. In this case, the thick workpiece results in large pressure development in the cavity during the hole formation. This is effected by the beam waist position and laser output energy such that large exit cone is resulted for thick workpieces. In addition, the exit cone becomes small for some combinations of these parameters.

Surface debris: Surface debris is a measure of amount of material at the surface around the hole circumference. In almost all cases, the surface debris is not observed. This is because the low ambient pressure. In this case, the material leaving the hole inlet and exit is accelerated due to the pressure differential. This results in less or no debris at the workpiece surface. The first order interaction of pressure and focus setting has a significant effect on the surface debris.

Mean hole diameter: The main effects of all the parameters are found to be most significant. The effects of first order interactions of pressure–thickness, and focus setting–thickness are most significant. The size of the mean hole diameter depends on the amount and the rate of mass removal from the cavity during the hole formation. In this case, increase in pressure in the cavity and low ambient pressure enhance the amount of mass removed and its rate. In addition, the energy coupling at the workpiece surface alters the rate of mass removal, i.e., improved energy coupling at the workpiece surface accelerates the mass removal rate. Moreover, the effects of pressure and focus setting vary with thickness, since the first order interactions of these parameters are most significant.

Overall quality: Overall quality is effected by all parameters provided that the main effects of focus setting and thickness are the most significant while pressure and energy are significant parameters. The first order interaction of focus setting–thickness is very significant while pressure–focus setting is significant. This indicates that overall quality is not only effected by each parameter, but the combinations of

pressure–focus setting, and focus setting–thickness also alter the overall quality.

1.12.5.1.2 Quantitative analysis

The quantitative analysis gives the functional relation between the affecting parameters and the response (geometric features of the hole drilled). Table 9 gives the quantitative analysis results. The relation for each parameter is given below.

Pressure: The linear effect of pressure found to be most significant for mean hole diameter, very significant for barreling, and significant for inlet cone. The quadratic effect of pressure is most significant for taper, very significant for inlet cone. The cubic effect of pressure is very significant for resolidified material and it is significant for mean hole diameter. This suggests that taper and inlet cone vary quadratically with pressure while barreling varies linearly with pressure. The cubic relation exists between the resolidified material and pressure.

Focus setting: The linear effect of focus setting is very significant for all hole geometric features, except surface debris. In this case, the linear relation exists between the resolidified material, taper, barreling, inlet cone, exit cone, mean hole diameter, and overall quality with focus setting, i.e., small variation in focus setting results in small variation in features of hole geometry, since the relation between the hole features and focus setting is linear.

Laser output energy: The linear effect of energy is most significant for inlet cone and mean hole diameter. The cubic effect of energy is significant for taper. Consequently, as energy varies, the inlet cone and mean hole diameter change with energy at almost same rate.

Thickness: The linear effect of thickness is most significant for all the features of hole geometry, except surface debris, which varies in cubic form with thickness. Some of quadratic and cubic effects of thickness are also found to be most significant for some hole features. This suggests that although the linear effect of thickness is dominant, but as far as the interactions are concerned this effect may not be linear.

1.12.5.2 Laser Cutting

The energy coupling at the workpiece surface plays an important role in laser cutting process. When the high power laser beam is absorbed by the workpiece material, the solid state heating, melting, and evaporation of the workpiece material are resulted. The melted and the evaporated material with existing of oxygen, due to impinging gas initiate high temperature exothermic reactions. This ionizes the evaporation

Table 10 Affecting process parameters and their levels

Variables	*P (W)*	*A*	*V (cm s^{-1})*
Levels	500 and 1500	0.3 and 0.6	1 and 4

front slightly and generates partially ionized surface plasma, which scatters the laser beam and modifies the focusing conditions of the incident laser beam. In addition, partially ionized surface plasma acts as a heat source enlarging the size of the melt in the kerf. Moreover, when the incident beam partially blocked by the surface plasma, less incident laser energy reaches the workpiece. This reduces the mass removal rate and the size of the surface plasma reduces which in turn results in more laser energy reaching the workpiece surface. This, later, accelerates the mass removal rate. Consequently, the high temperature oxidation reaction, in most cases, results in transiently varying energy coupling mechanism at the workpiece surface. Therefore, the energy coupling needs to be considered as one of the affecting parameters in the analysis. Two levels of each affecting parameter are considered, which are given in **Table 10**. The findings are presented in the light of the previous studies.[4–6]

In the analysis, the difference of kerf width size (Δw_k) due to each affecting parameter is also considered. The difference of kerf width size is determined from:

$$\Delta w_k = (w_k)_{P_n} - (w_k)_{P_{(n+1)}}$$

where P_n is the any affecting parameter at nth level. The variation of Δw_k due to percentage change of affecting parameters is also considered. In this case, any of the affecting parameter is increased gradually and the corresponding kerf width change is determined. Then, the amount of increment is normalized by the magnitude of the affecting parameter, i.e., $\Delta P_n/P_n$, where ΔP_n is the increment in the parameter at nth level and P_n is the parameter at nth level. This arrangement enables to identify the change in Δw_k due to certain percent of change in the parameter. If the laser processing parameters (affecting parameters) vary slightly during the cutting process, the striation is formed on kerf surface. This is because the change of Δw_k during the cutting process, i.e., variation of affecting parameters results in varying kerf width. Moreover, variation of kerf size due to variation of any affecting parameter identifies the significance of the parameter in the striation formation.

Figures 7(a) and **7(b)** show the kerf width with the cutting speed, and Δw_k with the percentage of cutting speed variation (dv_n/v_n). In general, kerf width reduces with increasing cutting speed. The high laser power results in small size of kerf width provided that the decrease in the kerf width is nonlinear with the cutting speed. When comparing the experimental results with the present predictions, they are in reasonably good agreement. In the case of Δw_k, high laser power with high energy coupling factor results in large Δw_k. Moreover, 5% variation in dv_n/v_n results in 2–4% variations in the kerf width for the condition of 1500 W laser power and 0.6 energy coupling factor. As dv_n/v_n increases Δw_k increases considerably. During the laser cutting process, if the cutting speed varies without regulating the laser output power, the size of the striation amplifies. This is especially true when odd-shaped curves or sharp corners are subjected to the laser cutting.

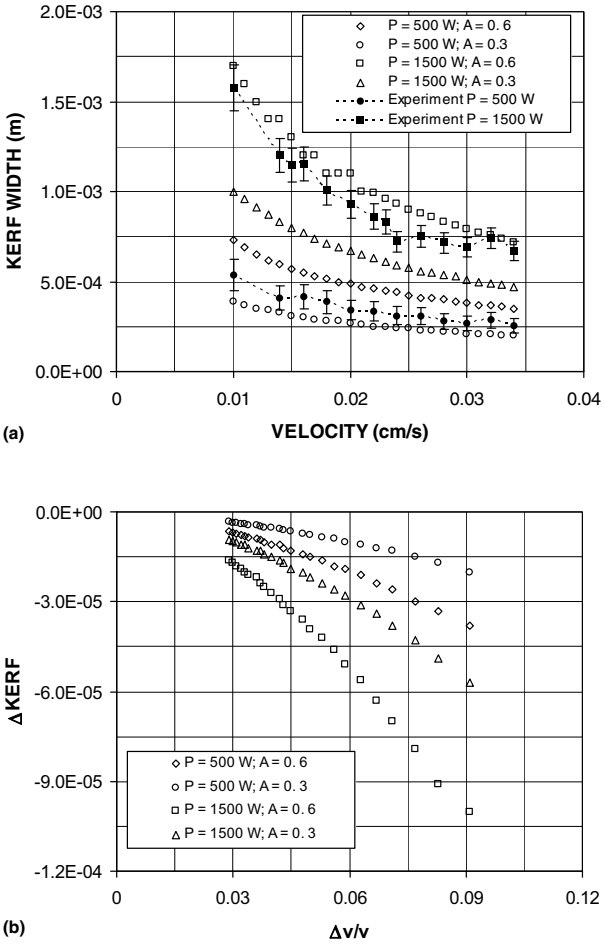

Figure 7 (a) Kerf width with cutting speed for different energy coupling factors and laser powers. (b) Variation in kerf width with cutting speed variation for different energy coupling factors and laser powers.

Figures 8(a) and **8(b)** show the kerf width with laser output power, and Δw_k with percentage of laser output power variation (dP_n/P_n). The kerf width increases with increasing laser output power for all combination of the affecting parameters. The increase in the kerf width is more pronounced as the cutting speed reduces while the energy coupling factor increases. When comparing the kerf width predicted from the present and previous studies,[23] and the experimental results, both predictions and the experimental results are in good agreement for cutting speed of 4 cm s^{-1} and $a = 0.3$. However, the present model over predicts the kerf width for the condition at which the cutting speed is 1 cm s^{-1} and $a = 0.6$. This may occur due to one or all of the following reasons: (1) the energy coupling at the workpiece changes as the cutting speed changes; in this case, the energy coupling improves at low cutting speed, but worsens at high cutting speed. Therefore, the energy-coupling factor should be greater than 0.3 at 4 cm s^{-1} cutting speed, and (2) the simplified model used at present predicts the kerf width with some error when the extreme cutting conditions are introduced. Nevertheless, the trends of

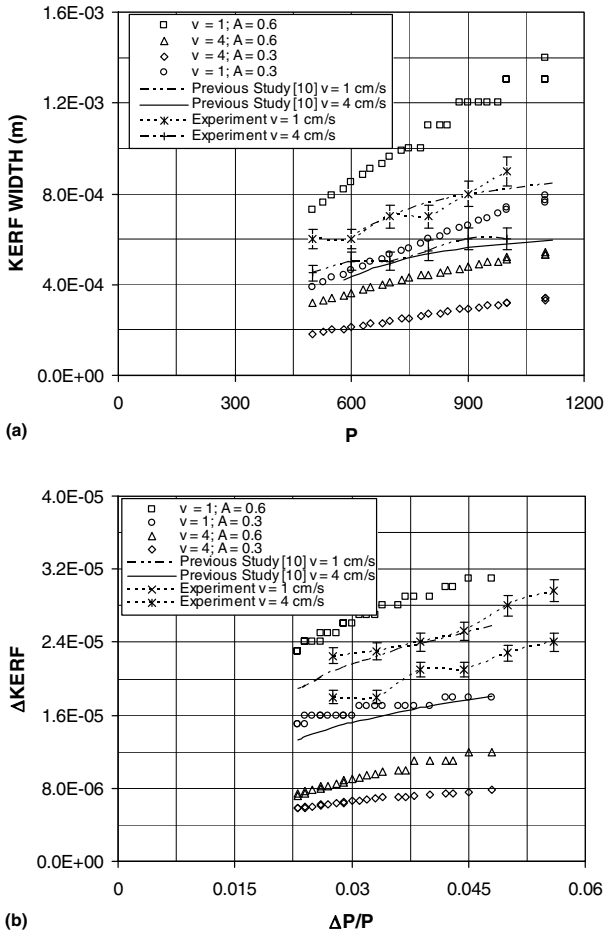

Figure 8 (a) Kerf width with laser power for different cutting speeds and energy coupling factors. (b) Variation in kerf width with laser power variation for different cutting speeds and energy coupling factors.

the predictions and the experimental results are similar. In the case of Δw_k (Figure 8(b)), Δw_k rises with increasing dP_n/P_n. The rate of increase in Δw_k is more pronounced for cutting velocity 1 cm s^{-1} and energy-coupling factor 0.6. Δw_k predicted from the present study agrees well with the previous and experimental results for the affecting parameters of cutting speed 4 cm s^{-1} and energy coupling factor 0.3. However, the present predictions slightly over estimate Δw_k for the cutting speed 4 cm s^{-1} and energy coupling 0.6 as compared to experimental findings. This suggests that the energy-coupling factor of 0.6 may not represent the actual case and it is on the high side. Moreover, it is observed that variation in laser output power modifies the size of the kerf considerably. In this case, the kerf size increases substantially.

1.12.5.3 Laser Bending

Thermal strain developed in the laser heated region results in elasto-plastic thermal deformation of the substrate material. This in turn causes thermal displacement and bending in the laser treated section. The findings and discussions related to the laser bending are provided in line with the previous findings.[28]

Figure 9 shows the geometric arrangements of paths and points at the workpiece. Figure 10 shows the temperature variation along the y-axis (along the line 1–2) as shown in Figure 9 for the time corresponding to the tracks ends. Temperature increases in the region where the laser spot is located. It should be noted that the laser beam intensity is considered to be Gaussian at the surface in the simulations in line with the experimental conditions. Temperature decay is gradual at the irradiated spot center and it becomes sharp as the distance from the laser scan tracks increases toward the workpiece edges. This behavior is attributed to laser beam intensity distribution at the surface, which is Gaussian and the volumetric absorption of the laser beam in the substrate material. However, in the neighborhood of the irradiated spot edge, temperature gradient becomes large because of the low substrate bulk temperature. Thermal diffusion from the irradiated spot increases toward the bulk of the substrate material due to the high temperature gradient in this region. As the number of laser scanning tracks increases, the peak temperature increases. This is attributed to the heating of the substrate material by the initially formed laser scan tracks. Thermal diffusion from the initially laser scanning track enhances the internal energy gain in its neighborhood so that temperature attains high values, despite the high cooling rates from the surface. It should be noted that convection boundary is assumed at the surface resembling the cooling effect of the assisting gas at the irradiated surface. Moreover, the location of the peak temperature changes along the y-axis as the number of laser tracks increases. This is because of the geometric location of the irradiated spot, which is along the line 1–2 (Figure 10) for the first track. However, this point shifts with an amount equal to the laser scanning track width along the y-axis for the following track. Although phase change due to melting is incorporated in the analysis, no mushy zone is observed, where temperature remains constant between the solidus and liquidus temperatures, along temperature profile. This indicates that the mush-zone generated along and above the solidus temperature is considerably narrow at the irradiated surface.

Figure 11 shows von Mises stress variation along the y-axis (along the line 1–2) as shown in Figure 9 for the time corresponding to the tracks ends. The time settings for von Mises stress variation are similar to those shown in Figure 10. The von Mises stress attains high values in the region where the temperature gradient is high, which occurs in the neighborhood of the irradiated spot edges, which is more pronounced for the first laser scanning track. Since the location of the laser irradiated spot center along the each tracks changes, von Mises stress behaves differently for each laser scanning tracks. In this case, von Mises stress attains the highest value for the end of the last scanning track. The self-annealing effect of the initially formed tracks is only effective in the close region of the tracks, since the self-annealing effect lowers stress levels in the region close to the laser scanning track. von Mises stress attains low value across the laser scanning tracks width for scanning track numbers 3–6, which is because of the self-annealing effect of the initially formed laser scanning tracks on the stress field.

Figure 12 shows thermal displacement along the circumference of the mid-plane of the laser scanned workpiece

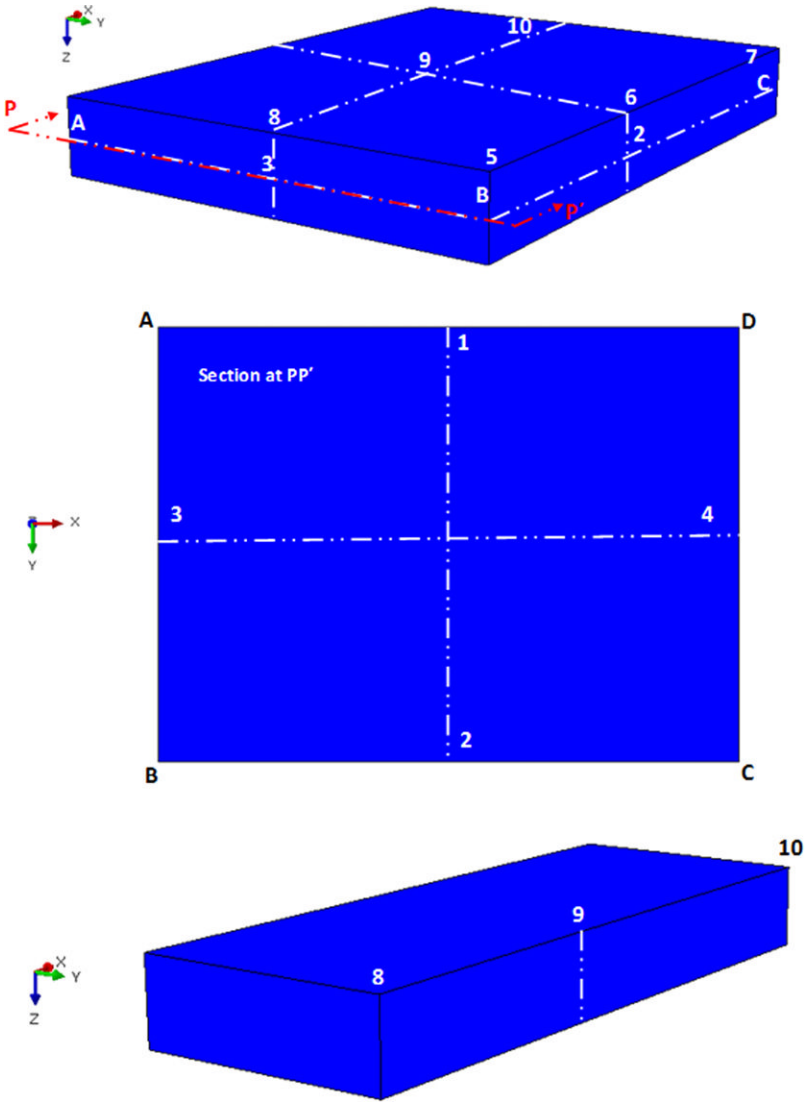

Figure 9 Geometric arrangements of paths and locations at the workpiece.[7]

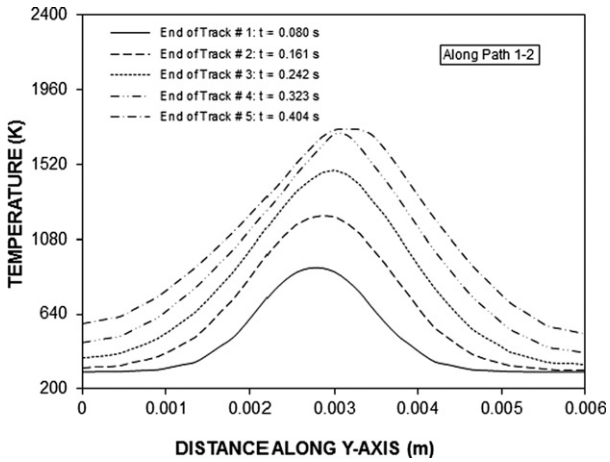

Figure 10 Temperature variation along the *y*-axis for different times corresponding to end of tracks and along path 1–2 (Figure 9).[7]

(Figure 9) for the times when the laser scanning track ends. Thermal displacement attains higher values in the region where the laser scanning takes place. The displacement takes the negative values due to the compression. Since the substrate material is not free to expand at the mid-plane, compressive stress is formed along this plane. The bending takes place under the compressive stress and the magnitude of displacement superimposes with increasing number of laser scanning tracks despite the fact that von Mises stress reduces along the scanning tracks with progressing number of laser scans. The thermal diffusion form the heated region toward the neighborhood of the laser scanning tracks reduces the thermal displacement in this region. Consequently, the region where the thermal displacement is effective by self-annealing is limited within the close region of the laser scanned tracks. This, in turn, causes sharp bending rather than forming a curvature through gradual bending in the vicinity of the laser scanning tracks. Therefore, the narrow

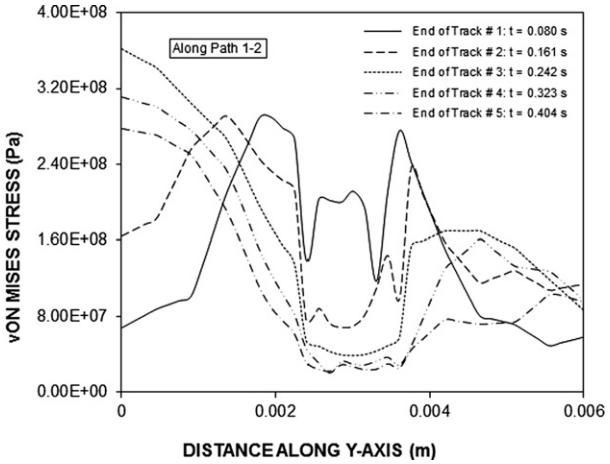

Figure 11 von Mises stress variation along the *y*-axis for different times corresponding to end of tracks and along path 1–2 (Figure 9).[7]

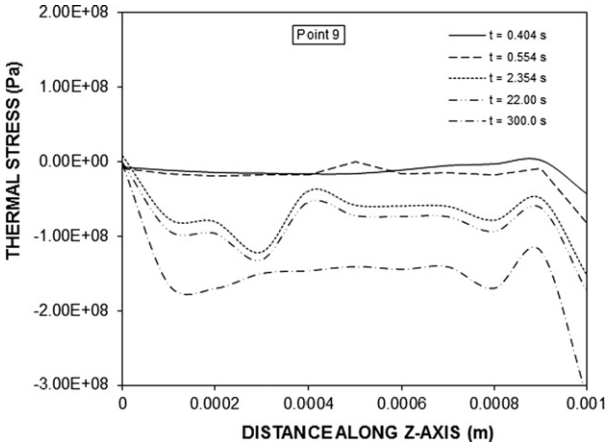

Figure 13 Residual stress variation along *z*-axis at location # 9 (Figure 9).[7]

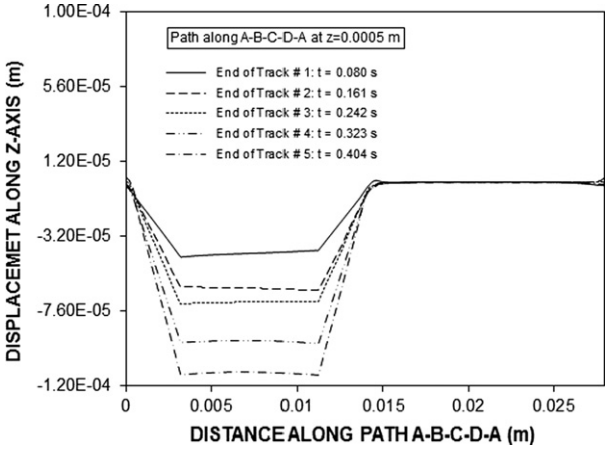

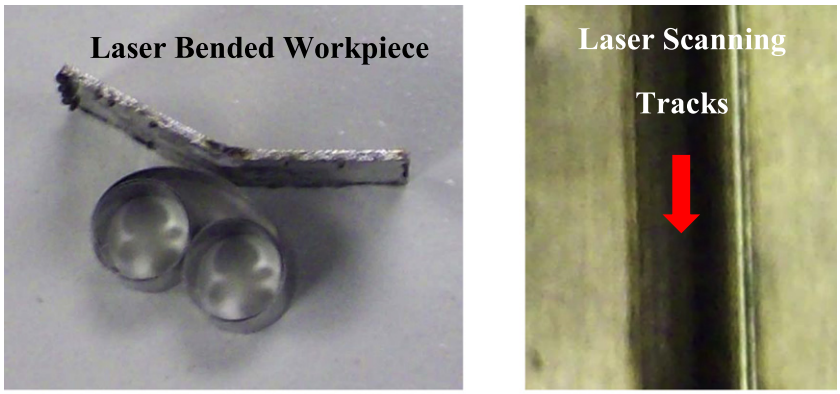

Figure 12 Displacement along the circumference of the workpiece and *z*-axis location is the mid-height of the workpiece (Figure 9).[7]

heat affected zone due to the occurrence of the sharp temperature gradient in this region is responsible for the sharp bending in this region.

Figure 13 shows residual stress distribution along the *z*-axis at location #9 for different times. It should be noted that the location # 9 corresponds to the middle point of the plate (Figure 9). In general, residual stress is compressive, which is more pronounced at the end of 300 s when the cooling period ends. In the early heating period where the laser scanning tracks are formed, residual stress is low, which is associated with the self-annealing effect of the previously formed laser scanning tracks. As the cooling period progresses after forming the laser tracks ($t > 0.404$ s), residual stress along the *z*-axis build up because of bending. This is more pronounced as the depth below the surface increases toward the bottom of the plate along the *z*-axis. The maximum magnitude of the residual stress is on the order of -300 MPa, which occurs at the bottom of the steel plate. The attainment of high residual stress is attributed to the relatively larger displacement at the bottom of the steel plate (Figure 10) as compared to that corresponding to the mid-plane Figure 9.

Figure 14 shows optical photographs and SEM micrographs of top surface of the laser scanned tracks. Optical photograph of laser bended section shows that bending angle is sharp and there is no evidence of geometric curvature in the bend section. This is associated with the high rate of strain formed under the high temperature gradients in the vicinity of the laser scanning tracks. The similar behavior is observed from the displacement simulations (Figure 12); in which case, displacement reduces sharply in the region of the bended section. The laser scan tracks are straight and parallel without showing large scale thermal defects at the scanned surface. This is also observed from the SEM micrograph. However, the closed examination of the laser scanning tracks reveals that few small cavities are formed at the surface. This is associated with the local evaporation at the surface, despite the fact that the laser parameters are selected to avoid the evaporation at the surface. It should be noted that in order to achieve deep penetration of melt layer, the laser power intensity is kept high at the surface. In addition, presence of oxygen in the treated section triggers high temperature oxidation reactions taking place at the surface, which contributes to the cavity formation through excessive heating at the surface. Although nitrogen at high pressure is used to avoid oxidation reactions, presence of small amount of oxygen is sufficient to initiate the exothermic reactions at the scanned surface. Since the laser scans the surface at high frequency repetitive pulses (1500 Hz) (Table 4), the overlapping of laser spots along the laser scanning tracks is notable and the overlapping ratio is of the order of 85%. The high overlapping ratio results in continuous melting along the laser scanning tracks at the surface. However, no excessive melting across the tracks is observed. In addition, self-annealing effect of the recently formed tracks results in crack free structure at the surface despite the fact that the cooling rate is high at the surface. It should be noted that the heat conduction from the recently formed tracks toward the initially formed tracks causes self-annealing effect on the microstructure at the surface.

1.12.6 Concluding Remarks

Laser machining is one of the thermal processing techniques, which can be used effectively in sheet metal industries. Since the process is involved with the high temperature phenomena, a care must be taken to minimize the thermally induced defects around the machined parts. This can be possible with proper selection of laser machining properties, which requires prior knowledge about the physical insight into the machining process. Consequently, statistical, numerical, and experimental studies associated with laser machining process become essential to develop such detailed database to achieve the required end product quality. In this chapter, laser drilling, laser cutting, and laser bending are presented in the light of the previous studies. The concluding remarks are given below according to the laser machining processes involved.

In laser drilling, all the factors considered have significant effect on the resulting features of the hole geometry. However, the effects of thickness, focus setting, and ambient pressure are identified as the most significant parameters. The effects of thickness and focus setting are most significant for overall quality of the hole drilled. From the qualitative analysis, the effect of each parameter on the hole geometry varies almost linearly, except thickness and focus setting which vary quadratic or cubic forms. This indicates that small variation of pressure and energy result in small changes in hole geometry, but this change amplifies once the thickness and focus setting vary.

In laser cutting process, increase in laser power, energy coupling factor, and reducing cutting speed result in increased kerf width. The kerf width size varies considerably as the velocity, laser power, and energy coupling factor changes slightly; in which case, striation size increases. The effect of laser power on the kerf width is highly significant, since small variation in laser power alters the kerf size considerably. The laser output power and the energy-coupling factor have a

coupling effect on the resulting kerf size. In this case, as the laser power and the energy coupling factor increase, the kerf width size increases substantially. Consequently, in laser cutting operation, small variation in laser power results in large variation in the kerf size.

In laser bending process, temperature remains high in the region of the laser irradiated spot, which, in turn, results in high temperature gradients in the neighborhood of the laser scanning tracks. The high temperature gradients cause the development of high stress levels in this region. The self-annealing effect of the recently formed tracks influences the stress levels in the heated region; in which case, von Mises stress reduces along the previously formed laser scanning tracks. The displacement along the *z*-axis is high because of the bending of the workpiece. The sharp change of displacement across the laser scanning tracks and the untreated substrate material indicates that the bending is sharp and the curvature bending does not take place in the substrate material. Laser scanned surfaces are free from large size defects and asperities, provided that few scattered shallow cavities are formed at the surface.

1.13.1 Introduction

Machining is a subtractive manufacturing process that is used for removing material controllably from a piece of raw material. The objective of this process is to produce final product with proper shape and controlled dimension from the workpiece (raw material). In order to manufacture product with accurate dimension, proper tolerance and acceptable surface finish, several things need to be considered during machining such as, tool material, workpiece material, type of machining process, etc. Relative motion between the tool and workpiece is the primary reason behind all machining process that causes material to be removed from the workpiece, however, tool shape and tool penetration into the workpiece are also responsible for this. Relative motion between the tool and workpiece is achieved by the combined action of the primary motion called 'cutting speed' and secondary motion called 'feed speed.' Modern days' machining process is mostly carried out by computer numerical control (CNC) machine in which software based automatic control

 doi:10.1016/B978-0-12-803581-8.09158-X

system carries out the movement and operation of the machine tools.

Machining processes can be divided into mainly two groups 'conventional machining processes' and 'non-conventional machining processes.' Turning, boring, milling, shaping, broaching, slotting, grinding. etc., fall under the category of conventional machining process. Similarly there are several examples of non-conventional machining such as abrasive jet machining (AJM), electro-discharge machining (EDM), electrochemical machining (ECM), and ultrasonic machining (USM), etc. In conventional machining usually harder material is used as tool for changing the shape of a workpiece by cutting operation. Machining hard metals and alloys using conventional methods involves longer time and higher energy, and therefore, an increase in costs. Conventional machining may also higher tool wear and deteriorated quality in the product owing to induced residual stresses during manufacturing. Conventional machining can be defined as a process of using mechanical (motion) energy. On the other hand, most non-conventional machining has no direct contact between the tool and the workpiece. It has several other features and the three main forms of energy that are used in these processes are thermal energy, chemical energy, and electrical energy. If one asks why we need the non-conventional machine? The simple answer is, in several industries, hard and brittle materials like tungsten carbide (used for making cutting tools), high speed steels (used for making gear cutters, drills, milling cutters), stainless steels, ceramics, etc., are often used. If such materials are machined with the help of conventional machining processes, either the tool undergoes extreme wear (in case of hard materials) or the workpiece material is damaged (in case of brittle materials). This is because, in conventional machining, there is a direct contact between the tool and the workpiece. Large cutting forces are involved, and material, are removed in the form of chips. A huge amount of heat is produced in the workpiece. This induces residual stresses, which degrades the life and quality of the workpiece material. To overcome all these drawbacks, non-conventional machining processes are used to machine hard and brittle materials. As well as to machine soft materials, in order to get better dimensional accuracy (DA). The best way to give a clear vision of these two machining groups (conventional and non-conventional) is to introduce a comparison between them. In conventional processes generally macroscopic chip formation by shear deformation. While material removal may occur with chip formation or even no chip formation may take place in non-conventional processes. For example, in an AJM, material removal occurs due to electrochemical dissolution at atomic level. Back to conventional processes, there is a physical tool present such as a cutting tool in a reamer machine. While there may not be a physical tool present in non-conventional processes such as in laser jet machining.

Again in conventional machining the tool should be harder than the workpiece under the machining conditions. While as mentioned in the above, there may not be a physical tool present in non-conventional machining. Tool life in the conventional might be less than the non-conventional (e.g., ECM) due to high surface contact and wear. In the conventional, there are always noisy operations that cause sound pollutions whereas in non-conventional machining sound pollutions is at minimal level. Conventional machining (unlike the non-conventional machining) requires lower capital cost and simple setup of equipment. Skilled or un-skilled operator can run the conventional machining, while only skilled operator can run the non-conventional that generally operates using automated processes. This chapter will be discussing in detail two manufacturing processes namely electrolytic in-process dressing (ELID) grinding (a conventional machining process to attain smooth surface) and EDM (a non-conventional machining process for conductive materials), and their implication in finish machining.

1.13.2 Background of ELID Grinding

In most of conventional rough machining like milling, turning are followed by finishing processes like grinding, polishing, and lapping. Grinding is a finish machining process to obtain a high degree of DA and surface finish on a part. This process uses microscopic abrasive particles for cutting. Grinding is a subset of cutting where each grain of abrasive functions as a microscopic single-point cutting edge with high negative rake angle. Rapid progress in electronic and optical devices (such as IC chips, MEMS, smart sensors, lenses) with the increasing requirement of their performance, demand of ultra-precision surface finish of the specialized glass, silicon wafer in nano-scale is growing. Conventional grinding cannot produce such surfaces with precise form accuracy; therefore, conventional grinding is still considered to be a preliminary finishing process. Typical ways for achieving final finishing of different materials are lapping and polishing. Though these methods have disadvantages like poor grind ability, waste water problem, mechanical damages, etc.[1] Chemical–mechanical polishing (also known as CMP) is another final finishing process for silicon wafer preparation in the IC industries. Some of the disadvantages associated with the CMP process[2] are:

1. Low efficiency due to low removal rates,
2. Non-uniform wafer surface due to the variation in relative cutting speed across the wafer surface, and
3. Relatively high cost involved in this process.

In order to overcome all these drawbacks associated with the conventional finishing processes, demand for nano surface generation by grinding (using super abrasives) to replace the polishing, lapping, etc., have been growing stronger and stronger in the manufacture of optical and electrical parts. In order to achieve ultra-precision surface finish by grinding two issues are needed to be addressed, first the abrasive of the grinding wheel has to be superfine and second the dressing of the grinding wheel needs to be in-process to maintain DA of the finished product. ELID grinding has been proven to be the most potent candidate technology in this regard. In ELID grinding super abrasive grinding wheel is dressed in-process by electrochemical method that employs the electrochemical machining principle to dress the wheel. In this case metal bonded grinding wheel is set as an anode and another metal electrode is set as a cathode.[3] Electrolytic dressing of the wheel applies the basic mechanism of electrolysis. This process converts electrical energy to chemical energy in an electrolytic solution in the presence of two electrodes (anode and cathode)

as shown in Figure 1. An electrical power supply is used to energize anode positively and cathode negatively. As the electric energy is applied ionic dissolutions occurs in the electrolytic solution and the negative and positive ions in the solution move to the positive and negative electrodes, respectively. This will cause anodic metal dissolution and formation of anodic oxide.

The mathematical form of metallic dissolution rate is governed by Faraday's law of electrolysis, which concludes that dissolution from anode material is directly proportional to the integration of current supplied to the electrolytic cell. The mathematical form of anodic dissolution can be written as follows,

$$m = \frac{\int_0^T i\mathrm{d}t}{F} \cdot \frac{M}{z} \tag{1}$$

where m is the mass of the substance altered from anode, i is the electric current passed through the cell, F is the Faraday constant, M is the molar mass of the substance, and z is the valence number of ions of the substance (electrons transferred per ion).

Basic elements of ELID grinding and its mechanism are shown in Figure 2. ELID cell consists of a metal bonded grinding wheel, a cathode electrode, a pulsed DC power supply and electrolyte. The wheel is connected to the positive terminal of the DC power supply thru a carbon brush whereas the electrode is connected to the negative pole of the power supply. Usually, alkaline liquids are used as both electrolytes and coolant for grinding. A nozzle is used to inject the electrolyte into the gap between wheel and electrode. The gap is usually maintained to be approximately 0.1–0.3 mm. An anodic oxide layer is formed on the circumference of the grinding wheel as a result of electrochemical reaction. The formation of this oxide layer is very crucial for the success of ELID grinding. It is soft and brittle in nature as compared to the original metal bond and gets easily worn off because of the excessive grinding force.

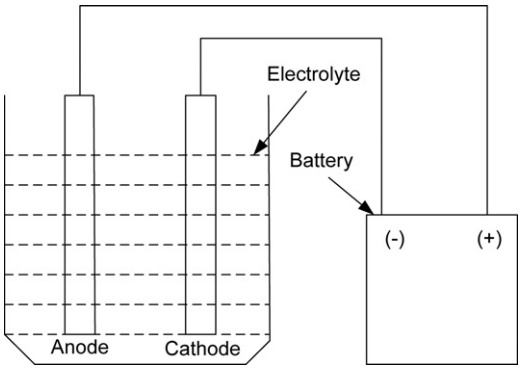

Figure 1 Basic principle of electrolysis.

The basic mechanism of ELID grinding has been explained in the zoom in section of Figure 2. After truing (Figure 2(a)), the grains and bonding material (metal) of the wheel surface are flattened. It is necessary for the trued wheel to be electrically pre-dressed to protrude the grains on the wheel surface and the dressing continues during the grinding operation as well. When pre-dressing starts (Figure 2(b)), the bonding material flows out from the grinding wheel and an insulating layer composed of the oxidized bonding material is formed on the wheel surface (Figure 2(c)) as explained in Figure 1. This insulating layer reduces the electrical conductivity of the wheel surface and prevents excessive flow-out of the bonding material from the wheel. At this moment the grits are held by both the bonding material and the oxide layer. It is important to note that the insulating oxide layer is soft and brittle in nature and wears off very easily as it comes in contact with workpiece during grinding operation (Figure 2(d)). Continuous grinding will cause wearing out of the diamond grains as a result cutting force increases. This excessive cutting force will cause falling off of the blunt grits, which is now mostly held by the brittle insulating material (Figure 2(e)). As a result of breakage of insulating layer, the electrical conductivity of the wheel surface increases and the electrolytic dressing restarts with the flow-out of bonding material from grinding wheel. The protrusion of new diamond grains from the grinding wheel therefore remains constant. This cycle is repeated during the grinding process to achieve stable grinding. There are few terminology widely used for ELID grinding which are used in this book chapters are as follows,

Peak voltage (V_p): This is the maximum voltage applied to the ELID cell by pulsed voltage supply.

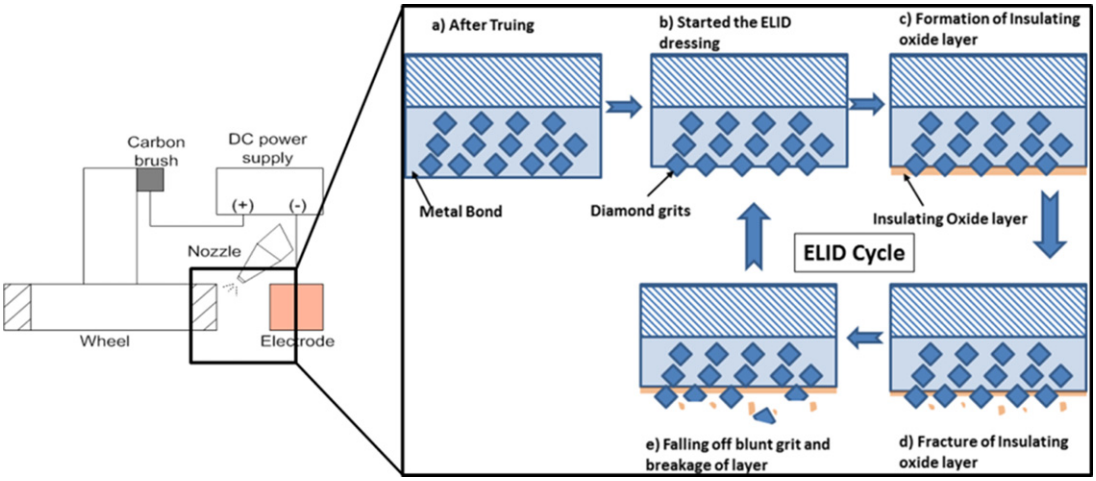

Figure 2 Components of ELID grinding and its mechanism.

Peak current (I_p): Maximum current drawn by the ELID cell when the peak voltage is applied.

T_{ON}: This is the pulse ON time and T_{OFF} is the pulse OFF time.

Duty ratio (R_c): Duty ratio is the % of ON time for one cycle of operation and can be calculated as follows

$$R_c = \frac{T_{ON}}{T_{OFF} + T_{ON}} \times 100\% \quad (2)$$

Considerable number of researches have been carried out and still continuing on various aspects of ELID grinding. This chapter will discuss in detail about different researches about ELID grinding in the subsequent sections.

Murata *et al.*[4] introduced ELID grinding technology in 1985 for structural ceramics as they were difficult for grinding because of their hard and brittle nature. Conventionally, softer grade wheels are used for grinding hard and brittle material which has problem of maintaining desirable form accuracy because of their higher tool wear. In order to cater this problem Murata *et al.*[4] performed ELID grinding operation on the above mentioned ceramics metal bonded grinding wheels with grit size of #80, #100, #150, and #400. Constant protrusion of sharp grits was maintained because of the ELID cycle as described in **Figure 2**. The experimental setup used by Murata *et al.*[4] is shown in **Figure 3**. This shows that ELID is being taken place in one side of the wheel continuously and grinding is being taken place on the other side. ELID has an inherent self-control mechanism that causes proper use of the grits till their life and protrusion of new grits as they are worn out, which is explained in **Figure 2**. This ELID principle ensures significant lower grinding force as observed by Murata *et al.*[4] (**Figure 4**) for grinding ceramics while compared to conventional grinding. In conventional grinding there is no in-process dressing mechanism that may cause the sharpening of the grinding wheel as the grits become dull, that is why the grinding force becomes high as grinding progresses. Further the surface roughness (SR) of the finished product was also found to be much improved when ELID grinding was used for the same underlying reason.

ELID grinding process was further investigated by Ohmori *et al.*[5] while he was experimenting to achieve mirror surface finish by grinding on silicon wafer. **Figure 5** describes the experimental setup that shows cast iron fiber bonded (CIFB) wheel as anode and copper/graphite as cathode. Pulsed DC voltage was used as the power source with grinding fluid as the electrolyte. Necessary isolation between the grinding wheel and machine structure was arranged during the ELID grinding experiment. Application of the pulsed voltage caused higher anodic current flow as shown in **Figure 6**. Eventually, the current decreases as the formation of insulating anodic oxide on the grinding wheel surface. As a result the working voltage also reaches to open circuit voltage gradually as explained in the I–V characteristic shown in **Figure 6**. Few notable issues were highlighted Ohmori *et al.*[5] in this paper,

1. ELID grinding doesn't require any special equipment. Conventional grinding machine can be used. Further die-sinking EDM power supply can be used as ELID power supply as well.
2. ELID produces highly stable and lower grinding force compared to conventional grinding because of continuous protrusion of sharp grits, this also ensures there will be no heat-affected area (caused by rubbing action of the dull grits) commonly known as grinding burn in the case of ELID grinding.

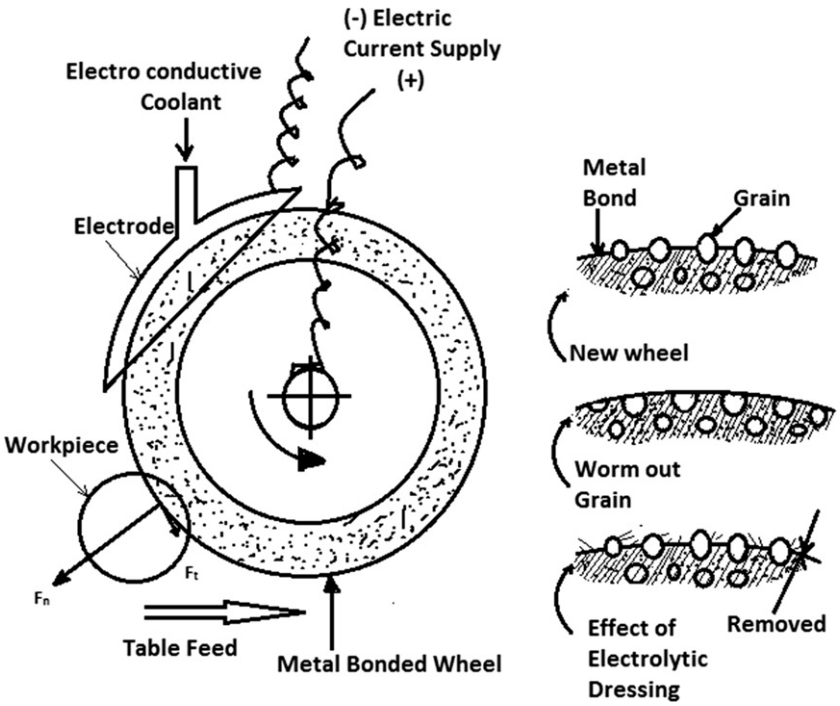

Figure 3 ELID grinding setup proposed by Murata *et al.*[4]

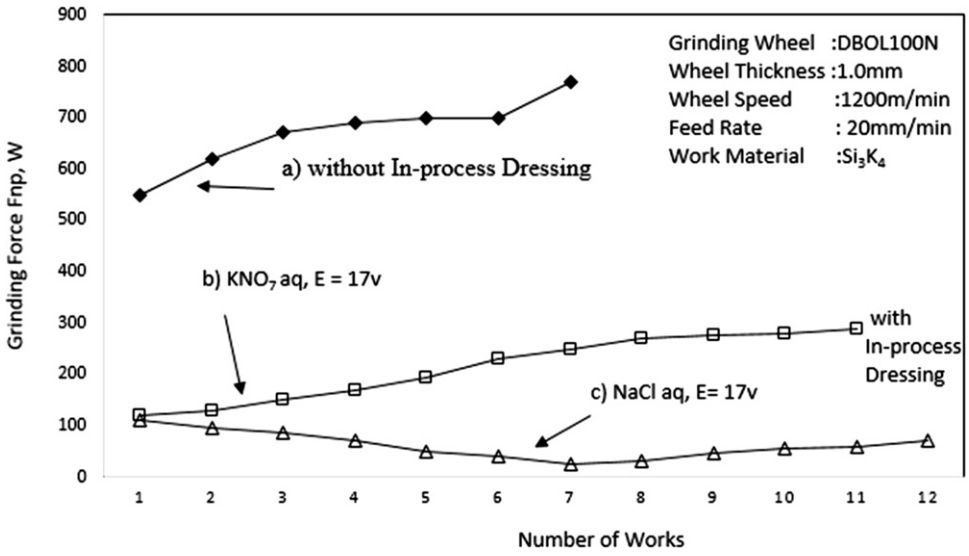

Figure 4 Significant reduction of grinding force when in-process dressing (ELID) is used.[4]

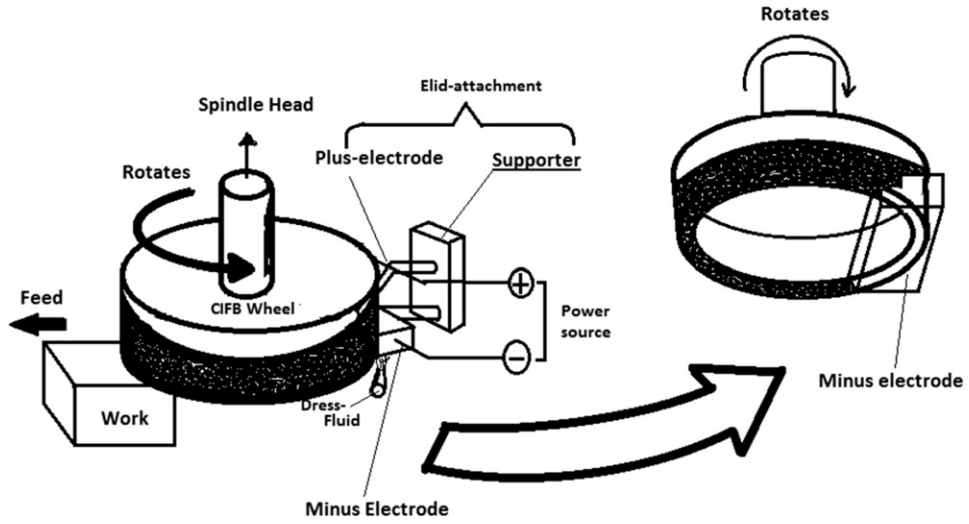

Figure 5 Experimental setup for ELID grinding of silicon wafer, proposed by Ohmori *et al.*[5]

3. As the advantageous effect of *b*, mirror surface can be achieved by ELID grinding without further processing method hence elimination of subsequent finishing process like polishing and lapping can be attained by introducing ELID.
4. ELID grinding can be applied for variety of machining system such as vertical/horizontal grinding machine, planner surface, or cylindrical surface grinding, etc., without any notable modification of the machine.

1.13.3 Classifications of ELID Grinding

Researchers' continued to investigate various aspects of ELID grinding in 1990s. Eventually, they divided ELID grinding into three major types, based on the materials to be ground and application method. However, the basic principle of dressing of the wheel remains the same which is the anodic dissolution metal bonded grinding wheel for in-process dressing. In order to have better understanding about various types of ELID grinding, section below discusses basic methodology of different ELID grinding system.

1.13.3.1 Electrolytic In-Process Dressing (ELID I)

This is the most widely used ELID grinding method used by manufacturing practitioners. In this case the wheel is dressed continuously in-process at one side and grinding is being taken place on the other side. Figure 7 explains the basic mechanism of ELID I method for peripheral grinding. A cathode electrode covers usually 1/4th to 1/6th of the cutting edges of the wheel whereas the other exposed portion of the wheel takes part in the grinding action. The gap between the electrode and the wheel is usually maintained to be 0.1–0.3 mm.

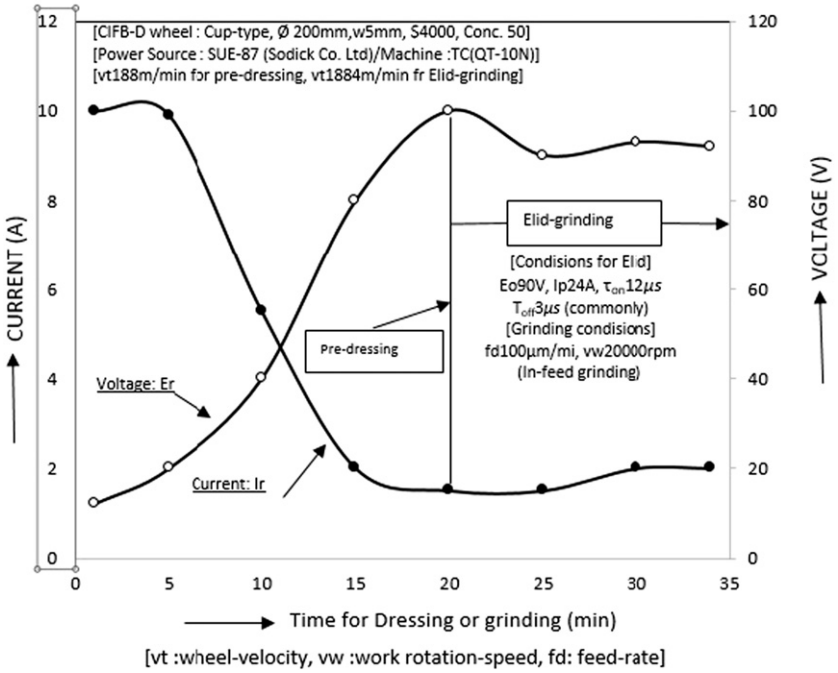

Figure 6 I–V characteristic for dressing of the wheel by ELID shows reduction of dressing current due to the formation of insulating layer.[5]

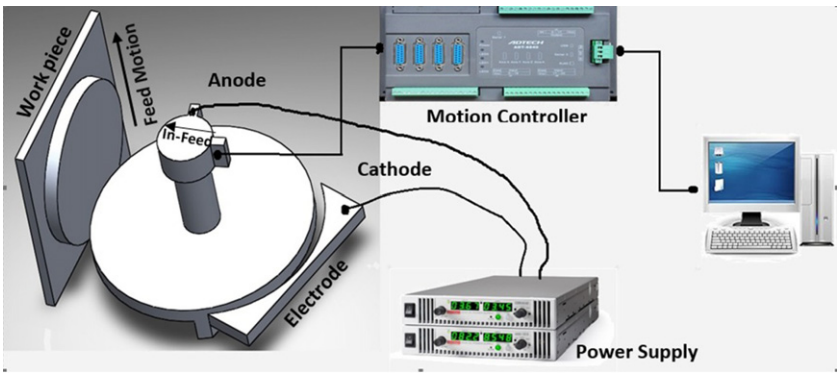

Figure 7 ELID I grinding system.

1.13.3.2 Electrolytic Interval Dressing (ELID II)

In the case of internal grinding of cylindrical surface ELID I method is mostly inapplicable as it is difficult to integrate cathode electrode with the grinding wheel especially for small holes. In order to cater this problem and to carry out precision grinding on the small holes on ceramic materials Zhang *et al.*[6] introduced ELID II method. In this method the dressing of the grinding wheel is carried out intermittently in contrast to ELID I method. In ELID I method wheel is dressed without any process condition monitoring, however, there is inherent self-controlling mechanism in the process that saves the wheel from excessive dressing as described in Section 1.13.2. On the contrary ELID II is an intermittent process and interval time between two successive dressings is set by the user. Therefore, it is necessary to monitor the grinding process, in order to select the interval time. Grinding force is a good choice as it indicates the attritions wear of the grits, thus in ELID II system interval time is set mostly based on pre-decided grinding force limit and sometimes by monitoring other grinding conditions. Figure 8 shows the schematic illustration of the interval ELID dressing and grinding. In this time of arrangement production time will be compromised as the wheel does not take part in the grinding action during dressing.

1.13.3.3 Electrode-Less ELID (ELID III)

The problem of ELID II method is absence of in-process dressing. It can be understood from Figure 8 that during dressing of the wheel no grinding action is being taken place. Therefore, the production time will be compromised when

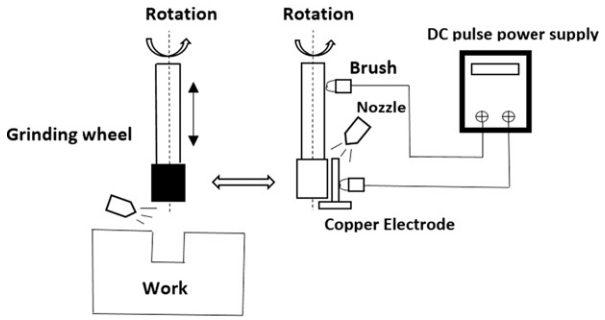

Figure 8 ELID II grinding principle.[6]

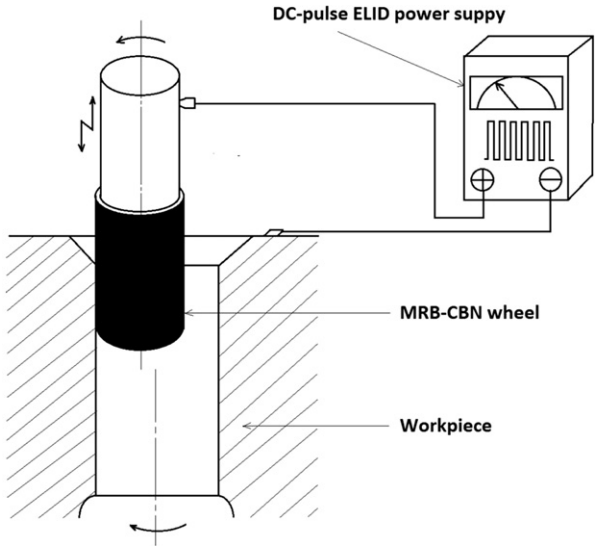

Figure 9 Electrode-less ELID grinding (ELID III).[7]

ELID II method is used. In order to tackle higher production time associated with ELID II system Qian *et al.*[7] introduced ELID III system. In ELID III system the cathode electrode is removed by the workpiece itself as explained in Figure 9. By doing this in-process dressing of the grinding wheel can be achieved and anodic dissolution will be taken place only on the metal bond of the wheel and not on the workpiece. However, this method is limited for grinding of conductive material only. Moreover, as all electrolytes has some degrees of dielectric property this process may introduce unwanted spark between the workpiece and the grinding wheel when pulsed DC power is applied between anode wheel and cathode workpiece (a similar concept of EDM). This may lead to unwanted micro/macrocavities on the wheel. Hence the wheel life will be reduced.

1.13.3.4 Electrode-Less ELID (ELID IIIA)

It is mentioned in the earlier Section 1.13.3.3 is that ELID III has a problem of initiation of unwanted spark that may damage the grinding wheel locally. In order to address this problem an alternating current (AC) power supply was introduced instead of pulsed DC power supply for ELID grinding. This causes the workpiece to become anode during half cycle of the current and cathode during other half cycle of the current. Therefore, anodic dissolution and formation of oxide film occurs not only on the grinding wheel but also on the workpiece material. This method is known as ELID IIIA and was proposed by Lim.[8] The principle of this type of ELID grinding is explained in Figure 10. This version of ELID will cause to create a thick oxide layer (passivation film) on the workpiece as shown in Figure 10(c) to prevent direct contact between the wheel and the workpiece, hence the electrical discharges.

1.13.3.5 Ion Shot ELID (ELID IV)

Ohmori *et al.*[9] developed a new ELID technique where the nozzles have two plates connected to the ELID power supply as shown in Figure 11. When the electrolyte hits the wheels it is already ionized and oxidation of metal bond (of the grinding wheel) can take place. However, it is also true that electrolyte will lose some ionization as it leaves the electrode gap, therefore, this technique is useful for fine grinding technique.

A comparison between various methods of ELID grinding is described in Table 1.

1.13.4 ELID Grinding for Nano Surface Finish

Researchers have been investigating the feasibility of ELID grinding for various types of hard and brittle materials to achieve nanometric surface finish. These include ceramics, optical glass, hardened steel, silicon, etc. The outcomes of these researches are very promising and indicate that ELID grinding can eliminate final finishing process like polishing and lapping. This section discusses research activities related to the applications of ELID grinding on various materials.

1.13.4.1 ELID Grinding for Ceramics

Ohmori *et al.*[10] carried out an experimental study to investigate the performance of ELID grinding on structural ceramics particularly for silicon nitrides. Two different types of silicon nitrides were used in this purpose namely a sintered reaction-bonded silicon nitride (SRBSN), and a cast-and-sintered silicon nitride (Si_3N_4). The effects of cutting speed, feed rate, and grit size on the surface finish of the product were investigated. The findings of the study are summarized in Table 2.

Figure 12 shows the effect of different mesh size of the wheel on surface roughness of Si_3N_4 (a) and sintered reaction-bonded silicon nitride (SRBSN) (b). It can be observed from Figure 12 that both cases sub-20 nm R_a surface finish be achieved, which is considered to be optical quality surface finish by ELID grinding without further material processing technique like lapping and polishing.

Bandyopadhyay *et al.*[11] studied the application of ELID technique for rough grinding operation with high material removal rate (MRR) and compared it with conventional grinding. The workpiece material was silicon nitride. It was observed for conventional grinding that the cutting force increases continuously as the volume of material removed increases; this is because the grinding grits become blunt as the

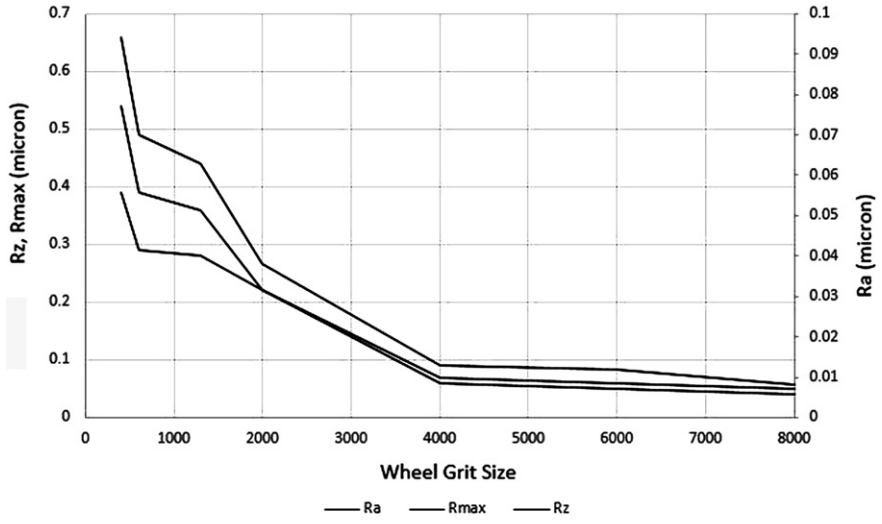
Table 1 Comparison between different types of ELID grinding

Attributes	*Electrolytic n-process dressing (ELID I)*	*Electrolytic interval dressing (ELID II)*	*Electrode-less ELID (ELID III)*	*Electrode-less ELID (ELID IIIA)*	*Ion shot ELID (ELID IV)*
Dressing interval	Continuous	Intermittent	Continuous	Continuous	Continuous
Separate electrode	Yes	Yes	No (workpiece is cathode)	No (workpiece is cathode)	No
Dressing current	Pulsed DC	Pulsed DC	Pulsed DC	Alternating current	Pulsed DC
Electrolyte property	Initially deionized	Initially deionized	Initially deionized	Initially deionized	Ionized

Table 2 Summarized result of the study[10]



Variable	*Material SRBSN*	*Material Si_3N_4*
Grit size	Higher mesh size wheel produces better surface and #4000 no wheel can produce mirror surface	Same trend was observed as SRBSN. Surface finish achieved by rougher wheel (#320) on Si_3N_4 is worse than that was achieved on SRBSN material, however, for finer wheel equivalent surface can be produced on both materials
Cutting speed	No significant effect on the surface finish of the material	Same as SRBSN
Feed speed	Rough wheel produces bad surface finish at higher feed rate, finer wheel has no significant effect	Similar trend was observed as SRBSN

grinding progresses as there is no in-process dressing for conventional grinding. On the contrary, ELID grinding shows significant reduction of normal force was observed under same cutting condition. The obvious reason behind this is the constant protrusion of new sharp grits during the whole-grinding process because of ELID operation. This also helped to improve the average SR by ~16% for ELID grinding as compared to conventional grinding. The variation of normal grinding force is shown from **Figure 13**. An interesting point to note from **Figure 13** is that higher normal force at the beginning of the cutting stable and low cutting force is achievable after 6000 mm^3 of material removal. The reason behind this is because at the beginning sharp grits are not exposed and electrolysis process is not fast enough to help the sharp grits to be protruded out. In order to address this problem authors proposed two solutions, first one is to use of dummy material for first few cutting cycle before the start of actual workpiece machining. The second solution which is more convincing is to introduce ELID pre-dressing. The pre-dressing condition was different from actual ELID grinding. It was performed in two stages before ELID grinding. In the first stage, the ELID dressing was performed with 90 V for 30 min. The oxide layer produces during ELID dressing was removed mechanically by an aluminum oxide stick. Then the second dressing was performed also with 90 V for 30 min. The ELID grinding was then performed with 60 V, by applying modified ELID dressing as explained above, a stable and low grinding force (almost 5 × lower) can be achieved from the beginning of the grinding operation which can be noticed **Figure 14**.

Katahira *et al.*[12] investigated the surface modifying effect caused by ELID grinding on AlN ceramics and identified the grit size that governs the transition between ductile mode cutting and brittle cutting. This is a very important finding as grit size plays a significant role in achieving nanometric SR on hard and brittle materials by ELID grinding. It was observed that ELID grinding technology can produce extremely smooth surface with nanometric roughness of only $R_a = 8$ nm. If the mesh size of the wheel is greater than #4000 a regular ductile surface with no cracks can be achieved with ELID grinding and the transition between ductile and brittle machining occurs between mesh size #2000 and #4000. **Figure 15(a)** shows the effect of wheel mesh size on the average SR of the material and **Figure 15(b)** explains the transition from brittle mode machining to ductile mode machining. Surface properties were also found to be greatly improved by ELID grinding. It was observed that ELID ground workpiece have better surface characteristics like higher hardness, less friction coefficient, etc., over the conventionally polished workpiece. The authors' investigation suggests that oxygen is diffused into the workpiece when ELID grinding is used for the finishing operation and they identified this diffusion phenomenon as the cause of the improvement of the surface characteristics of the ELID ground samples.

Yang *et al.*[13] developed a new control strategy for ELID grinding and applied it for grinding silicon nitride ceramics. Authors viewed grinding parameters to be constant for particular material with specific requirements, thus cannot be altered. On the other hand, authors concluded that oxide layer states are not the same under different dressing currents as the dynamic behavior of electrolysis and mechanical wearing of oxide layer play roles in ELID grinding. In order to maintain stable dressing current (hence the oxide layer) authors developed an ON-OFF control mechanism which monitors the dressing current and switches the supply of electrical power accordingly. By applying this researchers achieved more uniform dressing current (as shown in **Figure 16**) throughout the grinding process and mirror surface with $R_a = 12$ nm.

Xie *et al.*[14] studied the effects of elliptical torus-shaped diamond wheel for freeform axial-feed grinding of Si ceramics.

(a)

(b)

Figure 12 Effect of grit size on surface finish of Si_3N_4 (a) and SRBSN (b) with constant cutting speed, feed rate, and depth of cut.[10]

The wheel was developed by carrying out form truing of a non-elliptical in an elliptical interpolation paths. The objective of the research was is to understand how the ductile mode mirror grinding can be realized on hard and brittle material using this new wheel profile. It was found that elliptical wheel-profile produces larger wheel working area and more active diamond grains than the arc wheel-profile even in axial-feed grinding of steep freeform surface. This causes reduction in grain cutting depth to a lesser value than critical depth of cut (DOC) without having nanometric positioning capability. This leads more efficient ductile mode cutting. The experimental results confirmed reduction of brittle micro-crack and SR to ductile mode mirror grinding state with the increase of elliptical torus eccentricity as shown in **Figure 17**. Finally, authors concluded that accurate and mirror freeform grinding of hard and brittle material may be achieved by using an elliptical wheel-profile along with valid grain protrusion and suitable grinding variables.

1.13.4.2 ELID Grinding for Coated Film

Katahira *et al.*[15] investigated ELID grinding on TiAlN films. Authors in this research work compared ELID grinding with other finishing process. ELID grinding can produce a mirror surface with an average SR of 2.4 nm whereas other finishing process can only achieve an average roughness of 56.2 nm. Energy-dispersive x-ray spectroscopy revealed that ELID process creates an oxide layer on TiAlN film because of high reactivity of Ti, Al. However, this thin oxide layer enhances surface properties of the TiAlN film. The friction coefficient of the ELID-ground TiAlN film was found to be approximately two-thirds that of the non-ELID-ground TiAlN film (**Figure 18**) as studied in the ball on disk experiments conducted by the researchers.[15] The wear rate of the ELID-ground TiAlN film (disk specimen) also improved by 50% as compared to the non-ELID-ground TiAlN film; and the wear rate against of Al_2O_3 ball for ELID-ground TiAlN film is approximately one-tenth of

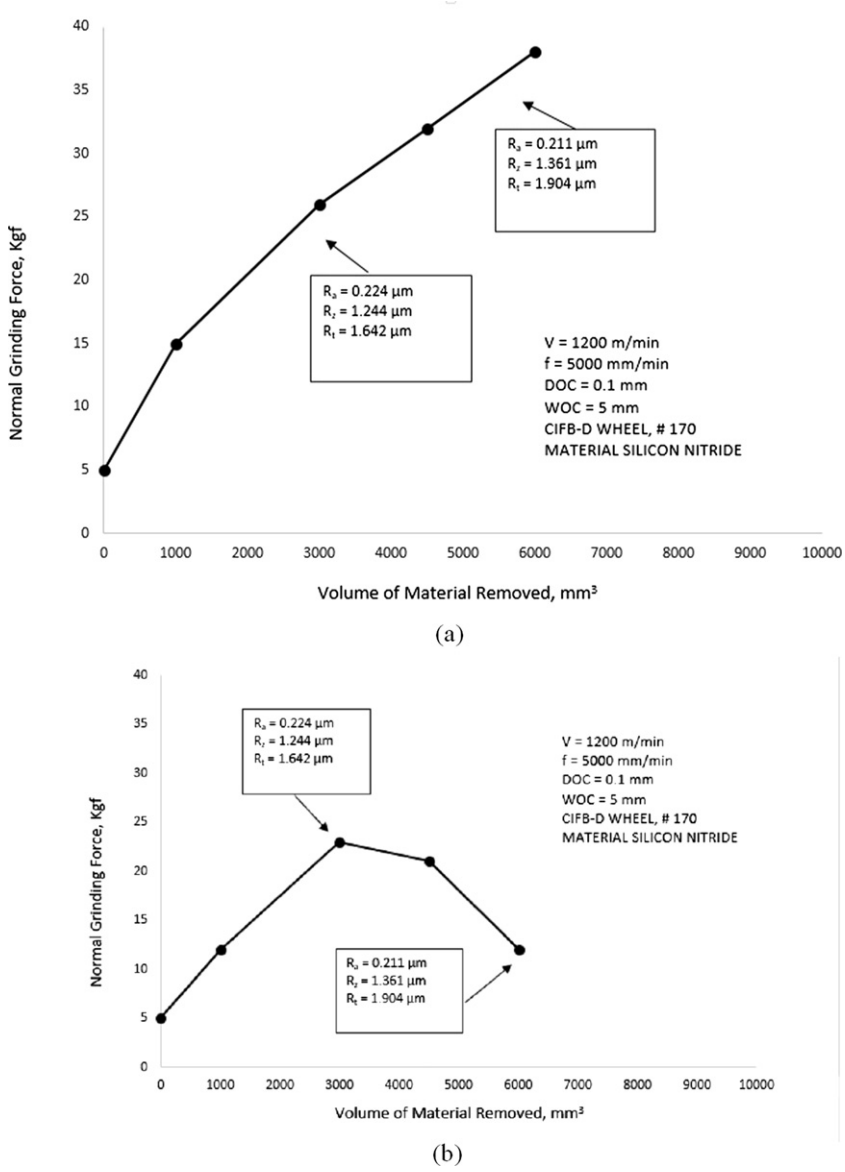


Figure 13 Variation of normal grinding force with volume of material removed (a) conventional grinding, (b) for ELID grinding.[11]

that for non-ELID-ground TiAlN film. The result is shown in Figure 19. The underlying reason behind these improvements in the tribological behavior of ELID ground samples is the diffusion of oxygen into the TiAlN film, which was confirmed by energy-dispersed x-ray diffraction system (EDX) study conducted by the authors (Figure 20).

Zhang *et al.*[16,17] compared ELID grinding with ordinary grinding where the cast iron bonded diamond wheel was dressed mechanically by abrasive stone. It was observed that ELID produces soft oxide layer which holds partially/fully the grits. On the other hand, in mechanical dressing case grits are only held by hard cast iron bond. This caused the ELID grinding to be more stable than conventional grinding and the SR of the ground samples was found to be better in quality in the case of ELID ground samples as described in Figure 21.

Moreover, the morphological study of the samples suggested that in ELID grinding ductile regime machining is the predominant mode of machining (with less pits and fractures) whereas in ordinary grinding both ductile regime and brittle facture machining occurs equally as explained in Figure 22. Therefore, the authors concluded that ELID grinding is a better choice in ultra-precision grinding to achieve nano surface.

1.13.4.3 ELID Grinding for Metal

Qian *et al.*[18] experimented and compared several finishing operation for bearing steel including ELID grinding (Figure 23). Traverse mode and plunge grinding were studied. Moreover, ELID grinding was compared with other finishing process like honing and electro-finishing methods. Experimental findings showed ELID grinding produces better surface finish on the

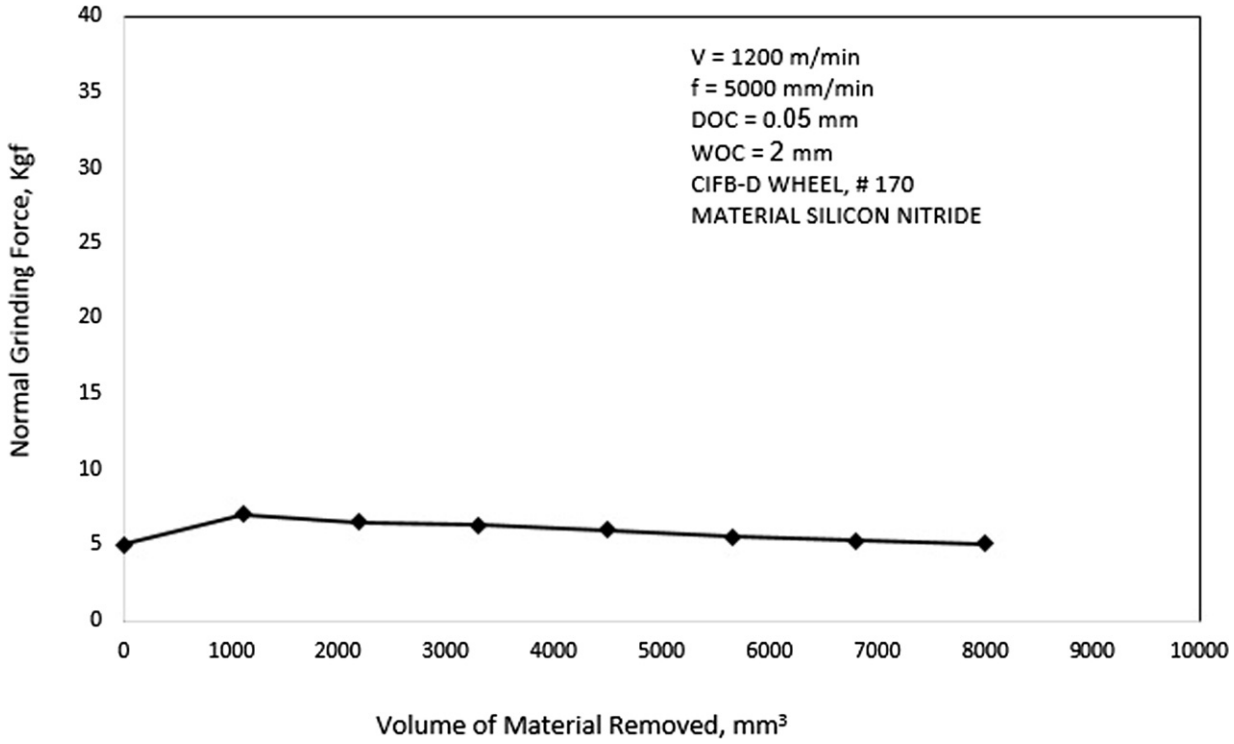

Figure 14 Stable and low grinding force after applying modified ELID grinding as explained in the text.[11]

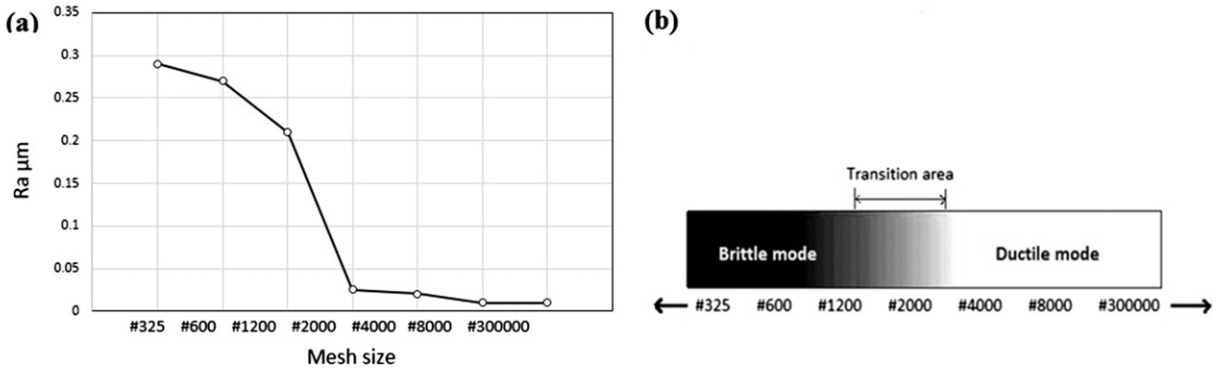

Figure 15 (a) Variation of surface roughness with wheel mesh size. (b) Brittle/Ductile mode transition.[12]

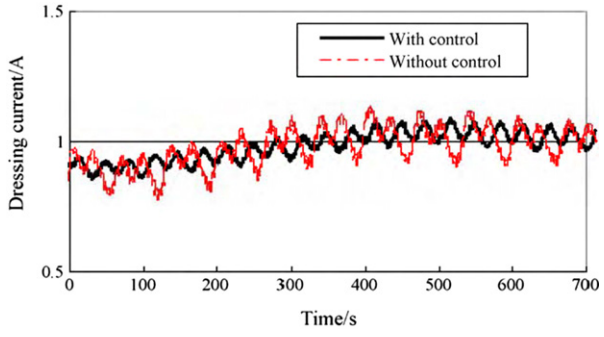

Figure 16 Variation of dressing current as observed by Yang *et al.*[13]

workpiece while comparing with other finishing processes as explained in Table 3.

Qian *et al.*[18] found that in ELID grinding of bearing steel traverse mode generated better surface quality (SQ) than plunge mode grinding, especially when coarser wheels were used. Similar observation was made for waviness of the finished product. Authors carried out metrological study of the samples and found similar degree of waviness on samples processed by ELID grinding honing and electro-finishing method as shown in Figure 24(a). Further, residual stress on the ELID ground sample was also found to be very low (Figure 24(b)). Only negative thing for ELID grinding was longer cycle time as compared to honing and electro-finishing

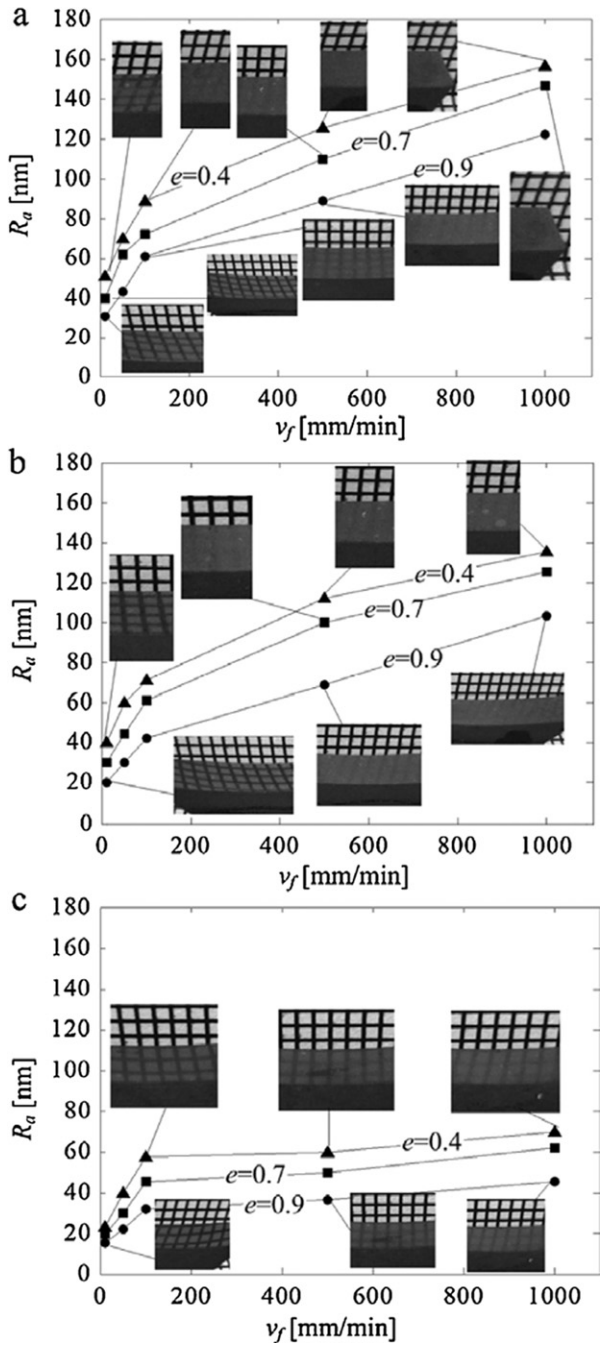

Figure 17 Surface roughness R_a versus elliptical torus eccentricity e and feed rate v_f: (a) wheel speed, v_w=16 m s^{-1}, (b) wheel speed, v_w=24 m s^{-1}, and (c) wheel speed, v_w=32 m s^{-1}.[14]

processes (Figure 24(c)), which indicates that technology should be used for small batch production situations.

Zhang *et al.*[19,20] investigated a similar approach described by Yang *et al.*[13] to carry out internal precision grinding of bearing steel. A similar on-off control mechanism was implemented to realize uniform dressing current and oxide layer thickness. The characteristics of the dressing current is shown in Figure 25, which reports the stability of the real time dressing current as the active control mechanism is applied.

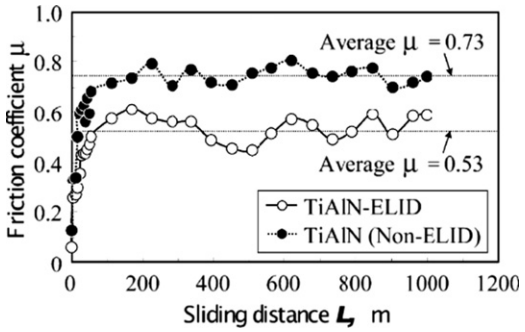

Figure 18 Friction coefficient obtained by ball and disk experiment for ELID-ground TiAlN and non-ELID finished TiAlN film.[15]

Finally, authors concluded that ELID grinding with active control could acquire almost equal SQ, MRR, and grinding force than that with the traditional ELID grinding. Moreover, the dressing current is more stable and in dynamic equilibrium, therefore the attainment of desired SQ would be faster in the proposed new method.

Lens mold requires ultrafine surface finish with high form accuracy. ELID grinding is a potent technology to cater these high end requirements for lens mold fabrication. Saito *et al.*[21] tested and compared the performance of ELID grinding with conventional finishing process like polishing for cemented carbide lens mold fabrication. They also investigated the effect of bond material (namely Cr bond and Cu bond) on the performance of ELID grinding. Authors' finding showed Cr bonded wheel produces better SQ as compared to ELID ground sample with Cu bonded wheel and polished samples (Figure 26). In most of the case of ELID grinding a soft insulating oxide layer is formed which somehow partially retards the protrusion of sharp grits, however, in case of Cr bonded wheel no visible oxide layer is formed on the wheel that causes more protrusion of sharp cutting grits hence better SQ. Moreover, higher oxygen diffusion to the workpiece material in case of Cr bonded wheel also enhances the SQ which is similar to that of Katahira *et al.*[15]

It was reported by other researchers that diffusion of oxygen into the work material during ELID grinding improves the surface property of the work material.[15,21] This inspired Ohmori *et al.*[22] to propose application of a weak positive potential at the workpiece as to control oxide layer formation during ELID grinding of stainless steel. The concept is described in Figure 27. Three different types of abrasive particles (diamond, alumina, silicon dioxide) were tested and compared. It was found that types of abrasive particles do not significantly affect the SR as all of them produced an average SR of 8–10 nm on the ground sample. When compared with conventional polishing it was found that ground samples showed superior surface properties including hardness, tribological and fatigue properties, corrosion and high-temperature oxidation resistances, and adhesive strength with coating films over conventionally polished samples. It was further observed that a stable oxide layer was formed on the ELID ground sample as anticipated by the researchers that enhances the surface characteristics of the ground sample. In addition, it was found very interestingly that the wettability of the processed surface varies with different method and wheel grit

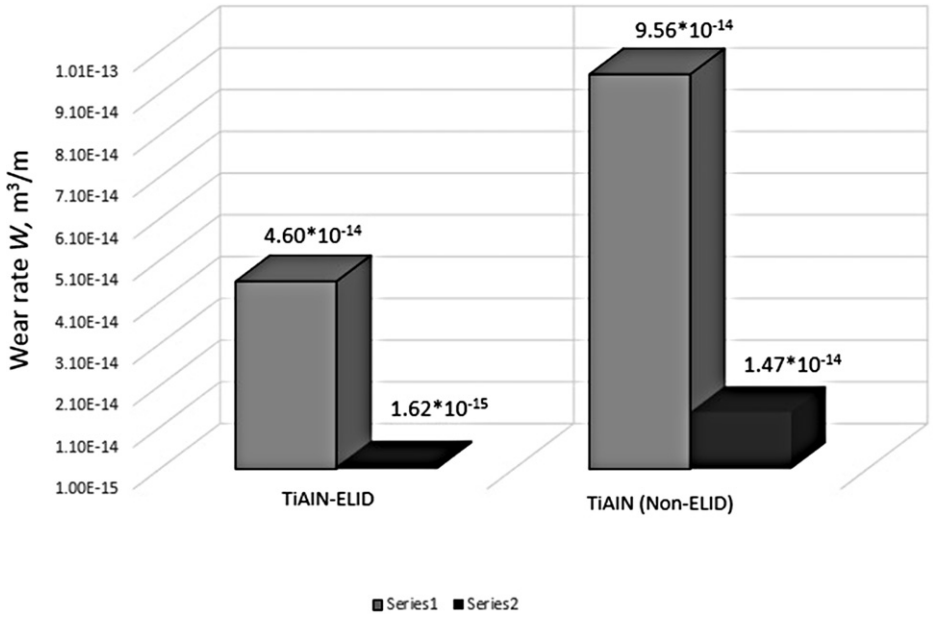

Figure 19 Wear rate of disk and ball specimens.[15]

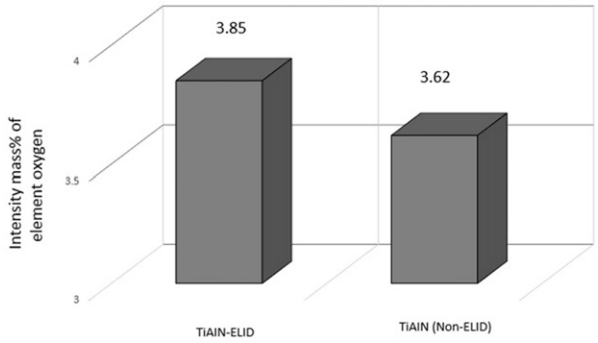

Figure 20 Analytical results of intensity of mass obtained by use of energy-dispersed x-ray diffraction system.[15]

materials. Therefore, researchers proposed that by varying the processing conditions and grinding wheel one can possibly control the surface behavior including hydrophilicity of the surfaces.

Raffles *et al.*[23] investigated different ELID technique (as discussed in Section 1.13.3) for finishing operation of bearing balls using metal-resin bonded CBN wheel. It was observed that a #12 000 series wheel can achieve 2 nm R_a (average SR) with ELID I technique, which is significantly better than balls produced by polishing. Moreover, without ELID MRB-CBN wheel was proven to ineffective for grinding operation as the wheel becomes glazed quickly. However, it was found that ELID I ($R_a = 2$ nm) is better than ELID II ($R_a \leq 10$ nm) because of continuous dressing. On the other hand, ELID III was observed to be unstable.

1.13.4.4 ELID Grinding for Optical Glasses

Optical glass is one of the materials on which ELID grinding technique has been tested for finishing operation. Ohmori *et al.*[24] used ELID grinding to process spherical glass lens. ELID grinding was proven to be more effective than ordinary grinding as it can achieve a SR of 18 nm compared to 138 nm by ordinary grinding method. This was an improvement of 10× times. The ELID ground sample had a very good shape accuracy of submicron range. The variation of the SR with different wheel mesh size is shown in **Figure 28**. Morphological study of the samples also confirmed that ELID grinding can produce much smoother surface than conventional grinding method.

Finishing operation by ELID grinding for BK7 glass was investigated by Kumar *et al.*[25] Kumar *et al.*[25] reported in their work that current duty ratio is one of the key elements to play a major role on the ELID grinding performance and resultant surface finish of the product. It was observed that grinding force was reduced and surface finish was improved as the duty ratio increases as explained in **Figure 29**. The main reason behind this is that higher duty ration dresses the wheel more, therefore renewal of sharp grits are more frequent that causes the improvement in the grinding performance. However, this comes with the price of the grinding wheel life. Higher duty ratio pumps in more dressing current that softens the wheel and eventually reduces its life. Authors also observed that #4000 series wheel with proper grinding condition can generate a flawless ductile surface with sub-10 nm average SR on BK7 glass.

Saleh *et al.*[26,27] developed an intelligent ELID grinding system to conduct nano finishing operation on hard and brittle material like BK7 glass. They first introduced a dedicated ELID grinding machine equipped with several sensory mechanisms with intelligent control. The performance test of the machine was conducted for vertical groove grinding on BK7 workpiece. Vertical grooves with optical SQ were machined using the developed ELID grinding machine. The best SR of 17 nm was achieved at 125 mm min^{-1} feed speed with 3 μm DOC.

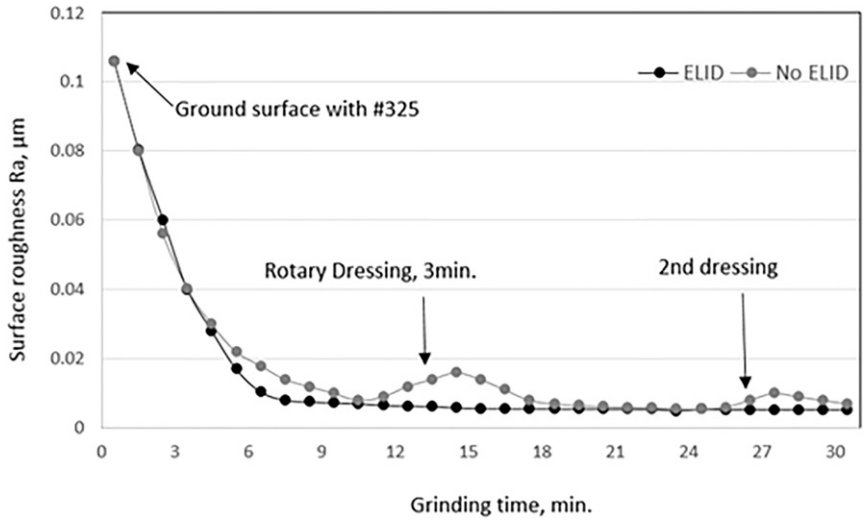

Figure 21 Variation of surface roughness R_a over grinding time.[17]

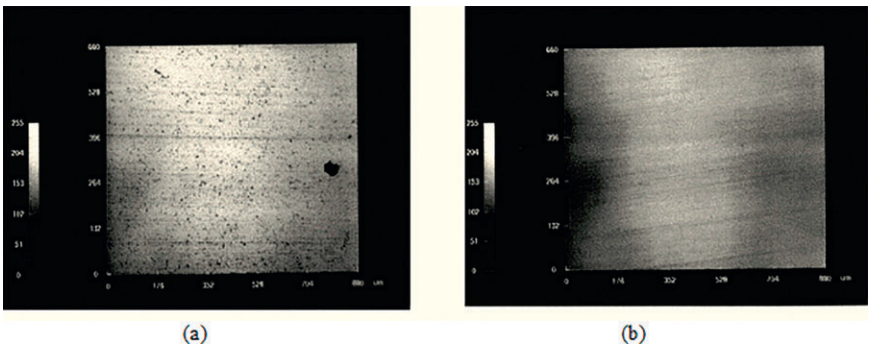

Figure 22 Topography of ground surface of CVD-SiC film (a) ordinary grinding method and (b) ELID grinding method.[16]

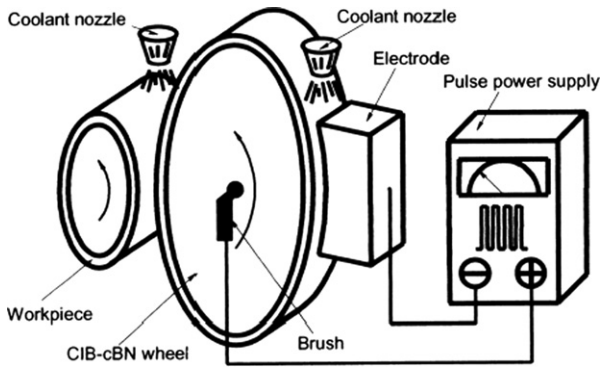

Figure 23 Cylindrical ELID I grinding for bearing steel.[18]

Table 3 Effect of finishing operation on bearing steel[18]

Finishing method	R_a (µm)	R_z (µm)	*Skew risk*	*Delta* q
Honing	0.06	0.5	− 1.1	0.95
Electric polishing	0.04	0.3	− 0.6	0.47
ELID grinding	0.02	0.2	0	0.2

Table 4 shows the effect of DOC/in-feed and feed speed on the SR.

From the table it can be understood that the best surface finish can be achieved at a certain DOC whereas lower feed rate gives better surface finish. It is known that there are three types of material deformation as a grain interacts with the workpiece during grinding: rubbing, plowing, and cutting. In rubbing mode of deformation the material removal is negligible though friction is apparent, which may even cause workpiece burn. Plowing occurs as the depth of penetration is increased; however, the chips are yet to form. With further penetration (the cutting stage) of the grits the actual chip formation occurs, which is desirable for grinding. Again too low in-feed/DOC produces bad quality surface which is due to the reason that rubbing takes place rather than cutting at a very low indentation of the grits as explained earlier. However, at a too high in-feed/DOC the cutting occurs in brittle mode rather than in ductile mode. This explains the trend of the variation of R_a with different DOC. Also lower feed rate produces better surface at a constant DOC/in-feed, as explained in Table 4, because higher the feed rate higher the probability to occur brittle mode cutting.

Overall the performance test of the machine revealed that it can produce an average SR of sub-20 nm, which is of optical

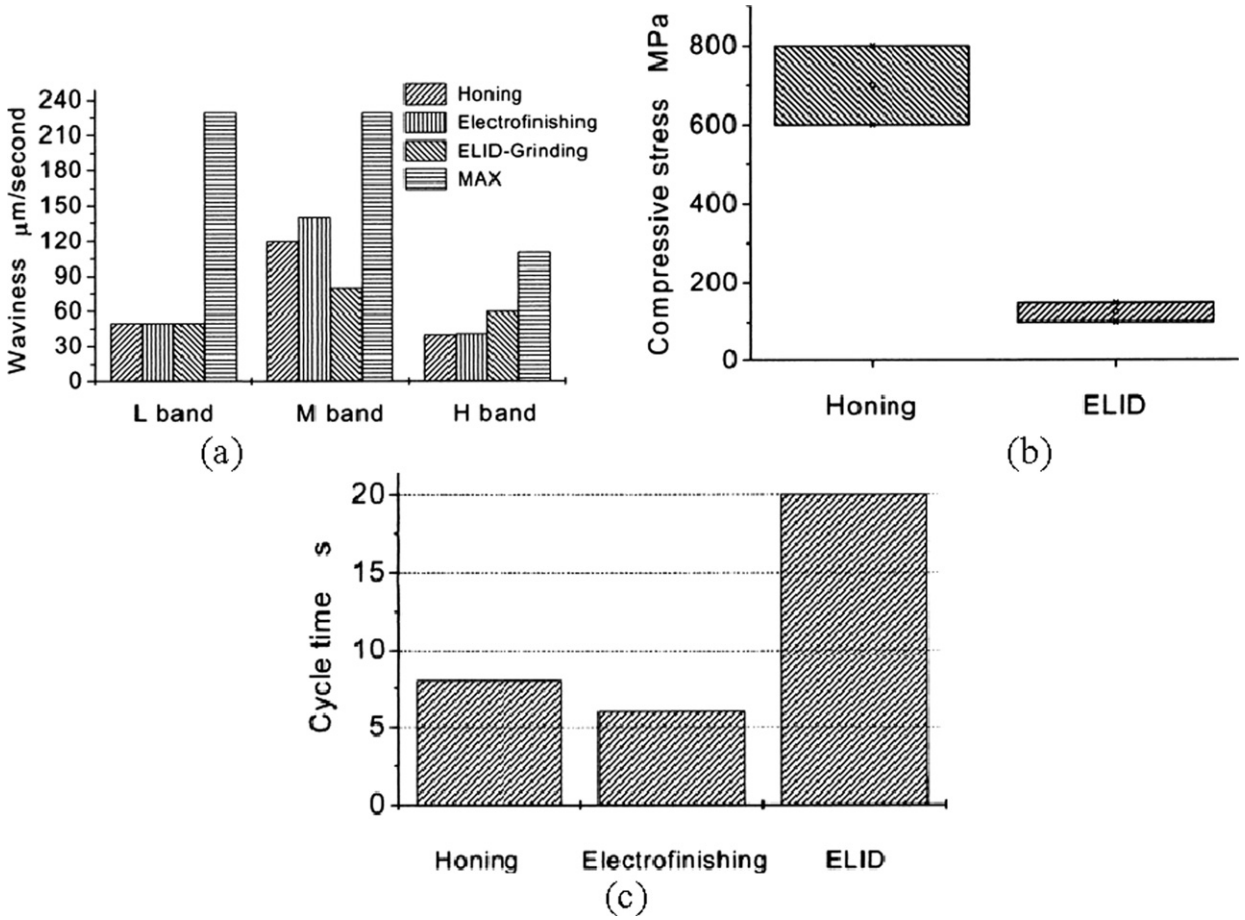

Figure 24 Comparison of ELID performance with different finishing processes for bearing steel (a) surface waviness; here MAX mean maximum allowable limit, (b) surface residual stress, and (c) cycle time of the process.[18]

quality with proper grinding parameters. In ELID grinding operation grinding wheel is dressed continuously therefore the diameter of the tool also changes during one grinding operation, which affects the form accuracy of the finished product especially for curved surfaces. In order to address this issue Saleh *et al.*[26,27] developed a tool wear compensation algorithm. According to this algorithm tool path for spherical lens grinding is generated by considering grinding wheel diameter and desired diameter of the glass lens. Once the lens is fabricated the diameter is measured using a touch probe based on machine measurement system. If the diameter of the lens is found to be offset the lens is reground using a new toolpath which is derived by considering the grinding wheel wear. This algorithm increased the form accuracy significantly as described in **Table 5**. The fabricated lens was found to be of optical quality with $R_a = 15$ nm as shown in **Figure 30**.

In another study Saleh *et al.*[28] developed a dressing control system by periodically observing the grinding wheel wear. Grinding wheel wear was gauged by measuring ratio of normal grinding force over tangential grinding force. When grinding force ratio exceeded a predetermined threshold value ELID power supply was turned on for dressing otherwise it was turned off to save the wheel from excessive dressing. The proposed system dressed the grinding wheel less than conventional ELID grinding because the dressing power is varied according to the change in the force ratio of grinding as explained earlier; however, it was found that the grinding force ratio was still under the critical value. It was also found that SQ obtained by conventional ELID grinding and proposed grinding was comparable. Based on these findings author concluded that dressing current profile over the whole-grinding cycle is much more uniform for the proposed methodology of wheel dressing. The tool wear was found to be only 48% of conventional ELID grinding for equal volume of material removal. However, the ground SQ was not sacrificed as mentioned earlier.

Wheel truing is different from wheel dressing; however, it is very important to maintain the form accuracy of the finished product. In conventional ELID grinding wheel truing is carried out separately by another method such as electrical discharge. Saleh *et al.*[29] proposed a pulse width control of the ELID power supply to carry out truing of the ELID simultaneously during electrolytic dressing. In the study conducted by Saleh *et al.*[29] a pulse width controllable power supply was developed for the in-process truing of the grinding wheel by monitoring the wheel profile on machine using an inductive sensor. The wheel roundness and the wheel workpiece contact were found to be improved significantly after implementing this power supply. Hence authors concluded that ELID is not only meant for wheel dressing alone, but in addition a controlled dressing

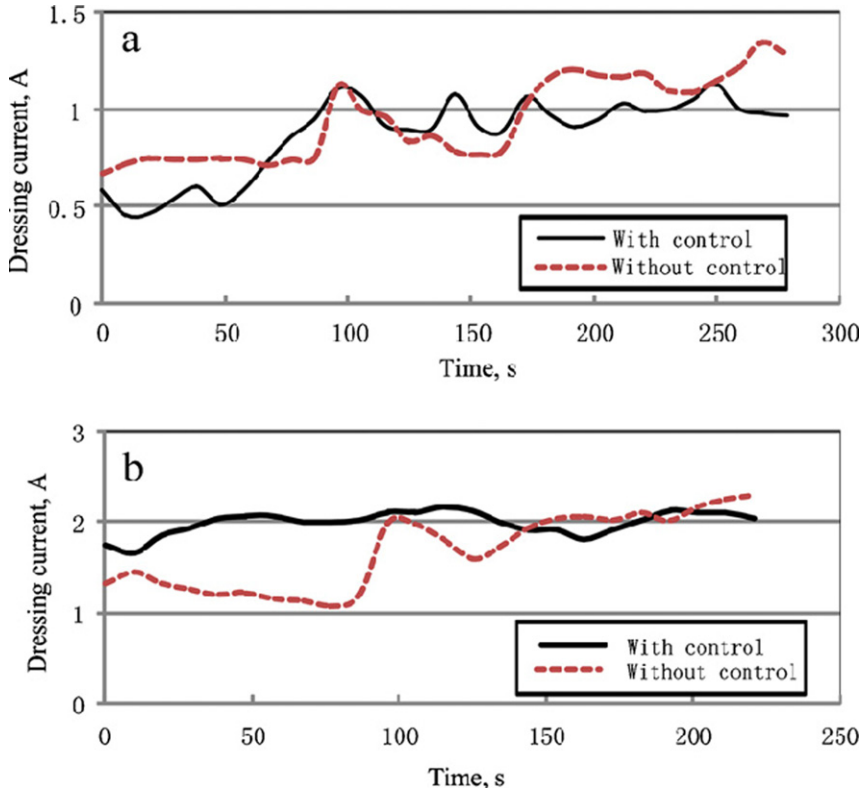

Figure 25 Dressing current change in internal cylindrical ELID grinding: (a) set value of 1 A and (b) set value of 2 A.[19,20]

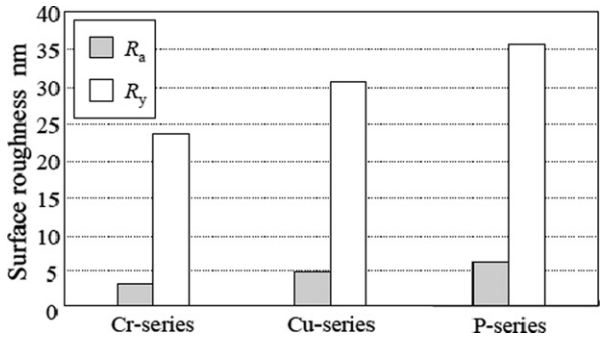

Figure 26 Comparison of surface roughness for wheels with different bond material (wheel mesh size #8000).[21]

can be applied to achieve the uniformity of the wheel thus a the need of separate system for wheel truing can be eliminated.

Studies conducted by Yin *et al.*[30] showed ELID grinding technique can produce a nano surface finish on Zerodur glass with an average SR of 5–10 nm when #4000 series wheels were used. The reason behind achieving such finish by ELID grinding is the ductile mode cutting, which was confirmed by the AFM study of the ground surfaces as described in Figure 31(a). It was found higher feed rate causes high grinding force (Figure 31(b)) that leads to more thermal damages to the surface. Ideal DOC to achieve ductile mode grinding for Zerodur glass was 0.4 μm. In another study conducted by Yin *et al.*[31] further developed a new grinding process and system for the fabrication of large non axisymmetric aspheric surface of fused silica (Figure 32), which is similar to the system described by Saleh *et al.*[26,27] in order to compensate the tool wear for ELID grinding. Notable improvement in form accuracy was observed after introducing compensation scheme as shown in Figures 33 and 34.

1.13.4.5 ELID on Silicon Wafer

Finishing of Si wafer by ELID grinding was investigated by Chao *et al.*[32] using metal and compared the grinding performance that uses resin bonded wheel. Amorphous layer, nanocrystals, polycrystals, dislocations, and microcracks were investigated in both cases. Grinding with resin bonded wheel was found to be superior in many aspects as compared to ELID grinding. ELID grounding was observed to be sensitive to grinding parameter selection and true optimized parameters were difficult to obtain and maintain. On the other hand, ground surface characteristics were less dependent to the machining conditions. Theoretically, formation of oxide layer in the case of ELID grinding weakens the rigidity of the bond material; hence dull grits held by oxide layer are expected to be fallen off by excessive grinding force. However in reality, there are still chances for some protruding grains getting excess attritious wear before it is pulled out in ELID grinding. This might cause unstable grinding condition and subsurface damage of the sample. However, in the case of resin bonded wheel self-sharpening effect of the lowers this chance. Further, in the case of resin bond wheel, except when feed rate is very low (say 2 μm min^{-1}) or wheel is loaded, the amorphous layer generated were normally thinner than

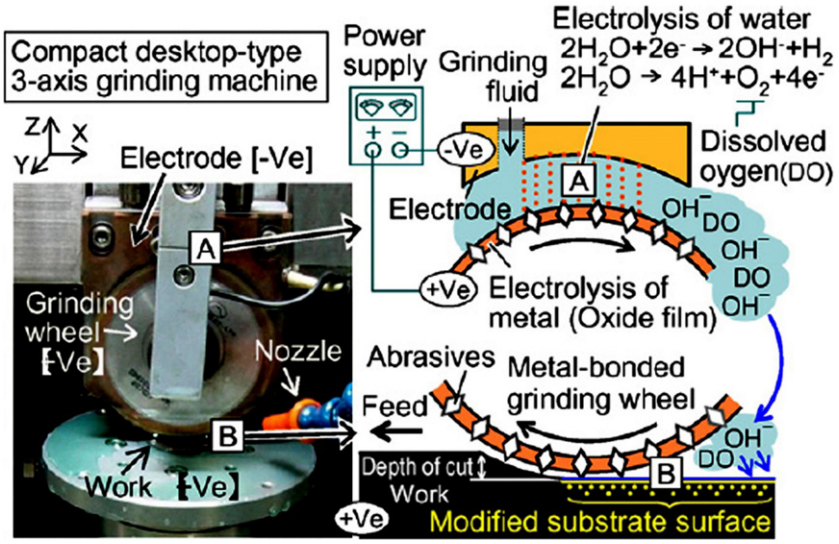

Figure 27 Overview of the proposed grinding system and a schematic illustration of surface modification reactions.[22]

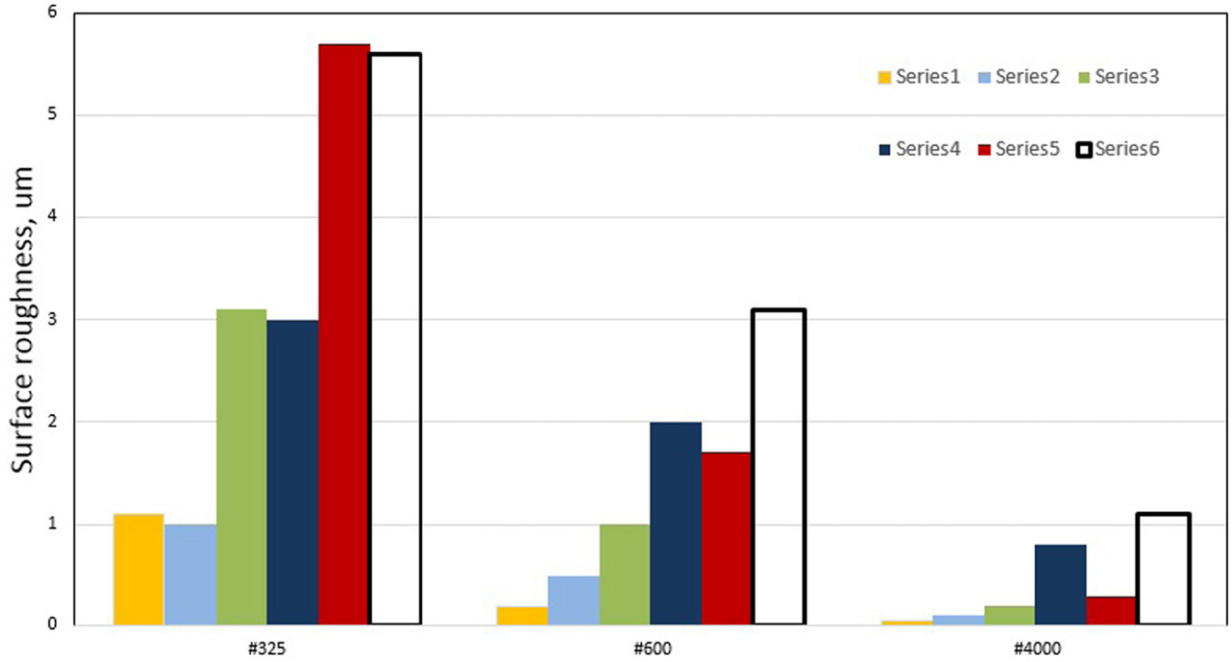

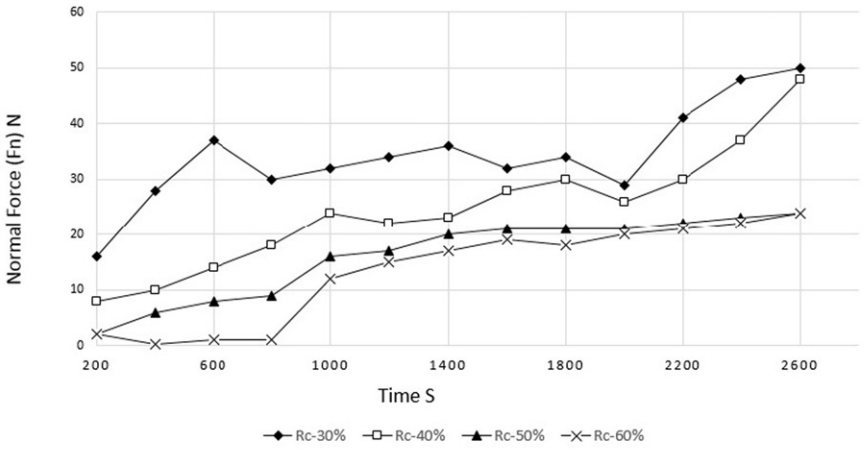

Figure 28 Variation of surface roughness of fabricated lens with wheel mesh number.[24]

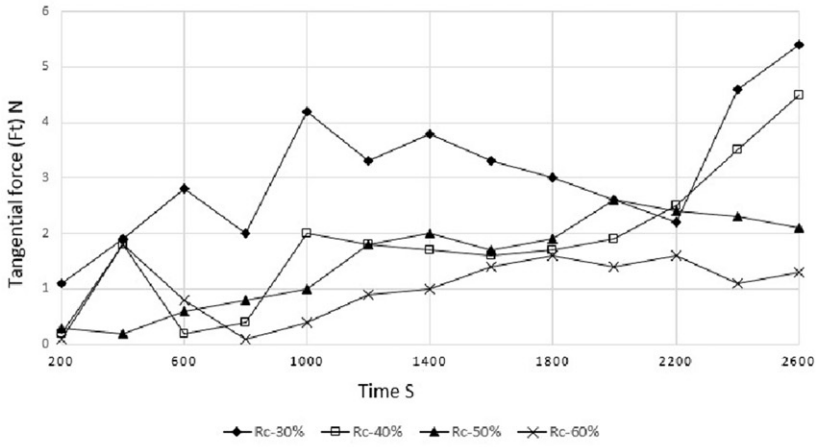
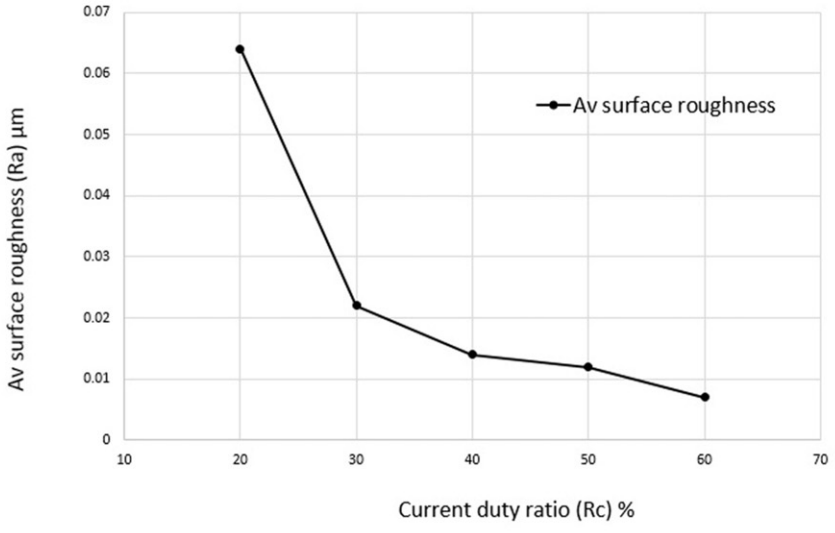


those generated by ELID grinding under the same grinding conditions.

Study on ELID lap grinding for Si wafer was performed by Itoh *et al.*[33] Stable grinding was performed using #8000–#3 000 000 series wheels. Ultrafine surface (sub-nano SR) with average SR of R_a=0.38 nm was obtained using #3 000 000 wheel whereas conventional lap grinding can generate SR R_a=0.47 nm. Another parameter of significant importance is the peak to valley roughness for Si wafer. ELID grinding improved peak to valley SR from 5.05 to 2.8 nm (**Figure 35**) as compared polishing. Moreover, morphological study of the ground samples with SEM and AFM also confirmed effectiveness of ELID grinding of Si wafer.



In conventional ELID grinding electrolyte fluid is supplied into the ELID cell by tangential flushing. Islam *et al.*[34] proposed a new idea of injection electrode (IE) in ELID grinding for thinning of silicon wafer. The concept of the system is described in **Figure 36**. This new technique enhances electrolyte filling between electrode-grinding wheel gap than conventional ELID flushing system. Because of this IE ensures better wheel dressing hence lower grinding force as compared to conventional ELID, which is described in **Figure 37**. With the help of IE assisted ELID grinding Islam *et al.*[34] successfully thinned down the silicon wafer from 750 μm to approximately 70 μm with sub-ten nano surface finish and without any visible cracking, pilling, and chipping.

Figure 30 A spherical lens is ground by ELID grinding with a surface roughness of R_a=15 nm.[26,27]

Islam *et al.*[35] further characterized the ELID lapping process for machining. In this study authors found that rate of formation of oxide layer is dependent on the current duty ration, however, not the total thickness of the layer. It was observed interestingly that intermediate range of current duty ratio and grinding parameter (feed rate) showed better wheel surface condition; as described in Figure 38. Higher current duty ratio is not favorable as it produces hard and thick oxide layer and dull grits do not fall by acting grinding force. This causes excessive grinding force and bad SQ. In the case of grinding parameter such as feed rate, authors found that excessive low feed speed makes the wheel to grind same area repeatedly which may cause excessive attrition wear of the grits resulting poor surface finish. ELID grinding process was found to be better than conventional grinding process for silicon wafer as it exhibited stable grinding forces with low magnitude. Moreover, the subsurface damages exhibited on the samples are significantly lower for ELID grinding process than conventional grinding. The ELID grinding process was able to achieve superior ground wafer SQ with R_a=4 nm. Under all experimental conditions, the ELID grinding process performs better compared to the conventional grinding process.

Researchers also studied the effect of diamond grain size on different aspects of Silicon wafer machining by ELID grinding such as SR, subsurface damage, and material removal.[36] The results are shown in Figure 39. It is clear from the result that smaller grain size improves the SR and reduces the depth of the subsurface cracks. However, MRR is much lower for superfine abrasive wheels. Therefore, it is recommended to use ultrafine abrasive wheel for final finishing operation.

1.13.5 Summary on ELID Grinding

In-process dressing of grinding wheel has been under research interest for several years in order achieve ground surface with better SR and form accuracy. This may eliminate the need for further finishing operation like polishing and/or lapping. Significant studies were carried out by many researchers on this subject area. ELID is proven to be the most effective method of in-process dressing. A lot of researches have been carried out by different researchers since its invention back in 1990s. Continuous anodic dissolution and formation of soft insulating anodic oxide layer ensures more protrusion of sharp cutting grits and lower grinding force than conventional grinding. Sub-10 nm average SR is achievable on hard and brittle materials like optical glasses, silicon wafer, ceramics, bearing steels, etc., by ELID grinding. However, wheel wear rate in ELID grinding is considerably high because of continuous anodic dissolution of metallic bond of the grinding wheel. This leads to low grinding ratio and wheel life. Further, it hampers the form accuracy of the finished products especially for aspheric or curved surface. Researchers proposed tool wear compensation scheme to overcome this problem. One very interesting thing about ELID grinding is that it can be implemented easily to the existing grinding without much modification. However, researchers also tried to develop dedicated intelligent ELID grinding system. Researchers also proved that pulse width control of the dressing current can make ELID grinding useful for in-process trueing of the grinding wheel. In a nutshell it can be concluded that ELID grinding is a promising technology to achieve nano metric surface finish on hard and brittle material and has the potential to eliminate final finishing process like polishing.

1.13.6 Background of EDM

Developed in the late 1940, EDM also called electro-discharge or spark-erosion machining has gained its popularity over the

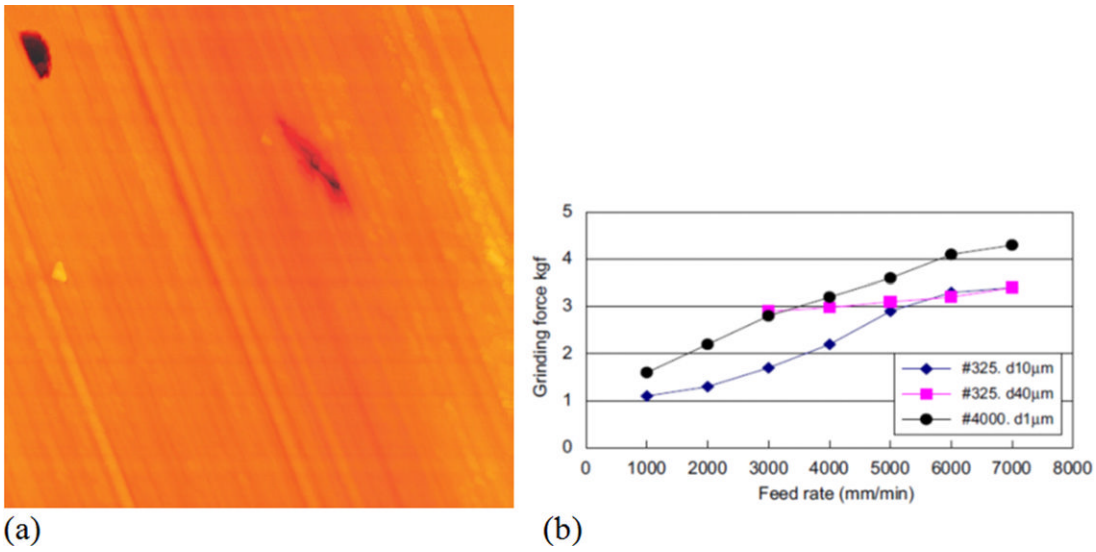

Figure 31 (a) AFM images of surfaces ground by #4000 wheel. (b) Effects of feed rate on grinding force.[30]

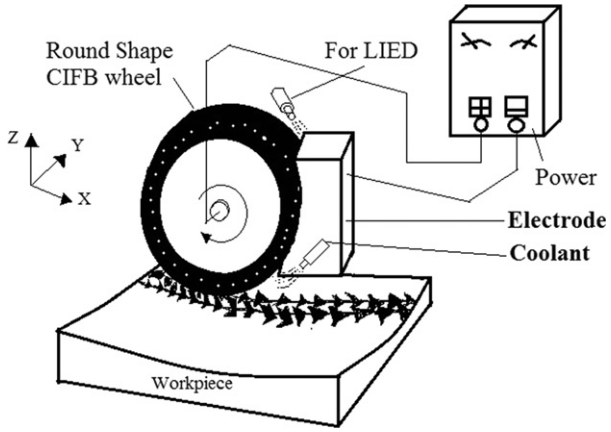

Figure 32 ELID grinding for 3-D arc enveloping grinding.[31]

years as a non-traditional machining method in the tool, die and mold making industries. The origin of EDM dates back to 1770 when British Scientist Joseph Priestly discovered the erosive effect of electrical discharges. EDM is the process of machining electrically conductive materials by using controlled sparks between an electrode and a workpiece in the presence of a dielectric fluid. The electrode usually is considered the cutting tool. The process works under principle of eroding conductive material by a series of discrete spark discharges, that is, only one spark occurs at any instant. Sparking occurs in a frequency range from 2000 to 500 000 sparks per second causing it to appear that many sparks are occurring simultaneously. The basic EDM system consists of a tool (electrode) and the workpiece, placed in nonconducting dielectric fluid. Dielectric fluid used in EDM machines are used for the following advantages: (1) controlling the sparking-gap spacing between the electrode and the workpiece; (2) cooling the heated material to form the EDM chip; and (3) removing EDM chips from the sparking area.[37] When the potential difference between the tool and the workpiece becomes high enough, the dielectric breaks down and a transient spark discharges through the fluid, causing the removal of very small portion of the workpiece surface. An overall EDM process is illustrated in Figure 40(a), while Figure 40(b) shows the discharge and metal removal.

The discharge occurs between the closest points of the two surfaces. The dielectric fluid provides a path for the discharge by being ionized. The erosion of the workpiece is achieved due to the localized melting and removal of the work surface caused by high temperature, which may go as high as 8000 °C.[39] The new flow of dielectric enters the inter electrode volume and flushes away the debris (chip) resulting from the machining.

The EDM process can be used on any material that is an electrical conductor. The melting point and the latent heat of melting are important physical properties that determine the volume of metal removed per discharge.[40]

1.13.7 Major Categories of EDM

To cope with advanced machining demands in the industries, EDM have been evolved based on the basic configurations. In general, we may classify EDM in two major categories, namely: (1) die sink (DS) EDM and (2) wire-cut (WC) EDM. DS EDM is the general process that was introduced in the early 1940 while WC EDM came up in the later years for the purpose of making tools (dies) from hardened steel. It uses a thin wire feeding through the workpiece by a micro-processor eliminating the need for elaborate pre-shaped electrodes, which are required in the EDM.[41] Die-sinker EDM machines are normally used for producing three-dimensional shapes while wire-cut EDM machines are always used for through-hole machining, since the electrode wire must pass through the workpiece being machined. The wires for wire EDM is made of brass, copper, tungsten, and molybdenum. Zinc or brass coated wires are also used extensively in this process. The wire used in this process should possess high tensile strength and good electrical conductivity. Wire EDM can also employ to cut

cylindrical objects with high precision. A wire drive system constantly presents fresh wire to the work so electrode wear (EW) is not a problem. Typical wire diameters range from 0.002 to 0.013 in. Figure 41 shows the wire EDM process.

Besides these two, EDM process can also be directed into drilling by using a rotating electrode and basically performs the same functions as a drill press, far better in quality and finish than what any drill press can produce. These holes may

have a depth-to-diameter ratio of 30 to 1 or higher.[37] However, with recent advancement in micro-manufacturing, the demand for micro-EDM (μEDM) has also been raised. Micro-EDM possesses various properties that are advantageous over other machining process. Micro-EDM can machine complex shapes that would be difficult to perform it with conventional cutting tools. Extremely hard material can be machined to very close tolerances. Very small workpiece can be machined using

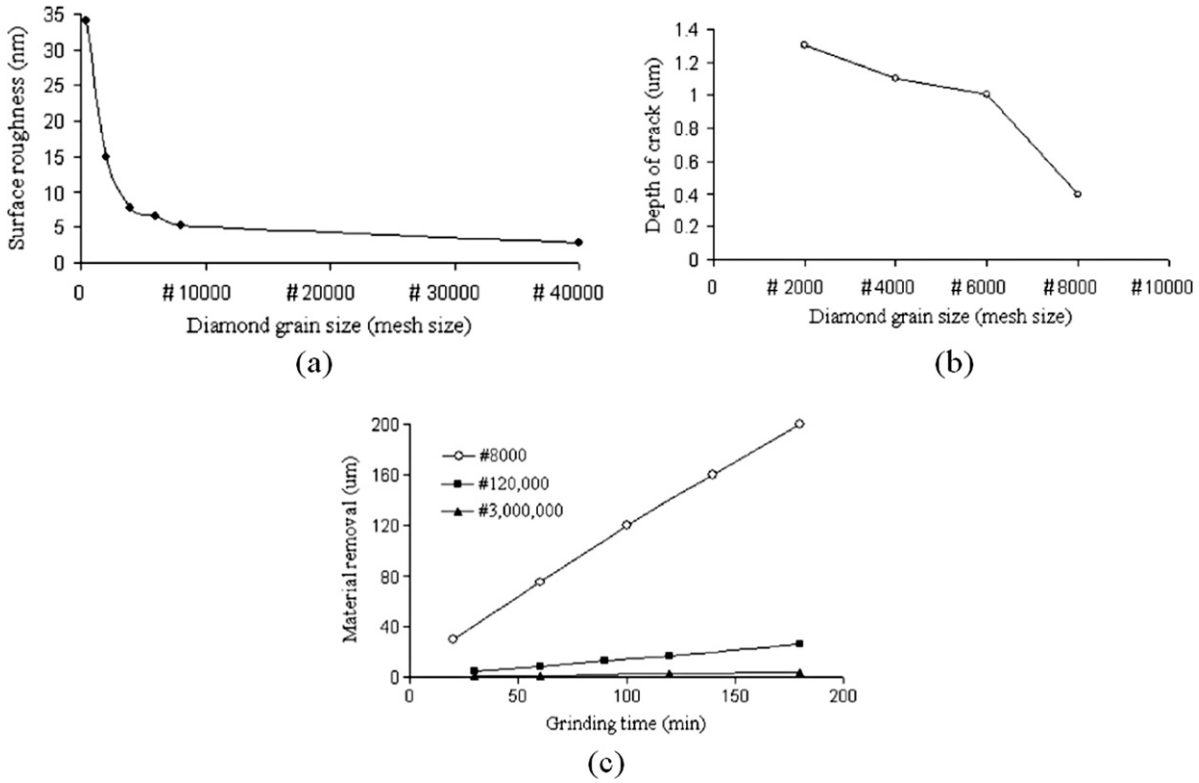

Figure 39 Effect of grain size for ELID grinding of silicon wafer (a) on surface roughness, (b) subsurface crack, and (c) material removal rate.[36]

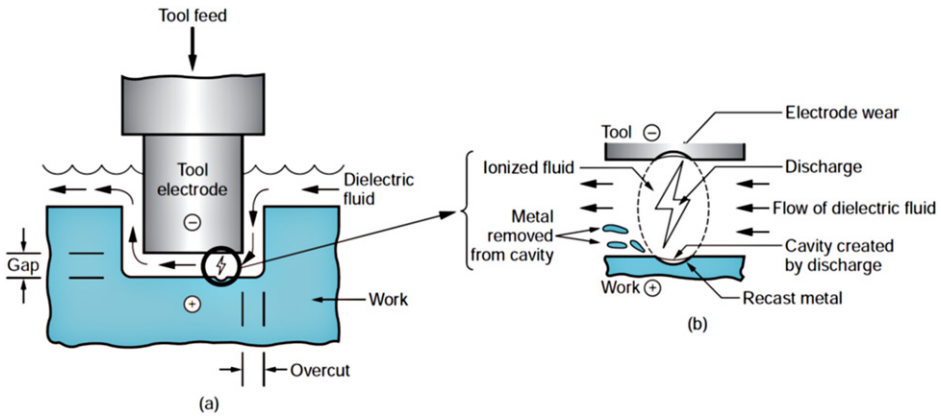

Figure 40 (a) Basic EDM process and (b)close-up of the spark gap.[38]

μEDM where conventional machining tools may damage the workpiece. When there is no direct contact between the tool and the workpiece, small parts and weak materials can be machined without any distortion. The disadvantages of μEDM are it will take a long time to finish the process. It is also very costly machining type. Micro-EDM is capable of machining not only micro-holes and micro-shafts as small as 5 μm in diameter but also complex three-dimensional (3D) microcavities.[42]

1.13.8 EDM Process Performance and Parameters

The EDM process performance is determined by MRR, EW, SR, SQ, and DA. The process parameters play an important role in affecting the performance and they have been classified by in eight major categories: (1) discharge voltage, (2) peak current, (3) pulse duration and pulse interval, (4) pulse waveform, (5) polarity, (6) electrode material, (7) type of dielectric flushing, and (8) rotary motion of electrode/workpiece. Effect of these process parameters influences the MRR and SQ. A brief discussion on the process parameters will be helpful for the readers to understand the extent of the EDMed SQ.

1.13.8.1 Discharge Voltage

Discharge voltage in EDM is related to the spark gap and breakdown strength of the dielectric.[43] The preset voltage is

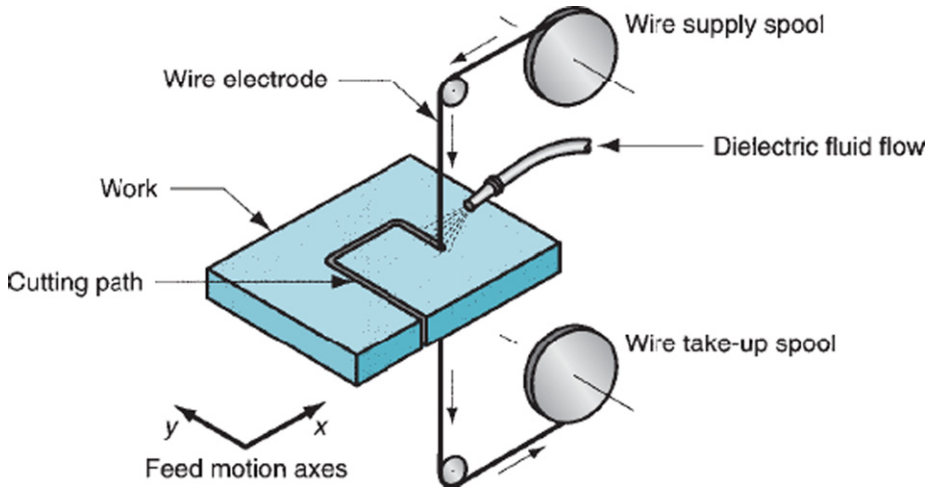

Figure 41 Wire EDM process.[38]

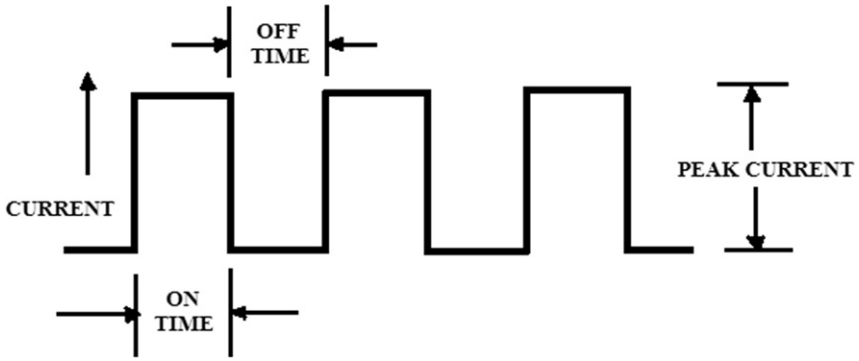

Figure 42 Pulse waveform of controlled pulse generator.[44]

the determining factor for width of the spark gap between the leading edge of the electrode and workpiece. The gap is increased by higher voltage settings, and it improves the flushing conditions thus stabilizes the cut. MRR, tool wear rate (TWR), and SR increases, by increasing open circuit voltage, as a result of increment in electric field strength. However, the impact of changing open circuit voltage on surface hardness after machining has been found to be only marginal.[44]

1.13.8.2 Peak Current

The most important machining parameter in EDM is peak current. The current increases gradually during the 'on' time pulse and reach a maximum value, which is called peak current as seen in Figure 42.

In both die-sinking and wire EDM applications, the maximum amount of current amperage is governed by the surface area of the cut. Higher amperage is used in roughing operations and in cavities or with large surface areas. Higher currents will improve MRR, and SR is also affected by current and frequency, as shown in Figure 43.

The best surface finish is obtained in EDM by operating at high frequencies and low discharge currents.

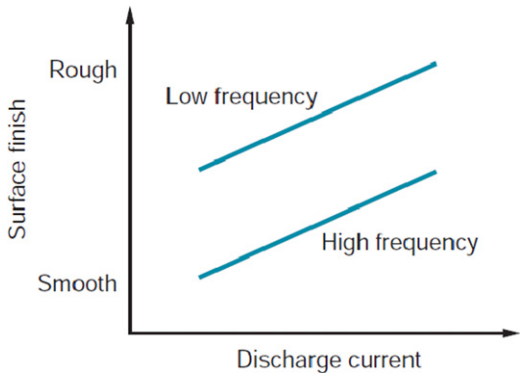

Figure 43 Surface finish in EDM as a function of discharge current and frequency of discharges.[38]

1.13.8.3 Pulse Duration and Pulse Interval

As seen in Figure 42, each cycle in EDM has an on-time followed by off-time that is expressed in units of microseconds. As all the energy is applied during on-time; the duration of these pulses and the number of cycles per second (frequency) are important to control the MRR. The total energy is controlled by the peak current and the duration of the on-time.

Pulse on-time is commonly referred to as pulse duration and pulse off-time is called pulse interval. With longer pulse duration, more workpiece material will be melted away. The resulting crater will be broader and deeper than a crater produced by shorter pulse duration. These large craters will create a rougher surface finish.[44]

1.13.8.4 Pulse Waveform

The pulse shape is generally rectangular but other shapes have been tried and a trapezoidal one could contribute to reduced tool wear.[45]

1.13.8.5 Polarity

The polarity of the electrode can be either positive or negative. It is recommended by Naveen and Pungotra[46] to use +ve polarity to obtain maximum MRR and minimum TWR whereas −ve polarity is recommended for minimum SR.

1.13.8.6 Electrode/Workpiece Material

The hardness and strength of the work material are not factors in EDM, because the process is not a contest of hardness between tool and work. The melting point of the work material is an important property, and metal removal rate can be related to melting point.[38] The high spark temperatures that melt the work and the tool at the same time, creating a small cavity in the surface opposite the cavity produced in the work. Electrodes materials commonly used are graphite, copper, brass, copper tungsten, silver tungsten, and other materials. The selection depends on the type of power supply circuit available on the EDM machine, the type of work material that is to be machined, and whether roughing or finishing is to be done. The prime requirement of any electrode material is that it must be electrically conductive and maintain less EW. In principle, the materials best suited should have a very high melting point and a very low resistance to electricity.[47]

Graphite is preferred for many applications because of its high melting. In fact, graphite does not melt. It vaporizes at very high temperatures, and the cavity created by the spark is generally smaller than for most other EDM electrode materials.[38]

1.13.8.7 Dielectric Fluid

Dielectric fluids used in EDM include hydrocarbon oils, kerosene, and distilled or deionized water. The dielectric fluid serves as an insulator in the gap except when ionization occurs in the presence of a spark. Its other functions are to flush debris out of the gap and remove heat from tool and workpart.[38] Performance improvement using powder-mixed dielectric fluid has been reported by Pecas and Henriques,[48] while the same researcher showed that the presence of powder particles in dielectric fluid and the concentration of powder creates conditions suitable for achieving a better SQ in the machined area.[49]

1.13.8.8 Rotational Motion of Electrode/Workpiece

Both cases of rotational motion applied to tool and workpiece have been investigated. Guu and Hocheng[50] provided a workpiece rotary motion to improve the circulation of the dielectric fluid in the spark gap and temperature distribution of the workpiece yielding better MRR and SR. On the other hand, the rotary motion of the electrode showed improvement in the performance of the EDM process which significantly improved the MRR and SR due to better gap flushing.[51]

1.13.9 EDM Applications

The EDM process has the ability to machine hard, difficult-to-machine materials. Parts with complex, precise and irregular shapes for forging, press tools, extrusion dies, difficult internal shapes for aerospace, and medical applications can be made by EDM process. Based on different materials, EDM applications can be classified in three broad categories as described below.

1.13.9.1 EDM for Heat-Treated Materials

EDM is a more suitable machining choice for heat-treated tool steels. The hardness limit for such steels for ordinary milling ranges up to HRC of 35.[52] However, with EDM, the metal can be fully hardened and still can be machined with secured dimensional stability.

1.13.9.2 EDM for Nonconductive Ceramic

Nonconductive ceramics cannot be machined by traditional metallic tools because of their high brittleness and hardness. EDM is a known process for producing structures from electrically conductive materials with high DA and good surface finish. Most of the engineering ceramics such as Al_2O_3, ZrO_2, Si_3N_4, and SiC are electrically nonconductive.[53] In EDM of conductive materials, material is removed mostly by melting and evaporation, but the main material removal mechanism in EDM of nonconductive ceramics is spalling which occurs due to the alternating thermal load of the electrical sparks.[54,55] In the recent years, either assisted electrode (EDM of ceramic/carbon nanostructure composites[56] or doping/adding with conductive particles to make the ceramic conductive enough are being practised.[57]

1.13.9.3 Modern Semiconductor/Composite Materials

The extensive usage of composites in the modern living has led to an expansion of EDM applications into the area of composite materials. The feasibility of machining ceramic–metal composite steel plate coated with WC–Co (tungsten carbide–cobalt) using plasma spraying was also examined.[58] Same goes with the machining of silicon semiconductor with wire electrodischarge machining (WEDM).[59]

1.13.10 EDM and Its Effect on Workpiece Surface Finish

The EDMed surface may become different in properties than the base material after machining. Due to the high-temperature

generated during machining the upper layer goes through heat treatment naturally. The thermal nature of EDM imparts a heat-affected layer on the machined surface. Generally, the thickness of the heat damaged zone is related to the amount of applied energy.[60] The following **Figure 44(a)** shows the different layer of the EDMed surface,[39] while **Figure 44(b)** provides a more detail about the different temperature zones on the surface layer.[37]

As seen in **Figure 44(b)**, zone A is the surface that faces directly the spark electricity. The temperature at this zone vaporizes the workpiece material, some portion of electrode and dielectric fluid. Temperature zone B is a part of zone A and consists of spherical-shaped projections that extend from the zone A surface. These small projections are named as globules and usually attached loosely to the zone A surface. The temperature at zone C is causes the workpiece surface to melt, but does not separate it from the spark cavity surface while in temperature zone D the heat is less than the heat at a melting point. Material in temperature zone E may be considered as the parent material since it is far enough away from the surface of the spark cavity that any temperature increase will not affect the workpiece material characteristics. The heat-affected zone (HAZ) consists of the total spark cavity surface area that has been changed due to the spark heating (zone A–D).

In many cases, EDM surface finish may be used without additional finishing operations, such as in plastic-injection molds or in press tooling to hold lubricant. EDM manufacturers provide data regarding spark-ON time and peak amperes to produce surface finishes that are acceptable for different applications. For EDMing of high-temperature materials that are highly stressed in their end use, it is necessary to define upto what extent the EDM surface conditions are acceptable. In some instances, the surface must be completely removed. A typical specification for this type of application could include the following items[37]:

i. A total thickness of the re-deposited and re-solidified layers: 0.001 in. (0.025 mm).
ii. A total thickness of the re-deposited, re-solidified, and changed material characteristic layers: 0.002 in. (0.05 mm).
iii. Electrode material present in re-deposited layer: none
iv. Cracks in re-deposited and re-solidified layers: acceptable (depending on the end use).
v. Cracks in parent material: not acceptable.

The reason for being cautious about presence of cracks in high-temperature materials to be used for high-stress applications is that the cracks will propagate and cause part failure. EDM for machine press die tooling is capable of producing very sharp corners in the die opening. As piece-part material is pressed through the die opening, considerable force is applied to the die-opening sidewalls therefore, any sharp corners can become highly stressed and cause failure.

It is found from the preliminary metallurgical studies of the EDMed surface that the changes arise mainly from the rapid cooling of the molten material which solidifies epitaxially on the crater bases.[62] The amount of molten material with each discharge is in the region of 8–10 times the final crater volume.[63] At the end of the discharge and erosion phases only about 10–15 per cent of the total molten material is removed while the remainder resolidifies on the surface to form the recast layer. Lee *et al.* focused on the recast layer's effect on surface crack formation for tool steels, according to their work.[64] The type of recast has been found to be related to the likelihood of the occurrence of cracks. The multi-layer type is most prone to cracks while the thin featureless is generally more crack-free. Cracks tend also to be more prevalent in or around humps on the work surface. The type of recast has been found to be related to the likelihood of the occurrence of cracks where the thickness of the recast layer has a major influence on the type of recast. In general, the three broad categories are the multi-layer, single layer, and featureless types. Lee *et al.* indicated in their studies that thermal conductivity of workpiece and occurrence of cracks are inversely related. The drawing of heat through the base of the workpiece has been shown to be able to reduce the susceptibility of the recast layer to cracks and also to reduce that thickness of the recast layer The multi-layer type is most prone to cracks while the thin featureless is generally more crack-free. Cracks tend also to be more prevalent in or around humps on the work surface. Prior to this work, Lee *et al.* focused on the surface transformation and damage for tool steels.[60]

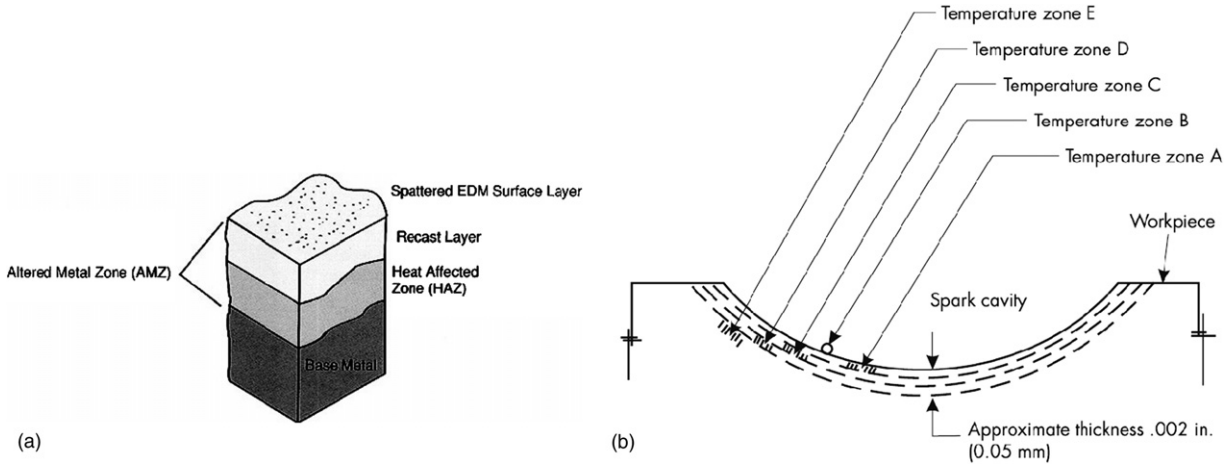

Figure 44 (a) Surface layers after electrical discharge machining.[61] (b) Temperature-range zones in the spark cavity.[37]

Attempts were made to quantify the depth of white (or damaged) layer with respect to the process parameters and SR after EDM. It is found that with a fixed dielectric and flushing condition, the damaged layer correlates well with the pulse energy irrespective of the tool steel material. In general, at low discharge energy, the craters are shallow and the density of global appendages and pockmarks is low. Whereas at higher discharge energy, the craters are deeper and global appendages are most evident. These global appendages are molten metals which were expelled randomly during the discharge and later solidified on the workpiece surfaces. As seen in **Figure 45** that the edge of some of the pockmarks are thin and sharp (arrowed), suggesting that the molten metal must have solidified at an extremely high rate. Otherwise the surface tension of the molten metal would have caused the sharp edges to be rounded off. The microstructure of the EDMed surface varies greatly from its parent metal.

Their work also revealed that under identical discharge conditions, the SRs of all the steels are quite similar. Their values, however, depend on both the pulse energy and current in a complex manner. By and large, at a given pulse energy, a poorer surface finish is obtained with a higher pulse current. This implies that the pulse current has a more dominant effect on the SR compared to the pulse-on duration. It is possible that a higher pulse current (or input power) may cause more frequent cracking of the dielectric, giving rise to more frequent melt expulsion. This in turn will result in a higher density of global appendages and poorer surface finish. Similar performance have been reported by Torres *et al.*[65] for machining on Inconel surface. According to them, current intensity and pulse time are the most influential factors for SR. Increasing current intensity leads to deeper craters but at the same time with greater diameter (lower number of peaks per cm). Minimum R_a (1.11 μm) is reached at 2 A and 50 μs. R_a values obtained with negative polarity are lower compared with the positive one, but the surface is more damaged because more pronounced microcracks appear.

1.13.10.1 Surface Modification Using EDM

Besides the natural heat treatment of the EDMed surface, researchers are trying to improve the EDMed surface in terms of roughness, strength, and residual stresses. Some widely used methods and their applications will be discussed in this section. In general, the surface modification have been tried by manipulating (1) conventional electrode materials, (2) composite electrode, (3) additives in dielectric, and (4) ball burnish machining.

1.13.10.1.1 Surface modification by conventional electrode materials

Playing with different electrode materials to obtain modified EDMed surface has been in practice for the last five decades. The very initial study on the electrode material conducted by Barash and Kahlon[66] revealed that the deposition of metals with a lower melting point on to those with a higher melting point progresses at a much lower rate than vice versa. So, whereas the deposition of tungsten carbide on to steel is fairly fast, the deposition of copper on to steel progresses extremely slowly. They also indicated from their experiments that when mild steel was eroded in liquid medium paraffin using copper electrode, the workpiece was coated with a very hard layer.

Over the years many other attempts have been taken to study the effect of electrode material on the workpiece surface properties. Jahan *et al.*[67] presented their work using different electrode materials and their effect on the fine finish of hard to machine tungsten carbide (WC) during μEDM. Three different materials, namely tungsten (W), copper tungsten (CuW), and silver tungsten (AgW) were used for electrode. It was found that the surface characteristics were dependent mostly on the

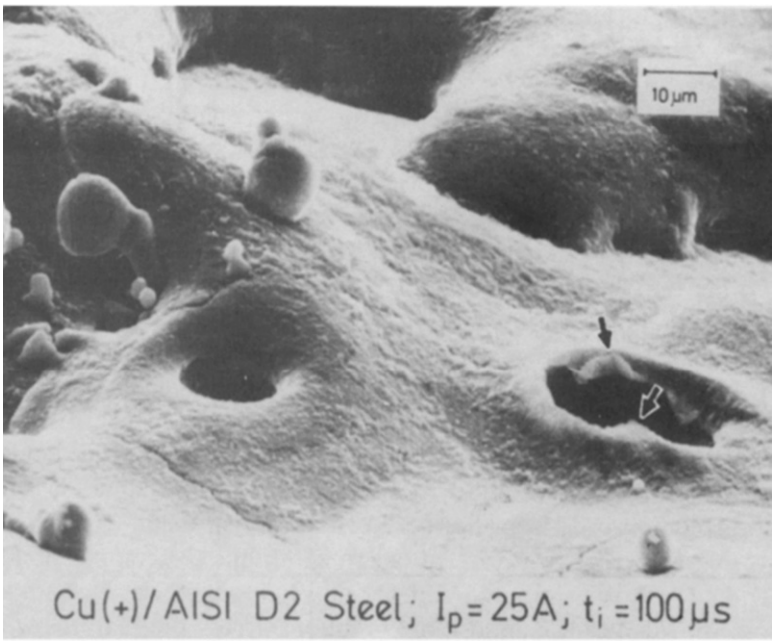

Figure 45 The surface of an AISI D2 tool steel specimen showing craters, global appendages, pockmarks, and cracks.[60]

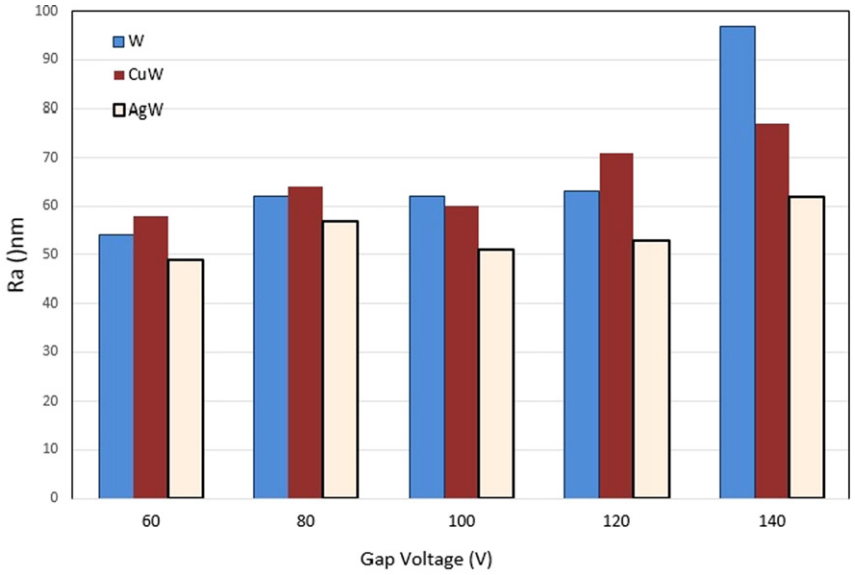

Figure 46 Variation of average surface roughness (R_a) of micro-EDMed WC with gap voltage.[67]

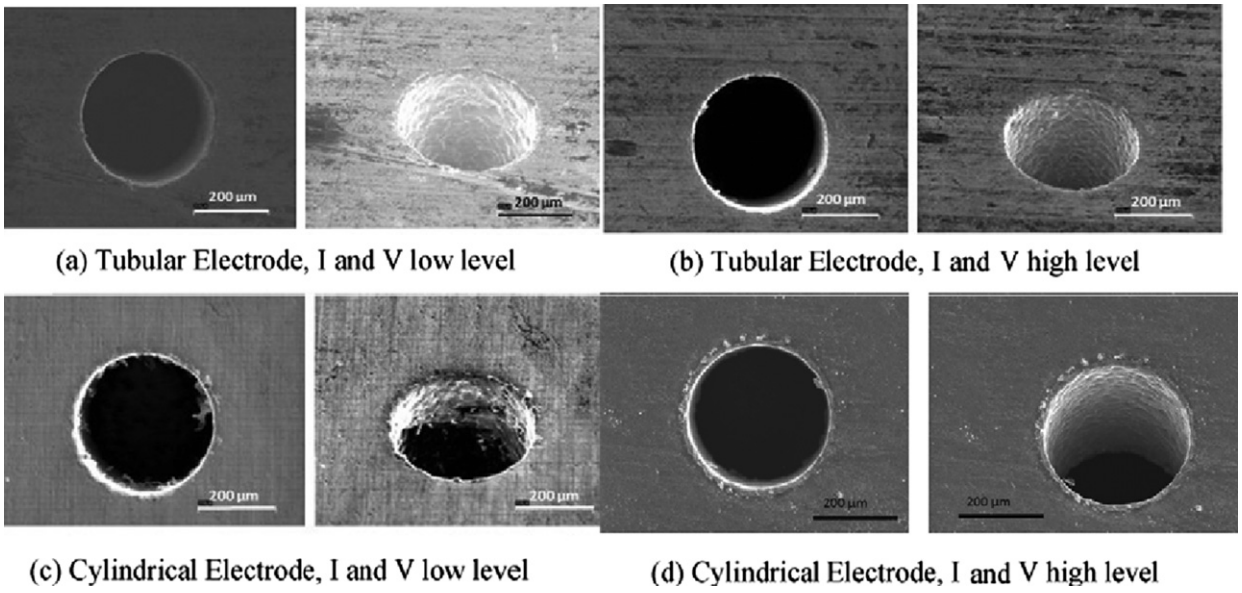

Figure 47 Micro-holes surface finishing for low and high level of peak current/voltage carried out with tubular and cylindrical electrodes.[68]

discharge energy during machining. A detailed experimental investigation was carried out on the finishing μEDM of WC using RC generator due to very small amount of discharge energy. As seen from **Figure 46**, with increased gap voltage, the SR value increased, while using AgW electrode always provided the smoothest surface among the three electrode materials.

It was also noticed that no traces of Ag were found on the workpiece surface, which is a better sign of a clean and shiny surface. Moreover, the percentage of parent material, i.e., W, is higher on the surface using the AgW electrode compared to that on the surface obtained by the W and CuW electrodes. Thus, using AgW electrodes, the properties of the WC after the μEDM process are expected to change very little compared to that when using W and CuW for better surface finish.

D'Urso and Merla[68] highlighted material variation for electrode and workpiece for a micro-drilling experience. The influence of four different workpiece materials (stainless steel, titanium, magnesium, and brass), three electrode materials (copper, brass, and tungsten carbide), and two different electrode shapes (cylindrical and tubular) was investigated.

A total amount of 160 through micro-holes were drilled on thin plates of different materials. **Figure 47** shows the micro-holes drilled using different electrode geometry and peak voltage and current settings while **Figure 48** shows micro-holes surface using different electrodes. In **Figure 47** where the electrode geometry was compared with changing peak current and voltage, it revealed that there was no significant difference in the SQ of the micro-holes made using tubular

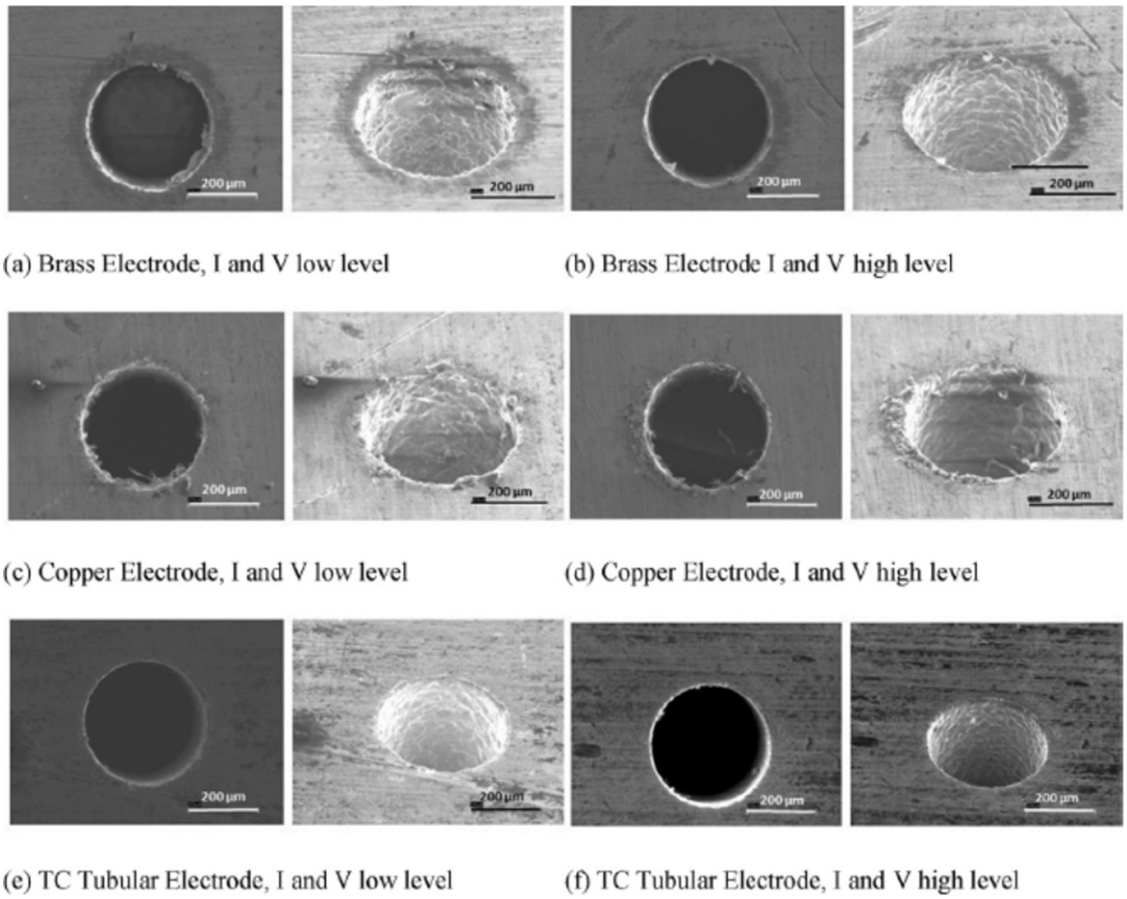

Figure 48 Micro-holes surface characteristics for brass tubular electrode with low and high level of peak current/voltage parameter (a, b); for copper tubular electrode with low and high level of peak current/voltage parameter (c, d), and for WC (tungsten carbide) electrode with low and high level of peak current/voltage parameter (e, f).[68]

electrode: both surfaces were almost burr-free. On the contrary, for the cylindrical electrode, the higher level of the peak current/voltage provided better quality of the surface of the hole. In general, it was concluded that the cylindrical electrode resulted in a surface with a larger amount of burrs if compared with the tubular one.

When considering electrode material, it became clear from **Figure 48** that the poorest SQ of the micro-holes was obtained for using copper electrode which with significant amount of irregularities and debris. Similar observation was found for the brass electrode. Also in this case the surface of the micro-holes was irregular and characterized by a considerable amount of burrs. On the other hand, for the WC (TC) electrode, the surface obtained was more regular and without absence of burrs. Moreover, for brass and copper electrode materials, the higher level of the peak current/voltage parameter resulted in a worse SQ. This could be due to the more aggressive parameter combination adopted for the machining.

The better performance in terms of surface finishing and burr-free surfaces are obtained when working magnesium and titanium workpiece. Copper electrode was used in both cases and the surfaces found were completely free from burrs and re-solidified material on the edge of the micro-holes.

A more recent work by Younis *et al.* showed the performance of two different graphite electrode on different types of workpiece material.[69] The effect of electrode material was studied to investigate improvement issues related to residual stresses, SR, and cracks during EDM. The electrode materials chosen were Dura graphite 11 and Poco graphite EDMC-3. Two grades of tool steels were used as workpiece materials: DIN 1.2080 and DIN 1.237. Machining mode had three categories: rough, medium, and soft. After the EDM process the test materials were examined using scanning electron microscope to observe the surface cracks, roughness, and then x-ray diffraction to examine the residual stresses generated after the three machining conditions. It was found that Dura graphite exhibited higher SR for DIN 1.2080 surface during all machining conditions caused by its easily eroding compressed graphite powder, and also due to the higher carbon content in DIN 1.2080 which solidified upon the surface during solidification and not flushed away.

Figure 49 shows the surface roughness obtained for the overall experimental variables.

Younis *et al.* concluded their results stating that rough EDM machining exhibited more microcracks as a result of higher pulse current while the most significant parameter affecting residual stresses occurred during EDM machining were the electrode material and machining condition.

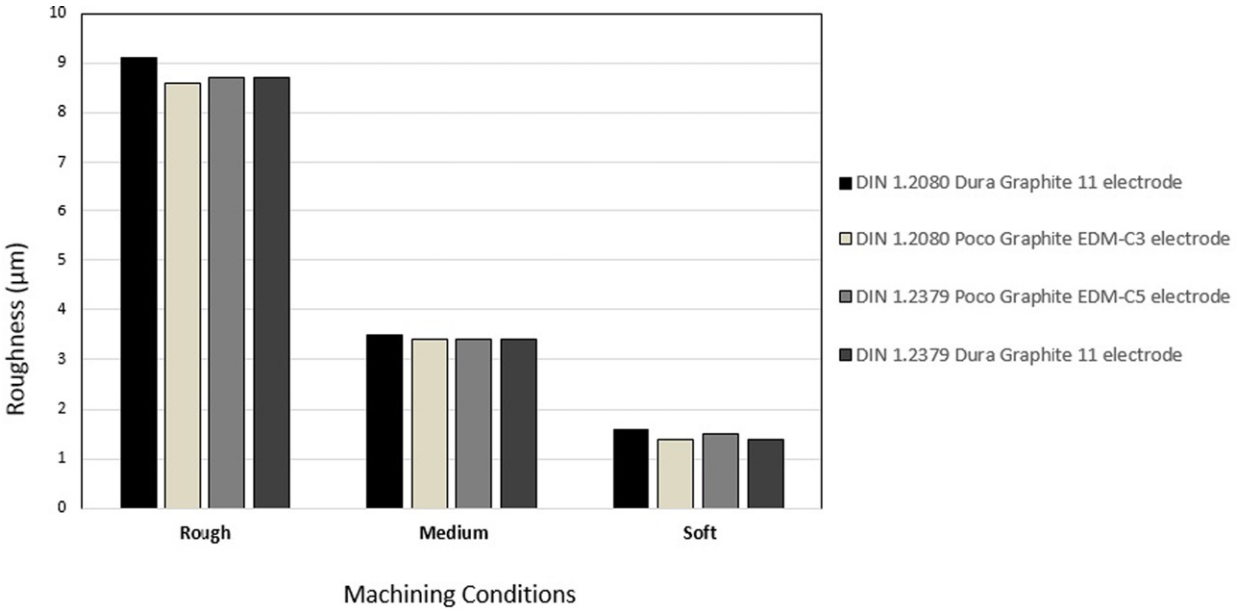

Figure 49 Surface roughness observations.[69]

1.13.10.1.2 Surface alloying using composite (PM) electrode

The composite electrode is also referred to as the green compact, sintered, or powder metallurgy (PM) electrode. Use of powders has propagated in recent years as it increases productivity and reduces workpiece SR/associated microcracks, because of greater electrical conductivity in the spark gap/reduction in the breakdown voltage and higher discharge frequency. A wide range of powders with alternative compositions can be used for the manufacture of tool electrodes. These tend to be materials which can form/transfer hard particles such as carbides and may incorporate a secondary binder phase, for example, WC/Co, TiC/WC/Co, W/CrC/Cu, etc. By using electrodes made from different materials, the possibility exists to 'engineer' one or more alloyed layers (which may be functionally graded) with different mechanical properties.[70] It has low thermal conductivity allowing the composite material to disintegrate from the electrode and alloy onto the workpiece surface producing less cracks, high corrosion, and wear resistance.[41]

PM electrode was applied as an alloying method by Ho *et al.*[71] The pulse generator employed a higher than standard open circuit voltage of 270 V with selectable peak currents of 0.1–2.9 A. The workpiece material was annealed Ti–6Al–4V cut into rectangular pieces 18 mm × 14 mm × 10 mm. The tool electrodes comprised solid HCHP copper bar and Ø10 mm PM copper slugs/buttons soldered on copper rods. The result revealed that PM electrodes produced greater alloying than the solid electrode and PM electrodes used with positive polarity produced thicker recast layers. On the other hand, under negative polarity, recast/alloyed workpiece hardness was in general of lower or of comparable hardness to the bulk material.

Wang *et al.*[72] worked on the electrical discharge coating (EDC) using EDM principle for surface modification of carbon steel. By using an ordinary EDM tool and kerosene, a layer of TiC ceramic about 20 µm thickness is created on the workpiece successfully with a Ti powder green compact electrode in a very short time. In general, the forms of electrodes are green powder compressed, or sintered, and so on. The powder green compact electrode has low thermal conductivity and rapid wearing speed that made it suitable for easy deposition. The resultant surface's lowest hardness achieved was four or five times higher than that of the base material. Ratio of Fe is reduced gradually from the base metal to the surface, and almost to zero at the end, while the ratio of Ti is increased gradually upto the surface. It can also be seen that there is no clear boundary between the layer and the base metal and this is how the EDC layer adheres strongly to the base metal.

Simao *et al.*[70] presented their experimental results on the surface alloying of AISI H13 hot work tool steel during a die sink operation using partially sintered WC/Co electrodes operating in a hydrocarbon oil dielectric. Die-sink surface alloying tests were performed using hydrocarbon oil dielectric BP 180 as the dielectric. The cylindrical PM tool electrodes were made from WC/6 wt.% Co binder in a partially sintered state. Experiments planned with Taguchi method showed the use of partially sintered electrodes made from WC/Co resulted in the formation of a uniform alloyed/modified surface layer with relatively few microcracks and an average thickness of up to 30 µm. Results from the confirmation experiment showed an increase in workpiece surface microhardness from ~640 HK(0.025) to 1319 HK(0.025). **Figure 50** presents the recast layer after Taguchi confirmation test.

The surface hardness value of the recast surface alloyed layer was substantially higher than either that of the hardened AISI H13 steel (~600–640 HK(0.025)) or the typical recast layer hardness (~600 HK(0.025)) when using 'conventional' graphite or copper tool electrodes. This increased value compares extremely favorably with hard chromium surfaces, typically applied by electroplating.

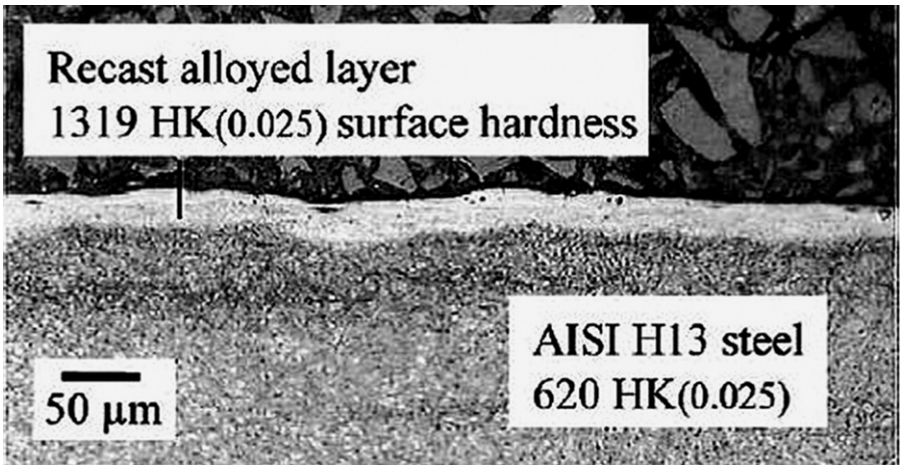

Figure 50 Cross-section of die sink surface machined using a partially sintered WC/Co tool electrode (Taguchi confirmation test).[70]

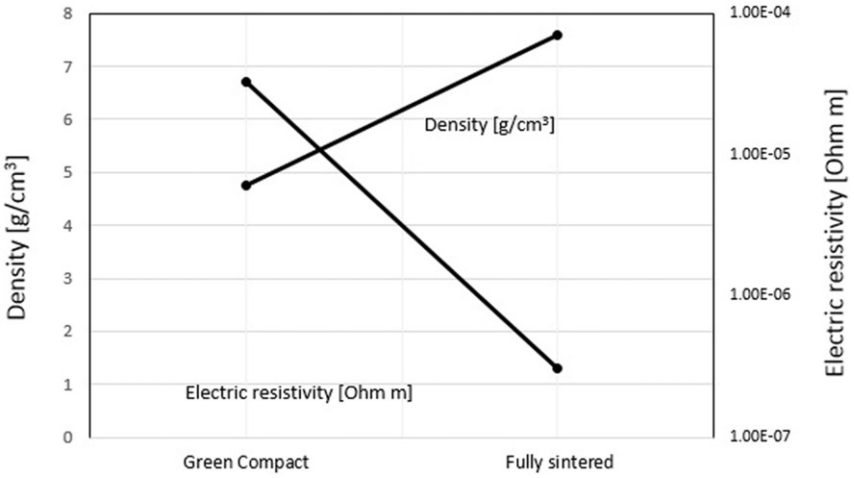

Figure 51 Variation of electrical resistivity (Ω m) with green density (g cm^{-3}) of the PM tool electrodes.[73]

Simao *et al.*[73] presented in their later work using two types of electrodes for electrical discharge texturing (EDT) of hardened AISI D2 Sendzimir rolls, used for the production of stainless steel strip. For moderate size cluster mills, EDT has been tested as an alternative to physical vapor deposition (PVD) method for improvement of the surface. Roll rotation direction (anticlockwise viewed from the tailstock end of the workpiece), roll surface speed (6 m min^{-1}) and electrode axial-feed rate (0.44 mm rev^{-1}) were kept constant throughout the tests, as was the servo gain (5/32). PM electrodes used for the tests were prepared under different compacting and sintering conditions and their properties evaluated, for example, density and electrical resistivity. EDT trials were performed using TiC/WC/Co and WC/Co tool electrodes, both in the green compact and fully sintered states. **Figure 51** shows the comparison in properties between two electrodes.

The use of high sintering temperatures increased the bonding between particles and hence erosion resistance, while electrodes sintered at lower temperatures were subject to rapid wear due to the weak bonding between particles and loosely bonded particles were detached leading to excessive gap contamination. The average SR R_a was much improved for the roll textured using powder sintered TiC/WC/Co electrodes when compared to the 'conventional' EDT roll. Microhardness measurements of roll cross-section samples made before rolling indicated a significantly higher roll white layer hardness of up to 950 HK using the sintered TiC/WC/Co tool electrodes.

1.13.10.1.3 Surface modification by dielectric

Usage of different dielectric materials has been investigated to obtain a better EDMed surface. Currently used dielectrics can be classified basically into three major groups. Moreover, the recent trend is to use nano-particles to the dielectric fluid and it has been reported that adding particles to the dielectric gives better MRR with lower TWR and improves the sparking efficiency.[74]

Jeswani,[75] Mohri *et al.*,[76] and Kunieda *et al.*[77] introduced the concept of using gas instead of liquid as dielectric medium. Later Xu *et al.*[78] applied ultrasonic vibration assisted EDM in gas experimentally with a copper electrode copper and

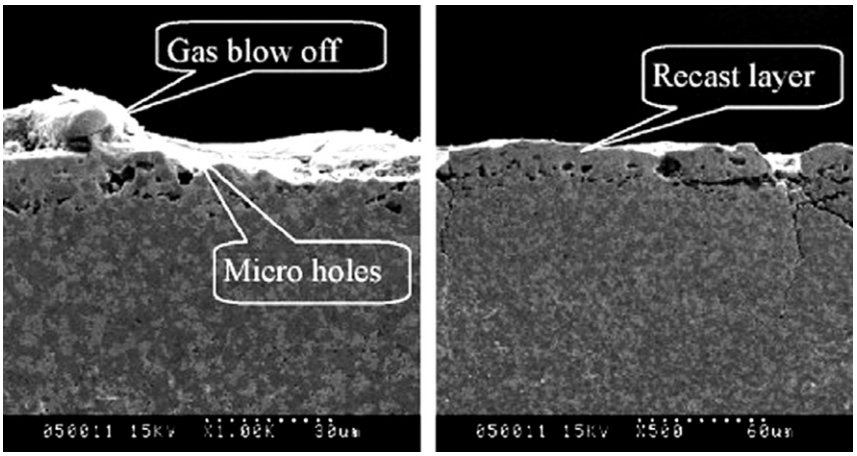

Figure 52 Cross-section of cemented carbide machined by UEDM in gas.

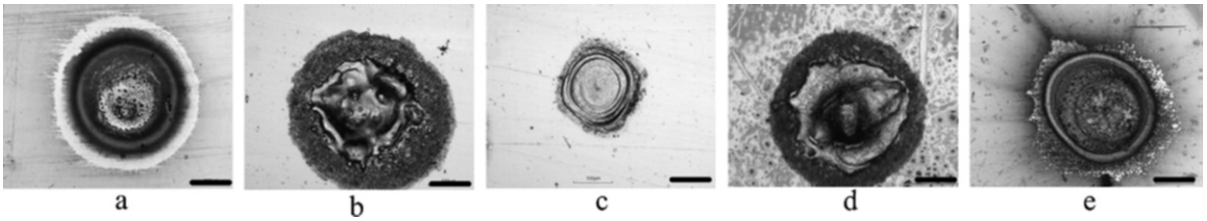

Figure 53 Comparison of the external appearances of craters formed in (a) air; (b) kerosene; (c) deionized water; (d) W/O emulsion; and (e) oxygen. Pulse duration = 105 μs (the length of the scale bar was 100 μm).

workpiece material used was YT15 cemented carbide. It was expected that the high pressure and velocity gas supplied through the internal hole of the electrode would flow over the discharging gap, which could enhance the removal of molten and evaporated workpiece material. In addition, it cooled and solidified the removed material and prevented them from adhering onto the surface of the tool electrode. Also, during the pulse-off time, the gas with a high velocity blew off the plasma formed by the previous discharge ensuring the recovery of the dielectric strength of the gap, and decreased the temperature of the discharge spot on the tool electrode and the workpiece due to heat transfer.

As can be seen from **Figure 52** that the material was melted first and then blown by gas medium with high pressure and velocity. Also, the recast layer is thin and full with many micro-holes and microcracks.

Chung *et al.*[79] studied effect of deionized water as a dielectric for EDM and for electrochemical dissolution for finishing process of micro-hole surfaces processed by μEDM. Thus, the total process is achieved by sequential process without working fluid change. The effects of finishing conditions such as the resistivity of deionized water, the voltage, the tool rotation and the finishing time on the SQ and accuracy of the shape were investigated. The inner surface of the hole was finished successfully via electrochemical dissolution in deionized water. Usage of water was considered as environment friendly dielectric and as there was no contamination of the work-tank by acid or by a neutral salt solution, continuous multiple holes machining including μEDM and finishing was carried out easily. Deionized water was used to remove a thin layer of the inner surface of μEDM hole, its higher resistivity was utilized to complete the finishing process without shape distortions. Considering the surface finishing is based on an electrochemical process, the resistivity of deionized water had an effect on the quality of the surface and the accuracy of the shape.

Zhang *et al.*[80] presented a rather comprehensive study by using five different dielectrics namely air and oxygen, deionized water, kerosene, and water-in-oil (W/O) emulsion. The whole geometry parameters of the craters, including the recast material in the craters, were precisely determined by metallographic method. Their previous study proved that surface with different characteristics can be obtained with different dielectric.

Their experimental work showed that different crater formation was obtained from five different dielectrics (**Figure 53**).

It was found that there was a huge difference of the geometry shape of the craters formed in different dielectrics even with the same experiments conditions. In kerosene, less volume of material was melted compared to other dielectrics.

For dispersion of powder in dielectrics, Mohri *et al.*[76] pioneered in order to break through the limit of roughness in finish EDM as silicon powder was suspended in working fluid at the stage of finish EDM. The powder in working fluid promoted the dispersion of discharging in finish EDM. A series of automatic die manufacturing processes was carried out on trial. A free-form shape with glossy surface was machined without any manual works. Kerosene was used as working fluid, while the electrode was made of copper and the

workpiece was steel, for finish EDM they summarized the effect of powder in dielectric as

i. Powder suspension enlarges the gap distance between electrode and work surface more than several times than that by conventional fluid.
ii. Powder suspension disperses discharges all over the gap region.
iii. Powder suspension decreases finish machining extremely.
iv. The machined roughness with powder suspended working fluid does not depend strongly on the working area.
v. Work surface by powder suspended fluid has strong corrosion resistance.

Jahan *et al.*[81] observed that the presence of semi-conductive graphite nano-powders in the dielectric can significantly improve the surface finish and they reported to have average SR of nano meter scale. For sinking and milling μEDM, added nano-powder lowered the breakdown strength. They also reported that for a fixed powder material and particle size, all the performance parameters varied significantly with powder concentration. Powder-mixed milling μEDM provided smoother and defect-free surface compared to sinking μEDM. The lowest value of R_a (38 nm) and R_{max} (0.17 μm) was obtained for an optimum concentration of 0.2 g l^{-1}.

Zhao *et al.*[82] presented a comprehensive study on powder-mixed EDM (PMEDM). PMEDM is capable of acheiveing machined surface with evenly distributed and large and shadow shaped etched cavities within the same discharge energy level, and eventually can obtain mirror effects in the finish machining phase. They presented their experimental works for rough EDM condition with red copper electrode, 45# steel workpiece. EDM special working fluid from Mobil was used for conventional EDM machining, and self-made powder-mixed working fluid was used for powder-mixed dielectric EDM (PMDEDM) machining the powder of which is aluminum powder 10 μm in granularity and 40 g l^{-1} in density.

Figure 54 shows the comparison between PEDMed and EDMed surface for rough cut. For PEDMed machining, the discharge breakdown was easier and it enlarged the discharge gaps and widened the discharge passage. Because of much loss of discharge energy in the discharge gaps and reduction of the ejecting force on the molten workpiece metal, the SR was smaller in PMEDM machining in comparison with conventional EDM machining.

Hu *et al.*[83] presented their study of surface property on a composite using powder based dielectric. The workpiece material used was SiC particle reinforced Al matrix composites (SiCp/Al). Conventional EDM and PMEDM were compared and surface micro-topography and wear resistance were analyzed. Copper electrode was used and the aluminum powder dispersed in working fluid (kerosene) had concentration of 35 g l^{-1} with Al particle sizes <2 μm. The comparison between two surfaces obtained from the conventional EDM and PMEDM is shown in Figure 55.

On an average, the PMEDM SR decreases about 31.5% with better corrosion resistance and wear resistance is twice of EDM. Besides, the variation range of the roughness was found to be smaller.

1.13.10.1.4 Ball burnish machining for EDM surface

Improvement of workpiece surface integrity has been tried using EDM with ball burnish machining (BEDM). BEDM uses hard smooth balls attached to the electrode to form a plastic deformation layer on the workpiece surface during sparking yielding a hardened and modified surface microstructure.[41] In a study by Yan *et al.*,[84] rotary EDM with ball burnishing for inspecting the machinability of Al_2O_3/6061Al composite was explored. Three ZrO_2 balls were attached as additional components with the rotating electrode tool to provide immediate burnishing following EDM (BEDM). Experimental results were observed for machining rate, SR and improvement of SR. The machining parameters considered were: categorized into two groups: (1) electrical parameters, i.e., peak current, pulse duration, and non-load voltage; and (2) non-electrical parameters, i.e., flushing pressure of dielectric, rotational speed of electrode, and residual height of hump. For the experimental steps, a hollow-tube electrode ($f=19$ mm, thickness 3 mm) was used to drill through the workpiece followed by an electrode tool of BEDM was used to machine through the workpiece to obtain a finer surface effect. The electrode tool developed for this purpose is seen in Figure 56.

The percentage improvement of surface roughness (ISR) was calculated by comparing the SR obtained from EDM with that from BEDM. In solving the Taguchi method, the observed values of MRR, SR, and ISR were set to maximum, minimum

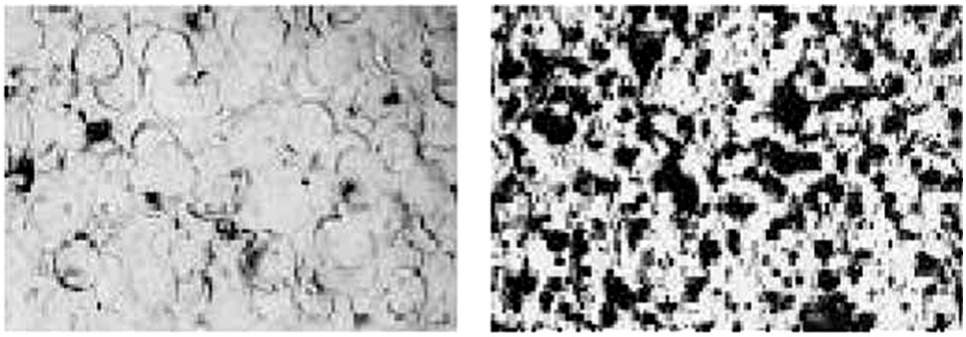

Figure 54 Surface obtained from PEDM and conventional EDM.

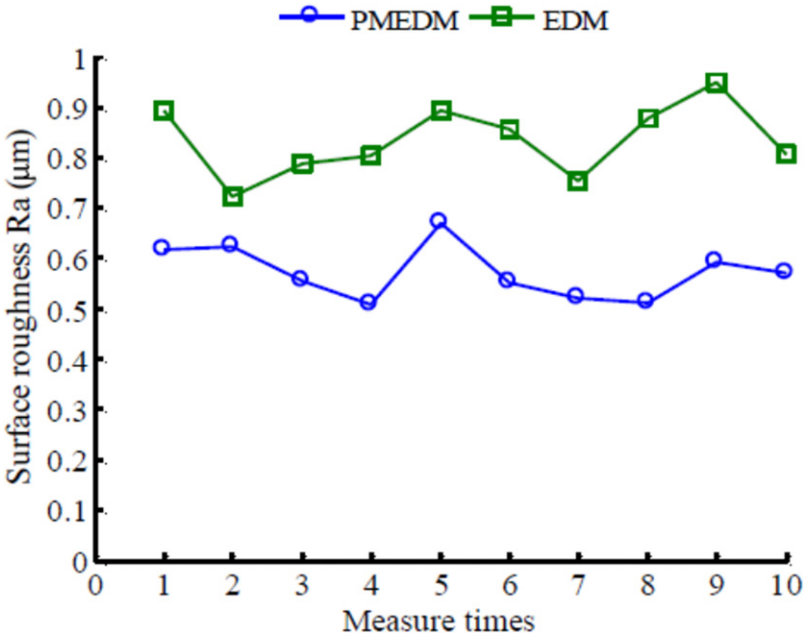

Figure 55 Roughness of the two kinds of surfaces.[83]

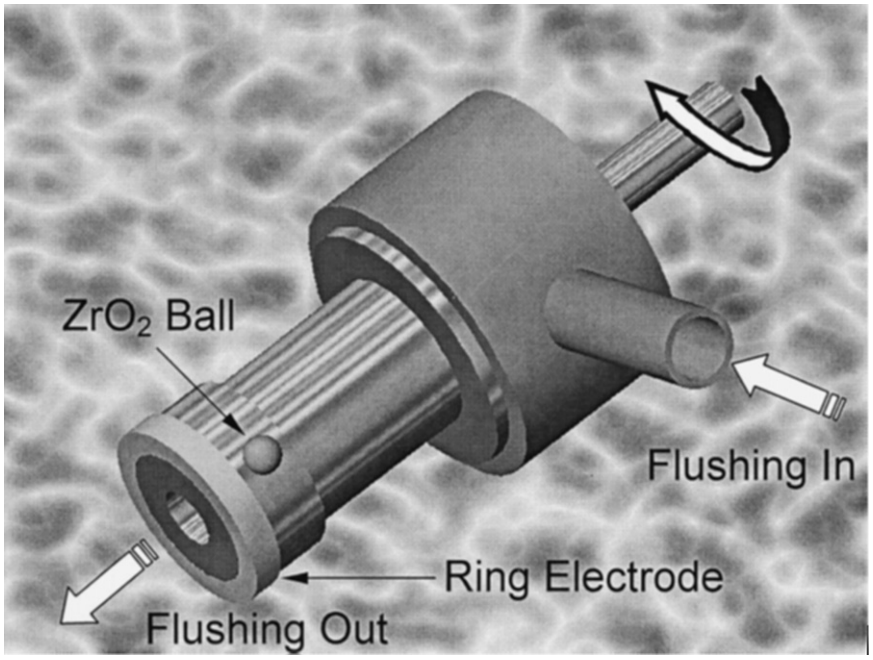

Figure 56 A newly developed electrode tool of BEDM.

and maximum, respectively. Figure 57 presents a comparison between the EDM and BEDM surface generated.

It was observed from results that the ISR increased from 55 up to 92% with various combinations of experimental parameters applying Taguchi method. It was also found that the BEDM process approaches both a higher machining rate and a finer SR. The machining rate was significantly affected by the peak current and non-load voltage parameters significantly affect the machining rate for the BEDM process. In contrast, the experimental parameters play only a minor role in evaluating the SR and the improvement of SR for the BEDM process.

In the later years, Yan and Lim[85] presented their study on surface modification of Al–Zn–Mg alloy by combined EDM with ball burnish machining (BBM). Machining parameters of the combined process, including machining polarity, peak current, power supply voltage, and the protruding of ZrO_2, are chosen to determine their effects on MRR, SR, and the

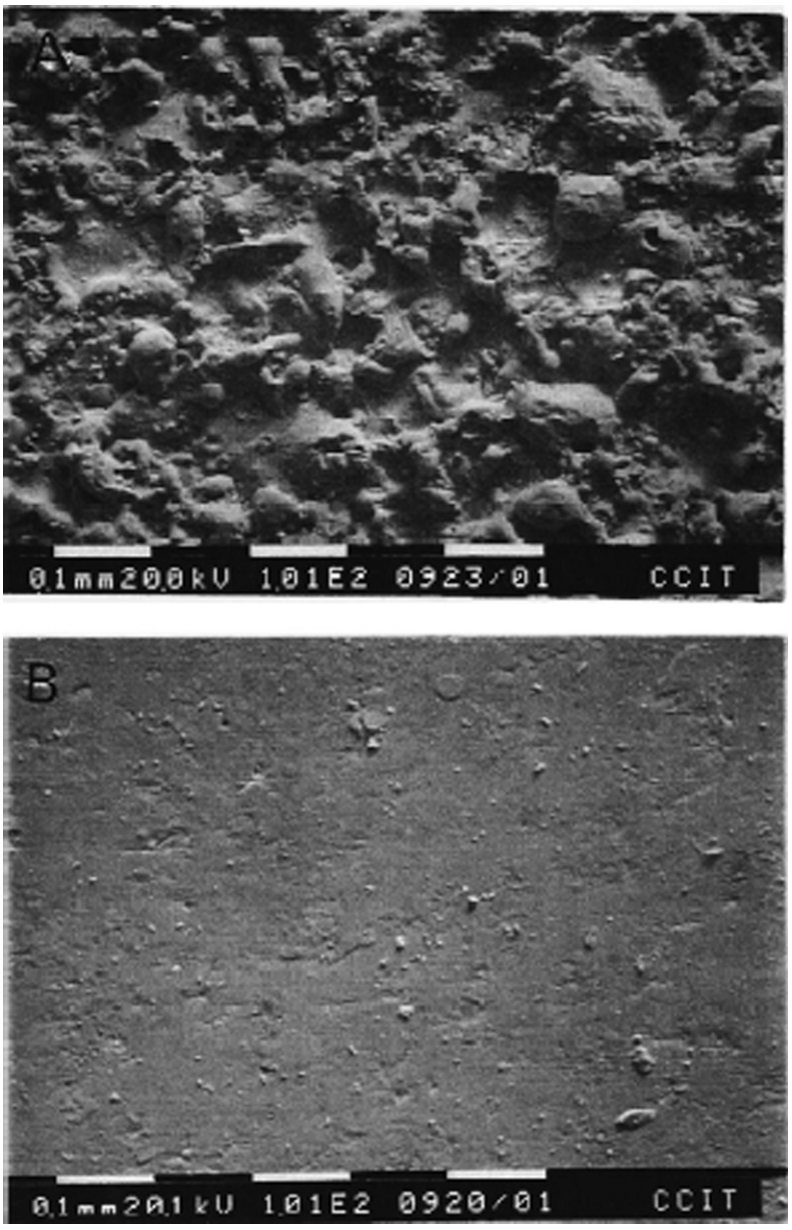

Figure 57 SEM photographs of the machined surface for (A) a surface that has been produced by EDM, (B) a surface that has undergone BEDM with the optimal combination of experimental parameters.

improvement ratio of SR (IRSR). The calculation of IRSR used the formula: $IRSR = (SR_{EDM} - SR_{EDM+BBM})/SR_{EDM} \times 100\%$; SREDM is the SR obtained by conventional EDM (μm R_a); $SR_{EDM+BBM}$ is the SR obtained by combined EDM with BBM (μm R_a). The electrode material was a ring-shaped copper material in which the outer and inner diameters were 32 and 24 mm, respectively, and the thickness of copper electrode was 5.0–4.75 mm to control a situation in which the protruding distance of ZrO_2 balls was fixed at 0–0.25 mm from the electrode surface. Their results showed that the surface integrity produced by the combined process was flatter and finer than that of the conventional EDM under various peak currents. Besides, increasing the peak current would not only cause the SR of conventional EDM to become coarser but also induce the SR of combined EDM with BBM to be rougher. While evaluating the cross-section of the machined surface, it was found that the microcracks and pores with various dimensions distributed on the conventional EDM surface, as caused by an electrical discharge inducing thermal stress and extreme heat, were eliminated by the smooth ZrO_2 balls burnishing to generate plastic deformation on the machined surface. Therefore, the surface integrity became a fine-finishing one. **Figure 58** shows the improved surface with combined EDM and BBM.

1.13.10.1.5 Special applications

Besides these widely used surface modification processes, researchers now a days are interested to broaden their experience in EDM by approaching new method. With rapid progress in

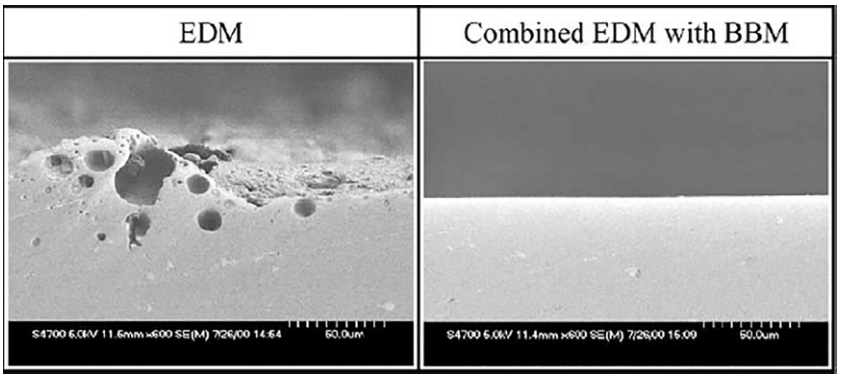

Figure 58 Improvement of combined process for eliminating the micropores and cracks (polarity: (+), peak current: 5 A, power supply voltage: 60 V).[85]

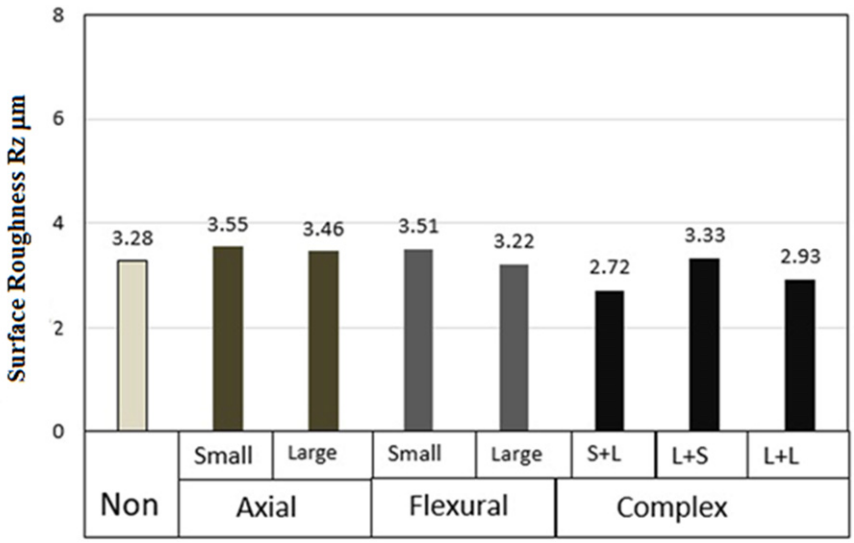

Figure 59 Workpiece surface roughness with and without vibration for EDM on PCD.[89]

polymer development over the years, conductive polymer are being used as electrode or workpiece. Ultrasonic vibrations are also applied to obtain superior quality machined surface. Some of these works will be presented in this section.

Anwar[86] reported micro-patterning of polypyrrole based conductive polymer on μEDM. The patterning feasibility is investigated using air and EDM oil as the dielectric media for the process. When air as dielectric medium, the patterned structures exhibited surface damages including microcracks in both drilling and milling processed structures. It was experimentally shown that stable, high-precision micro-machining of the material could be performed using wet μEDM in commercially available EDM oil instead of dry μEDM in air. Polymer electrode was tried out by Curodeau *et al.*[87] for a standard die-sinking EDM process, where a thermoplastic composite electrode, instead of solid graphite, is used to perform fine EDM finishing with air as dielectric medium. A proof of concept has demonstrated that the process can be used to reduce a 44 µm R_a surface finish down to a 36 µm R_a with three electrodes forming iterations using constant EDM settings. Curodeau *et al.*[88] in their later works tried EDM polishing and texturing process with conductive polymer electrodes. To carry out these new EDM processes, an electrically conductive polymer electrode made of styrene-carbonaceous composite was used and design of experiments was utilized to minimize its electrical resistivity (0.08 Ω cm) and maximize its thermal conductivity. Water was used as dielectric in the projected EDM processes. Micrographs of the electrode and workpiece confirmed that SR peeks can be effectively flatten to 0.21 mm PV, by a replicate electrode of the mold geometry. It was also shown that a fine graphite grade and positive polarity current impulses are contributing to improve the workpiece surface finish.

EDM machinability of PCD was investigated by Iwai *et al.*[89] They used a copper electrode giving ultrasonic vibrations in three modes (axial vibration, flexural vibration, and complex vibration). It was found that EDM efficiency became three times higher than the ordinary EDM without vibration. Reported SR is seen in **Figure 59**. The maximum height of the machined surface R_z was in the range of 2.72–3.55 µm in any experimental conditions, and no big difference was observed.

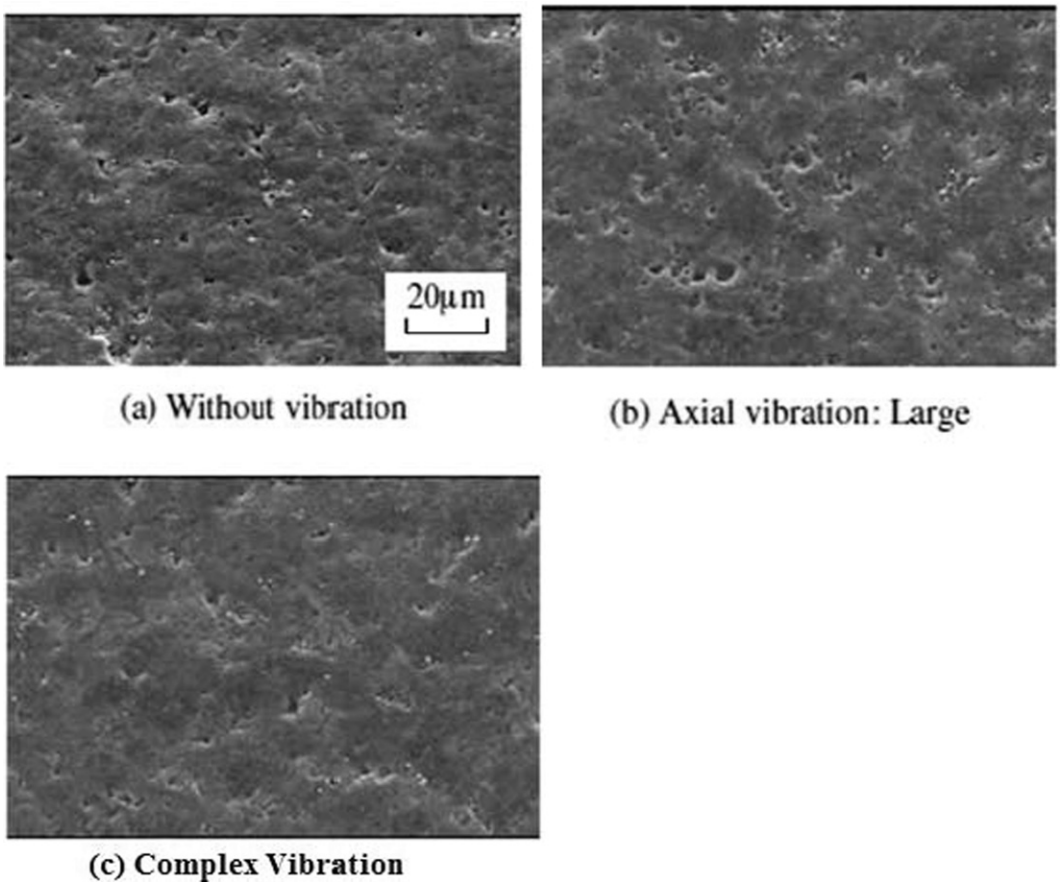

Figure 60 SEM observation results of the surface condition of the worked PCD under different vibration conditions.[89]

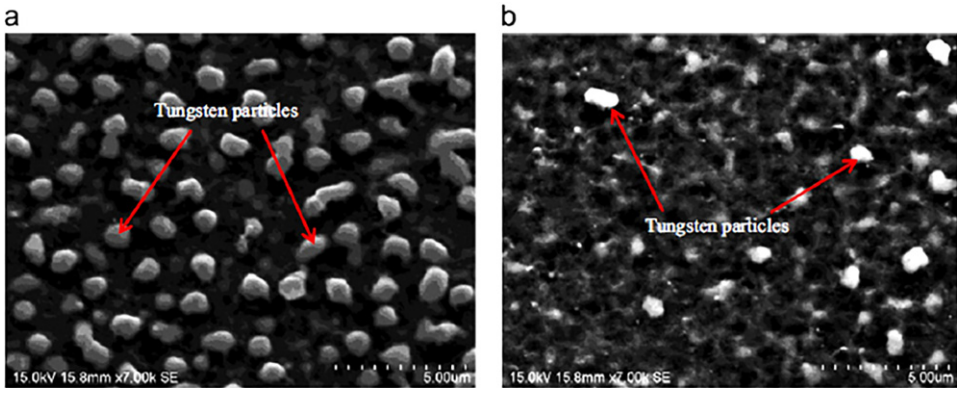

Figure 61 SEM micrograph of surface machined with carbon nanofibers addition (a) without ultrasonic cavitation and (b) with ultrasonic cavitation.[90]

Further investigation on SQ showed no deep discharge mark was found and the worked surface exhibited relatively good condition in any experimental conditions. **Figure 60** shows the SEM of surfaces under different condition.

Liew *et al.*[90] presented their work on μEDM of deep micro-holes in ceramic materials. Results show that ultrasonic vibration not only induced stirring effect but also caused cloud cavitation, which is helpful for removing debris and preventing tool material deposition on machined surface. The machining characteristics are strongly affected by the vibration amplitude, and the best machining performance is obtained when carbon nanofibers are added into the vibrated dielectric fluid. An important ceramic mold material, RB-SiC was used as workpiece while the tool electrode used was tungsten. Commercially available EDM oil was used as dielectric fluid. It has been shown in **Figure 61** the effect of adding of carbon nano fibers in dielectric fluid with/without ultrasonic vibration.

Without ultrasonic cavitation, many tungsten particles are deposited on the workpiece surface. In contrast, with ultrasonic

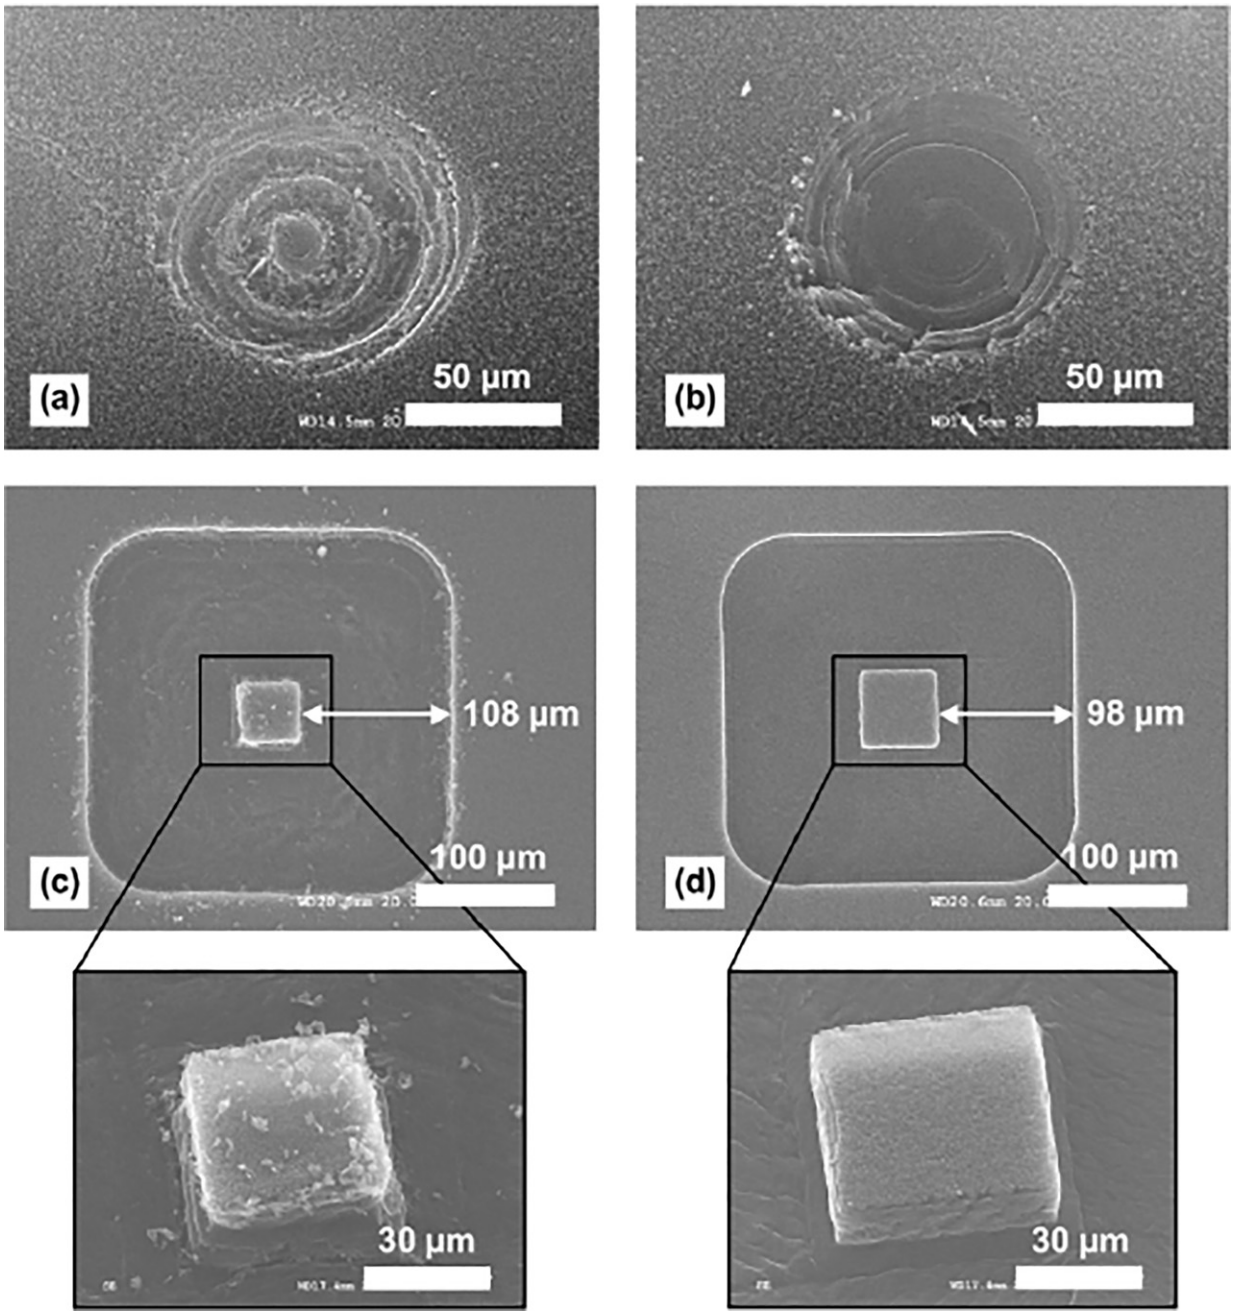

Figure 62 The upper two SEM images show shallow cavities machined in a CNT forest using 20 V and 10 pF with (a) normal polarity and (b) reverse polarity. The lower two SEM images show micropatterns machined in a CNT forest using 10 V and 10 pF with (c) normal polarity, and (d) reverse polarity, for a depth of 40 μm with 1-μm-step electrode feeding in the Z direction. The images in (c) and (d) also show close-up views of the microstructures created in the cavities.[91]

cavitation the tungsten particle deposition is reduced significantly, as seen in Figure 61.

Recently patterning of advanced material like vertically aligned carbon nanotubes (VACNTs) also commonly known as CNT forest has been carried out by several researchers. Saleh *et al.*[91] investigated reversed polarity μEDM of CNT forest and reported its several advantages over conventional μEDM of VACNTs. CNTs are known to be better field emitters; hence discharge sparks can be generated at low applied potentials. Based on this hypothesis, Saleh *et al.*[91] carried out their study and it was observed that the process with the reverse-polarity condition increased the discharge current, because of the enhanced field-emission properties of CNTs that served as the cathode in reversed μEDM. At higher voltage reversed μEDM was found to be detrimental as it generated uncontrolled sparks with bad SQ on the resultant patterns. However, as the operating voltage was lowered this concept was proven to be much better as it could produce more precise structure with good SQ as shown in Figure 62.

Thus authors[91] concluded that the structures machined with reverse μEDM at low voltages can produce higher precision and smoother and cleaner surfaces with almost no debris compared with those produced using conventional, normal-polarity processing. Reverse μEDM was also found to enable more stable and faster machining of the forests. Raman and EDX analyses revealed that reverse μEDM did not cause significant crystalline defects in the processed CNTs and contamination of the forest surfaces with the electrode element, respectively.

Laser machining is also used for micro-machining, however, it is has a disadvantage of producing inferior SQ because of HAZ. On the other hand, μEDM has a great advantage of producing superior SQ on the finished product but its processing time significantly slower as compared to laser machining. Ahmari *et al.*[92] combined the advantage of faster machining time of laser processing and smoother finish of μEDM to propose a hybrid machining technique based on laser processing and μEDM operation. They[92] investigated the process on Ni–Ti based shape memory alloy and found it to be very effective. In their study they conducted the experiments only for drilling operations. It was found that the proposed hybrid machining process resulted in 50–65% reduction in machining time without affecting the quality of micro-holes as compared to the standard μEDM process.

1.13.10.2 Surface Modification Using Wire EDM

In the 1970s with the development of CNC machining wire-cut EDM became a practical machining system. The basic difference between the brief summary about surface finish controlling factors for wire EDM will be discussed in this section. The surface characteristics of the wire-cut machine are very similar to those of the die-sinker machine. Both die-sinker and wire-cut machines use sparking to remove electrically conductive material. However, they do not normally use the same kind of dielectric fluids or electrodes. Therefore, its visual appearance is different due to the deionized water that is used as the dielectric fluid. Since water does not have carbon as a by-product as it breaks down in the sparking process, the machined surface remains clean and the chance of DC arcing is minimized due to the deionized water that is used as the dielectric fluid.[37]

Gupta *et al.*[93] highlighted about analysis and optimization of SR parameters (i.e., average roughness R_a and maximum roughness R_t) of wire electrical discharge machined fine-pitch miniature spur gears. The material used was brass. Experimental effects of four EDM machining parameters (i.e., voltage, pulse-on time, pulse-off time, and wire feed rate) on the SR parameters were observed and it is reported from their studies that the SR increased with higher voltage and longer pulse-on time and decreased with longer pulse-off time and higher wire feed rate.

Huang and Chen[94] presented experimental studies on WEDM to identify the significant factors affecting SR. The controlling factors considered were: type of pulse generating circuit (PS), conductivity of the dielectric (K), resistance in the circuit (R), capacitance in the circuit (C), applied voltage (V), feed rate of the table (F), and pulse-off time (T_{off}). Taguchi quality design was adopted to select appropriate number of experiments. After analyzing the effect of each relevant factor on SR, appropriate values of all parameters are chosen and a fine surface of roughness R_a equals to 0.22 μm was achieved.

Kurian and Yeldose[95] investigated effect of wire EDM parameters on SR of stainless steel. The steel workpiece used was 15-5 PH stainless steel, which was martensitic, precipitation hardening stainless steel. It has excellent strength, transverse toughness and ductility widely used in corrosive as well as high-pressure environments. SR (R_a) were considered for optimizing machining parameters. The surface finish value (in μm) was obtained by measuring the mean absolute deviation, R_a (SR). The minimum value of R_a found from their work was 0.5037 μm.

Saleh *et al.*[59] proposed an improved μ-WEDM and μEDM of silicon (Si) by temporarily coating Si with a high conductive metal (gold in this study). Micro-WEDM process stability was found to be improved ($\sim 100\times$ for different machining condition) if coated Si wafer is used as compared to uncoated Si workpiece. In this research, a p-type pre polished (mirror quality) silicon wafer of 650 μm thickness was used. The wafer was coated with conductive material (Au in this research) using ion spattering machine on the both sides before the start of the actual μ-WEDMing/EDMing process. Three types of samples were prepared for the machining experiment. The first group of samples was silicon (Si) without any coating, the second and third groups were Si coated for 5 min (Si(1)) and 10 min (Si(2)). The resultant surfaces for three different coating are shown in **Figure 63**.

It is seen that machined surface for uncoated Si wafer was rough with visible bumps, whereas machined surface for coated Si wafer (10 min) is remarkably smooth. And the SQ of Si(1) falls in between. Stability of machining could be one reason for enhanced SQ for WEDMed surface for gold-coated Si. Further, during machining, gold-coated Si spark generation was consistent, which led to smoother SQ; on the other hand, inconsistent spark generation for uncoated Si made the machined surface rough with visible bumps.

1.13.11 Summary on EDMed SQ

The surface produced by EDM sparking is non-directional and nonreflective and is made up of many spherical cavities because EDM works under the principle of molten metal removal. Many attempts have been reported in the chapter to focus on the recent improvements in EDMed surfaces. We may summarize few salient points regarding surface generated in EDM, its possible improvements and parameters affecting the SQ:

- Higher spark energy has adverse effect on EDMed surface. The more the spark energy is available, more volume is removed by the process ending up in a coarser surface.
- Electrode material plays an important role on the EDMed surface as sometimes part of it may be associated with the workpart surface. Therefore, the electrode materials thermal conductivity and melting point have significant influence on the EDMed surface besides electrical conductivity.
- Use of a PM or composite electrode has been proved to be a viable alternative to expensive surface coating processes.

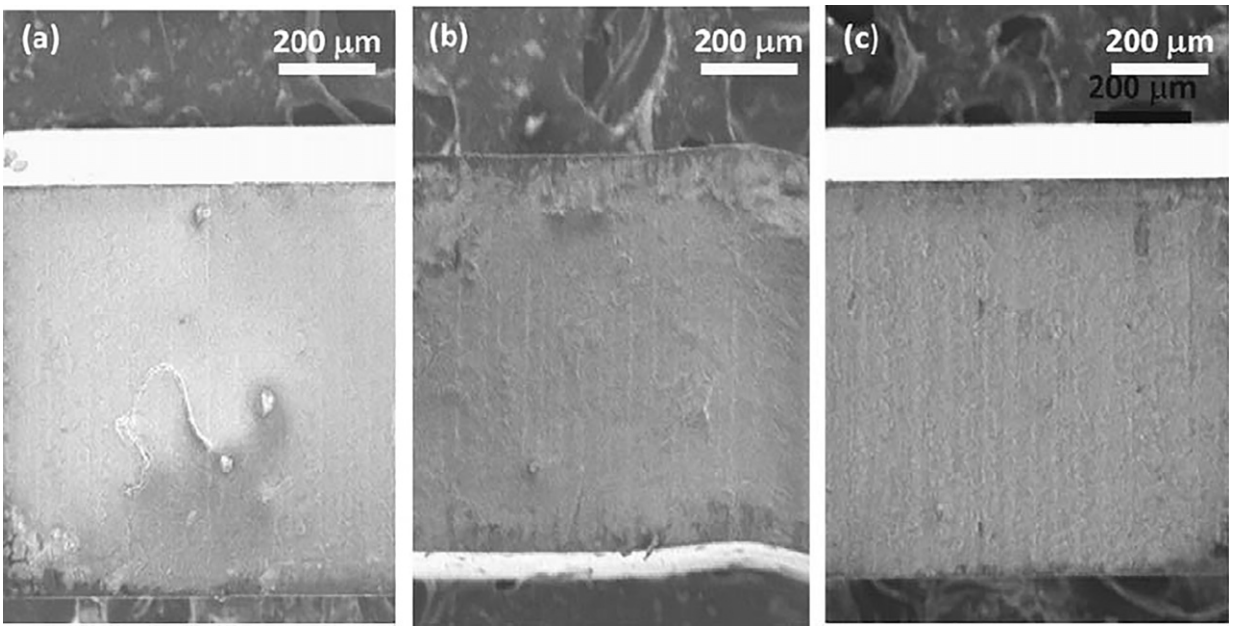

Figure 63 SEM image of the cut surface of the machined slots by μ-WEDM process with machining condition of 95 V and 1 nF for (a) uncoated Si, (b) Si(1), and (c) Si(2).[59]

Table 6 Comparison between ELID grinding and electro-discharge machining

Attributes	*ELID grinding*	*EDM*
Machining type	Conventional grinding	Non-conventional machining
Speciality	Grinding tool is dressed in-process by electrolytic reactions	Machining is taken place by controlled electrical sparks between tool and workpiece
Work materials	Hard and brittle materials can be glass, ceramics, Si wafers, bearing steels, etc.	Difficult to cut materials and conductive metals, carbon nano tubes, conductive polymers, etc.
Machining fluid	Electrolytes	Dielectric
Machining domain	Mostly macro	Macro to micro
Machining arrangement	Planner grinding, lapping grinding, traverse grinding, parallel grinding, cylindrical grinding, etc.	Die-sinking EDM, milling EDM, wire EDM, etc.
Attainable surface roughness	Average surface roughness ranges from sub-nanometers to 10s of nanometers	Minimum, average surface roughness achieved was 30s of nanometers in micro-EDM

- Dielectric is also a determining factor for surface finish. Dielectric with conductive nano-particles dispersed in it has resulted in excellent surface finish for μEDM.
- Ball milling or burnishing can be a good combination to be used with EDM electrode for a better surface finish.
- EDM with conductive electrode, powder associated dielectric combined with ultrasonic vibration, EDM on different conductive polymer have shown promising applications. Further research outcomes are expected from such applications.

1.13.12 Conclusion

ELID grinding and EDM are two subtractive manufacturing processes discussed in this chapter. In ELID grinding actual machining action is conventional; however, dressing of the grinding wheel is taken place by electrolytic reaction. ELID grinding is under research interest for last two decades and has evolved considerably since. On the other hand, EDM is a non-conventional machining process that removes material from the workpiece by controlled and repetitive electric sparks without any physical contact between tool and work materials. Table 6 shows a comparative study between these two machining technologies.

It can be understood from Table 6 EDM is mostly applicable for conductive material in both macro and micro-domain. On the other hand, ELID can be used for both conductive and nonconductive material mostly in macro domain. Sub-10 nm average SR is very common on the product finished by ELID grinding however, best SR achieved in EDM is in several 10s of nanometer and micro-domain. It can be concluded that EDM as the finish machining has the strength to be used in both macro and micro-domain with a capability to produce complicated features, whereas ELID grinding is promising to

achieve mirror surface finish on hard and brittle materials which may potentially eliminate subsequent finishing process such as polishing.

1.14.1 Introduction

Laser surface modification in engineering materials has attracted wide attention due to rapid growth in the applications of lasers. The modification changes not only the surface composition but also the microstructure of material to give desired properties. Laser surface modifications enabled by the development of a high-power laser are: (1) laser surface heat treatment; (2) laser surface melting (or glazing); (3) laser direct metal deposition (cladding, alloying, coating); (4) laser physical vapor deposition; and (5) laser peening. Of these, laser peening is a new surface modification technology made possible by the development of high laser power density and very short-pulsed laser beams.

Several techniques have been developed to introduce compressive stresses in the substrate material. Some of these include shot peening, sand blasting, and surface rolling. However, the efficiency of the process and the magnitude of compressive stress are limited for these techniques. In recent years, laser-aided manufacturing and materials synthesis techniques have been developed. Laser peening is one of these recent developments. It is a promising surface treatment technique that is an alternative to conventional treatments and has been very effective in strengthening metals that are irradiated by very short pulsed and high-power lasers. Laser peening has many advantages over conventional methods, such as nonmechanical contact between the laser source and the metallic material, local treatment, and precision of operation. Laser peening can produce a layer of residual compressive stress in the surface region that is four-times deeper than that attainable from conventional shot peening techniques. Besides providing higher compressive stress with metallurgical properties, such as dislocations, twins, and stacking faults (SFs), and producing favorable surface integrity, laser peening can also be used to fabricate various micro-surface structures such as dent arrays or thin sections with high accuracy using an automatic x–y positioning system. A higher dislocation density results in plastically affected zones and higher surface hardness and strength development in the materials. Deeper levels of compressive stress in laser peening provide greater resistance to potential fatigue and corrosion failures. The laser peening process increases component life and reduces maintenance costs. The process strengthens designs that are structurally vulnerable without adding metal and weight.

The process had been discovered in the early 1960s, and the investigations mainly focused on process development, understanding the mechanisms, use of high laser intensity, progress in physical models, and determining the optimum

 doi:10.1016/B978-0-12-803581-8.09160-8

shock conditions and mechanical effects. The irradiated surfaces are exposed to a shock wave, which generates compressive residual stresses beneath the treated surface of the metallic materials.

Laser peening has many applications in various fields such as aircraft engines, turbomachinery, medical implants, specialized gears, and components with notches and holes. The process involves recoil pressure acting on the surface by avoiding heating effects. These conditions make the process a good candidate for surface treatment of metallic materials.

1.14.1.1 Conventional Shot Peening

Shot peening is a conventional surface treatment technique, and this technique has been used in industry since the 1940s. Metal or ceramic balls act as small, rounded hammers, and every shot strike creates a dimple in the affected region of a metal surface (**Figure 1**). Compressive volume under the dimpled regions is generated. A thin layer is created in shot-peened metal by overlapped dimples. This layer can be resistant to corrosion and crack initiation and propagation. During the shot peening process, an elastically deformed layer around the plastically deformed layer is produced. The plastically deformed layer tends to expand and the adjacent elastically responding material prevents this from occurring.[1,2] As a result of this, the surface layer up to a certain depth is exposed to permanent residual stresses. The shot peening process has some advantages: it is relatively inexpensive[3]; enduring process equipment is used in this process; and it can be easily used for large surface areas. However, this process has some disadvantages: the process is semiquantitative, especially in estimating shot peening intensity[4]; the compressive residual stress is restricted in depth, generally in soft alloys such as aluminum alloy, and does not exceed in 0.25 mm (in hard metals it is even less); it is unsuitable for treating local areas and small surface areas; and it can generally result in a rough component surface, especially in soft alloys such as aluminum. The rough layer is generally removed for industrial applications; therefore, the compressive residual stress layer can also be removed. The actual depth of compressive residual stresses, which are induced during laser peening, is generally in the range of 0.5–1 mm or more,[5] depending on material properties and processing conditions, which could be four-times deeper than that of shot peening.[6] In addition, shot peening can lead to distortion of thin sections, but laser-peened surfaces do not normally lose any dimensional accuracy.[7] Residual stresses are 'confined' stresses in a component. Residual stresses play an important role in fatigue of engineering materials because fatigue crack initiations occur due to tensile stresses, and these are decreased by residual stress.[8]

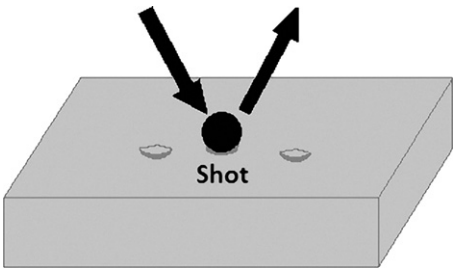

Figure 1 Schematic view of shot peening.

1.14.1.2 Laser Peening

Laser peening is an innovative surface treatment technique that is generally used to improve the material properties of the substrate such as fatigue, wear, corrosion, and strength and hardness.[9–13] Fatigue strength and fatigue life are considerably improved by compressive residual stress that is induced in laser-peened material. Strength and hardness of the material are increased by high-density and tangled dislocations and sub-grain formation, which are developed under the high strain rate of laser peening deformation. Moreover, nano-grains and nano-twins near the surface region are formed by increasing the misorientation of nano-sub-grains under laser shock loading.[14,15]

It was discovered in the early 1960s that an ns-level pulsed laser beam could create an effective shock wave in the metallic materials.[16] Laser peening studies began in US Battele Columbus Laboratories in the United States of America in 1968,[17,18] and studies on improvements continued until 1981.[19] First, the effects of unconfined surfaces were investigated and reported between 1963 and 1968.[16,20,21] Later, the confined ablation mode was reported by Anderholm in 1970, in which gigapascal-level pressures were obtained on confined surfaces. The 'direct ablation' mode is a laser–material interaction with freely expanding plasma; the 'confined ablation' mode is confinement of the plasma arising from laser–material interactions, and this mode enables the magnitude of generated plasma to be substantially increased during its expansion.[22] Further studies also investigated confinement of the plasma, and different transparent overlays were investigated by O'Keefe *et al.* and Yang.[23,24] Significantly increased peak pressures during the confined ablation mode were researched and developed in detail.[25,26] The first laser peening patent was granted to Mallozi and Fairand in 1974.[27] By improvements in laser peening and following the first patent, several patents were granted relating to major modifications in material properties due to the process.[28–30] Laser peening can be used in various metallic materials, stainless steels, aluminum alloys, titanium alloys, and, frequently, super alloys.[31–34]

Laser peening has various commercial trade names and may also be frequently referred to as laser shock processing, laser peening, or laser shot peening. A schematic view of laser peening is shown in **Figure 2**. A target material is irradiated by a short ns-laser pulse at high intensities. The heated zone is vaporized, the vapor continues absorbing laser energy so temperatures reach in excess of 10 000 °C, and it is transformed into plasma due to ionization. The plasma absorbs laser energy until the end of the laser pulse length. Rapid expansion of plasma is confined by transparent overlay (such as water, glass, quartz), which is called 'confined ablation.' The irradiated surface is generally coated with an opaque overlay like a metallic foil tape, dielectric black tape, or plastic paint to avoid heating effects on the metallic surface. High pressure (GPa) is generated at the evaporated surface. Because the process is very short and the magnitude of pressure is very high, the pressure causes shock waves to propagate in the target material and confining medium. Plastic deformation occurs to a depth

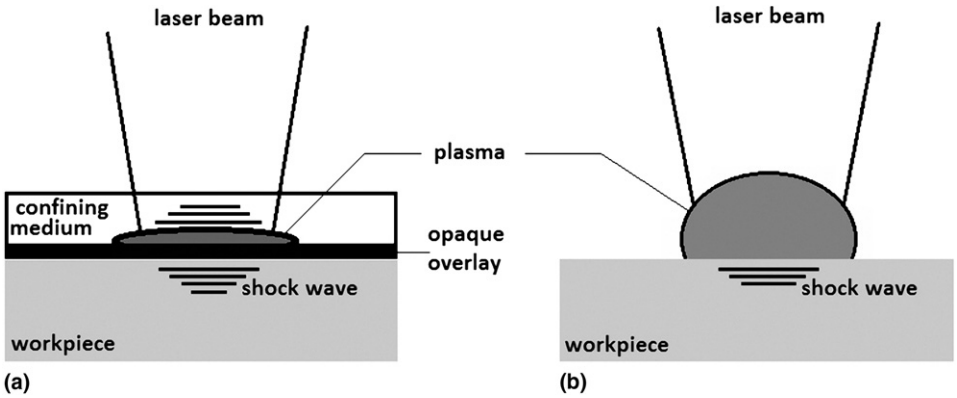

Figure 2 Schematic view of laser peening illustrating the laser beam irradiating the material surface: (a) confined ablation and (b) direct ablation.

where peak pressure exceeds the Hugoniot elastic limit (HEL) of metal and residual stress develops in the plastically affected depth. In the laser peening process, high pressure and short-duration shock waves can offer desirable mechanical and metallurgical results.

The physics of the laser peening process can be used to harden surfaces and strengthen thin sections. Moreover, laser peening has a broad range of applications, especially in the aerospace industry. It is used for many products, including turbine blades, fan blades, compressor blades, rotor components, bearing components, and gear shafts. Also, it can be applied in welded joints, fastener holes, and stop holes in aircraft structures.[5,35–38] Laser peening is an effective surface treatment technique in critical areas that have risks in terms of crack initiation and preexisting notch configurations. It is also preferred for general industrial applications such as land vehicles and weapon systems as well as for the aircraft industry. Furthermore, automotive parts, orthopedic implants, dies, and tooling are potential applications of this process.

1.14.1.3 Laser Peening versus Shot Peening

The residual stress produced by shot peening may be adequate for the intended use for some applications. Laser peening offers different surface enhancement technology and is sufficient for specific applications.

Shot peening intensity is insufficient to generate enough compressive residual stresses and therefore cannot prevent some critical parts from failing. The residual stress distribution below the peened surface is much deeper for laser peening than it is for shot peening.[5] Much higher shot peening intensity is necessary to achieve deeper stresses with shot peening, and achieving deeper stresses causes surface deterioration. Laser peening does not result in a significant alteration of the surface topography.[3] Laser peening usually produces the highest compressive residual stress just below the surface. The deep compressive stresses are due to the shock pressure being maintained above the dynamic yield strength to greater depths than with shot peening.

Laser peening treatment brings about better pitting resistance, and shot peening is also a beneficial influence of mechanical surface treatments that demonstrates localized corrosion properties.[39] Shot peening treatment leads to a dimpled surface finish; however, laser peening treatment produces the smoothest finish.[40] A deleterious material surface induced by shot peening can counterbalance the beneficial effect of residual stress by activating the pitting. A reduction in the passive current density occurs on laser-peened surfaces, and this indicates the increase in corrosion resistance.[39]

Laser peening enhances notched fatigue strength and provides resistance to fatigue cracking. Laser peening appears to be more successful in increasing the fatigue life than shot peening. Hatamleh *et al.*[41] investigated the influence of shot peening and laser peening treatment on the fatigue crack growth of friction stir-welded 7075-T7351 aluminum alloy joints. The laser-peened specimens showed a significant reduction in fatigue crack growth and striation spacing. This situation is attributed to the deeper compressive residual stress induced by laser peening. The improvement in shot-peened specimens is negligible or only minor for crack growth rates in 7075-T7351 aluminum alloy.[42] Gao *et al.*[43] determined the fatigue strength for 1×10^7 cycles of 7050-T7451 aluminum alloy for unpeened, laser-peened, and shot-peened specimens. The results showed that a deeper compressive residual stress layer was obtained for a laser-peened specimen, and that laser peening induced better surface finish; therefore, fatigue properties improved more efficiently. There are many thin metal components that are induced by the two-sided 'peening' process in military airplanes and space vehicles. In thin sections, the use of the shot peening method is not practical due to the potential damage. Laser peening is more suitable for thin sections.[7] Laser peening has the capability of local treatment and process control; for example, laser peening can be applied only to selected regions of a component because the process has the ability to precisely dictate the position of the laser.[44] Therefore, this process can be easily applied to fastener, fastener holes, and weld joints. Laser peening is used in numerous applications, especially airframe structures to combat fatigue, fretting fatigue, and stress corrosion cracking (SCC). The plastic strain induced by the shock wave during laser peening extends much deeper than that during conventional shot peening, and therefore produced a much deeper compressive zone.[45] Compressive residual stress extends to a depth of between five- and ten-times greater than is possible with shot peening.[35]

1.14.2 Fundamentals and Physical Mechanisms of Laser Peening

1.14.2.1 Laser Systems for Laser Peening

Selection of a suitable laser system is necessary to fulfill the steps required for the laser peening process; otherwise, obtaining the effective material properties is not possible. The Q-switched laser system is used in many laser peening studies. Q-switched systems have an electro-optic switch to attain a pulsed output beam. Therefore, a pulsed laser can be obtained in fast switching time during laser peening. Laser beams are commonly produced by neodymium-doped glass (Nd:Glass) or neodymium-doped yttrium aluminum garnet (Nd:YAG) crystal lasing rod. The efficiency of laser peening can be increased by a high repetition rate of laser pulse and a suitable laser wavelength in metallic components. The production of recoil pressures by vaporizing metal surfaces requires irradiation with a short (tenths of nanoseconds), intense (more than 1 GW cm^{-2}), focused laser pulse. The output of the laser with an average power level of several hundred watts to kilowatts and a short nanosecond pulse has been used during progression of laser peening. The common laser system for laser peening is high-energy with a wavelength of 1064 nm. Recently, low-power laser and visible wavelength were found to be favorable in laser systems. **Table 1** shows some typical laser systems used in the laser peening process in the open literature.

The plasma pressure pulse induced by laser peening is a function of laser intensity (laser power density). An increase in the laser intensity increases the magnitude of pressure pulse on the target material. Accordingly, the laser intensity is the most critical parameter in laser peening. A small laser beam spot size ($\sim$1 mm) is preferred to obtain higher laser intensity from a laser system that has lower laser pulse energy (a level of several hundred millijoule). High peak pressure (in GPa levels) can be generated in laser systems with low pulse energy through a small laser beam spot size. Relatively low laser energy is used (50–750 mJ) because low-cost laser systems are commercially applicable.[8]

Three wavelengths are most commonly used in laser peening. These are ultraviolet (355 nm), green (532 nm), and near-infrared (IR) (1064 nm) wavelengths. A water confinement regime is generally performed in IR at a wavelength of 1064 nm. Near-IR wavelength has a good absorption coefficient in the water confinement regime. Short laser wavelengths have a detrimental effect on the water breakdown of plasma. However, the laser interaction in the confined regime is more efficient in ultraviolet irradiation than in IR irradiation.[64] Also, the decrease in wavelength from IR to UV can increase the photon–metal interaction, which provides shock wave generation, although metals are highly reflective.[7] With the photoelectric effect, energy absorption results from electromagnetic radiation of very short wavelengths such as visible or UV radiation.

1.14.2.2 Shock Wave Formation

When a laser beam at high laser intensity with a pulse duration of a few nanoseconds is irradiated at the target material, the surface instantaneously vaporizes and the vapor generates high pressure plasma (in the GPa range) by continuing to absorb the laser energy. In blowing off, the plasma pressure level increases as a consequence of confining medium by inducing a mechanical impulse in the solid. A shock wave is propagated through both the metallic target and the confining medium.[65,66] **Figure 3** presents the geometry for the confined ablation process with relevant parameters used in analytical modelization. The geometry is composed of a bulk material and a transparent confining medium. In the confined ablation mode, the pressure generation depending on shock wave occurs in a three steps:

1. The laser energy is absorbed until the end of the laser is switched off, and the plasma generates at the interface and creates pressure that induces two shock waves (with velocities D_1 and D_2). This pressure propagates in the bulk material and the confining medium. Therefore, an opening of the interface (L) between the two media is defined by the fluid motion and thickness of the interface increases.
2. In the second step, when the laser pulse is switched off, the plasma proceeds to adiabatic cooling and subsequently decreases, but the shock pressure is maintained due to the increase of the plasma interface.
3. Finally, after the complete recombination of the plasma, the projectile like expansion of the plasma in the interface adds further mechanical momentum to the target.[65,67]

The pressure generated by the plasma is adequately strong to drive shock waves. Thus, the displacement of interfaces derives from fluid motion of two shock waves.[26] In eqns [1–3], P is the pulse pressure, L is the length of interface, and V is the expansion velocity between the material surface and the confining medium; u_i ($i=1,2$) is the fluid velocity and Z_i the shock impedance.

$$L(t) = \int [u_1(t) + u_2(t)]\mathrm{d}t_1 \quad [1]$$

$$I(t) = P(t)\frac{\mathrm{d}L(t)}{\mathrm{d}t} + \frac{3}{2\alpha}\frac{\mathrm{d}}{\mathrm{d}t}[P(t)L(t)] \quad [2]$$

$$V(t) = \frac{\mathrm{d}L(t)}{\mathrm{d}t} = \left(\frac{1}{Z_1} + \frac{1}{Z_2}\right)P(t) \quad [3]$$

Pressure (P) is estimated by Fabbro *et al.*[26] as follows:

$$P(\mathrm{GPa}) = 0.01\sqrt{\frac{\alpha}{2\alpha+3}}\sqrt{Z(\mathrm{g\ cm^{-2}\ s^2})}\sqrt{I_0(\mathrm{GW\ cm^{-2}})} \quad [4]$$

Peyre *et al.*[68] established a physical method to predict the peak pressure for a water confinement mode. In this kind of configuration, eqn [4] gives:

$$P(\mathrm{GPa}) = 1.02\sqrt{I_0(\mathrm{GW\ cm^{-2}})} \quad [5]$$

According to eqn [5], it can be said that the peak pressure is directly proportional to the square root of laser intensity in the water confinement mode.

The change of momentum between the evaporating front and solid surface results in recoil pressure formation at the interface.[69] The magnitude of recoil pressure depends on the

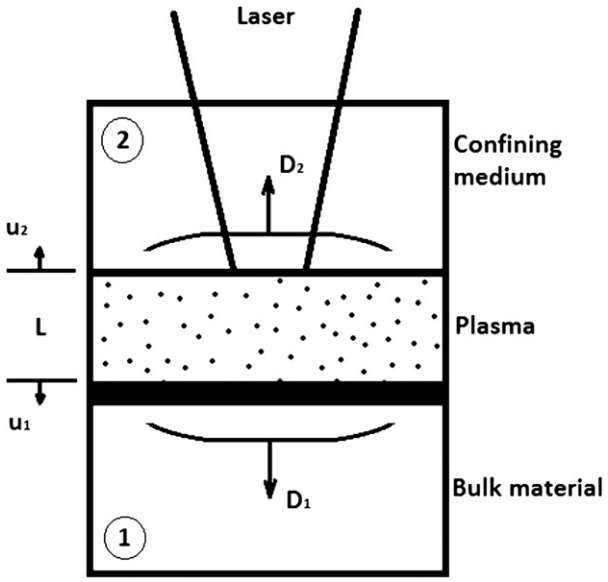

Figure 3 Scheme of the confined ablation process.

laser intensity and pulse duration. The recoil pressure that can be attained is approximately tens of gigapascal. In the confining medium, expansion of the generated plasma is restricted, and thus higher pressures than in the direct ablation mode are generated. In comparison with the direct ablation mode (without any confining medium), pressure of approximately 5 GPa can be easily generated; therefore, magnitude of the pressure is greater than direct ablation for the same laser intensity, and the generated pressure is two- to three-times longer than the laser pulse duration.[65]

Berthe *et al.*[70] studied parasitic plasma and pressure measurement in laser peening by using velocimetry interferometer system for any reflector (VISAR) and a fast camera. They experimentally found that the pressure is a function of laser intensity. The experimental data, which give the relation between pressure and laser intensity, revealed that an increase in pressure occurs when the laser intensity is increased from 1 to 10 GW cm^{-2} and the corresponding pressure is scattered or saturated. This saturation is attributed to a confining water-breakdown phenomenon. The parasitic effect of the water breakdown is questionable beyond 11–13 GW cm^{-2}.

The pressure pulse depends on the magnitude of laser intensity, and other variables produce plastic deformation near the surface of the metal. As the shock wave moves down to the bottom of workpiece, the magnitude of the shock wave decreases. Past a certain depth, the shock wave is below the proportional limit and the waves become purely elastic. The final outcome of the process is a compressive residual stress in the component.[71,72]

In general, investigation of the stress propagation in nonlinear medium is extremely difficult. The material behaves differently in various strain rates. During laser shock loading, the strain rate reaches approximately 10^6 s^{-1} typically, and this rate is much higher than conventional strain rates ($\sim 10^{-6}$ s^{-1}). This ultra-high strain rate is attributed to a shock wave or impact loading. Materials behave differently in static loading (or low strain rates) and dynamic loading (or high strain rates $>10^3$ s^{-1}). Higher stress is necessary to reach the yield strength in impact loading than in the case of slow loading.[71] If the peak stress of the generated shock wave is above the dynamic yield strength of the material, then the material plastically deforms. If the HEL of the material is exceeded, then a shock wave propagates into the material after the elastic stress wave. HEL is defined as the maximum stress sustainable by a solid in one-dimensional shock compression without irreversible deformation taking place at the shock front.[73] When the magnitude of the shock wave exceeds the HEL of the substrate material, plastic deformation takes place, and modification of the microstructure, properties, and state of stress levels of the specimen in the region where the shock wave is effective occurs.[62]

1.14.2.3 Residual Stresses Induced by Laser Peening

1.14.2.3.1 Generation of residual stresses

According to previous discussions, when a laser pulse (high laser intensity $\sim$1–30 GW cm^{-2} and short pulse duration $\sim$1–30 ns) is irradiated on a confined target (confined ablation mode), a plasma is produced.[67] Compressive pressure and shock wave systems result in local plastic strain in the material. A local laser-induced stress wave interacts with a metal and generates mechanical effects. The mechanical effects mainly depend on whether the target is covered with a protective overlay or not covered. Without any protective overlay, thermal effects dominate and tensile stresses develop due to partial melting on the metallic surface. The opaque overlay absorbs the laser energy and protects the metallic surface from the thermal effect. Thus, a pure mechanical effect is created inside the metallic target.

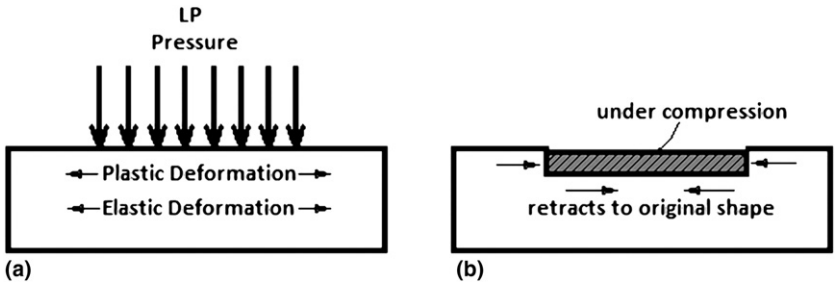

Figure 4 Schematic of compressive residual stress generation: (a) during interaction and (b) after the switch-off the laser pulse.

During shock wave propagation and interaction, the volume affected by the shock wave is plastically strained, whereas the deformation in the surrounding regions is nearly purely elastic (Figure 4). After the switch-off of the laser, the surrounding material responds to the plastically affected volume, so it is opposed to this straining. Whereas the elastically deformed region attempts to return back, plastic deformation is permanent. Thus, the surrounding material induces compressive residual stress in the irradiated region.[65,67]

Detailed analysis of mechanical effects introduced by laser peening was performed by Ballard *et al.*[74] by considering shock wave propagation into an elastic perfectly plastic body. They considered the shock waves to be longitudinal and planar, and considered the pressure pulse to be uniform on the impacted area.[67] A laser-peened metallic target is considered in a biaxial condition. It obeys the von Mises yielding criterion. The model assumed that the plastic deformation occurs when the peak pressure exceeds HEL:

$$\mathrm{HEL} = \left(1 + \frac{\lambda}{2\mu}\right)\sigma_y \qquad [6]$$

σ_y is the uniaxial elastic limit of the target, and λ and μ are the elastic Lame's constants of the target. Plastic deformation increases between HEL and 2HEL. It is assumed to reach its maximum above 2HEL. Above 2.52HEL, surface release waves occur[67] and amplify from the edges of the impacts; therefore, the residual stress field is modified regardless of the impact shape (Figure 5).[4] L_P is plastically affected depth and σ_{sur} is surface residual stress:

$$L_P = \frac{C_{el}C_{pl}\tau}{(C_{el} - C_{pl})}\ \frac{P}{\mathrm{HEL}} \qquad [7]$$

$$\sigma_{sur} = \mu\varepsilon_P\left(\frac{1+\nu}{1-\nu}\right)\left[1 - 4\frac{\sqrt{2}}{\pi}(1+\nu)\frac{L_P}{a}\right] \qquad [8]$$

C_{el} and C_{pl} are elastic and plastic shock wave velocities, respectively. P is shock wave pressure, ε_P is plastic surface strain, μ is pulse duration, ν is Poisson's ratio, and a is side of square impact. If we substitute the equations:

$$\sigma_{sur} = \frac{P}{2\left(1 + \frac{\lambda}{2\mu}\right)}\left[1 - \frac{4\sqrt{2}}{\pi r}(1+\nu)\frac{C_{el}C_{pl}\tau}{(C_{el} - C_{pl})}\right] \qquad [9]$$

r is the radius of the impact.

These equations are considered valid only when P is greater than twice the material's HEL.[4] Consequently, if the shock conditions exceed 2.52HEL, then an inhomogeneous stress field can be produced that can lead to detrimental reverse strains.

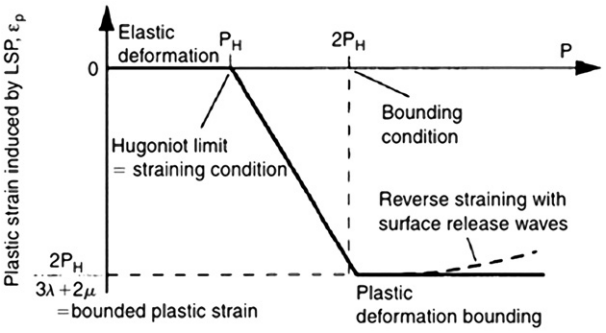

Figure 5 Plastic deformation induced by laser peening as a function of peak pressure.[75]

The magnitude of residual stress and the depth of modification depend on a few process parameters that determine the pressure pulse profile. The depth of compressive residual stress is related to the depth of the plastically affected region. The laser peening parameters can be optimized to generate a higher residual stress magnitude and a higher compressive stress volume.[71] These parameters are laser intensity, pulse duration, pulse shape, spot size, overlapping rate, number of impact, protective coating type, transparent overlay, and others. Residual stress magnitude and depth influence the mechanical properties of impacted material.

1.14.2.3.2 Measurement of residual stresses

There are several residual stress measurement methods. X-ray diffraction (XRD) and hole-drilling techniques attract the most attention. XRD has become one of the standard methods for residual stress measurement over the past few decades. The term stress measurement is a bit misleading, because stress is an extrinsic feature and it is not directly measurable. What is measurable is the strain. All methods of stress determination require measurement of the intrinsic property and the calculation of the associated stress.[76]

1.14.2.3.2.1 XRD method

XRD measures the strain by determining shifts in diffraction peaks due to external stress or residual stress. The measured strains are transformed into the stress via Hooke's law.[76,77] Measurable volume depends on X-ray penetration depth. The penetration depth of X-rays is managed by the linear absorption

coefficient of the material by depending on radiation.[76] For aluminum-based alloys in all of the X-ray sources, more than 70% of the diffracted radiation comes from approximately 100 μm of the top of the material. The penetration depth depends on radiation. For example, Cu-Kα radiation, Co-Kα radiation, and Cr-Kα radiation are various types of radiation used in laboratory settings.

The XRD technique is generally preferred to measure residual stress generated in the surface due to restricted penetration depth. However, via destructive etch/layer removal, the residual stress gradients in metals have typically been measured using XRD.

The strain measurement in material from XRD is performed using Bragg's law, $n\lambda = 2d\sin\theta$, where λ is the wavelength, 2θ is the diffraction angle, and d is the lattice spacing of crystal planes. The choice of the diffraction peak considerably influences the precision of stress measurement. The greater diffraction angle (2θ) brings about the greater sensitivity of residual strain measurements and the greater precision of stress calculations; therefore, in general, the largest diffraction angle (2θ) should be used for certain radiation if possible.[78] Any change in the lattice spacing, d, results in a shift in the diffraction angle, 2θ[76] (**Figure 6**). The sample is rotated by a ψ-angle of the sample's normal during analysis. Initially, when $\psi = 0$, it is known that d_0 is the interplanar lattice spacing and is the d-spacing. d_ψ is the interplanar spacing of the lattice when the sample is rotated ψ-angle from the normal, N. If d-spacing changes, then the diffraction angle, 2θ, will be changed as the sample is rotated from $\psi = 0$ to $\psi = \psi$. Measurement of the strain (the change of d-spacing) by using XRD is a basic principle.[78] In practice, the diffraction angle, 2θ, chosen is required to be higher than 120°.[76,79] If the surface is under compression, then the d-spacing decreases and the diffraction angle increases as a result of the tilt.[80]

Higher speed and more convenience measurements can be gained by making a few key assumptions about the nature of the stress in the surface of crystalline materials. Assuming a plane stress distribution, which has a zero component in the z direction of the strain, leads to simplification of eqn [10]. This approach is well known as the 'd *vs.* $\sin^2\psi$' technique. And it has been beneficial for the determination of biaxial stresses for more than 60 years. When there is zero in-plane shear stress, eqn [10a] is applied. Equation [10b] also calculates for any in-plane shear stress.[78]

$$\frac{d_{\phi\psi} - d_0}{d_0} = \frac{1+\nu}{E}\sigma_\phi \sin^2\psi - \frac{\nu}{E}(\sigma_{11} + \sigma_{22}) \quad [10]$$

$$\sigma_\phi = \sigma_{11}\cos^2\phi + \sigma_{22}\sin^2\phi \quad [10a]$$

$$\sigma_\phi = \sigma_{11}\cos^2\phi + \sigma_{12}\sin 2\phi + \sigma_{22}\sin^2\phi \quad [10b]$$

σ_ϕ is the stress in a given S_ϕ direction (S is the incident beam) and d_0 is known as unstressed plane spacing.[81] σ_{11} and σ_{22} are the principle stresses. d_0 cannot be known in most instances, but it can be replaced by the lattice spacing measured at $\psi = 0$.[78]

Equation [10] can be modified as eqn [6]:

$$d_{\phi\psi} = d_0\frac{1+\nu}{E}\sigma_\phi \sin^2\psi - d_0\frac{\nu}{E}(\sigma_{11} + \sigma_{22}) + d_0 \quad [11]$$

In eqn [11], the multiplier of the term $\sin^2\psi$ is the slope of d versus $\sin^2\psi$ plot. Equation [11] can be rearranged for slope m.

$$m = d_0\frac{1+\nu}{E}\sigma_\phi \quad [12]$$

Equation 12 can be further modified to obtain the stress, σ_ϕ. Therefore, the very simple eqn [13] gives the residual stress.

$$\sigma_\phi = \frac{m}{d_0}\left(\frac{E}{1+\nu}\right) \quad [13]$$

The advantages of the XRD residual stress technique are multidirectional, commonly used, have a wide material range, and are portable. The advantages of this technique include fundamental measurements, laboratory-based systems, and favorable for small components.

1.14.2.3.2.2 Hole-drilling method

The hole-drilling technique is based on drilling a small hole in a stress field. This technique measures the strain released around the drilled hole; therefore, the released strain can be measured to calculate initial residual stress. Electronic speckle pattern interferometer (ESPI) is a system that is adapted to the hole-drilling method to measure the residual stress. The ESPI technique is used to convert the measured deformation around the hole to a value of in-plane residual stress. The ESPI/hole-drilling technique is faster than the strain gage hole-drilling method, can be used in a wider range of materials and surfaces, and provides much more detailed information about the strains that develop as a result of drilling the hole.

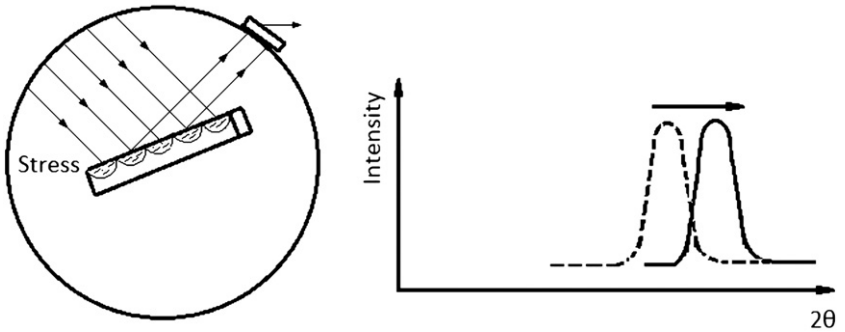

Figure 6 When the sample is tilted, diffraction will take place from other grains but from the same planes (that satisfy Bragg's law). The peak takes place at higher values of 2θ.[80]

Krempazsky *et al.*[82] reported that the strain gage hole-drilling method gives a relative error of approximately 10% and the ESPI/hole-drilling method gives a relative error of approximately 5%. ESPI produces data regarding the displacements in the target surface by mathematically associating the interferograms that are saved as digital before and after the deformation. This method does not need any surface preparation of the materials and is also applicable to rough and inclined surfaces. The main disadvantage of this method is the necessity to isolate the system from vibrations to obtain a fringe pattern with good contrast.[83]

Hole drilling removes a volume of the material. If the volume has residual stress, then drilling will cause distortion around the hole. ESPI directly measures the surface displacement. During the ESPI technique, the image sets before and after the drilling is analyzed by software and transformed into displacement and then correlated with the stress on the surface plane by using elastic properties of the material. For multiple depth measurements, the displacements after each drilling are analyzed together and the depth profile is also completed.[84]

1.14.2.3.2.3 XRD method versus hole-drilling method

Rickert[84] obtained the case depth dependence of the residual stress from ESPI/hole-drilling and XRD methods in shot-peened StE355, X45NiCrMo16, and an aluminum alloy and compared the results. The materials were removed from the surface by electro-polishing each layer to measure the residual stress dependent on the depth with XRD. It was stated that XRD measurements in the aluminum specimen were affected by relatively coarse grains; however, the measurements at and near the surface were acceptable in the regions with a fine-grained structure due to high deformation. Regarding depth, StE355 steel showed a similar trend in both ESPI and XRD data. However, the magnitude of stresses, which was obtained by ESPI measurement, was higher (maximum 35%) than that found with the XRD measurement, and X45NiCrMo16 steel also has similar trend. However, there was less difference between the two methods for StE355 (maximum 15%), and even less for aluminum alloy (maximum 5%).[84] Peyre *et al.*[68] investigated the residual stress generation in laser-peened 7075 aluminum alloy and A356 and Al12Si aluminum alloys. In the study, the residual stress measurement was performed by XRD in 7075 alloy and by hole drilling in A356 and Al12Si alloys. The hole-drilling method was applied on cast A356 and Al12Si alloys because of grain size coarsening up to 300 μm, which is detrimental for XRD measurements.

In laser peening applications, the distribution of the residual stress is investigated. Laser peening appears to achieve a much greater depth of residual stress than shot peening. After laser peening, the residual stress is usually highest at the surface and decreases gradually with distance below the surface. Maawad *et al.*[85] revealed that compressive residual stress in surface layers was much deeper than that caused by shot peening. They investigated the fatigue performance of titanium alloys. The depth profiles of near-surface stresses were deduced by XRD. The effect of laser shock without coating on residual stress was examined in the scanning direction of the laser beam (x direction) and perpendicular to the scanning direction (y direction). The results are showed in **Figure 7**.

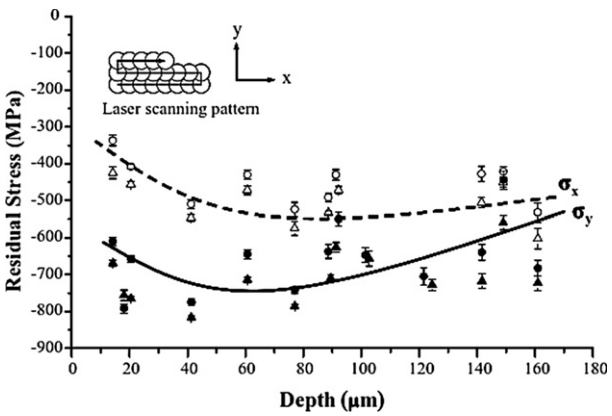

Figure 7 Residual stress distribution in x direction and y direction induced by laser peening without coating.[85]

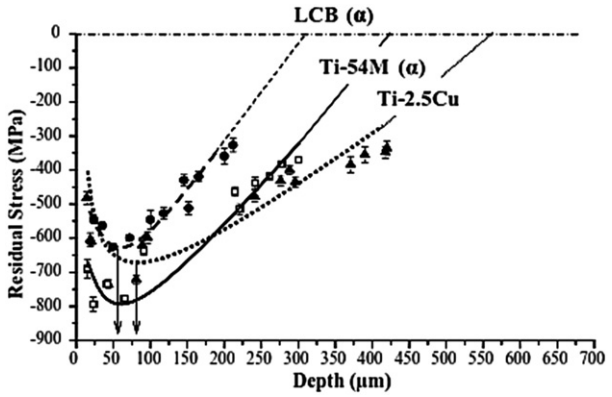

Figure 8 Residual stress distribution in y direction in the alpha phase of Ti–2.5Cu, Ti–54M, and LCB induced by laser peening without coating.[85]

The magnitude of residual stress in y direction after laser peening without coating (LPWC) was larger than in x direction. As shown in **Figure 8**, the residual stresses (σ_y) in the LCB (α), Ti–54M (α), and Ti–2.5Cu alloys were compared. The difference of the residual stress among titanium alloys was explained by the difference in the yield strength.

Saklakoglu *et al.*[32] investigated near-surface modification of 6061-T6 alloy induced by laser peening. The residual stress variation throughout the depth of the workpiece was determined by the ESPI/hole-drilling technique. Residual stress was measured perpendicular to the laser peening direction. Maximum compressive stress measured at a depth of 20 μm was -465 MPa in two laser peening impacts (**Figure 9**).

Montross *et al.*[4] found that compressive stresses could be generated deeper below the surface by applying successive shocks. Saklakoglu *et al.*[32] reported that the depth of compressive residual stress did not change significantly with the increase in laser impact number. The depth of the plastic deformation layer was almost independent of the laser impacts because the plastic deformation near the laser peening-affected region could be saturated. Sathyajith *et al.*[86] investigated the effect of LPWC on 6061-T6 alloy with a low-energy Nd:YAG laser. They measured the surface stress by XRD along the x direction and y direction of the laser-peened area.

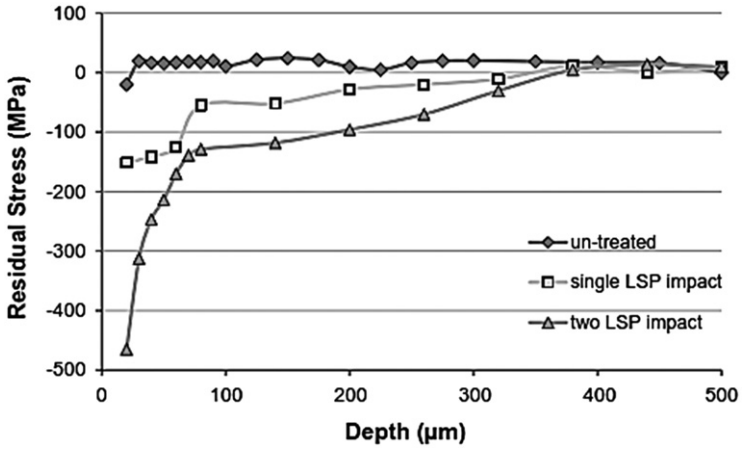

Figure 9 Residual stress-depth profiles of laser peening-treated and untreated material.[32]

A maximum compressive stress of -276.9 MPa was observed in the y direction and -38.8 MPa was found in the x direction. The value of residual stress showed an anisotropic behavior between the x and y directions. Sathyajith *et al.*[86] asserted that lower pulse density introduced lesser anisotropy. Gencalp Irizalp *et al.*[87] studied effects of laser peening on residual stress that were measured by the $\sin^2\psi$ method from the surface after single laser shot and double laser shot. Residual stress measurements were performed at $\varphi = 0^\circ$, 45°, and 90°. Although the residual stress in the direction of 90° is more than 45% with respect to the residual stress in the direction 0° for single-shot laser peening, it is more than 58% for double-shot laser peening. 0° is the main direction and 90° is the perpendicular direction to the laser peening. These results showed that the increasing laser shots increased both compressive stress and anisotropy. Hfaiedh *et al.*[88] discussed that σ_y stresses perpendicular to the laser peening direction are higher than σ_x stresses. They also found that more homogenous stress fields during laser peening can be obtained by increasing the overlapping. Luo *et al.*[89] reported that a single laser peening impact generated the plastic deformation layer approximately 900 μm in the AISI 304 stainless steel. Maximum residual stress of -305 MPa was located at the surface after laser peening. Residual stress distribution was determined by XRD with the $\sin^2\psi$ method.

1.14.2.4 Crystallite Size and Micro-Strain

XRD used for determining the crystallite size and lattice strain in a material is called X-ray line profile analysis (XLPA). XLPA is an effective and nondestructive method for the characterization of the microstructure in crystalline materials. XLPA determines the size and shape of diffracting crystallites. In addition, the method helps to determine the lattice defects.

Intensity of the diffracted beam is measured by a diffractometer detector and results in a diffraction peak. Ideal peak shape is without any widening (i.e., a line). The broadening of the diffraction peak comprises the source of determination of the crystallite size and lattice micro-strain in a material. In general, the width of a peak is measured as half of the intensity's maximum value. Peak broadening can depend on three factors: instrumental effects, crystallite size, and lattice micro-strain.[90,91] Instrumental effects can vary with each diffractometer and occur by imperfect measurement capabilities, such as focused beams and unresolved α_1 and α_2 peaks.[92] Crystallite size and lattice micro-strain contribute to the peak broadening. Lattice micro-strain comprises a combination of mechanical deformation, chemical composition, defects, and SFs.[91] Primarily, the instrumental effect should be quantified to identify the crystallite size and lattice micro-strain on the peak broadening. The XRD pattern of a standard calibration crystal is used to determine the instrumental effect. By subtracting the instrumental broadening effect from the diffraction pattern, the remaining diffraction peak broadening is attributed to small crystallite size and lattice micro-strain.[92]

The peak broadening due to crystallite size is expressed by the Scherrer equation[90,91]:

$$\beta(2\theta) = \frac{K\lambda}{L\cos\theta} \qquad [14]$$

$$\beta = C\varepsilon\frac{\sin\theta}{\cos\theta} \qquad [15]$$

In eqn [14], $\beta(2\theta)$ is the width of the diffraction peak (rad), L is the crystallite size, K is the Scherrer constant, and λ is the wavelength. The aforementioned width of the diffraction peak is expressed in terms of the angle of full width at half maximum of the peaks on the XRD pattern. In eqn [15], the width of the diffraction peak also refers to the lattice micro-strain; ε is the micro-strain and C is a constant.

Plastic deformation modifies lattice structure in target material during laser peening. Woo *et al.*[93] and Mordyuk *et al.*[57] reported that the diffraction broadening resulted in an increase in lattice micro-strain and a decrease in crystallite size of strain-hardened materials. When the target material was exposed to severe deformation, the plastic deformation in the crystal lattice and nonuniform strain led to broadening in the full width at half maximum (FWHM) value of the diffraction peak.

The slope of the Williamson–Hall plot is shown in the micro-strain component ($C\varepsilon$). The Williamson–Hall plot ($\beta\cos\theta$ vs. $\sin\theta$) is obtained from XRD results. As the laser impact increases, the slope of the Williamson–Hall plot

increases.[62,94,95] Due to strain hardening, the width of the diffraction peak increases as a result of the increase in lattice micro-strain and the decrease in crystallite size. The shock wave induced by laser peening produces plastic deformation in the surface layer of the target material. During multiple laser impacts, the superposition of the deformation zone occurs in the laser-irradiated layer. Gencalp Irizalp *et al.*[62] stated that multiple laser impacts are more effective in terms of reducing crystallite size and increasing micro-strain. Sathyajith *et al.*[86] studied the effect of laser peening hardened aluminum alloy in terms of microstructures and mechanical properties. They stated that the laser-peened specimen with lower pulse density exhibited lesser anisotropy broadening in different crystal planes. Saklakoglu *et al.*[32] determined the crystallite size by XRD in laser peening-treated 6061-T6 alloy. A very short interaction time and high plasma pressure during the process could separate the crystalline grains into several coherently diffracting domains. They characterized the crystallite size and dislocation density by using a Williamson–Hall plot obtained from XRD analysis. The crystallite size noticeably decreased by approximately 38% due to the formation of secondary grains in the laser peening-treated region. Also, higher dislocation density resulted from multiple laser peening impacts.

However, transmission electron microscopy (TEM) is another way to determine the crystallite size. However, it is a general observation that grain size or sub-grain size obtained by TEM is much higher than crystallite size determined by XRD analysis. This phenomenon was discussed in light of several studies. Marmy *et al.*[96] investigated the microstructure of ferritic/martensitic steel by TEM. It was found that the dislocation density results obtained from XLPA are relatively high according to TEM. Zhilyaev *et al.*[97] investigated severely plastically deformed Al, Al3%Mg, and Ni. They discovered that grain size obtained from TEM is four-times to six-times higher than the crystallite size determined by XLPA.

The sub-grains and/or dislocation cells in the materials produced by severe plastic deformation (SPD) can be observed by TEM investigations, which can be distinguished by means of low-angle grain boundaries. The crystallite size in severe plastic-deformed metals determined by XRD is equivalent to the mean size domains that coherently scatter X-rays. XRDs recognize the dislocation cells separated from each other by small differences in orientation, typically less than 1°–2°. TEM investigations of severe plastic-deformed metals (by visual observations, in general) provide the size of high-angle grain boundaries. As a consequence, TEM grain size is higher than the dislocation cell size obtained by XLPA. A similar inference for the titanium produced by ECAP was reported by Zhu *et al.*[98] The mean cell size obtained from XLPA is in the range of 30–70 nm. The grain size observed in TEM is higher, at approximately 270 nm. The main mechanism in grain refinement during SPD is dislocation multiplication and rearrangement in the cell to minimize the strain energy. Dislocation cells have low-angle grain boundaries. The orientation difference between the cells is lower (1°–2°), and thus there is no measurable contrast difference between them in TEM micrographs. They can be observed separately by high-resolution TEM investigations.[99] It is more appropriate that primary particle size can be evaluated by TEM and crystallite size can be evaluated by high-resolution TEM.[100] Anand Kumar *et al.*[101] investigated the influence of laser peening on the microstructure of Ti–6Al–4V. They stated that the process generated a large amount of dislocation and the nanocrystallites formed in the material. The formation of nanocrystallites is caused by annihilation and recombination of dislocations to accommodate a high rate of plastic strain generated during SPD. The crystallite size from TEM investigations was obtained in the range of 20–50 nm. However, they found that this result contradicted with XRD observations. In X-ray observations, the diffracted peak has no broadening effect on the laser-peened surface. They asserted that this situation may be because the foils for the TEM investigation were prepared with a thickness of 5 μm and the penetration depth of XRD was approximately 10 μm. Mordyuk *et al.*[57] also characterized laser shock-peened surface layers of AISI 321 stainless steel. They found that cell size in the surface layer was approximately 500 nm in TEM. They measured the physical broadening of refractions, and the relation between the physical broadening, β, and the diffraction angle, θ, was analyzed to characterize the crystallite size. The crystallite size, which is obtained from FWHM values in the study, is approximately 77 nm. XRD crystallite size is lower than TEM cell size.

1.14.2.5 Laser Peening Advantages and Disadvantages and Applications

Laser peening has many advantages such as easy operation, local treatment, and short processing duration.[11,102–104] However, this process induces deeper compressive residual stress, lower surface roughness, and better controllability compared with conventional methods.[105] It requires very little in terms of area accessibility. Laser peening treatment includes precision operation and fast processing time as well as low process cost.[106] During the process, the laser pulse generates a high-amplitude shock wave that propagates into the material. An opaque overlay and transparent overlay prevent the thermal effect and provide effective shock pressure. As a consequence, the material is cold-worked or plastically deformed at the surface. In the confined ablation mode, laser peening produces surface compressive residual stresses at a depth of ~1 mm (four-times deeper than shot peening). There is no surface melting or other heat effects because of the opaque overlay used in laser peening. The optimization of laser peening parameters is considered to generate significantly compressive residual stresses beneath the metallic material surface.[7] Laser peening rarely requires complete surface processing. This process is fully controllable and repeatable; therefore, the benefits of laser peening depend on the processing parameters as well as the specimen geometry and materials. Laser peening can be used to treat various kinds of metallic materials such as titanium alloys, steels, stainless steels, aluminum alloys, nickel alloys, and carburized and nitride steels, among others.

All of these advantages have a wide field of applications: engine components for the Air Force, fatigue-critical components such as F-16 bulk heads, wing attachments, flight control mechanisms, wheels, breaks and landing gear, welded aging aircraft parts for improved reliability, welded aluminum and titanium components for improved reliability, fasteners and

fastener holes to combat fatigue, fretting fatigue, and SCC. However, laser peening is suitable for Army applications, especially those used in fatigue-prone helicopter parts such as transmission gears and other drive train components. The laser treatment can improve the performance and reliability of rapid cycling firearms, artillery on top of vehicle components, and support systems in tanks and armored vehicles. Other potential applications are stress relief of nuclear propulsion system parts for improved SCC resistance. In addition to these, the reliability of automotive and truck parts such as transmission gears and engine parts and the reliability of medical applications such as orthopedic implants (hip, knee replacement joints, spinal fixation devices) are increased by applying laser peening.[107]

Laser peening has existed as a process for nearly 40 years. The General Electric Infrastructure Aviation (GEA) has worked since the early 1990s. One laser peening application that GEA has developed involves the processing of the leading edge and tips of airfoils to abate fatigue failures and produces significant foreign object damage tolerance. The use of laser peening on an existing component increases serviceable limits without the need for airfoil redesign, thus maintaining the aerodynamic performance of the component. To date, GEA has produced in excess of 100 000 laser peening airfoils for US Air Force (USAF) applications such as stage 1 fan blades in the F101-GE-102- (B-1B Lancer) and F110-GE-100-, and -129 turbofans (F-16 Falcon, F-15 Strike Eagle).[108] Rolls-Royce adopted a laser peening system to ensure the safe lifetime of Trent engine fan blades. It is now used to treat all Trent 500, Trent 800, Trent 1000, and XWB blades. The Rolls-Royce Trent engine design is widely used in commercial aircraft, including the latest designs such as Boeing's 787 Dreamliner as well as the Airbus A350 and A380. Sales of 1200 treated Trent XWB engines alone are worth more than £60 billion. In the early 2000s, two high-capacity laser peening systems and peening cells were built at LSP Technologies Inc.'s facility to handle a variety of aerospace components. In 2003, LSP Technologies Inc. began producing laser peening on Pratt & Whitney's F-119 fourth stage IBR for the Air Force's F-22 Raptor.

Some investigations[109–114] propose that laser peening treatment may induce near-surface microstructures and residual stress states that exhibit higher mechanical or thermal stability than those induced from conventional mechanical surface treatments, such as shot peening or deep rolling (DR) treatments. GEA has performed extensive thermal relaxation tests on the high-pressure compressors in which temperatures can exceed 1000 °F. The results indicate that because laser peening imparts deep compressive stress, thermal relaxation is not an issue of the same magnitude as shot peening. In fact, it has been shown that the laser peening fatigue strength is reduced approximately 15% on titanium alloys when thermally cycled at more than 1000 °F for more than 200 h. This simulates the worst case allowable engine temperatures in the compressor.

Because of these advantages, laser peening becomes more and more popular as an innovative technique in surface treatment technology. The disadvantages of the laser peening method are as follows.

Laser peening equipment requires high capital loss, and a clean room environment is necessary for this process. For multiple laser peening processes, repeated coating with opaque overlay requires avoiding thermal effects. Control of the processing variables can be difficult due to complex laser equipment; therefore, process quality control can be slow. Even when the laser power is precisely controlled, variation in the thickness of the water layer (transparent overlay) can vary due to splashing.

1.14.3 Mechanical and Metallurgical Effects by Laser Peening

1.14.3.1 Metallurgical Modifications During Laser Peening

The laser peening causes plastic deformation of the near-surface material and induces beneficial microstructural changes in the affected layer of the material and thus modifies the microstructure and properties of material that induced the shock wave. Various studies have been conducted to observe the microstructure changes. These observations generally indicate the microstructural defects, especially dislocations and SFs. Microstructural analysis has usually been performed via TEM. High-pressure laser shock waves induce grain refinement mechanism.

The generated shock wave can induce SPD in the laser peening-treated region. The microstructure of laser-peened Al–Mg–Si alloy with laser pulse energy of 2.8 J is presented in **Figure 10** by the TEM image.[114] The TEM micrograph shows the high-density dislocations in heavily tangled arrangements. The dislocation density was determined by the

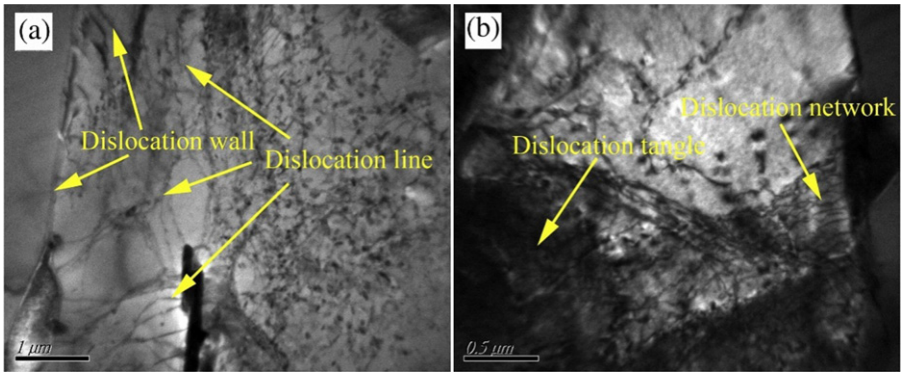

Figure 10 TEM micrographs of 6061-T651 aluminum alloy after laser peening: (a) and (b).[114]

Smith–Guttman linear intercept technique. An example of the procedure for dislocation density measurements is seen in Figure 11.[115] The dislocation density of untreated material is 12×10^{13} m^{-2}; the dislocation density of laser-peened material is in the range of 29×10^{13} m^{-2}. The similar increasing trends in dislocation density in metallic materials exposed to laser peening are also observed in various studies.[4,116,117] In general, the dislocation distribution is not uniform, and heavily tangled dislocation structures attract the attention.[118–120] High-density dislocation tangles (DTs) are randomly rearranged and create new sub-grains. The sub-grains, which are separated with dislocation walls, are also presented in Figure 10.[114]

With the increase of shock wave pressure, high-density dislocations are transformed into dislocation cells by slip, accumulation, and interaction. The schematic illustration in Figure 12 shows how the microstructure is modified as the laser-induced shock wave is propagated into the material.[121] These different microstructures along the depth are related to the shock pressure. Nanocrystalline structure can be developed in the near-surface microstructure due to SPD during laser peening. During SPD, the misorientation of cell boundaries can increase and grain refinement can decrease into the nanometer range. High strain rate deformation can activate more slip systems,[122] and therefore a nanocrystalline structure develops. Also, SFs and deformation twins can induce during SPD. SPD is generated under the influence of high shock wave pressure. Therefore, change in crystal orientation, lattice distortion, dislocation multiplication, dislocation slippage, twins, and other crystal defects can occur as a result of laser peening. These microstructural transformations are characterized by TEM. Figure 13 presents the original TiAl alloy and laser-peened TiAl alloy with a laser pulse of 9 J. However, after laser peening, the microstructure involves heavily tangled dislocations, dislocation walls, and refined grains. TEM examination

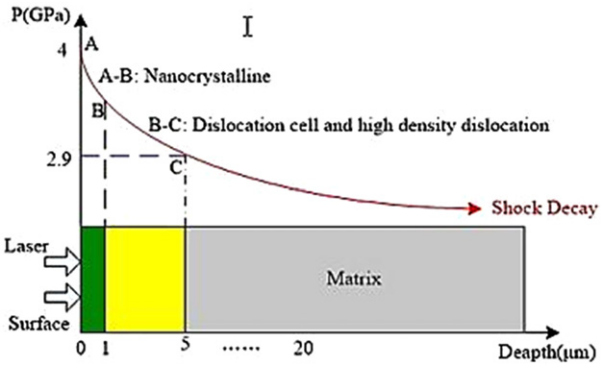

Figure 12 The laser-induced shock decay inside the material. The regions of A–B and B–C along the shock decay represent the typical corresponding microstructures at different depths. The severe plastic deformation is induced by laser shock wave.[121]

also shows that sub-boundaries are produced on the surface of TiAl alloy and the grain size is reduced in the nanometer scale (~120 nm).[123]

TEM images in Figure 14 present NiTi shape memory alloy after laser peening.[124] Figure 14 shows the amorphous and crystalline phases in the laser-peened alloy. The amorphous structure is a result of severe lattice distortion. Lattice structure can be locally disordered by high and short laser pulse pressure. The SFs and nano-twins can form after being processed via severe plastic deformation.

Figure 15 is the TEM image of the laser-peened Al–Mg–Si alloy that irradiated without coating in 2.8 J pulse energy.[115] The presence of SFs in the vicinity of the grain boundary is shown in Figure 15(a). It is well known that the materials with high stacking fault energy (SFE) do not exhibit SFs and twinnings, but SF can form in high SFE metals and alloys with the effects of SPD during laser peening. It can also be seen that the dislocation accumulation contributes to the formation of nano-sized grains (Figure 15(c)). TEM observations have significant importance in laser peening studies.

When no protective opaque overlay is used on the material surface or when multiple laser peening procedures with protective opaque overlay is applied on the material surface, the surface melting and vaporization on the material surface can occur. The surface morphology of laser-peened materials has been investigated by scanning electron microscopy (SEM) observations, atomic force microscopy (AFM) observations, and roughness measurements. The resulting changes in microstructure after laser peening place emphasis on systematic investigations. The surface morphology of laser-peened 6061-T6 aluminum alloy is significantly influenced by peening parameters.[62] The opaque overlay is still present on the treated surface of one laser impact, so melting does not occur on the metallic surface. For multiple laser impacts, the opaque overlay disappeared from the surface and partial melting took place on the metallic surface according to SEM observations (Figure 16).

Without a protective overlay, surface ablation leads to surface melting and therefore the treatment becomes thermo-mechanical. For thermo-mechanical conditions, the combination of ablation and melting of surface layers reveals ablation craters, micro-cracks, and dimples as well as an oxide layer. SEM observation at higher magnification shows these surface defects in Figure 17.[125]

The failure of the structural component can start at the deterioration of surface quality. The surface integrity of

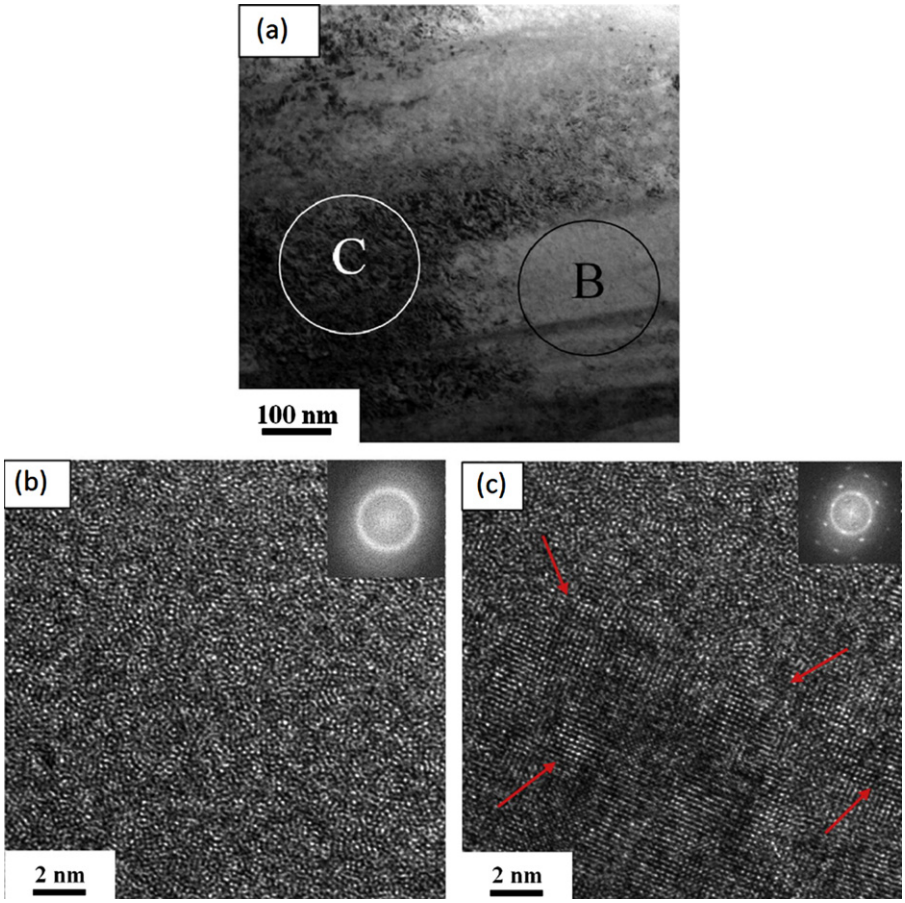

Figure 14 Microstructure after LP: (a) transmission electron microscopy (TEM) images after laser peening showing amorphous and crystalline phase; (b) representative high-resolution TEM images from region B and the corresponding fast Fourier transform (FFT); and (c) representative high-resolution TEM images (the arrows point to the crystalline phase) from region C and the corresponding FFT showing the amorphous halo rings and the bcc[99] direction.[124]

laser-peened specimens should be analyzed in terms of surface topography and roughness.[86] **Figure 18** shows AFM surface topography of specimens that were both un-peened and laser-peened without coating. The surface roughness increases without the protective coating during laser peening.

1.14.3.2 Fatigue Properties

Laser peening is an innovative technique for a novel industrial treatment to improve fatigue properties of metals.[126,127] A shock wave occurs on irradiating the surface with a pulsed laser. When the pressure of the shock wave exceeds the dynamic yield strength of the metal, plastic deformation occurs, thus imparting residual stresses to the surface.[128] It is similar to shot peening, which uses very small metal or ceramic balls to bombard the surface of a metal object. It is a cold work process used to finish metal parts to prevent fatigue and stress corrosion failures and prolong product life for the part. This technique is considered to be a potential substitute for the conventional shot peening process because the residual compressive stresses from laser peening extend deeper below the surface than those from shot peening, usually resulting in a significantly greater benefit in fatigue resistance after laser shocking.[129]

Peyre *et al.*[68] performed a series experiment on 7075 aluminum alloy's fatigue behavior after laser peening and shot peening. As shown in **Figure 19**, the fatigue limits increased to approximately +22% for laser-impacted specimens and only to +10% for shot-peened specimens. Peyre *et al.*[68] explained that laser peening generated general depression of the material with no roughness changes; shot peening strongly affected the surface and created potential initiation sites.

Zhang *et al.*[126] indicated that laser peening decreased the surface roughness. The micro-indents at the surface of the specimen would be generated after laser peening. However, the surface roughness of the micro-indents was relatively lower than that of the untreated specimen. They found laser peening increased fatigue life at least twofold. It is well known that during the fatigue testing, the local stress concentrations will be generated due to the high surface roughness, resulting in the initiation and growth of the fatigue cracks. Hence, the decrement of the surface roughness after laser peening may lead to the increment of the fatigue life of the specimens.

One of the most important effects of laser peening is the generation of residual stresses. The waves produced during laser peening plastically deform the surface and compressive stresses are extended into the subsurface. These dynamic compressive stresses are highest on the surface and decrease with depth into the material.[67,129] Laser peening produces deeper penetration of compressive residual stresses and therefore may produce better fatigue resistance than shot peening.[130,131] Luong and Hill[132] indicated that laser peening produced a layer of compressive residual stress three-times deeper than that of the shot peening for 7050-T7451 Al alloy.

Laser peening has a higher effect on compressive stress than four-pass ECAP (**Figure 11**).[133] As shown in **Figure 20**, although the maximum compressive residual stress is located at the subsurface after shot peening, it is much deeper in laser peening.

Srinivasan *et al.*[128] showed that residual stress after laser peening extents to 1 mm depth of Ti–6Al–4V and large spots with high intensities yielded higher residual stress (**Figure 21**).

The pulse swept direction is one of the important parameters affecting the magnitude of the compressive stress component. Rubio-González *et al.*[134] found that, as seen in **Figure 22**, the compressive stress component perpendicular to the swept direction was much higher than that parallel to that direction (S_2 is the compressive residual stress perpendicular to the pulse swept direction and S_1 is parallel to the pulse swept direction).

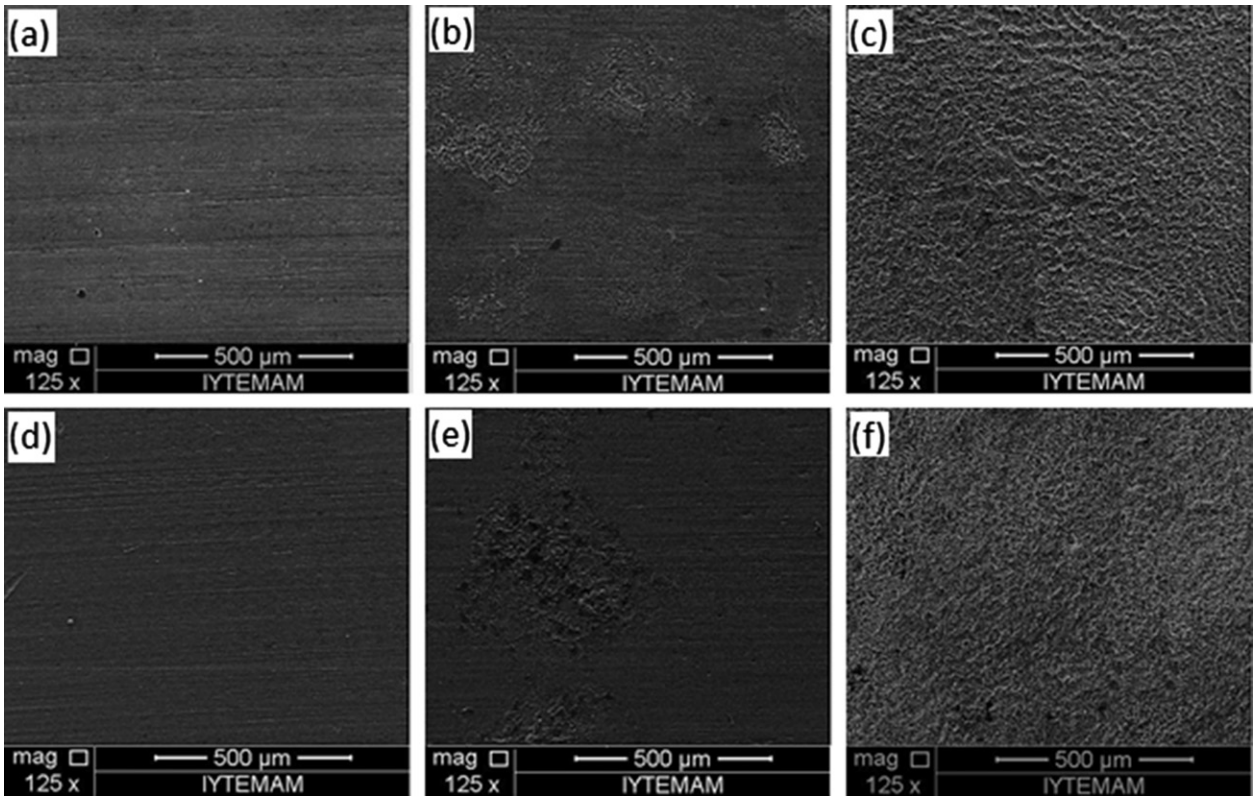

Figure 16 SEM photographs of laser-peened surfaces: (a) 1 shot-1 mm; (b) 2 shot-1 mm; (c) 3 shot-1 mm; (d) 1 shot-2 mm; (e) 2 shot-2 mm; and (f) 3 shot-2 mm.[62]

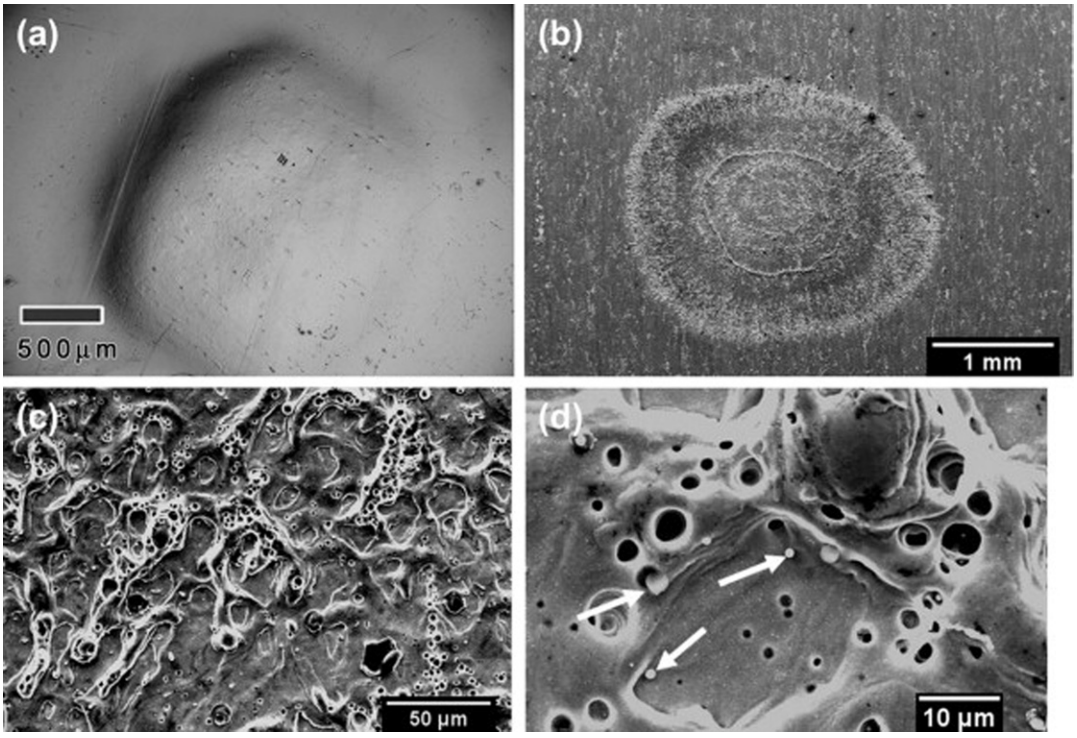

Figure 17 Representative SEM micrograph of the Inconel 718 surface after laser peening: (a) single dimple with overlay and (b), (c), and (d) without protective overlay.[125]

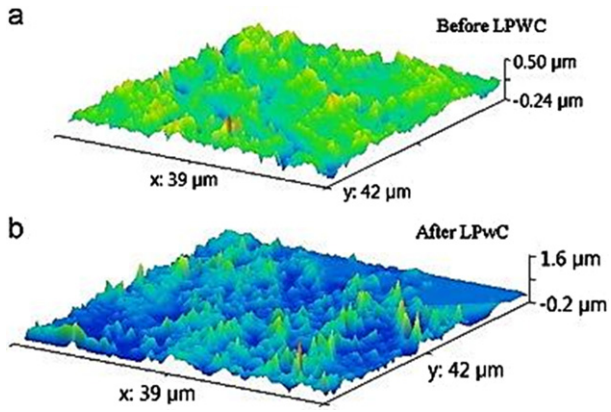

Figure 18 AFM surface topography: (a) unpeened and (b) after laser peening without coating (LPWC).[86]

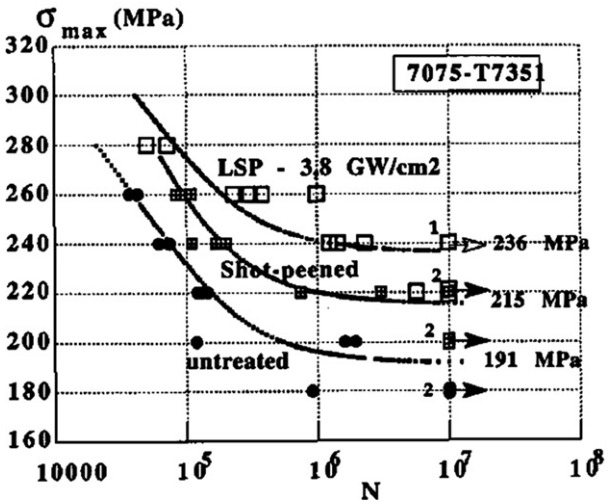

Figure 19 σ_{max}–N curves for unshocked, shot-peened, and laser-shocked 7075 alloy.[68]

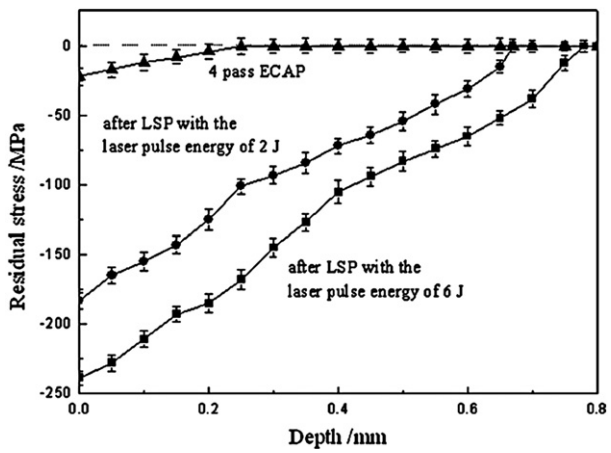

Figure 20 Residual stress profiles of the samples before and after different laser peening pulse.[133]

However, the number of shocks has an important influence on the magnitudes of the residual stresses in the laser-shocked region that has a significant effect on fatigue resistance. When

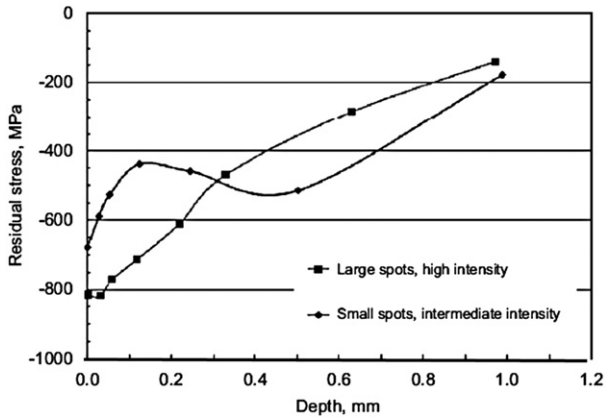

Figure 21 Representative residual stress profiles for two of the laser peening conditions used.[128]

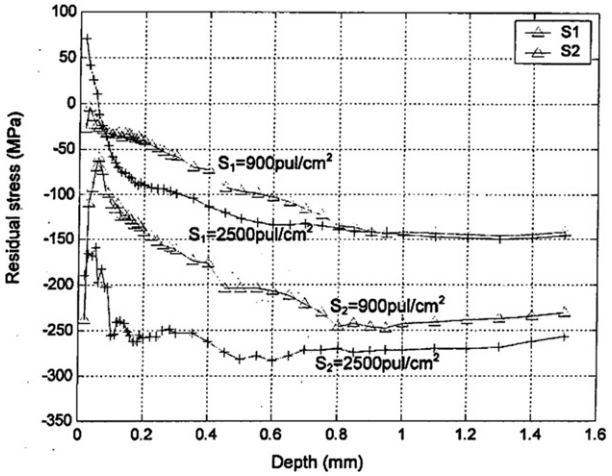

Figure 22 Residual stress distribution induced by laser peening.[134]

the number of laser shocks increased from one to two, the maximum residual stress located at the center increased from 340 to 420 MPa (**Figure 23**). Hence, Zhang *et al.*[135] proposed that the repeated shocks have a beneficial effect on the compressive residual stress levels on the surface. An increment of residual stress developed the microhardness and fatigue life.

Laser peening is considered a promising techniques in terms of its ability to repair or strengthen of the materials after service. Ganesh *et al.*[136] studied a laser peening-treated spring of partly fatigue-damaged in-service spring steel components (~50%) and compared the fatigue life with that of untreated specimens. In that study, laser peening-rejuvenated specimens remained unfailing until $5.2–6.6 \times 10^6$ cycles, whereas the specimen suffered failure after enduring 3×10^6 cycles. Ren *et al.*[61] investigated the effects of laser peening on fatigue crack behavior and residual stresses of the hole on 7050-T7451 aluminum alloy. The results revealed that laser peening resulted in restrained distance between fatigue striations and increased the number of striations. Therefore, the crack expansion distance was reduced, which means that laser peening has a restraint effect on the material fatigue crack initiation and expansion. In another interesting study, the effect of laser peening on the fatigue

behavior of the fastener hole was investigated by Zhang *et al.*[137] As seen in Figure 24, although the initial axial displacement of the unshocked specimen was approximately 0.27 mm and its ultimate fatigue life was 77 720 cycles, it was 0.122 mm and 275 420 cycles for the laser-shocked specimen. The results showed that the final fatigue life was approximately 350% longer than that of untreated case, which revealed that the laser peening treatment appeared to be an effective approach to increase the fatigue life of the fastener hole. Fracture morphologies (Figure 25) obviously showed that laser peening resulted in lower spacing between fatigue striations and higher density of the fracture striations.

1.14.3.3 Tensile Properties and Deformation Mechanism

Shock waves generated during laser peening in the nanosecond or sub-nanosecond range with power density typically greater than 10^9 W cm^{-2} alter the surface microstructure and mechanical properties of materials, such as hardness and fatigue strength.[138,139]

During laser peening, the peak pressure of the shock wave reaches several gigapascal levels.[73,121,123] Under this peak pressure (approximately several GPa and only tens of nanoseconds),[7,52,65,68] plastic deformation occurs in the material just beneath the laser-shocked area. Therefore, SPD is induced in the material by laser shock wave. The plastic deformation layer revealed by laser peening is composed of the SPD layer and the minor plastic deformation (MPD) layer.[118] Lu *et al.*[118] also pointed out the grain refinement on the plastic deformation (SPD) layer.

There are many articles[11,60] that investigated the mechanical properties of metallic materials subjected to laser peening. All of them explain the increment of mechanical properties depending on plastic deformation mechanisms and grain refinement.

Lu *et al.*[11] experimentally investigated laser peening-treated LY2 Al alloy. It was found that laser peening could develop the UTS, the flow stress, and the elongation of the laser peening-treated samples due to grain refinement. TEM investigations revealed that although the grain size was approximately 100–200 nm at the top surface, the size of the original grain was approximately 8–10 μm.

Trdan *et al.*[115] proposed the grain refinement mechanism schematically (Figure 26) in the following sequence:

1. The first phase: the high-energy plasma and shock waves propagate formation of dislocation lines (DL) and dislocation movements within the original grains.
2. The second phase: repeated plastic deformation increases strain and strain rate on the material yielding to the

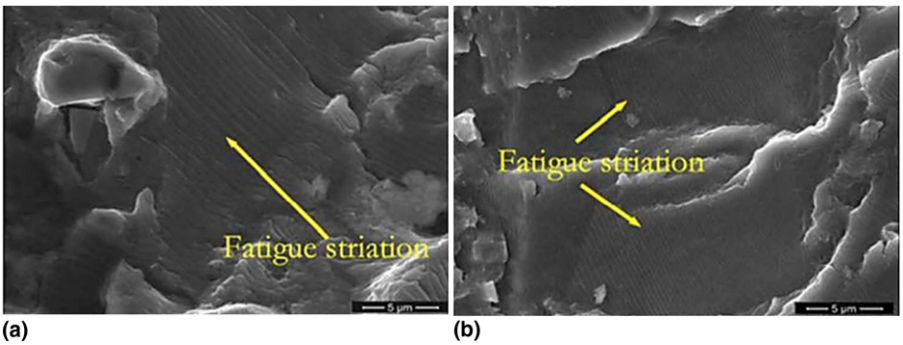

Figure 25 Morphologies of the fatigue crack growth region on LY12CZ specimens: (a) without laser peening and (b) with laser peening.[137]

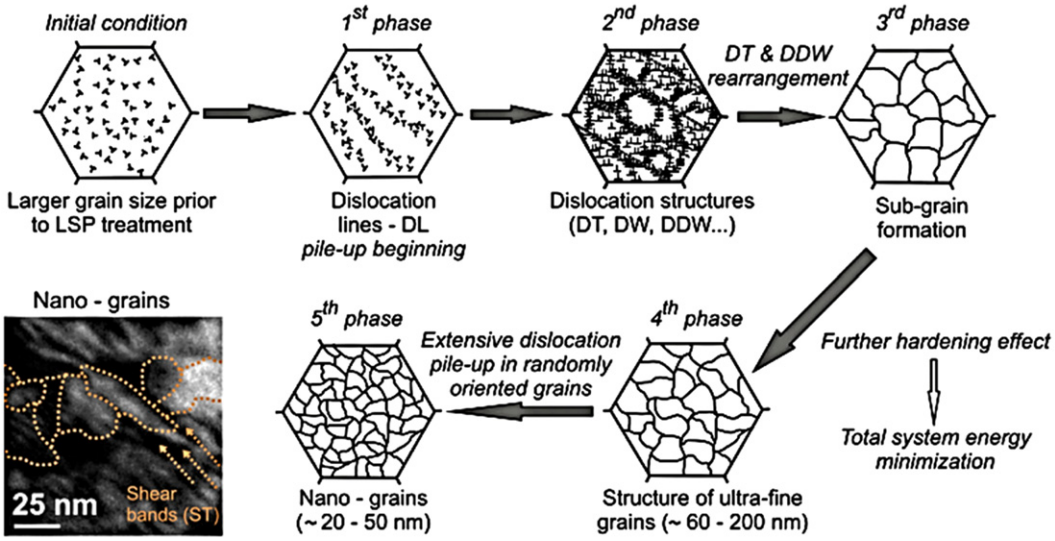

Figure 26 Proposed schematic presentation of the grain refinement mechanism of laser peening without coating of processed 6082-T651 Al alloy.[115]

dislocation movements along the dislocation planes and cross-slips, so high-density dislocations occur. This produces complex/completely random dislocation structures in the form of DT, dense dislocation walls (DDW), and dislocation cells. This type of dislocation has an important blocking effect during slipping at higher strains.

3. The third phase: as plastic deformation increases, the amount of strain increases, resulting in subdivision of original coarse grains into sub-grains with DTs and DWs.
4. The fourth phase: the total energy due to repeated shock waves is minimized by the dislocation annihilation by the formation of multiple shear bands (SB), which further divide sub-grains (formed in the third phase) into ultra-fine grains with high-angle grain boundaries.
5. The fifth phase: extensive amounts of ultra-high strains propagate the sub-grain boundaries, causing nano-grained structures. Dynamic recrystallization (DRX) may have taken place in the final grain refinement process, resulting in the formation of a nano-structured surface layer practically free from dislocations.

In brief, the grain refinement during laser peening involves[140]: formation of high-density dislocation; grain subdivision; and evolution of ultra-fine grain crystalline structure.

Lu *et al.*[118] confirmed three typical deformation-induced microstructure features: DLs, DTs, and DDWs. Laser peening can improve the high-temperature mechanical properties. Ren *et al.*[60] studied laser peening-treated 00Cr12 alloy's mechanical properties at high temperatures. They showed that laser peening successfully enhances the yield strength and tensile strength at high temperatures. It was proposed that the residual compressive stress would counterbalance the tensile stress partially in the stretch process, which was equivalent to reducing the load of the material, so the tensile strength was improved.

Laser peening can enhance the mechanical properties with more impact times.[141] The UTS can make the material withstand being stretched or pulled before necking, when the material cross-section starts to significantly stretch. Lu *et al.*[141] proposed that the UTS of the treated sample with one laser peening impact was close to that of the nonlaser-peened sample, indicating that one laser peening impact could not clearly improve the UTS of AISI 304 stainless steel in the aforementioned strain rate range. The treated sample with two laser peening impacts has the biggest UTS and exhibits excellent UTS resistance. Xiong *et al.*[133] also showed that after four laser peening impacts the ferrite grain size was approximately 150 nm. Another interesting result is that the lattice parameter of α-Fe increased with the laser pulse energy, which indicated that the cementite dissolution increased.

Some researchers expressed the improvement of mechanical properties, such as hardness and yield stress in terms of microstructure, such as dislocation density, SFs, and twins. Chu *et al.*[142] observed the dislocation substructure in the low-carbon steel after laser peening. Liucheng *et al.*[143] explained that as the deviatoric elastic reaches a critical level, dislocations occurred. When the shocks are applied on the surface of the material repeatedly, the shock wave propagates. Therefore, the stress wave caused by shock wave provides an energy for the dislocation movement and an increment. Chen *et al.*[144] indicated that high-density SFs, dislocation loops, and deformation twins occurred on austenitic stainless steel 2Cr13Mn9Ni4 under ultra-fast strain rate by laser peening. Moreover, the density of the SF was greatly increased by the repeated laser shocks and extended to three orientations. It showed that SFs were formed when large amounts of perfect dislocations were dissolved into partial ones. Schneider *et al.*[145] performed some experiments on Cu–2%Al and Cu6%Al to investigate the effect of the laser shock compression. They found that the SF width was 250 nm on average and the spacing was 300 nm. Luo *et al.* denoted[89] that the original grains were subdivided by mechanical twins (MTs) into thin twin–matrix (T–M) ranges from 40 to 400 nm, and the MT width was approximately 50 nm on the laser peening-treated ANSI 304 austenitic stainless steel. Chu *et al.*[142] signified a considerable amount of twin

formations during laser peening. Clauer *et al.*[146] observed the twin formation in Fe–3 wt.%Si alloys at a relatively low shock pressure (0.9 GPa).

A disruption of the long-range stacking sequence can produce two other common types of crystal defects: a SF and a twin region. A change in the stacking sequence over a few atomic spacings produces a SF, whereas a change over many atomic spacings produces a twin region. SFs are commonly produced in face-centered cubic metals (fcc) during treatments such as irradiation, aging after quenching, and deformation.[147] The SFE plays a critical role in the deformation properties of fcc metals and alloys. The SFE influences important phenomena such as the formation of partial dislocations, the ability of a dislocation to cross-slip, and the formation of twin boundaries; all of these have an effect on yield behavior. Fcc metals with SFE such as Al and Cu deform predominantly by slip. However, at low temperatures or high strain rates, deformation twinning can occur even in SFE fcc metals.[148] In fcc metals with low stacking energies such as α-brass, stainless steels, and MP35N (nickel–cobalt–chromium–molybdenum alloy), twinning serves as an important mode of plastic deformation Deformation twinning is one of the major plastic deformation modes in metals and alloys. Under extreme conditions such as shock-wave loading, the material deforms at a very high strain rate and twinning may play an important role.[148] Ye *et al.*[149] affirmed that the location of existing SFs yielded potential for forming new partial dislocation. There was also potential for forming new SFs around the location of the old SFs. Ultimately, old SFs transformed into twins through successively sweeping the partial dislocation on different lattice plane, as seen in **Figure 27**. In **Figure 28**, twin and SF formations on polycrystalline copper treated by laser peening are shown.

The effect of laser peening was characterized depending on the distance from the surface to depth by Lu *et al.*[118] The characteristic of dislocation or grain refinement of the hardening layer from the cross-section is illustrated in **Figure 29**. The change of the dislocation structure can be clearly seen at different layers, that is, it varies from DLs to DTs and DDWs and from sub-grains to refined grains as functions of the distance from the top surface.

Many researchers reported and debated the combination of high strength and high ductility resulting from SPD. Therefore, laser peening can be an alternative method to SPD for thin-sectioned metals. It has been reported that ultra-fine grain and nano-twins in material lead to a combination of high strength and ductility.[150–159] Gencalp Irizalp *et al.*[87] affirmed that laser peening could improve the uniform elongation as much as tensile strength. It is well known that when conventional deformation methods such as rolling, extrusion, or drawing are applied, strength of materials can be significantly increased and ductility decreases. According to Gencalp Irizalp *et al.*[81] this high-strength and high-ductility paradox is related to ultra-fine grain formation on top of the microstructure in the metal after laser peening. Wang *et al.*[155] reviewed and concluded the high-strength and high-ductility mechanism in nanocrystalline materials. According to this argument, partial dislocation emission from grain boundaries in metals with medium-to-high stacking fault energies plays a major role in the deformation of fcc metals with grain sizes of a few tens of nanometers. This consequently produces deformation twins in nanocrystalline fcc metals. Such twins are effective in increasing the dislocation storage capacity, which may be used to improve the ductility. These fcc metals usually do not twin when deformed at room temperature at low strain rates in their coarse-grained states because conventional dislocation sources, such as Frank–Read sources, operate in the interiors of the large grains. It is concluded that nanotwinned metals exhibit an unusual combination of ultra-high yield strength and high ductility.[160,161] Compared with twin boundary (TB), SF, as one other kind of defect in nanocrystal, seems to draw much lower attention to mechanical properties. According to the strengthening mechanism of TB, it still remains unknown whether the SF would strengthen the fcc metals in a similar way. Song showed when the SF spacing is rather fine, the SF acts as strong barrier like TB.[162]

In brief, it is obvious that laser peening results in grain refinement in nanocrystalline sizes and deformation-induced microstructure features such as DL, DT, and DDWs that increase strength. Moreover, laser peening produces unusual deformation mechanism such as TB and SF, and this creates an unusual combination of ultra-high yield strength and high ductility.

1.14.3.4 Corrosion Properties

Many studies have examined the effects of laser peening on the corrosion resistance of austenitic stainless steel.[10,15,32,39,163] Sano *et al.*[163] investigated laser peening without protective coating on SUS304 (type 304) and SUS316L (type 316L) austenitic stainless steels for SCC susceptibility. Typical results

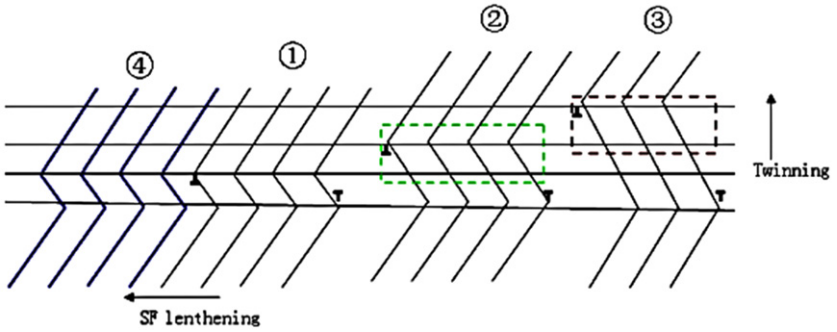

Figure 27 Schematic diagram of partial dislocations sweeping to form twins and lengthen stacking faults (SF).[149]

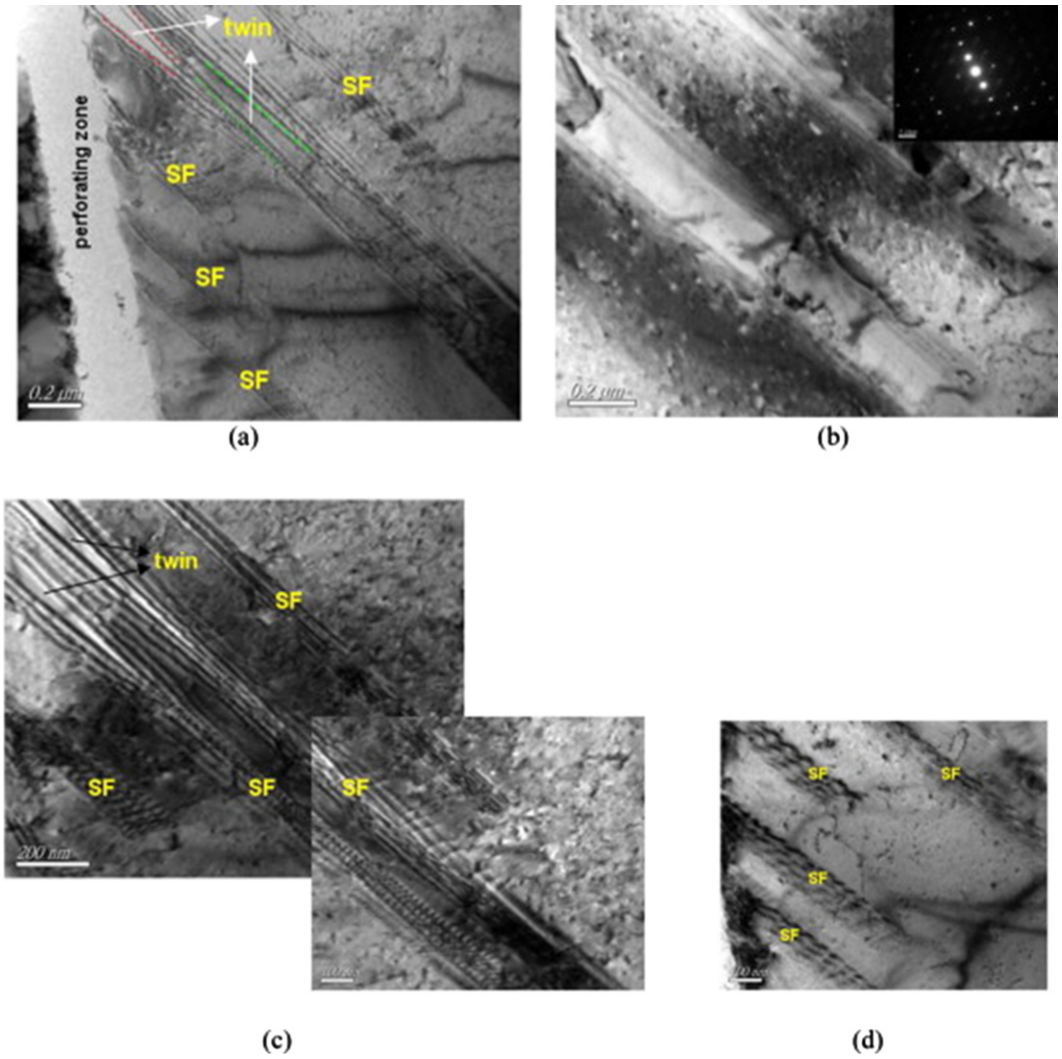

Figure 28 TEM images of the twins and stacking faults obtained through two instances of femtosecond laser shock.[149]

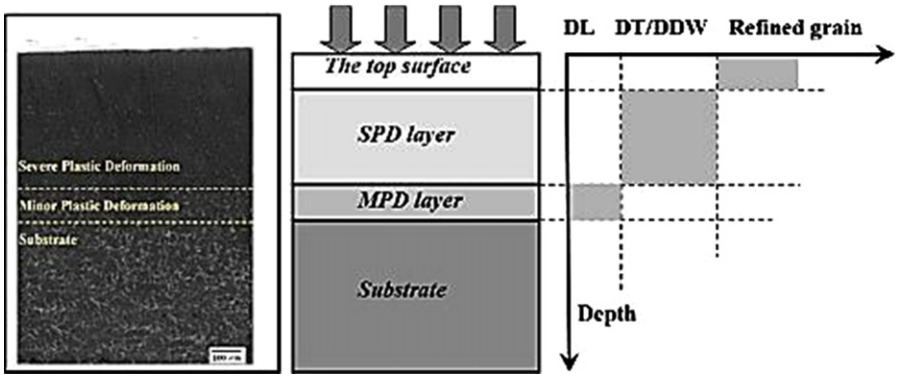

Figure 29 Schematic illustrations of microstructure characteristics along the depth direction in the hardening layer subjected to three laser peening impacts.[118]

are given in Figure 30. Laser peening without protective coating with a Q-switched and frequency-doubled Nd:YAG laser was conducted for SUS304 (type 304) and SUS316L (type 316L) austenitic stainless steels. Regarding the effects on SCC susceptibility, although SCC occurred in all the samples without laser peening without protective coating, there were no cracks in the shocked samples. This means that laser peening without protective coating completely prevented the

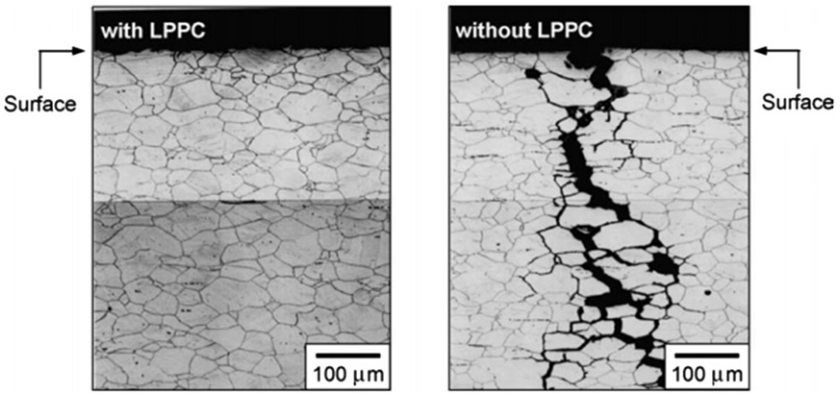

Figure 30 Stress corrosion cracking test results of SUS304.[163]

SCC initiation and propagation of small pre-cracks in high-temperature 42% $MgCl_2$ solution.

Peyre *et al.*[164] presented and evaluated the SCC behavior of 316L steel and uniform corrosion behavior of G41400 steels after laser peening. Their results revealed a 30–120% reduction of G41400 corrosion current in acid medium. They suggested a mechanochemical effect possibly due to a modification of the hydrogen–metal interaction after laser peening. It is obvious that mechanical surface states such as compressive stresses can lead to an inhibiting effect on dissolution rates. Kalainathan *et al.*[165] exhibited the effects of LPWC on the electrochemical corrosion behavior. Laser peening on 316L steel demonstrated that the laser-peened specimen exhibited a nominal increase of current density and, hence, an increase in corrosion rate. However, the corrosion potential (Ecorr) showed that the LPWC specimen had less susceptibility to corrosion and reduced pit growth.

It was reported[10,166,167] that the improvement of the SCC resistance of AISI 304 stainless steel was caused by compressive residual stress and grain refinement during the laser peening process. Although Lu *et al.*[10] found a number of eroding pits with a size of approximately 2 –5 μm for the as-machined specimen, it was reduced up to 0.2–1 μm for the laser-peened specimens. Amar *et al.* revealed[168] that no intergranular corrosion developed in the matrix, pitting potential increased, and the matrix remained passive after laser peening.

Saklakoglu *et al.*[32] observed that laser peening led to a reduction in number of pits in 6061-T6 aluminum alloy that was immersed in 1 g NaOH–1 ml HCl–50 ml water, as seen in Figure 31. It is believed that a work-hardened region resulting from laser peening became more noble and more resistant to pit initiation and that a mechanical state affects surface reactivity.[12,50,51] It is presumed that the pits are composed of dissolved inclusions.[32] Peyre *et al.*[125] proposed that laser peening reduced the potential gap between inclusions and the surrounding matrix; therefore, local galvanic couplings reduced and so did pit initiation. A passive film of 316L stainless steel after laser peening became thinner but more compact and more resistant because of high recoil pressure.[125] Consequently, work-hardening resulting from both SPD and high residual stress level can reduce the pit initiation. Davis *et al.*[169] proposed that pits preferentially occur on some orientations. They found that the (111) crystal face showed the highest number of pit formation, whereas (110) had the least number of pits. Vukelić *et al.*[58] performed a series of experimental and numerical studies using an aluminum bicrystal under laser peening. They revealed that crystallographic orientation was changed as a consequence of lattice rotation. Buggayev *et al.*[170,171] studied laser peening-treated Inconel 600 alloy and 316L stainless steel in a water confinement layer. They found that a column like microstructure was tilted in the direction of laser spot scanning. Chen *et al.*[172] performed lattice rotation of laser shock-induced Al and Cu materials and performed measurements using the electron backscatter diffraction (EBSD) method; they found that maximum in-plane rotation was approximately 3° in Al and approximately 2° in Cu, and the measured rotation distributions were compared with numerical simulations. Toppo *et al.* also point out that the crystallite refinement resulting from laser peening develops the passive film stability by making it more adherent. The high density of grain boundaries, sub-grain boundaries, and twin boundaries can restrict the movement of metal ions from the metal surface to the solution; therefore, passive film is stronger and diminishes pit formation.[172]

As a result, it is believed that laser peening alters the pitting potential as follows: formation of a more passive aluminum surface because of plastic work and compressive residual stress state; reduction of the potential difference between inclusions and the surrounding aluminum; and changing of crystallographic orientation due to nonuniform strain that can occur from different local deviations of the lattice planes.

1.14.3.5 Welded Joints Subjected to Laser Peening

The mechanical properties of the welded joints can significantly decrease compared with the base metal because of the weld and fusion zone structure. The weld zone and fusion zone become the weakest areas.[173] Safety and reliability requirements of producing welded components have attracted increasing attention. Residual stresses and microstructure are very important factors because they seriously affect the strength and service life of welded components.[174] Tensile residual stresses in welded zone reduce the tensile strength and fatigue life.[175] Dendritic microstructure and tensile residual stress that can develop after welding treatment significantly affect the mechanical properties. These residual stresses can seriously influence the service performance of welded materials by facilitating the fatigue crack growth process, SCC, and the lowering of fatigue life by affecting crack nucleation.[50]

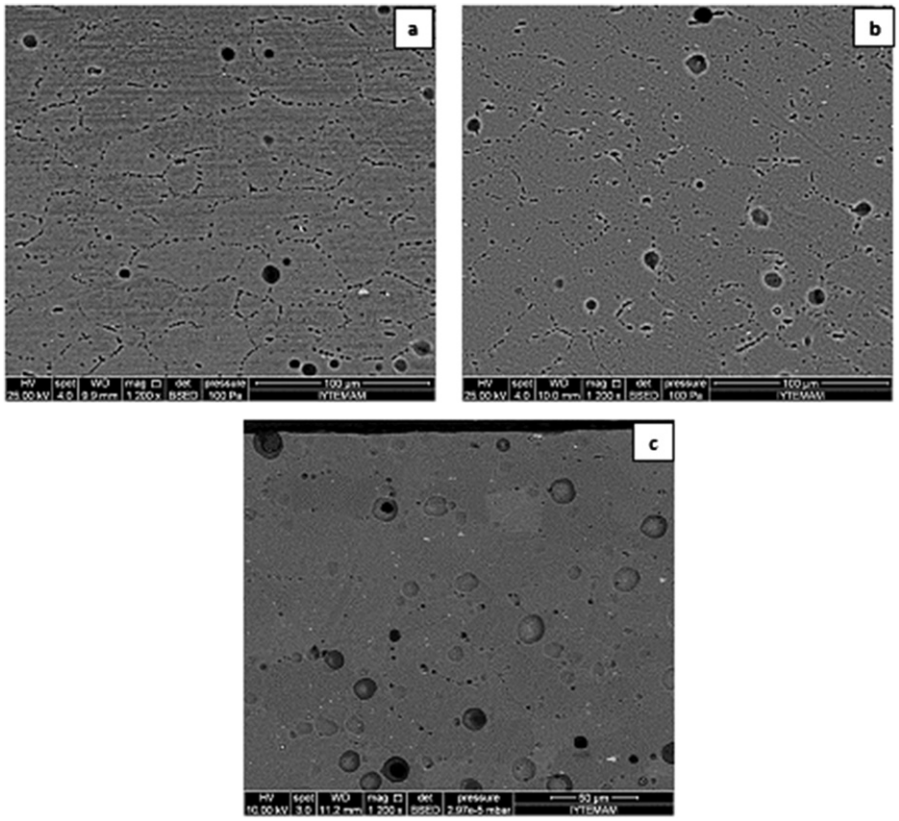

Figure 31 The pits at two different magnifications of 6061-T6 alloy: (a) single laser peening impact; (b) two laser peening impacts; and (c) untreated.[32]

Postweld heat treatment can improve the weld strength, but this is not always an option in welded joints. Welding technology has potential significant applications in various fields, including the aerospace and automotive industries.[176]

Laser peening is beneficial to rapid development of material properties due to its fast and efficient surface application to harden selected areas in complex structures.[174] Accordingly, laser peening can be successfully used for core parts and weld seams. Postweld innovative treatments, such as shot peening, laser peening, or ultrasonic peening, should be performed to improve the structure of the weld joint and to reduce the stress concentration. There are limited availability studies in the literature. Shot peening, laser peening, or LPWC and ultrasonic peening techniques have been applied to welded joints of various metals and alloys.[38,175,177,178]

Laser peening applied to welded joints that are commonly conducted with a friction stir-welding technique has been applied most commonly to aluminum alloys. Friction stir welding is a promising solid-state process that is used to weld the high-strength aerospace aluminum alloys. The use of friction stir welding is becoming more popular due to the advantages according to other conventional fusion welding techniques. However, laser peening has also been utilized in laser-welded and gas metal arc-welded joints. Friction stir welding was invented by the Welding Institute in England in 1991.[179] Friction stir welding has emerged as a promising solid-state process, and this technique has the potential for welding of hardened aluminum alloys.[180] Friction stir welding utilizes a nonconsumable cylindrical pin rotating at high speeds and plunges into butting edges of the workpiece. The friction heating occurs and the metals transform into a plastic state along the joining line, and then the workpiece is welded under pressure.[173,180] The problems resulting from melting temperatures associated with fusion welding are eliminated. However, the residual stresses developed in the weld zone can significantly degrade the material performance of the welds.[180] Five distinct microstructural zones produced during the friction stir welding process can create potential discontinuities in strength and fatigue volume properties.[177]

Laser welding has some advantages, such as smaller deformation of the workpiece and heat-affected zone, narrower fusion zone, lower weld distortion, and higher degree of automation. However, the porosity and crack initiation can be generated in the weld zone requiring laser welding. The strength of the welding joint can decrease due to the volatilization of the elements during melting.[181] The materials may be deformed due to thermal effects during welding processes. Laser peening is a useful way to improve its mechanical properties. Laser peening is a technique with the capability of inducing the residual compressive stresses.[50] Moreover, laser peening becomes attractive for welded joint applications because the process has local surface treatment capabilities.

For instance, LPWC has been applied to friction stir-welded A6061-T6 aluminum alloy. Effects of laser peening on the fatigue performance and mechanical properties have been investigated. As a result, the fatigue strength of friction stir welding

plus laser peening increased. The LPWC induced compressive residual stresses on the friction stir-welded joints.[178] The laser-welded ANSI 304 stainless steel joint treated by laser peening was investigated and the results demonstrated that laser peening could enhance tensile strength and yield strength.[38] The effects of laser and shot peening on tribological properties of friction stir-welded 2195 aluminum alloy joints were investigated, and long-term friction was found to be lowest for samples with no peening treatment.[181] Fatigue crack growth in friction stir-welded 7075-T7351 aluminum alloy joints subjected to laser and shot peening was investigated. The fatigue striation spacings for the laser-peened specimens were assessed and found to be small compared with unpeened and shot-peened samples. Therefore, slower fatigue crack growth rate emerged from laser peening.[41] The laser peening effect on SCC of the friction stir welding joints was investigated on the basis of slow strain rate and tensile tests were performed in an aggressive medium. Laser peening affecting the overall mechanical behavior of the friction stir welding joint induced a surface hardening affect. Also, laser peening positively influenced the overall friction stir welding joint plastic deformation.[182]

1.14.4 Relaxation Behavior of Laser-Peened Materials

Various mechanical surface treatment technologies (shot peening, laser peening, DR, low plasticity burnishing) have been developed for the purpose of improving fatigue performance of metallic materials.[111] These techniques have the beneficial effect of delaying the propensity for fatigue initiation or growth by inducing compressive stresses on the surface and near-surface regions.[183] Laser peening is a surface treatment technique whereby a solid-state laser beam is pulsed on a metallic surface, producing a planar shock wave that travels through the material.[184] It propagates into the material, causing plastic deformation and residual stress.[183]

Numerous studies[112,183,185–187] of steels, titanium, and nickel-based superalloys have shown that residual stresses were generated via surface treatment relaxation when subjected to elevated temperature exposure or mechanical loading. In service, metals experience severe mechanical and thermal loading conditions, particularly high-cycle and low-cycle fatigue cycles resulting from high-frequency vibrations or variable loads. This mechanical or thermal loading can provoke relaxation of residual stresses. The relaxation of residual stress implies the reduction of beneficial effects produced by various techniques decreasing fatigue life.[63] The residual stress relaxation can be categorized as mechanical relaxation of residual stress or thermal relaxation of residual stress. In brief, mechanical relaxation of residual stress occurs when the superposition of applied stress and residual stress reach the yield strength of material. Thermal relaxation of residual stress is a thermal recovery process in which elevated temperature accelerates the rapid annihilation of crystalline defects.[188] Research into relaxation of residual stresses subject to mechanical loading has followed a much different path than thermal relaxation. For thermal relaxation, temperature and exposure time are the primary parameters, whereas for mechanical loading the important factors are temperature, maximum and minimum applied stress, loading frequency, hold time, waveform shape, and number of applied cycles.[189] Residual stress relaxation consists of three different stages, as explained by Holzapfel *et al.*[190] relaxation due to specimen heating; relaxation during the first cycle; and relaxation with the logarithm of cycle count. According to Cao *et al.*[191] thermomechanical relaxation takes place in a two-stage process: the first stage is shakedown of the initial residual stresses described by a monotonic stress–strain law, and the second stage, which is slower, is described by a cyclic softening related to the logarithm of the number of the applied cycles.

1.14.4.1 Mechanical Relaxation of Residual Stress

Fatigue is a failure mechanism arising from cyclic loading. Crack initiation and propagation both involve the concept of cyclic accumulated damage. Monotonic stress–strain relationship controls simple deformation and ultimately fracture, whereas the cyclic relationship controls the finite life fatigue process.[192]

The compressive residual stresses can be beneficial for fatigue durability provided that they are stable. Kodama[193,194] first reported the residual stress relaxation behavior in shot-peened mild steel under uniaxial cyclic loading and suggested a logarithm linear relationship between residual stress and number of cycles. According to the results, residual stress decreased with an increasing applied number of fatigue cycles, and the major residual stress relaxation occurred during the first load cycle.

It is well known that the residual stress relaxation via mechanical processes is a complex phenomenon that may depend on interaction of several factors such as amplitude of the applied cyclic stress, loading mode, number of cycles, actual material and its microstructure, strength properties, and the surface finishing process.[187,195] The main residual stress relaxation normally takes place in the first cycles, followed by further gradual relaxation during the lifetime. Quasi-static loading occurs in the first cycle, resulting in relaxation when the superposition of the applied and residual stresses exceeds the monotonic yield strength of the material in tension and compression. Relaxation during successive cycles is related to the cyclic yield strength. The latter is the most difficult and has attracted the attention of several researchers by using experimental and numerical approaches.[187] Monotonic and cyclic relaxations are the reasons why residual stresses are not stable at high cyclic loads.

Cyclic yield strength is yield strength measured during cyclic loading. In many cases, cyclic yield strength is determined at the same 0.2% offset as static or monotonic tensile strength.[196] This was first observed by Bauschinger. The experiments indicated the yield strength in tension or compression is reduced after applying a load of the opposite sign that caused inelastic deformation. In previous studies, Quadfasel *et al.*[197] extended the phenomenological description of stress relaxation in the Hart–Solomon relationship.[198] Deviations from the Hart–Solomon relationship were also reported.[197]

In the literature, studies of mechanical relaxation of mechanical treated metals focus on shot peening.[185,193,195,199–204] A few studies cover the effect of laser peening.[205,206]

1.14.4.2 Thermal Relaxation of Residual Stress

Some studies focused on thermal relaxation mechanism, which is related to the thermal stability of residual stress that is mainly contributed by the applied thermal loads. Nickel alloys are preferred for high temperatures, as in turbine engine components, due to their outstanding mechanical property, corrosion resistance, and welding characteristics. Thermal relaxation induced by high engine temperatures is one of the primary mechanisms causing significant loss of the protective compressive layer of residual stress on the surface of high-temperature components such as Ni alloys used in turbine engine components. Therefore, the stability of high-temperature alloys during mechanical or thermal cycles is of great importance for the design of components.[183,185] Ti–6Al–4V alloy is also a material commonly used in components of gas turbine engines, and its maximum usage temperature is approximately 275 °C. In a recent study,[207] shot-peened Ti–6Al–4V showed longer fretting fatigue life than unpeened Ti–6Al–4V at room temperature; however, this increase in fatigue life was significantly reduced at elevated temperature, and the difference in fatigue life between shot-peened and unpeened Ti–6Al–4V became negligible at 260 °C.

The beneficial effect of surface treatment arises from the compressive residual stress at and near the surface region; understanding the thermomechanical stability of the residual stress in the service stage is critically important in the prediction of the life of component alloys.[206] Many investigations[4,184,208] show that laser peening results in a higher fatigue life compared with shot peening due to much deeper effective penetration in the material, compressive stress fields much further from the surface, and lower surface roughness. The benefit of high-temperature fatigue resistance from the mechanical surface treatments is thought to be primarily associated with the formation of a near-surface work-hardened layer with a nano-scale microstructure that is stable during thermal exposure or fatigue cycling at high temperatures.[3,111] Some investigations[109–113] propose that laser peening treatment may exhibit highly work-hardened nanoscale surface microstructures and eventually make material have higher thermal stability than those induced from conventional mechanical surface treatments, such as shot peening or DR treatments. Therefore, material surface after laser peening would be expected to be suitable under the high-temperature fatigue conditions.

The stability of residual stress, microstructures, and fatigue resistance in the temperature range of 25–600 °C of laser peening and untreated ASTM: 410L 00Cr12 steel were investigated by Ren *et al.*[113] The ASTM: 410L 00Cr12 steel is one kind of heat-resistant steel with good thermostable susceptibility and organization stability and is usually utilized at elevated temperatures. They found that compressive residual stresses up to 1 mm were approximately 400 MPa after laser peening; laser peening enhanced fatigue life approximately 53.8% in the low-cycle regime at 10^5 cycles at elevated temperatures up to 600 °C; laser peening resulted in more stable near-surface microstructures, deformation-induced martensite, and higher dislocation densities; and the pinning effect, which means surface grain refinement induced by laser peening, is the main reason for prolonging the fatigue life at high temperatures.

Ren *et al.*[114] investigated the influences of laser peening on residual stress relaxation and metallographic structure evolution of 6061-T651 aluminum alloy at elevated temperatures (up to 500 °C). They found that the affected layer of 6061-T651 aluminum alloy by laser peening has a higher magnitude of residual compressive stress between 25 and 300 °C, and laser peening still has a beneficial effect on residual stress at temperatures above 300 °C. The grain size began to enlarge, and the number of precipitated phases tended to grow at the temperature of 400 °C. The primitive grain was phagocytized by the new grain, and the DRX had been completed at 500 °C. Prevey *et al.*[109,209] compared the thermal stress relaxation of the compressive layer produced by shot peening, gravity peening, and laser peening in Ti6Al4V and IN718. They found that both the magnitude and rate of relaxation depended primarily on the degree of cold working (plastic deformation) developed during processing. Initial thermal relaxation of highly cold-worked surfaces can be extremely rapid in both alloys and can result in 50% loss in less than 10 min, even at moderate engine temperatures. However, for laser-peened coupons, only a small relaxation near the surface occurred in Ti6Al4V, and no thermal stress relaxation was found in IN718 at even the highest temperatures (670 °C), which was due to the fact that little cold working of the surface was produced by laser peening.

Nalla *et al.*[3] compared thermal relaxation of residual stresses in Ti–6Al–4V induced by DR and laser peening at 25, 250, and 450 °C. As shown (**Figure 32**), although laser peening resulted in an improvement in fatigue strength, DR was found to be more effective for the process parameters investigated. In this study, for the process parameters used, DR was found to induce the larger near-surface compressive residual stresses and degree of work hardening as compared with laser peening. Moreover, DR was observed to remarkably reduce the surface roughness. In a previous work,[111] similar results were reported. It was found that the residual stress state and work hardening induced by laser peening were less stable under isothermal cyclic loading at elevated temperatures as compared to the deep-rolled condition. However, DR is restricted to certain component geometries. Finally, it can be said that this beneficial effect of both DR and laser peening processes persists in

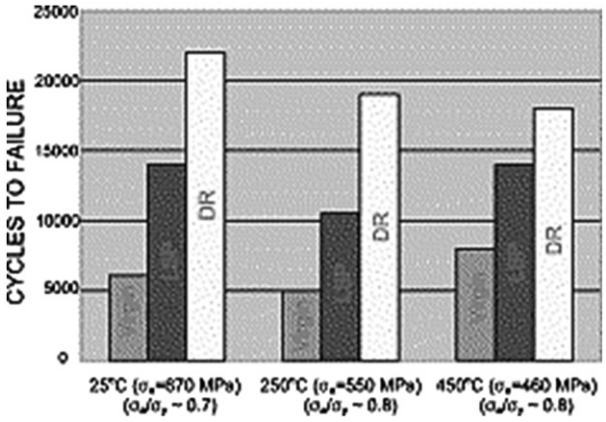

Figure 32 Enhancement in fatigue lifetimes following deep rolling (DR) and laser peening for test temperatures of 25, 250, and 450 °C and stress amplitudes of 670, 550, and 460 MPa, respectively.[3]

Ti6Al4V at temperatures as high as 43% of the melting temperature.

Researchers have found that temperature, exposure time, and initial cold hardening are the primary influencing factors for residual stress relaxation. Aghdam *et al.*[210] studied the time-independent thermomechanical residual stress relaxation around cold-expanded fastener holes in aluminum alloy 7075-T6 and suggested that higher temperatures caused more relaxation of residual stress. Ren *et al.*[63] studied the thermal relaxation of residual stresses in laser-peened iron GH2036 alloy exposed to different temperatures. As shown in **Figure 33**, the applied temperature and exposure time of annealing had significant effects on the magnitude of thermal relaxation. As the temperature increased, the thermal relaxation magnitude increased. The surface residual stress released much more easily than the subsurface. Moreover, the highest relaxation occurred at the depth of maximum compressive residual stress. They indicated that the primary mechanism of thermal relaxation was the mechanism involving rearrangement and annihilation of dislocation.

The relaxation is related to dislocation movement and plastic strain accumulation.[187] Ren *et al.*[63] proposed a mechanism of stress thermal relaxation that involves the evolution of dislocation density and morphology. As shown in **Figure 34(a)**, laser peening propagates formation of high-density dislocations in the specimen, and the dislocations have the majority of storage energy obtained from laser peening. It is known as work hardening. However, this part of the energy is a thermodynamic instability state, and the metal has a spontaneous tendency to return to the steady state of lowest free enthalpy. As temperature increases, the following processes occur, causing thermal relaxation:

1. The self-diffusion activation energy decreases and dislocations are activated and start to slip and climb. During this time, unlike dislocations meet and counterbalance, so that the dislocation density in the sample decreases. However, the pinning effect of precipitated phases delays the movement of dislocations and causes the formation of dislocation walls and dislocation cells (**Figure 34(b)**).
2. Unlike dislocations, the dislocation cells continue to counterbalance, which causes diminishing of the dislocation density (**Figure 34(c)**).
3. Edge dislocations gather at the cell walls, the cell walls become thinner, and sub-grain boundaries form gradually (**Figure 34(d)**).
4. Dislocations on the sub-grain boundaries transfer to the adjacent boundaries through climbing and slipping. Then, the primary grain boundaries disappear and a large-angle sub-grain is formed (**Figure 34(e)** and **34(f)**). The entire process consumes the majority of dislocation density, which means residual stresses release quickly during this period. Moreover, metastable crystalline defects induced by the peening process will reorganize and creep-controlled dislocation will rearrange, resulting in material softening at elevated temperatures.[206] After that, sub-grains rotate and move inside the crystals, releasing the storage energy in the metal. Residual stresses continue to release, but slowly.

Another interesting point is that the residual stress relaxation occurs not only during material softening at elevated temperatures but also during nonuniform distribution of compressive residual stress. As a result, the initial value of residual stress will accelerate the visco-plastic flow, leading to the relaxation of residual stress.[63]

The residual stress and work hardening induced by laser peening are more stable at elevated temperatures, compared with the untreated state. The effect of the work-hardened layer is to reduce the plastic strain amplitude, which acts to lessen the driving force for fatigue damage.[114] Ren *et al.*[113] studied ASTM: 410L 00Cr12 to reveal the effects of laser peening on microstructures and fatigue resistance in the temperature range of 25–600 °C. The results showed significant fatigue strength at the elevated temperatures. They pointed out that the formation of high-density dislocation and the pinning effect at the high temperatures results in stronger surface, lower residual stress relaxation, and a more stable dislocation arrangement. The residual stresses in laser-peened Inconel 718 Ni-based superalloy and their thermal relaxation behavior were investigated by Zhou *et al.*[206] They observed that stress

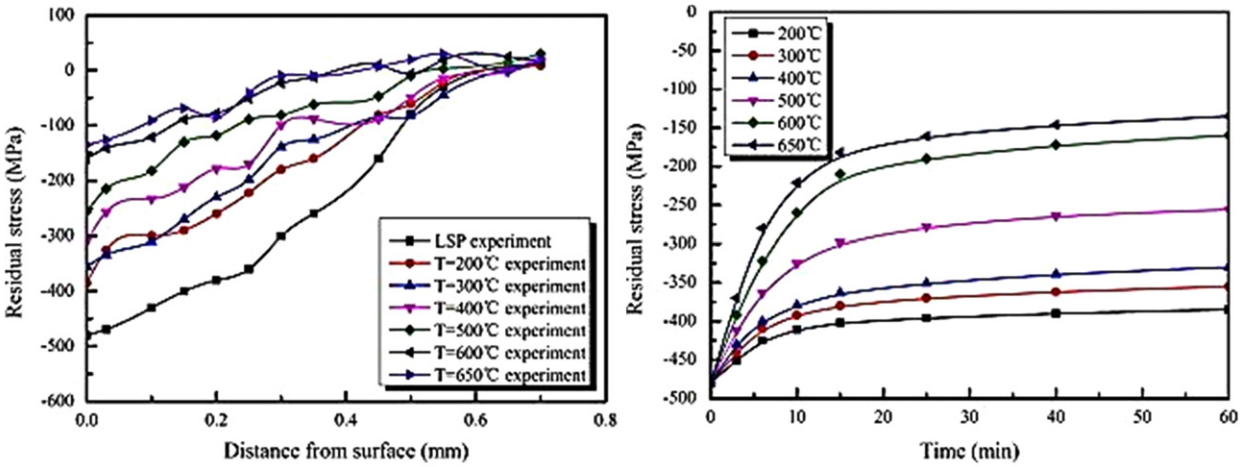

Figure 33 The residual stress distribution along with the depth at elevated temperatures and stress relaxation at different exposure times with annealing temperatures.[63]

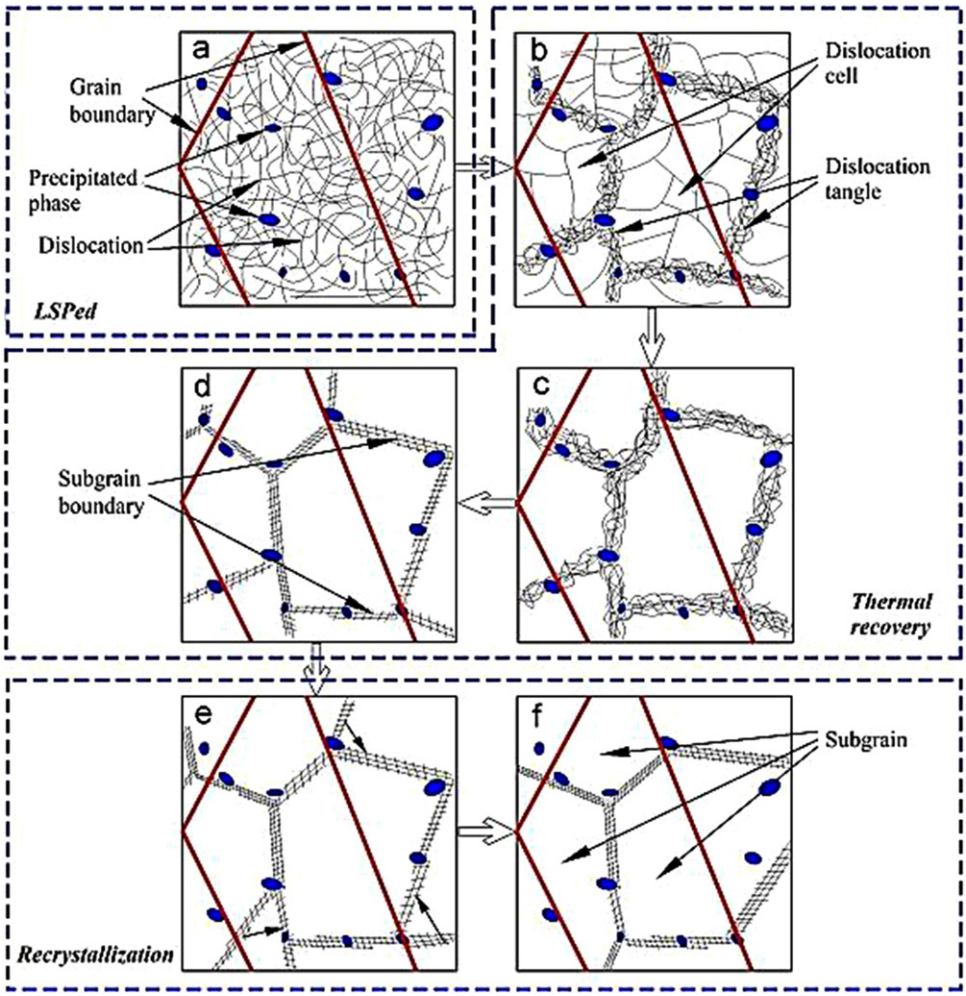

Figure 34 Schematic of grain and dislocation evolution during isothermal annealing: (a) high-density dislocation induced by laser peening; (b) dislocation slip and climb; (c) dislocation counterbalance in cells; (d) sub-grain boundary forming; (e) sub-grain boundary moving; and (f) sub-grain growth and coalescence.[63]

relaxation mainly occurs during the initial period of exposure, and the relaxation amplitude increases with the increase of applied temperature and as-peened plastic deformation. Laamouri *et al.*[187] and Zhou *et al.*[206] showed similar results. Laser peening induced residual stresses in Ti–6Al–4V, and their thermal relaxation due to short-term exposure at elevated temperatures were investigated by Zhou *et al.*[206] They observed that maximal relaxation occurred at the depth of maximum compressive residual stress, and lower initial stress was subjected to less stress relaxation.

The effects of applied temperature and exposure time on thermal relaxation are controlled by a thermally activated mechanism. The residual stresses decrease with increasing annealing time and temperature. According to previous research, thermal relaxation of residual stress can be described by using the Zener–Wert–Avrami function[63,206,211,212]:

$$\frac{\sigma^{RS}}{\sigma_0^{RS}} = \exp[-(At_a)^m] \quad [16]$$

where σ_0^{RS} is the initial stress before annealing, σ^{RS} is the residual stress at a given time, t_a, and temperature, T_a, m is the numerical parameter depending on the dominant relaxation mechanism, and A is the function associated with material properties and temperature.

The function is given as:

$$A = B\exp\left[-\frac{\Delta H}{kT_a}\right] \quad [17]$$

where B is the material constant with the value of 2.05×10^{12} min^{-1}, k is the Boltzmann constant and the value is 8.617343×10^{-5} eV K^{-1}, ΔH is the activation enthalpy of material for the relaxation process, and T_a is the annealing temperature.

Equation [16] can be deduced as

$$\ln\left[\ln\left(\sigma_0^{RS}/\sigma^{RS}\right)\right] = m\ln A + m\ln t_a \quad [18]$$

The process of residual stress relaxation of GH2036 at elevated temperatures was investigated and the plot of $\ln\left[\ln\left(\sigma_0^{RS}/\sigma^{RS}\right)\right]$ versus $\ln t_a$ at a given annealing temperature, T_a, according to experimental data and simulation results was drawn by Ren *et al.*[63] As shown in **Figure 35**, the relationship

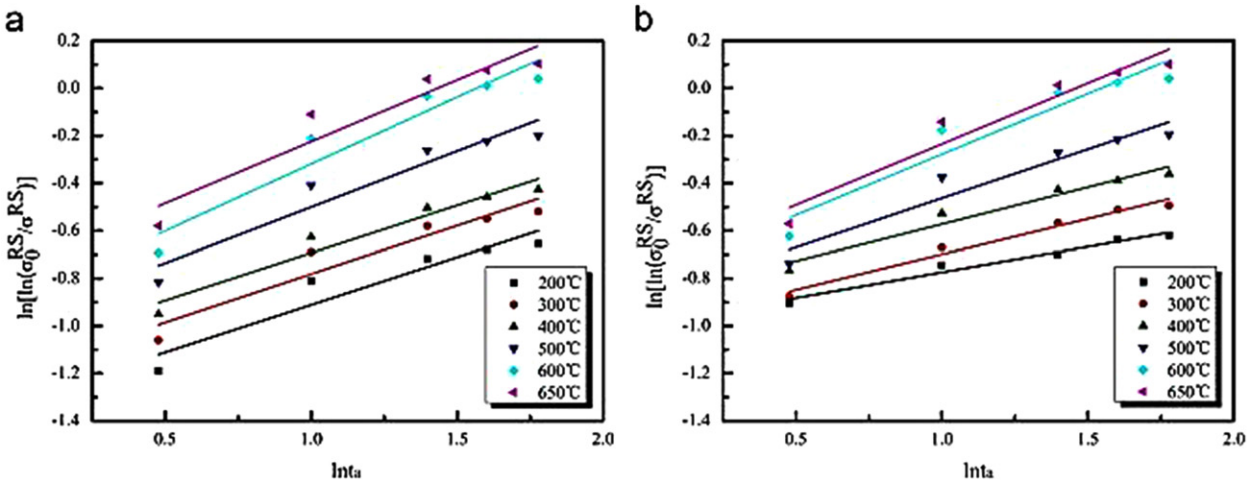

Figure 35 Influence of exposure time on the thermal relaxation of laser peening GH2036 at 200, 300, 400, 500, 600, and 650 °C: (a) experimental data and (b) simulated results.[63]

between $\ln\left[\ln\left(\sigma_0^{RS}/\sigma^{RS}\right)\right]$ and $\ln t_a$ is an approximate linear relationship at a constant annealing temperature and the slope of straight line is m. The value of m is determined by the mean value of these slopes. According to eqn [17], the activation enthalpy ΔH of the relaxation process can be determined. Ren *et al.* determined that while the mean value of m was 0.46 according to the experimental data and the calculated activation enthalpy ΔH was approximately 1.86 eV, the values based on the simulated data were 0.38, and 1.88 eV, respectively.

Similar conclusions were shown by Zhou *et al.*[206] They found that the activation enthalpy ΔH of the relaxation process in laser peening-treated Ti–6Al–4V was calculated in the range of 0.71–1.37 eV, which is close to values reported for self-diffusion of Ti and other solutes in titanium alloys.

1.14.5 Future Trends

Laser peening studies focused on aluminum alloy,[9,11,17,32] titanium alloy,[33,54,67,76] stainless steel[10,31,38,89] and some other steels,[213] and a few metallic glass or ceramics[214] to develop their mechanical properties such as fatigue, tensile, microhardness, and corrosion properties. One of the other potential applications for laser peening is biodegradable materials. Recently, a number of biodegradable metallic alloys have been introduced as implants with the ability of absorption. These biodegradable implants have mechanical strengths similar to that of bones, thereby reducing bone asthenia and helping to hold the clamp implant screw.[215] Laser peening has the potential for corrosion reduction by improving compressive residual stress on a biodegradable metallic implant surface. A few studies have been conducted involving biodegradable materials.[215,216] Laser peening of a biodegradable Mg–Ca alloy has been initiated to improve corrosion performance of orthopedic implants, creating superior surface integrity.[216] In addition to this, selective peening can be performed precisely and the peening of tiny workpieces such as biodegradable cardiovascular stents would now be possible.[215] There are also a few studies about improving welded materials that show a beneficial effect of laser peening.[182,217–219] Iordachescu *et al.*[182] proposed that laser peening can positively affect the welded materials in the uniform elongation zone and delay its failure beyond the ultimate tensile strength.

Another prospective industry for laser peening is fastener holes, which are used in airplane skin to joint skin parts into the whole body with rivets or bolts.[137,220] Zhang *et al.*[220] indicated worthwhile effects of the compressive residual stresses generated due to laser processing on the stress intensity factor. Ivetic *et al.*[37] determined that laser peening treatment increased the fatigue performance of open-hole aluminum specimens. They indicated that laser peening can be a good solution for 'in production' applications with open holes to be drilled after laser peening treatment.

1.14.6 Concluding Remarks

The main points affecting the magnitude of enhancement of material properties after laser peening include the laser spot size, power density, confine layer, pulse swept direction, the number of shocks, the subjected materials, and others. These parameters have a great influence on the residual stress, dislocation density, and, thus, on the morphology and microstructure of the laser-peened area. It is well known that laser peening can improve the fatigue life, strength, and corrosion resistance of materials, and also it has a great potential to improve the mechanical properties of metallic materials. According to the theoretical and experimental results, laser peening can be a powerful tool to supply a reliable design of structural components for the enhancement of mechanical properties like fatigue resistance and SCC resistance.

One of the advantages of laser peening is that the laser system can have direct integration into manufacturing production lines with a high degree of automation using an automatic x–y positioning system for treatment of localized fatigue critical areas without masking. Laser peening also has a high ability to make design changes that would not be

possible using alternative methods for increasing fatigue resistance. The manufacture of blades, disks, and vanes for aircraft gas turbine engines, of gears, connecting rods, and crankshafts for automotive engines, and of medical implants are among the applications that have been identified.

Laser peening has significant advantages for processing thin surface layers of different materials. As the laser technology progresses and high-power laser systems develop, laser peening will have extensive application areas.

a micro channel radius
a numerical parameter
A_i constants in Moldflow second order model
A rate constant
b_i data-fitted coefficients
B viscosity model fitting constants
c constant
c_P heat capacity, j kg^{-1} K^{-1}
C constant
C_i viscosity model fitting constants
C_P specific heat of material
d_o original distance
D_i constants
D an external characteristic length
h average value defined in equation
h_a heat transfer coefficients of air
h_t the heat transfer coefficient
h_w heat transfer coefficients of mold wall
k constant
k thermal conductivity, W m^{-1} K^{-1}
k_m the thermal conductivity of the plastic melt
m constants in power law model
m mass, kg
M_α interfacial force acting on phase α due to presence of other phase
n constants in power law index
P pressure, MPa
P_a pressure of gas/air, kN m^{-2} or kPa
P_o pressure at point O, MPa
P_{total} total pressure, MPa
P_{static} static pressure, MPa
Q flow rate
R universal gas constant, Nm kgK^{-1}
r radius along the radial direction
S_o the filling length. At the instant of time
s length along the channel direction
S_E Energy source, kg m^{-1} k^{-3}
S_M Momentum source, kg m^{-2} K^{-2}
$S_{M\alpha}$ momentum source due to body source
$S_{MS\alpha}$ user specified mass sources
t time, sec
t^i discrete time domain
T temperature, Kelvin
T_W temperature of the mold wall, K
T_s mean temperature, K
T_m melt temperature, K
v Velocity, m s^{-1}
v_s velocity along the micro channel, m s^{-1}
V volume, m^3
V_0 specific volume at zero gage pressure
X direction in the thickness of the main cavity
γ_o distance from the flow front to the point o

Greek letter

η viscosity, Pa s (N s m^{-2})
η_0 viscosity at zero shear rate, Pa s (N s m^{-2})
η_∞ the viscosity at infinite shear rate
η_b the macroscopic viscosity
λ time constant
$\dot{\gamma}$ Shear rate, (s^{-1})
ξ nondimensional constant
ρ density, kilogram per cubic meter, kg m^{-3}
e Specific total energy, kJ kg^{-1}
υ specific volume, m^3
τ Shear stress, N m^{-2}
μ Dynamic viscosity, kg m^{-1} s
α the thermal diffusivity (m^2 s^{-1}),
β subscript to indicate that the quantity applied to air
τ^* Tau, Pa
ω Thermal expansion coefficient, K^{-1}
Γ Diffusivity, (s^{-1})
$\Gamma_{\alpha\beta}$ mass flow rate per unit volume from α phase to β phase

1.15.1 Introduction

Injection molding is one of widely used plastic processing techniques for the plastic products manufacture. It is well suited for mass production because the raw material conversion into a final product usually requires only a single operation. Moreover, minor or no finishing process is required. The process is capable of producing very complicated part geometries with tight specifications. Due to high productivity and flexibility, injection molding applications have grown rapidly in various industries. The process starts with applying heat to solid plastic material, changing solid plastic to liquid state and delivering with high velocity into mold cavity through injection mechanism. As the high injection speed is applied to plastic melt, flow front will pass through runner, gate, and finally flow into the mold cavity. High injection pressure used to compensate the plastic shrinkage and ensuring complete mold cavity filling. This phase is called filling phase, where a plastic melt fills an empty mold cavity. During the filling phase, hot plastic melt makes contact with the wall, and a solidified layer occurs on the mold wall. Once the mold cavity is filled, plastic melt is cooled and the packing phase takes place. The heat is conducted from plastic melt to the mold and then to the cooling line, where the heat transfer is by convection through the coolant circulation. Solidified part is ejected from the mold as soon as the plastic has sufficiently solidified and the cycle repeats. Injection-molded parts are commonly used in automotive, hydraulics, pneumatics, aerospace, packaging, home appliances, optics, medical, electronics, telecommunication, and toy manufacturing.

1.15.2 Micro Plastic Injection Molding

With the recent development in micro engineering technologies there is an increasing demand toward product

miniaturization. Micro part fabrication is an important issue in broadening the use of injection molding. Micro injection molding is one of the important technologies for micro manufacture because of large production quantities, high accuracy, and low production cost. This technology will bring improvements in complexity, reliability, efficiency, and lead to advanced applications in various engineering fields. Micro molding parts accelerate the rapid development of mechanical, electronic, automobile, medical applications, and also have great potential in MEMS sectors.

The micro injection molding is not simply a scaling down of the conventional injection process, rather it requires some radical changes in methods and practices. The capabilities of this process have to be studied consistently in order to identify the process constraints. In micro molding, the ability for the plastic melt to flow into the micro component is a crucial factor for successful molding. It depends greatly on their size, aspect ratio, and cavity surface quality. The travel distance of the plastic melt into the micro structure also depends on the flow rate, which is a function of the geometric dimensions. Micro part has high surface-to-volume ratio which makes the plastic melt fill freeze or solidifies much faster compared with conventional injection molding and leads to an incomplete filling. The achievable aspect ratios and high surface quality also constitute a major fabrication constraint in applying injection molding in a range of microscale applications. The precision requirements for micro plastic parts are around micron and the surface roughness requirements may exceed submicron. To improve the micro molded quality, many research groups investigated different factors that affect micro injection molding process. In particular, these include works in process optimization, material rheology, numerical simulation, and tooling technologies.

The micro injection molding is a material processing technique to produce microscale plastic components.[1] Micro molding is a subset of injection molding process, where a plastic melt is forced into micro cavity, allowed to cool and then removed. Micro injection molding is attracting more attention and showing great commercial potential nowadays.[2] Recent advances in microtechnology are devices with a huge range of applications in the sensors, medical equipment, telecommunications, biomedical, and automotive sectors. Many micro devices, such as micro heat exchangers,[3] biochips,[4] and optical elements[5] have been successfully produced by injection molding.

Micro molding implies that parts produced have various types of parameters on the micron scale, but the term has taken on a relatively liberal definition. There are several definitions for a micro injection-molded parts. Kukla *et al.*[6] defined the micro plastic parts as:

1. Micro weight, parts with few milligrams masses, but not necessarily the size in micrometer scale.
2. Micro structured regions, part with local micro-features.
3. Micro precision dimensions, part size tolerances in the range of micrometer.

1.15.2.1 Machine for Micro Injection Molding

The machine used to mold plastic part can be classified according to their type, tonnage capacity, barrel size, maximum temperature, maximum injection pressure, and overall size. The common machines classifications are horizontal and vertical injection molding machine. There are also machine used for specific application such as rotary injection molding and two color component molding.

The development of molding machines for micro parts fabrications have always been a challenge for machine fabricator. Although, it uses a heating and pressure devices, researchers still are working to find out the best method to fabricate a micro plastic part. Currently, many researchers used Battenfeld Microsystem 50 in their studies on micro plastic part fabrication.[7,8] Other than Battenfeld Microsystem 50, there are few injections molding machines available in the market with capability to produce complex plastic parts. Giboz *et al.*[9] listed the machines that are capable of producing micro plastic parts.

Currently, many researchers introduce their ideas to control, monitor, and even fabricate new machine to make it more fascinating. Processing plastic for microtechnology applications requires high precision process and injection dynamics. Producing plastic part with small production volume does not require expensive machine. Therefore a low cost machine with capability to produce same part quality is more preferable. By using basic principles of plastic injection molding, researchers designed and fabricated their own machine for specific plastic part fabrications. This was due to higher price of commercial micro injection molding machines available in the market.

Michaeli and Spennemann[10] and Michaeli *et al.*[11] had developed an injection molding machine with two stage plungers to analyze the molding properties of micro parts. The injection plunger diameter was 2.0 mm, while the plasticizing plunger had a 5.0 mm diameter. The shot size was 0.01 g at each time and used CO_2 liquid for mold cooling. Spennemann[12] also fabricated a micro injection molding machine for smallest plastic volume. Chang *et al.*[13] developed an external module for thermoplastic molding. The system consisted of two modules; hot runner plunger-type and reciprocating screw-type. From the experimental analysis, performance of the external molding module was comparable with the two stage screw–plunger injection molding machine.

Huang[14] molded the nano-features using a custom-made injection machine. This machine consisted of clamping, melting, and injection units. The clamping unit moved forward and backward using hydraulic press device. The melt unit with hot runner heaters provided energy for the plastic melting. Injection unit consisted of 2.0 mm injection plunger and hydraulic piston, which was used to deliver the plastic melt into the cavity. The maximum recorded injection pressure and shot were 0.7 MPa and 120 mm^3, respectively. The maximum allowed mold and melt temperature were 200–300 °C. With the same machine, Huang[15] investigated the plastic part moldability with nano-ceramic added materials. In the investigation, parts with micro-features have been successfully molded.

Another micro molding machine used to produce micro parts was developed by Quadrini *et al.*[16] This machine was capable of molding three different plastic materials: HDPE, PS, and ABS. Yang *et al.*[17] designed and fabricated a hot runner micro injection molding module and installed in an injection molding machine reciprocating screw device. The performance

of this module was tested with two stage reciprocating screw- and plunger-type micro injection molding machine.

1.15.2.2 Flow Observation

The observation in plastic melt flow can be divided into two categories, during melt flow and after it solidifies. The plastic flow behavior inside mold cavity during filling phase is necessary for earlier quality prediction of molded plastic parts. Ability to monitor and control plastic flow will benefit in designing a mold cavity for complex plastic shapes. There are lots of works done on investigating the plastic flow behavior inside the mold cavity during filling phase.[18] The transparent inserts are embedded into the mold and the moving melt inside the cavity can be observed.[19–21] This method required usage of optical elements and a high speed camera to capture the fast cavity filling. Dvorak *et al.*[22] fabricated a mold with clear glass window for observing the melt flow during injection phase for ceramic injection molding process. An injection molding experiment was conducted to monitor the filling behavior. They also studied the gate size effect and jetting problem with various injection process parameters. Liu and Wu[23] studied the phenomenon of filling-assisted injection molding techniques using fluid dynamics visualization. A thick glass was mounted on the mold base for melt flow visualization. A high speed video camera was used to record the rectangular cavities filling phenomena with different channel geometries.

Yang and Yokoi[24] demonstrated a flow behavior in plastic sandwich molding using dynamic visualization technique. The setup of visualization experiment included 'glass-inserted mold' and in-line high speed camera in the cavity flow. Sato and Yokoi[25] also developed a mold visualization technique with a glass-inserted structure which enabled plastic melt observation behavior inside the cavity along its thickness direction. The visualization window was made from quartz glass for high durability. The melt front profile and surface behavior were observed using a high speed video system and then analyzed with image processing software.

Yokoi *et al.*[26] developed a system which can dynamically measure the flow front position. The system allowed flow front speed measurement at velocities up to 350 mm s^{-1}. The high speed video camera was attached in the driving unit which moved together. In addition to flow marks problem, the system was also capable to capture pictures of the silver streaks formation for the first time. The results of system can be used as a tool for exploring fountain flow formation and detection of molding defects.

Video camcorder with 25 fps capabilities was used by Özdemir *et al.*[27] to record the flow behavior of melt thermoplastic materials. The captured images were transformed to photo capture program for analysis. With same molding parameters, melt flow front profile results were compared with those of analysis software. Although the experiment melt front profiles were similar to the Moldflow results, but the filling times were different. Bociga and Jaruga[18] observed the cavity filling by looking at a specially created flow lines pattern. The flow lines can be used to diagnose the problems during cavity filling. The molded part surface was observed in reflected light using the optical microscope. The experimental results were comparable with Moldflow plastics insight analysis software.

1.15.2.3 Flow Model

1.15.2.3.1 Macro flow model

Improving the knowledge of injection molding technology by trial and error method to produce high quality parts is no longer viable. Many researchers have successfully developed various mathematical models to predict the flow and correct any problems even before actual part being molded. This approach has led to improvements and innovations in molded part quality. Since early nineteenth century, the governing equations of conventional flow for a viscous fluid were developed based on three equations[28]:

1. The continuity equation, plastic deformation accompanying the flow during the filling process while mass is conserved.
2. The equations of momentum, Newton's second law derived momentum (acceleration condition) or the balance of force generated by the plastic flow.
3. The energy equation, which is a system of energy conservation and the law of conservation of flow material in an incompressible fluid.

The basic form of the equations remained unchanged and researchers have been modeling the melt flow for specific needs and solving techniques. This is done by including nonlinearity aspects such as heat transfer, compressibility, scaling effect, rheological, and non-Newtonian characteristics. Hele-Shaw flow formulation originated from simplified creeping-flow lubrication model merged the continuity and momentum equations into a single Poisson-like equation in pressure and fluidity terms. Even though the equations and geometry has been simplified, the Hele-Shaw flow model is successfully applied to the nonelastic liquid, non-Newtonian with non-isothermal conditions in conventional injection molding.

Since then, many researchers modeled the plastic flow based on Hele-Shaw flow approximation. For 30 years, the CAE software for mold cavity filling has been developed based on Hele-Shaw model.[29–31] However, the Hele-Shaw model also has some limitations. It cannot capture physical phenomena when simplifying the equations.[32] In addition, this approach is not capable of representing regions with complex kinematics flow front. A simpler version of this phenomenon is addressed by many researchers through experimental, analytical, and numerical methods. This leads to a model of basic flow kinematics without solving the complex three dimensional (3D) flows.

1.15.2.3.2 Micro flow model

Shen *et al.*[33] and Huang *et al.*[34] stated that the CAE packages have become an accepted tool in mold design. Prediction of micro flow using numerical simulation also received an interest among researchers.[1,33,35–39] The generalized Hele-Shaw flow model proposed by Hieber and Shen[40] simplified the equations for non-isothermal viscous fluid as used by most injection molding analysis software. This model is considered

fully developed, but compressibility, inertia and gap-wise distance is ignored for plastic melt flow in thin cavities. As a result, 3D flow regions cannot be used in Hele-Shaw model. Therefore, only the 3D analyses based on Naiver–Stokes equations are capable to simulate the real situations.[33,34]

1.15.2.3.3 Macro – micro flow model

The plastic melts traveling from macro to micro size is an interesting area to discover. It is not as simple as reducing the plastic melt size to micro, but other factors such as viscosity and friction on the wall will have a significant effect. Feigl and Tanner[40] developed and evaluated micro–macro algorithm for the plastic melt flow. The model employed momentum and mass conservation equations for continuum mechanics, including the plastic stress microscopic-based rheological model. For a macro algorithm, velocity, and pressure fields were generated by solving mass and momentum equations using the finite elements method (FEM). In the micro part algorithm, the updated velocity field was used to compute and update the plastic stress from rheological model.

A fully implicit time integration scheme was carried out for solving time-dependent micro–macro viscoelastic flow using brown fields configuration. Plastic melts micro–macro simulations of momentum and mass conservation equations at macroscopic level using differential equation was presented by Jourdain *et al.*[41] The equations were discretized by a FEM coupled with a Monte Carlo method. The solution method was applicable for a one dimensional (1D), and might be applied to two dimentional (2D), and 3D cases.

1.15.2.3.4 Viscosity model

The viscosity model represents the plastic melt behavior. Using suitable viscosity model, reliable results of injection molding numerical simulation can be achieved. Koszkul and Nabialek[42] presented viscosity functions for modeling an injection molding process. Common viscosity functions available are:

1. Power law models.
2. Moldflow second order model.
3. Cross viscosity model.
4. Carreau viscosity model.
5. Castro Macosko viscosity.
6. Carreau–Yasuda viscosity model.
7. Cross-Exponential Macosko viscosity model.

The well-known Power law model also is given by

$$\eta = m\dot{\gamma}^{n-1} \qquad [1]$$

When $m=\mu$ and $n=1$ the relationship for a Newtonian fluid is obtained. For plastic melts, the constant n lies between 0 and 1. Taking natural logarithms of both sides,

$$\ln\eta = (n-1)\ln(\dot{\gamma}) + \ln(m) \qquad [2]$$

Temperature dependence is usually included by multiplying eqn [1] by an exponential term. That is,

$$\eta = m\dot{\gamma}^{n-1}(\exp cT) \qquad [3]$$

Equation [3] is the first order viscosity model available in Moldflow flow analysis software. The Moldflow second order model is given by

$$\ln\eta = A_0 + A_1\ln\dot{\gamma} + A_2T + A_3(\ln\dot{\gamma})^2 + A_4T\ln\dot{\gamma} + A_5T^2 \qquad [4]$$

The first and second order MoldFlow models were based on empirical observations. The first order model fits experimental data and the second order model is able to characterize the plastic melts behavior.

The cross viscosity model is

$$\eta = \frac{\eta_0}{1+(\lambda\dot{\gamma})^n} \qquad [5]$$

The η_0, can be modeled using the widely accepted seven-constant cross model where

$$\eta_0 = D_1\exp - \left\{\frac{A_1[T-(D_2+D_3p)]}{\tilde{A}_2 + D_3p + [T-(D_2+D_3p)]}\right\} \qquad [6]$$

Another viscosity model, Carreau viscosity model is define as

$$\frac{\eta-\eta_\infty}{\eta_0-\eta_\infty} = \left[1+(\lambda\dot{\gamma})^2\right]^{(n-1)/2} \qquad [7]$$

Anturkar[42] used a Petrov–Galerkin finite element method for computing flow front position, velocity, pressure, and temperature distributions during mold filling with adoption of Castro Macosko viscosity function. A good agreement was found between the numerical and experimental results in the flow front region. The Castro Macosko viscosity function which depend on the temperature is given by

$$\eta(X,T) = \eta(X)\cdot\eta(T) = A_\eta\exp\left(\frac{E_\eta}{RT}\right)\left(\frac{X_g}{X_g-X}\right)^{(A+BX)} \qquad [8]$$

Chen *et al.*[29] used a modified cross model with Arrhenius temperature dependence as viscosity function incorporating numerical algorithm to simulate the filling stage of injection-compression molding process. Modified cross model with Arrhenius temperature dependence viscosity function represent a non-Newtonian characteristics of plastic melt viscosity[43]:

$$\eta(X,\gamma) = \frac{\eta_0(T)}{1+(\eta_0\gamma/\tau^*)^{1-n}} \quad \text{with} \quad \eta_0(T) = B\exp\left(\frac{T_b}{T}\right) \qquad [9]$$

This flow model was based on Marrucci–Greco–Lanniruberto model with the effects of viscoelasticity. The Carreau–Yasuda viscosity model or generalized Newtonian models based only on shear-thinning behavior without elastic properties were developed by Bird *et al.*[44] the viscosity model is given by

$$\eta = \eta_0(1+[\lambda I_2]^a)^{(n-1)/a} \qquad [10]$$

where I_2 is the second invariant of the rate-of-strain tensor $d=(\kappa+\kappa^T)/2$. Moon *et al.*[44] performed 3D-numerical simulations to study the flow characteristics during the injection molding of die stacked package using cross-exponential Macosko

viscosity model. The cross-exponential Macosko viscosity model is for the non-Newtonian viscosity behavior of the plastic melt and described by following equation

$$\eta = \frac{\eta_0(T)}{1+\left(\frac{\eta_0(T)\dot{\gamma}}{\tau^*}\right)^{1-n}} \cdot \left(\frac{\alpha_g}{\alpha_g-\alpha}\right)^{(C_1+C_2)} \quad \text{with} \quad \eta_0(T) = B\exp\left(\frac{T_b}{T}\right) \qquad [11]$$

This simulation showed that the increased mold gap clearance and a decrease in melt viscosity can help achieve a more uniform flow front.

1.15.2.3.5 Viscosity for micro injection molding

Xu *et al.*[45] and Rosenbaum and Hatzikiriakos,[46] reported that the micro flow behavior was opposed to the macro flow. The viscosity increased as the channel size decreased below the 10 μm. Plastic melt slipped over the wall as the channel size dropped below 1 μm. From micro-features experiments and numerical simulations done by Yu *et al.*[47] the microscale geometry and surface tension had a significant influence on the melt flow. Cavity surface roughness, wall slip or even the heat transfer behavior in microscale were another characteristics that might have influence. Young[1] analyzed a filling distance in cylindrical micro-features without considering viscosity and wall slip effect on the channel. Griffiths *et al.*[7] explained the melt temperature and injection speed effects on viscosity in micro injection molding. Increasing the melt temperature improved the plastic flow by reduction of viscosity. A high injection speed can improve the filling of micro cavities by delaying the premature freezing in thin walled sections. This effect can reduce the viscosity of the material and help in the filling process.

Su *et al.*[39] used an analytical solution to investigate the impact of microscale phenomena in the wall slip and surface tension during micro channels filling. They simulated the micro channels filling process for polymeric materials using the viscosity model proposed by Eringen and Okada.[48] The viscosity model introduced a nonlocal continuum theory with the molecular orientation effects. Therefore, the equation for viscosity was:

$$\eta = \eta_b\left[1+\xi(g/D)^2\right] \qquad [12]$$

where η_b is the macroscopic viscosity from eqn [5]. The macroscopic viscosity is corrected to microscopic viscosity using a micro size factor following the Eringen–Okada equation which is represented by

$$\eta(\dot{\gamma},T,p) = \Phi(z)\eta_b(\dot{\gamma},T,p) = \left(1+\xi\frac{g^2}{z^2}\right)\eta_b(\dot{\gamma},T,p) \qquad [13]$$

1.15.2.4 Factors Affecting Micro Injection Molding

A successful good quality macro plastic parts fabrication is highly dependent on the mold, machine and processing condition. The development in understanding the plastic and its relation to the processing factors are undertaken by focusing on the molding parameter such as mold temperature, melt temperature, injection pressure, holding pressure and clamping force.[35,48–50] The question is, whether changes in processing condition to archive quality molded parts can be applied to micro plastic parts. Generally, a good quality micro molded part is achieved by increasing the flow rate and velocity. This can be done by increasing the mold temperature, melt temperature and injection pressure. But, the clamping force and viscosity have to be reduced for better result. The cavity sizes also will affect the selected processing conditions. Therefore, researches plays with these factors to find the best processing condition for micro molded parts. The major molding parameters investigated by researchers are melt temperature, mold temperature, injection speed and injection pressure due to their direct effects on the melt flow property in micro injection molding.[35,38,39,51] Mönkkönen *et al.*[50] Zhao *et al.*[52] and Yu *et al.*[48] found that the injection speed, melt temperature and holding pressure were the most influential factors in micro injection molding.

Differences in their results can be explained by different plastic materials used and different test structures. Although high settings of molding parameters can improve the melt flow, this also have a negative effect on micro molded parts. For example, high mold temperature can lead to temperature-induced defects, increased cycle time and processing costs. On the other hand, the high melt and mold temperatures and high injection speed has a positive effect on the flow of plastic melt into a micro cavity.

1.15.2.4.1 Temperature

D'Amore *et al.*[53] and Whiteside *et al.*[54] found that the mold temperature was a key parameter for the micro parts fabrication. Therefore they suggested to increase the mold temperature to be the same or higher than the plastic softening temperature. As a result, more aspect ratio can be achieved. Shen *et al.*[36] Shen and Wu[35] suggested that a high mold temperature above the glass transition temperature or close to melt temperature, improved the micro filling capabilities.

Sha *et al.*[55,56] studied the effects of melt temperature, mold temperature, injection speed, injection pressure, clamping pressures, and cooling time to achieve high aspect ratios. They found that melt temperature, mold temperature and injection speeds were the most influential factors affecting the micro-features aspect ratios.

1.15.2.4.2 Pressure

The pressures used in the micro injection molding can reach more than 200 MPa, however conventional injection pressures are generally ten times lower. Sub-milligram products are highly sensitive to changes in injection pressure.[54,57] The injection pressure has to be increased in order to increase the injection speed to have successful filling.[58] According to several researchers,[59] Despa *et al.*[60] Yu *et al.*[48] higher injection speeds increases the mold cavity filling by reducing the plastic viscosity. Therefore, total injection cycles time is reduced. These conditions also can be achieved by taking consideration of runners and gate design.

1.15.2.4.3 Micro flow model factors

Currently, the plastic melts flow behaviors in micro cavities are not fully understood. Flow problem in micro parts are governed by their sizes, wall slip behavior, surface tension, viscosity, forces and thermos-physical property. Because of large surface-to-volume ratio, surface effects will dominate the flow behavior at the microscale. A number of researches indicated that microflows were different from macroflows.[61]

1.15.2.4.4 Size

Besides common injection molding parameters, the geometric configuration of parts is also a factor affecting plastic melt flow in micro molding. For example, Yu *et al.*[48] studied the distance effect between micro cavity and the gate. The result showed that micro cavity near the flow end would be better filled. Also, the study by Mönkkönen *et al.*[50] showed that the angle of micro-features could result in different filling depth. These studies provided useful information for mold design that incorporates micro-features. Geometric configurations showed different responses to changes of molding parameter in micro injection molding. Thus, it is very important to study the combined effects of relevant factors. Yao and Kim[62] investigated the effects of microscale phenomena such as viscosity, wall slip and surface tension on the filling process of plastic materials into micro channels. The results indicated the importance of employing size-dependent viscosity and wall slip to predict micro filling behaviors. But, the surface tension effect was not important in micro molding. Despa *et al.*[63] used available injection molding simulation packages to predict the moldability of micro-features. Micro channels experiment with dimensions of 10 μm have shown that, the viscosity close to the channel wall is higher than the bulk fluid viscosity.[61]

1.15.2.4.5 Viscosity in micro molding

Xu *et al.*[46] and Rosenbaum and Hatzikiriakos[47] reported that the flow in the microscale was different from macroscale. The plastic melt was found to slip over the wall surface as the channel size was down below about a micrometer. Roughness of cavity surface, wall slip conditions and the heat transfer behaviors in the microscale had an influence. For analysis simplification, Young[1] analyzed a filling distance in cylindrical micro-features for micro injection molding without considering viscosity and wall slip effect. Yao and Kim[62] used simulation to study the consequences of size-dependent viscosity on the micro channels filling process. Griffiths *et al.*[7] studied the effect of viscosity on melt temperature and injection speed in micro injection molding. An increase of melt temperature improved the plastic flow due to viscosity and shear stress reduction. Also, some plastics may show shear rate increment at a higher melt temperature. This effect can reduce the viscosity of the material and thus assist the process of filling.

1.15.2.5 Summary of Literature Reviews

There is a need to explore more on micro injection molding in the areas of micro parts, molding machine, and micro melt flow analysis. With current classification on micro parts, analysis, and fabrication of micro parts are the main challenge. As tight specifications are required, controlling injection molding parameters with appropriate viscosity model are highly useful for successful micro molding. This study will design, fabricate, and validate a custom-made injection molding machine suitable for micro molding application. A special mold incorporating viewing window will be designed for the purpose of melt flow observation. Study of micro melt flow starts with straight micro channel and continues with more complex shapes including variable molding parameters. A dedicated micro gear shape case study will be conducted in order to verify the findings in simple and complex micro channel shapes with variable sizes.

1.15.3 Custom-Made Vertical Injection Molding Machine

A custom-made vertical injection molding machine was designed, built, and tested based on the basic principles of plastic injection molding, which was heating a solid plastic into liquid state and injecting to mold cavity and finally ejecting from mold cavity after solidification. The machine consisted of melting chamber, plunger, temperature, and pressure controllers. The overall view of custom-made vertical injection molding machine which consists of vertical injection structure, injection mechanism, plasticizing unit, and custom-made mold are shown in **Figure 1**. The system can be considered as bench top or desktop injection molding machine. There are four solid rods of 25.4 mm diameter and 370 mm length which are used to connect top and bottom plate in vertical arrangement. The top plate is used to support pneumatic cylinder and bottom plate is used as table for the mounted mold. The sizes of both plates are 150 mm × 150 mm × 25 mm. The overall structure is very rigid and strong enough to absorb pressure from pneumatic cylinder during vertical injection operation. To increase the rigidity during operation, the structure is mounted on a working table.

1.15.3.1 Plasticizing Unit and Injection Mechanism

The plasticizing unit consists of melting chamber, nozzle, heating element, and thermocouple. The inner size of melting
