Garlic crops are infected by *Onion yellow dwarf virus* (OYDV) and *Garlic latent virus* (GarLV) (synonym for *Shallot latent virus* (SLV)), capable of causing significant losses. A duplex RT-PCR assay was developed for the simultaneous detection of OYDV and GarLV in total RNA extracts obtained from garlic leaves or cloves using virus-specific primer pairs. The assay detected both viruses in all ten selections of garlic plants grown in the field. GarLV was detected in all samples while OYDV, although detected in all ten selections, could be detected in only four of five samples from two selections. No amplification occurred in samples from healthy control garlic plants. As the viruses were not present in equal concentrations in infected plants, a two-fold increase in GarLV primers improved its detection by duplex RT-PCR assay. The sensitivity of duplex RT-PCR assay of OYDV and GarLV was not reduced, as detection of both viruses could be achieved to the same level as in simplex RT-PCR format. Duplex RT-PCR assay was efficient in detecting both viruses in samples from leaves and cloves, saving time and cost of testing compared to standard RT-PCR format (Majumder et al. 2008).

Black pepper crops are seriously infected by stunt disease with which *Cucumber mosaic virus* (CMV) and *Piper yellow mottle virus* (PYMoV) are associated. A single-tube multiplex (m) RT-PCR assay was effective in simultaneously detecting both CMV and PYMoV in the mother plants. Two amplicons of expected sizes – 650 bp for CMV and 450 bp for PYMoV – were amplified from the total nucleic acids extracts of infected plants used as templates. No amplification of the virus-specific fragments was seen in the extracts from healthy pepper plants. The mRT-PCR format was found to be

effective in detecting both viruses in the nursery and field-grown plants and was amenable for large screening of pepper samples rapidly (Bhat and Siju 2007).

A multiplex RT-PCR assay was developed for the detection of *Dasheen mosaic virus* (DsMV), *Turnip mosaic virus* (TuMV), *Konjac mosaic virus* (KoMV), and *Zantedeschia mild mosaic virus* (ZaMMV) in the calla lily plants in Taiwan. Based on the sequences of 3' terminal region of respective viruses, specific primers were designed. In addition, a primer pair specific to plant mitochondria *nad5* mRNA was used to produce a 185 bp fragment as an internal control to prevent false-negative results. The primer pairs TuRD/TuCPF1 for TuMV, ZUNR1/ZUNF2 for ZaMMV, DRO/DF2 for DsMV, ZRD/ZF3 for KoMV, and mtR1/mtF2 for *nad5* mRNA employed in this protocol amplified fragments of 1077, 792, 457, 260, and 185 bp, respectively, when the individual clones were tested. They were specifically amplified by the primer mixture of TuMV, ZaMMV, DsMV, KoMV, and mt control. Generally the yield of amplicons for the viruses DsMV, KoMV, and mt was less in multiplex PCR compared with simplex PCR format, and all tested primers were specific to their targets. Optimization of primer concentration of individual viruses was therefore carried out for amplification of expected RT-PCR products for four viruses and mt target to the desired level. Total RNAs purified from virus-infected plants were used directly or mixed in different combinations. The specificities of primers were verified by employing simplex and multiplex PCR formats. Samples of fully expanded leaves of calla lily randomly collected from fields were tested by multiplex RT-PCR assay. Calla lily samples showed single-virus infection to an extent of 72% (35/50), while two-thirds (23/36) of plants were infected by two or more viruses. Using indirect-ELISA format, virus infection in only 50% of plants could be detected by employing potyvirus-specific antibodies. Multiplex RT-PCR protocol developed in this investigation was suitable for sensitive, rapid, and reliable detection of potyviruses infecting calla lily plants, particularly for producing virus-free stocks by certification programs (Hu et al. 2010).

The results of multiplex RT-PCR indicated that the expected RT-PCR products could be specifically amplified and identified on the basis of their molecular sizes. Sensitivity of detection by RT-PCR assay was greater (25–625 times) than that of indirect ELISA test depending on the virus. During field surveys multiplex RT-PCR assay was able to detect more single- as well as mixed-infection samples than indirect ELISA format. The multiplex RT-PCR protocol was found to be simple, rapid, and reliable for simultaneous detection of the four potyviruses infecting calla lily plants, and the assay could save cost and time when testing large numbers of samples (Hu et al. 2010).

Cymbidium mosaic virus (CymMV) and *Odontoglossum ringspot virus* (ORSV) are important viruses infecting orchids, inducing considerable adverse impacts on production. A multiplex RT-PCR assay was developed for the detection of CymMV and ORSV. These primers amplified the respective viral coat protein (CP) genes. In addition, a primer pair derived from the plant mitochondrial NADH dehydrogenase gene (*nad5*) was tested for the amplification of *nad5* mRNA as internal control in the multiplex RT-PCR. The fragment of internal control mRNA was consistently amplified from total RNA of healthy and infected plant extracts. The primer pair for CymMV CP-F1/CymMV CP-R1 and the primer pair for ORSV CP-F1/ORSV CP-R1 amplified a 669 bp fragment and 474 bp fragment in the RT-PCR assay, respectively. The amplification efficiency of RT-PCR assay was not affected when the same amount of CymMV and ORSV RNAs were added alone or together to the plant total RNA. The specificity of three designed primer pairs for CymMV, ORSV, and *nad5* mRNA was confirmed by simplex

and multiplex RT-PCR assays. The detection sensitivity of multiplex RT-PCR was 1 pg for CymMV and 10 pg for ORSV, regardless of the presence of one or two viruses in the samples. The presence of CymMV and ORSV in *Phalaenopsis* orchids sold in a flower market was detected in three infected plants. The expected cDNA fragments of the viruses and internal control were amplified in infected samples, indicating the applicability of the multiplex RT-PCR assay for detection of viruses infecting orchid plants (Lee and Chang 2006). The RT-PCR assay was applied to determine the involvement of *Odontoglossum ringspot virus* (ORSV) and *Cymbidium mosaic virus* (CymMV) and tospoviruses in leaf yellowing of *Phalaenopsis* orchid plants. ORSV and CymMV were efficiently detected simultaneously by RT-PCR from total RNA extracts, using commercial kits, the simple direct-tube (SDT) technique, and the primers designed in this investigation. The presence of ORSV and CymMV was detected in 55% and 34% of plants, respectively. Severe symptoms were observed in plants infected with both viruses. Using SDT technique, RNA could be extracted effectively and the RT-PCR protocol was cost-effective for screening for disease incidence in commercial orchards intended for production of high-quality virus-free plants. Furthermore, RT-PCR protocol detected the presence of *Orchid fleck virus* (OFV) in Australian orchids by employing virus-specific primers. None of the samples showed infection by the tospovirus *Capsicum chlorosis virus* (CaCV) reported earlier on *Phalaenopsis* orchid plants (Yamane et al. 2008).

As sugarcane is a vegetatively propagated crop, screening for viruses infecting sugarcane is important to restrict the introduction and/or prevention of virus disease spread during germplasm exchange and seed cane production. In order to assess the incidence of *Sugarcane mosaic virus* (SCMV), *Sorghum mosaic virus* (SrMV), and *Sugarcane streak mosaic virus* (SCSMV) on cultivated sugarcane and noble canes, a survey was undertaken. In the one-step RT-PCR assay, virus-specific primers generated amplicons of expected size of 900 bp and 5850 bp for SCMV and SrMV, respectively. The absence of an amplicon specific for SCSMV indicated that the virus was absent in the samples tested. The amplified RT-PCR products 33 and 10 for SCMV and SrMV CPs, respectively, were directly sequenced to confirm the specificity of the assay. The nucleotide sequences of the RT-PCR products shared more than 76% homology with CP gene of the corresponding virus. RT-PCR data indicated that most of the hybrid and noble canes in southern China were commonly infected by either SCMV or SrMV singly or doubly with both viruses (Xu et al. 2008a).

In a later investigation, a quadruplex RT-PCR assay was developed to detect *Sugarcane mosaic virus* (SCMV), *Sorghum mosaic virus* (SrMV), *Sugarcane streak mosaic virus* (SCSMV), and *Sugarcane yellow leaf virus* (SCYLV). Virus-specific primers were designed for simultaneous detection and differentiation of SCMV-F1/R1, SrMV-F/R, SCSMV-F/R, and SCYLV-F/R of these viruses. The primers specific for SCMV, SrMV, SCSMV, and SCYLV amplified DNA fragments of 720 bp, 860 bp, 1160 bp, and 512 bp, respectively, and each of the RT-PCR bands produced using these primers was observed clearly following gel electrophoresis. No significant primer pair interactions or primer-dimer formation was observed. The best cycling conditions for the quadruplex RT-PCR assay were one cycle of 50°C for 30 min and 95°C for 2 min, followed by 30 cycles of 94°C for 30 s, 54°C for 30 s, and 72°C for 1 min in a quadruplex assay. All four viruses could be detected using sample dilutions up to 10^{-7} , 10^{-8} , 10^{-4} , and 10^{-5} for SCMV, SrMV, SCSMV, and SCYLV, respectively, and virus-specific bands were visualized after gel electrophoresis. All four target viruses were detected in 202 field samples collected throughout the entire growing season. Most of the positive samples showed the presence

of single virus and 29 samples contained mixed infection by 2 viruses. The multiplex RT-PCR may be preferred because of reduced cost, labor, and time required compared to simplex RT-PCR assays (Xie et al. 2009).

7.2.3.3 Combination of RT-PCR with Other Diagnostic Assays

The sensitivity and specificity of RT-PCR assay may be enhanced substantially by combining antibody binding with virus protein followed by PCR amplification. Immuno-PCR is a highly sensitive procedure in which a DNA fragment is linked to an antigen–antibody complex using protein A (linking antibody) and streptavidin (attached to DNA). Protein A and streptavidin have a strong affinity to each other. This complex is then bound to a biotin-labeled DNA sequence which is subsequently amplified by PCR. The sensitivity of immuno-PCR assay may be about 10^5 times more than that of ELISA test (Sano et al. 1992). In immunocapture (IC), the virus is captured (concentrated) by using specific antibody and the specific RNA sequence of the captured virus particles is amplified. Woody plants contain large quantities of phenolic compounds or polysaccharides that can interfere with nucleic acid template preparation, resulting in inhibition of PCR amplification. The virus particles may be selectively concentrated by applying the immunocapture procedure, prior to PCR amplification (Nolasco et al. 1993). The availability of antigen-specific antibody is the only requirement for performing immuno-PCR assay, whereas nucleic acid sequence data is also needed for immunocapture (IC-) RT-PCR procedure. These techniques have been demonstrated to be effective for sensitive and reliable detection of several plant viruses in symptomatic and/or asymptomatic planting materials.

Plum pox virus (PPV) could be efficiently and reliably detected by employing IC-RT-PCR assay. The sensitivity of this technique was about 250 times greater than the standard PCR format (Wetzel et al. 1992). In a later investigation, the higher level of sensitivity of detection of PPV by IC-RT-PCR was revealed by the positive results for the presence of PPV in 31% of ELISA-negative leaf samples and in 23% of ELISA doubtful samples from field-grown plants, collected during field surveys taken up to assess the extent of PPV incidence. In addition, the identity of majority of isolates was determined as M-serotype of PPV analysis of PCR products by random fragment length polymorphism (RFLP) (Varveri and Boutiska 1998).

In another study, the presence of PPV was detected in 92–100% of root samples from plum trees by IC-RT-PCR assay. However, ELISA test could only detect PPV in 36–65% of the root samples, indicating that bulked samples from fibrous roots were more suitable tissues for the detection of PPV since the frequency of detection by IC-RT-PCR format was not significantly different from that of ELISA test, probably due to uneven distribution of PPV in aerial plant tissues (Adams et al. 1999).

Plum pox virus (PPV) was detected in wild apricot and cultivated plum maintained in a germplasm collection in Kazakhstan using triple-antibody sandwich (TAS-) ELISA format and IC-RT-PCR assays. The universal PPV-specific MAb5B was used as the secondary antibody and the primers P1 and P3 were employed for amplification of a 243bp fragment of the coat protein (CP) coding region. The 836bp fragment in the P3-6K1 region of the genome was amplified using the primers PC1 and PP3. Clarified plant extracts were incubated in microtubes precoated with the PAbA1PPV. The IC-RT-PCR reaction was carried out providing the conditions essentially as for RT-PCR assay. The PPV-specific 243bp fragment and the 836bp product were amplified from samples using RT-PCR assay. In several samples, the 243bp product appeared as weak

ethidium bromide-stained band. IC-RT-PCR assay targeted the PPV CP region, allowing the amplification of 243 bp fragment in nine wild apricot accessions, including eight ELISA-negative samples and one ELISA-positive ASR2. RFLP analysis of the amplified 243 bp product following treatment with endonucleases *AluI* and *RsaI* was performed in plum and apricot samples. An amplified 836 bp cDNA fragment derived from the P3-6K1 coding region of both plum and apricot isolates had restriction profiles typical of strain D. Nucleotide identities of 99–100% were observed for the 243 bp fragment of the Kazakhstan isolates when compared with the corresponding regions of strain D, and 94–95% identity with strain M (Spiegel et al. 2004).

Apple and pear cultivars are frequently infected by *Apple stem pitting virus* (ASPV) and *Pear vein yellows virus* (PVYV), which are closely related. These viruses were sap-transmitted to the assay host *Nicotiana occidentalis* ssp. *oblique*, which responded with characteristic symptoms early. The effectiveness of IC-RT-PCR assay was evaluated for its sensitivity, specificity, and reliability, as the standard RT-PCR format did not provide reproducible results. IC-RT-PCR was also unable to provide detection of the viruses to the desired level. A bacterially expressed protein employing ASPV CP gene as chimerical protein was used as an immunogen. Antiserum (647) produced against this protein was utilized for capturing the ASPV virions followed by RT-PCR procedure. When used as a trapping antibody, the antiserum (647) effectively trapped the virus particles and reacted specifically in immunosorbent electron microscopy (ISEM) and in Western blot. The antibodies positively reacted with ASPV- and PVYV-infected leaf extracts of *N. occidentalis* in PTA-ELISA format. The results indicated that the sensitivity of IC-RT-PCR assay employing antiserum 647 was high enough for its application for detection of ASPV in apple and related viruses in pear in a certification program for producing virus-free planting materials (Jelkmann and Keim-Konrad 1997).

The effectiveness of application of ribavirin (1- β -ribofuranosyl-1, 2, 4-triazole-3-carboximide) with antiviral activity on the elimination of *Plum pox virus* (PPV), causing sharka disease from *Prunus domestica* cultivar Cacanska shoots (grown under tissue-culture conditions), was assessed. The DAS-ELISA test and IC-RT-PCR assay were employed to assess the health status of the shoots two years after treatment with ribavirin. The percentages of PPV-free plants increased with increase in the concentration of ribavirin used for treatment. The DAS-ELISA test was unable to detect low concentrations of PPV present in the treated plants, and higher percentages of plants had to be considered as PPV-free. However, IC-RT-PCR assays showed that only 15.38% and 16.5% of plants treated with 40 and 60 mg L⁻¹ of ribavirin, respectively, were PPV-free, whereas 76.9% and 100% of treated plants were indicated to be virus-free by the results of DAS-ELISA tests. The results clearly revealed the higher level of sensitivity of IC-RT-PCR assay, facilitating the detection of low virus titers in plants treated with the antiviral chemical. The results of IC-RT-PCR assay could be relied upon for the programs aiming to produce virus-free stocks in vitro (Paunović et al. 2007).

Immunocapture (IC-) RT-PCR assay was applied for the detection of *Citrus tristeza virus* (CTV), the citrus decline strain. This format combines the specificity of PCR and simplicity of ELISA test and consequently sensitivity of detection was enhanced significantly. The sequences of the CP gene of CTV strains were used to design the primers and fluorescent probes. Intensity of fluorescence was assessed after performing PCR amplification, instead of electrophoretic analysis, after carrying out PCR amplification. The IC-RT-PCR assay could detect CTV strains in all ELISA-positive samples and also in additional 20% of the samples that were ELISA-negative, indicating the greater

sensitivity of this protocol (Nolasco et al. 1997). In a later investigation, primers corresponding to both ends of the CP gene were designed for use in the IC-RT-PCR assay for the detection of CTV in planting materials. The extracts from the bark tissues of infected citrus plants were tested. The presence of CTV was detected in all samples collected from orchards in the coastal regions of Croatia-Montenegro and Albania (east Adriatic region), indicating the sensitivity and specificity of IC-RT-PCR format. Single-strand conformation polymorphism (SSCP) analysis revealed the coexistence of different genomic variants within isolates of CTV. The results suggested that mixed infections due to variants might result in variation of biological characteristics of the isolates. Regardless of absence of visible symptoms in field trees, severe CTV variants appear to be widespread and present for a long time in the Adriatic region, making it a reservoir of severe strains of CTV (Cerni et al. 2009).

Grapevine plants are infected by several virus diseases, of which grapevine leafroll disease complex caused by genetically distinct viruses designated *Grapevine leafroll-associated virus 1-9* (GLRaV-1-9), was found to be economically most important. These viruses could be detected by PCR assays. Immunocapture (IC-) RT-PCR procedure was applied for efficient and sensitive detection of *Grapevine leafroll-associated virus 1* and 3 (GLRaV-1 and -3) by using specific primers. The presence of these two viruses was detected both in infected grapevine plants and infective mealy bug (*Planococcus ficus*) (Acheche et al. 1999). In another investigation, specific primers were designed based on the sequences of conserved heat shock protein (HSP 70) region of Closteroviruses for the detection of GLRaV-1. No amplification occurred in extracts of grapevine tissues infected by GLRaV-2, -3, and -4, indicating the specificity of the primers for GLRaV-1. This protocol was about 125 times more sensitive than ELISA test (Sefc et al. 2000).

The usefulness of IC-RT-PCR assay for the detection of other viruses infecting grapevines has been reported. *Arabis mosaic virus* (ArMV) and *Grapevine fan leaf virus* (GFLV) were detected simultaneously by IC-RT-PCR procedure with higher level of sensitivity and specificity. A single pair of degenerate primers designed from the sequences coding for movement proteins of the target viruses was employed in the procedure developed in this investigation. The IC-RT-PCR format was 10 times more sensitive than ELISA tests (Wetzel et al. 2002). Isolates of *Grapevine virus A* (GVA) belonging to *Vitivirus* (*Flexiviridae*) were detected and differentiated based on the type of symptoms induced in the indicator host *Nicotiana benthamiana* inoculated by mechanical transmission. DAS-ELISA test detected GVA in 14.2% of the grapevine samples tested. Using RT-PCR or IC-RT-PCR formats, a fragment of 430bp of the coat protein (CP) gene was amplified from infected plant extracts by employing the primer pair H587/C995. The identity of the virus isolates could be established by cloning and sequencing of amplicons, which showed that GVA isolates shared 100% nucleotide homology with each other and they were identical at a molecular level (Misbeh et al. 2007).

ELISA formats have been extensively applied for the detection of several viruses in planting materials; however, the levels of sensitivity for detection of certain strains of viruses that are present in low concentrations, especially in dormant trees, were not found to be satisfactory. In such cases, PCR-ELISA (PCR-microplate hybridization) combination was effective and more sensitive in detecting virus strains that were undetectable by standard ELISA format. PCR-ELISA combination was employed for the simultaneous detection of *Prunus necrotic ringspot virus* (PNRSV) and *Apple mosaic virus* (ApMV). Multiple alignments of PNRSV and ApMV CP genes were made to select PCR primers in the regions conserved between two viruses. Virus-specific

oligonucleotides were used as capture probes in the PCR-ELISA method. The selected primers were effective for the detection of both PNRSV and ApMV, as indicated by the analysis of a range of isolates of both viruses. Simultaneous application of the specific capture probes of both viruses resulted in the improvement of levels of sensitivity of detection of PNRSV and ApMV by PCR-ELISA combination (Candresse et al. 1998). Detection of *Plum pox virus* (PPV), *Cherry leafroll virus* (CLRV), and *Citrus tristeza virus* (CTV) could be effectively accomplished by using PCR-ELISA combination (Olmos et al. 1997; Rowhani et al. 1998). *Grapevine fan leaf virus* (GFLV) transmitted by the nematode vector *Xiphinema index* is one of the economically important viruses with the potential for ruining grape production. *Chenopodium quinoa*, the assay host plant, was inoculated by sap transmission for rapid multiplication of the virus. GFLV was purified from *C. quinoa* and the antiserum positively reacted with Tunisian grapevine samples in DAS-ELISA tests. Oligoprobe-RT-PCR was employed for the detection of GFLV in ELISA-positive samples. The assay amplified a 606bp region of GFLV CP gene sequence. PCR products amplified by H2042 and C2647 primers were digested with endonuclease *AluI*. Two strains of GFLV were precisely identified based on the restriction profiles. RT-PCR-RFLP combination of techniques has the potential for providing reliable data for epidemiological and resistance-breeding investigations (Fattouch et al. 2005).

The TitanTM one-tube RT-PCR System (Boehringer Mannheim, Germany) was applied as per the manufacturer's recommendations, using the primer pair ASGV4F/ASGVR for the detection of *Apple stem grooving virus* (ASGV). The ASGV viral replicase gene sequences were directly amplified from diluted plant sap of either ASGV-infected *Chenopodium quinoa* (assay host) or sap from leaves or bark tissues of apple. The RT-PCR system was used for the first strand synthesis and a mixture of *Taq* and PWO DNA polymerase for the PCR step. The RT-PCR products were hybridized with both a biotin-labeled capture probe linked to streptavidin-coated microtitre plate and a digoxigenin (DIG-) labeled detection probe. The complex was detected with an anti-DIG-conjugate-labeled with alkaline phosphatase. It was possible to detect as little as 400fg of ASGV in plant tissue extracts spiked with purified virus preparation. Using the protocol developed in this investigation, the primers ASGV4F/ASGV4R specifically amplified the virus in ASGV-infected apple trees from different locations. There was no signal when the amplification products obtained from primers targeting viral coat protein (CP) region of ASGV genome or with primers specific for *Apple chlorotic leaf spot virus* (ACLSV) and *Apple stem pitting virus* (ASPV) were used. The diagnostic procedure employed in this investigation combined the power of PCR to increase the number of copies of the target gene sequence, the specificity of DNA hybridization, and the ease of colorimetric detection and sample handling in microplates. This protocol is suitable for large-scale application in indexing planting materials as required for certification programs, since about 100 samples could be processed simultaneously in one microplate (Marinho et al. 2003).

Detection of *Potato leafroll virus* (PLRV) directly in dormant potato tubers by ELISA was found to be unreliable. Furthermore, performing ELISA tests on leaf extracts of sprouted tubers was labor-intensive and required at least 5 weeks to obtain results. A gel-free reverse-transcription (RT-) based fluorogenic detection method was therefore designed for PLRV detection in dormant potato tubers. A PLRV sequence-specific oligonucleotide (Roche Molecular Systems Inc., CA) containing a 5'-terminal reporter fluorescein and a 3'-terminal rhodamine "quencher" was specifically degraded during

amplification, resulting in a relative increase in reporter-associated fluorescence. This system was coupled to immunocapture (IMC) of PLRV from tuber sap by paramagnetic beads coated with an antiserum against the virus. The addition of cell-wall-degrading enzymes, cellulose, and macrozyme to tuber sap was essential to make detection of PLRV possible on tubers after a storage period. By combining IMC with RT-PCR, the detection limit of PLRV in tuber sap was at least 100 times lower compared to conventional ELISA test. Another advantage of IMC/RT-PCR over ELISA test is the possibility of assessing the intact virus, whereas ELISA tests give positive results for the presence of virus protein. The IMC/RT-PCR format was found to be fast and easy to perform and also robust. It showed potential for development into a fully automated system requiring only minimum laboratory manipulations. With this assay procedure, the inspection time of seed potatoes for PLRV could be reduced from 5 weeks to 1 day (Schoen et al. 1996).

Accurate and rapid methods of detection of strains of *Potato virus Y* (PVY) in dormant potato tubers are primarily required for the production of virus-free and high-yielding seed tubers. Although ELISA tests were adopted widely for virus detection, the level of sensitivity of ELISA formats was considered as a limiting factor. An immunocapture (IC) step prior to RT-PCR concentrates virions present in the dilute plant extracts, resulting in enhancement of detection sensitivity. The comparative efficiency of DAS-ELISA and one-step immunocapture (IC-) RT-PCR assay for the detection of PVY was assessed. Both methods detected all isolates tested and showed sensitivities around the expected detection levels attained by them. DAS-ELISA detected PVY up to 10 ng mL^{-1} ; IC-PCR provided a 1000-fold increase in sensitivity over that of DAS-ELISA test (Fig. 7.12). The combination of PCR and ELISA procedures was employed to detect the amplicons generated by PCR amplicons, followed by their adsorption on a microplate wells. The IC-PCR mixture was diluted 200-fold into microplate well and PCR-ELISA was performed to obtain absorbance values from 100 fg mL^{-1} of virus for the IC-PCR product. The IC-PCR-ELISA procedure offered an overall 100,000-fold increase in the sensitivity over DAS-ELISA test. The purified PVY from tobacco extract

Figure 7.12 Comparative levels of sensitivity of DAS-ELISA, IC-PCR and IC-PCR-ELISA techniques for the detection of *Potato virus Y*. IC-PCR-ELISA was more sensitive than other two techniques tested. Source: Varveri (2000). Reproduced with the permission of Springer Science, Heidelberg, Germany.

was detectable at 100 fg mL^{-1} and PVY was detected in potato sample at a dilution endpoint of 10^{-7} equivalent to 1 ng tissue. Furthermore, this highly sensitive procedure coupled with the print-capture (PC) modification to avoid specific sample preparation was found to be a most practical and useful tool for the detection of PVY in plant samples as well as in single aphid vector of PVY (Varveri 2000). A multiplex assay for the detection of *Tobacco rattle virus* (TRV) and *Potato mop-top virus* (PMTV) in potato tubers was developed by combining PCR with tube fluorescent product detection (TaqMan®). This protocol could be employed in place of two separate assays (an RT-PCR for TRV and an ELISA for PMTV). Forty isolates of TRV and PMTV could be reliably detected with high sensitivity (100–10,000-fold). In addition, the IC-RT-PCR assay offered the advantages of reduction in contamination and elimination of electrophoresis step, in addition to time and cost savings of post-PCR manipulations as compared to standard RT-PCR format (Mumford et al. 2000a).

Potato mop-top virus (PMTV), the type member of the genus *Pomovirus*, causes symptomless infections, making detection and identification of the causal virus difficult. PMTV has a three-partite, single-stranded RNA genome constituted by RNA-1, RNA-2, and RNA-3. The coat protein (CP) gene and read-through domain of RNA-2 and 8K gene and 3'untranslated region of RNA-3 were characterized from 37 PMTV isolates detected in potato tubers from field-grown plants in Finland and a screen house in Latvia. Sequencing and RFLP analysis of PCR amplicons indicated that the majority of isolates infecting tubers comprise restrictotypes RNA-2II and RNA-3B. The infections in 5 lots of 100 asymptomatic minitubers were tested by DAS-ELISA and IC-RT-PCR assays. Fourteen tubers were positive for both assays. These minitubers were grown from in vitro plants of cultivar Saturna. Analysis of PMTV in 37 naturally infected potato tubers revealed 2 distinguishable types of RNA-2 and RNA-3. The combination of RNA-2II and RNA-3B was more common than any other combination, and comprised the typical genomic composition of PMTV strains infecting potato in Finland. The genetic diversity of PMTV was largely due to the existence of two alternative types of RNA-2 and RNA-3. Indexing tubers for PMTV with anti-CP antibodies or using CP gene-specific primers in IC-RT-PCR assay was evaluated for reliable and sensitive detection of PMTV in dormant seed tubers, which were mostly asymptomatic. By pooling 50 sprouts in one sample, large-scale indexing of tuber lots by IC-RT-PCR with higher detection sensitivity could be achieved (Latvala-Kilby et al. 2009).

The detection of plant viruses in cultivated plants as well as in weed plants present in the field and adjacent areas may be useful to reduce the incidence of virus diseases in the principal crops. Plants belonging to 21 different weed species were inoculated with *Potato virus Y* (PVY) by aphids and sap inoculation. DAS-ELISA and IC-RT-PCR assay were employed for detecting PVY in the inoculated weed plants. The presence of PVY in *Erodium cicutarium*, *Geranium pusillum*, *Lactuca serriola*, and *Lamium purpureum* was detected by ELISA test. IC-RT-PCR tests performed on *G. pusillum* and *L. purpureum* failed to detect PVY directly, but PVY could be detected by IC-RT-PCR only in samples picked from tobacco plants back-inoculated with the inoculum of PVY from *G. pusillum* and *L. purpureum*. The failure of IC-RT-PCR assay in detecting PVY in these two weed species might be associated with the difficulty in obtaining quality templates for amplification (Kaliciak and Syller 2009).

Potato virus Y (PVY), considered a serious problem for the seed potato industry, has a maximum allowable infection level of 2% in certified seed tubers. The emergence of genetically recombinant and serologically distinct strains of PVY led to the development

of diagnostic assays to determine strain identity and to detect mixed strain infections more easily, sensitively, and precisely. An assay procedure incorporating the advantages of ELISA and multiplex RT-PCR assay was developed for detection of PVY in single or mixed infections. The virus titer was enhanced by ELISA and then virions were lysed by heating to release the viral RNA for the action of reverse transcriptase. The cDNA product was used as the template for detection of PVY infection by multiplex PCR format, eliminating the need for RNA extraction and handling. The IC-RT-PCR assay was more sensitive in detecting PVY in infected plant sap than multiplex RT-PCR or ELISA alone, while retaining the ability to differentiate strains of PVY that infected potato crops. The IC-RT-PCR protocol developed in this investigation was found to be particularly useful for potato seed tuber certification and diagnostic laboratories as a confirmatory test in conjunction with ELISA tests (Mallik et al. 2012).

Garlic crops are commonly infected by *Onion yellow dwarf virus* (OYDV) along with other viruses belonging to the genera *Potyvirus*, *Carlavirus*, and *Alexivirus*. In order to identify garlic isolates of OYDV-G, causing yellow stripes in garlic plants, a PAb antiserum was used in indirect ELISA format for the detection of OYDV-G in infected plant tissues. IC-RT-PCR assay was performed using the one-tube single-step method to confirm the specificity of virus detection. The virions of OYDV in infected garlic tissues and purified preparations were immunocaptured by specific OYDV-IgG, resulting in the release of viral RNA for use as the template when primers capable of amplifying the central region of OYDV CP gene were employed. A single fragment of c. 601 bp was amplified and recognized as a single band following agarose gel electrophoresis and staining with ethidium bromide. No amplification in extracts from healthy plants was observed. The distribution of OYDV in garlic plants was studied. OYDV concentration was low in young apical leaves and increased up to sixth leaf below the apex. OYDV titer was higher in older leaves compared with apical leaves. Cloves of garlic were found to be more suitable for detection of OYDV than leaf initials of the dormant plantlets (Mahmoud et al. 2007).

7.2.4 Real-Time PCR Assay

Real-time PCR assay overcomes the limitations of conventional PCR format. PCR products are detected by real-time PCR as the reaction is progressing, and therefore post-PCR steps can be avoided. Real-time PCR assay using specific instruments and fluorescent probes provides the advantage of combining the amplification, detection, and quantification of target DNA fragments in a single step. Specific methods employ oligonucleotide probes labeled with a donor fluorophore and an acceptor dye (quencher) that produce a light signal according to the fluorescence resonance energy transfer (FRET) chemistry. The specific methods are TaqMan, molecular beacons, and scorpion PCR procedures. Nonspecific methods involve the use of dyes such as SYBR Green I that emit fluorescent light when intercalated into ds-DNA. Fluorescence is increased in proportion to the amount of total ds-DNA present in the reaction. Real-time PCR permits the increase of specific PCR amplicons to be monitored during successive amplification cycle. A pair of PCR primers and an internal hybridization oligonucleotide probe provided dual specificity. TaqManTM (PE Biosystems) chemistry utilizes the 5' → 3' nuclease activity of *Taq* DNA polymerase to cleave specific probe which is labeled with a 5' reporter (FAM) and 3' quencher (TAMAR) fluorescent dye during strong elongation of target sequence. A detectable fluorescent signal is generated during amplification.

The PCR assay involves annealing of the probe to a complementary strand of an amplified product, followed by cleaving of the probe by *Taq* polymerase during extension of one of the primers and the dye molecules are displaced and separated. After separation, the electronically excited reporter cannot be suppressed by the quencher dye. This leads to variation in the green emission intensity, depending on the concentration of PCR amplicons in the reaction. The PCR cycle number at which the fluorescent signal (emission) exceeds a certain background fluorescence level is known as the threshold cycle (Ct), and is directly proportional to the amount of target DNA present in the sample. Fluorogenic probes may be labeled with different distinguishable reporter dyes to amplify and detect two or more distinct sequences in a single PCR reaction tube without the need for melting curve analysis. Real-time PCR systems are fully automated with “closed tube” product detection, eliminating the risk of cross-contamination to the maximum extent. Another advantage of real-time PCR assay is the possibility of testing as many as 96 samples at a time without the need for post-PCR manipulations. However, the requirement of expensive fluorescent probes and instruments limit the feasibility of using the real-time PCR procedure in many laboratories (Belgrader et al. 1999). Real-time PCR technique has also been applied for the detection of fungal and bacterial plant pathogens in seeds and propagules.

Real-time PCR assay was shown to be very efficient and precise in detecting grapevine viruses in planting materials in Italy. A 1157 bp fragment of *Grapevine fan leaf virus* (GFLV) RNA-2 coat protein gene was amplified. A fluorescent scorpion probe based on the highly conserved CP region was employed for the detection of GFLV (Finetti-Sialer and Ciancio 2005). Different isolates of *Grapevine leafroll-associated virus 1, 2, 3, 4, and 9* (GLRaV-1, -2, -3, -4, and -9) were collected from South Africa, Europe, Australia, Asia, Latin America, and the USA. TaqMan® probes and primers that targeted the regions with 100% sequence identity to the GFLV isolates were designed. Real-time TaqMan® and conventional RT-PCR assays were compared for their efficiency in detecting GLRaVs in purified total RNA and crude extracts from test plants. TaqMan® RT-PCR format was more sensitive than the conventional one-step RT-PCR for detecting different isolates of GLRaV-1, -2, -3, -4, -5, and -9 in purified total RNA preparations and also in crude extracts of infected grapevine tissues from different locations. TaqMan® real-time RT-PCR format provided sensitive, reliable, and specific detection and differentiation of the isolates of grapevine leafroll viruses (Osman et al. 2007).

Mixed infections of grapevines by viruses and phytoplasmas causing grapevine yellows disease (GYs) became a serious threat to grapevine production in Italy. A method was developed for multiple detection of *Grapevine leafroll-associated virus 1* and *2* (*Ampelovirus*) and *Grapevine virus A* (GVA) (*Vitivirus*) as well as Flavescence dorée (FD) and Bois noir (BN) phytoplasmas using the same crude extract as template. Real-time RT-PCR assay was applied for the detection of FD, while real-time nested PCR assays following RT-PCR was used for detection of BN, GLRaV-1 and -3, and GVA. The sap was prepared by semi-automatic maceration requiring minimal time and effort, consisting of a tissue grinding step in carbonate buffer and boiling step in glycine buffer. Real-time RT-PCR for FD phytoplasma detection was five orders of magnitude more sensitive than RT-PCR method used previously. For the detection of BN, the real-time RT-PCR assay required a nested step to achieve high sensitivity because of possible low concentration of the template in the host plant tissue. The TaqMan fluorogenic assay developed for the detection of FD and BN was optimized for GLRaV-1, -2, and -3 and GVA detection by designing a real-time nested PCR format

following a one-tube RT-PCR. As grapevine viruses had RNA genomes and were strictly localized to the phloem (as for phytoplasmas), sampling could be done from the same tissue and RT-PCR allowed use of the same tissue and extent without the need to perform separate nucleic acid extractions. The real-time nested PCR was more sensitive than ELISA and real-time RT-PCR assays previously employed for virus detection (Margarita et al. 2009).

Infected budwood is considered as the primary source of inoculum for the spread of *Citrus tristeza virus* (CTV) over long distances or to different countries, and natural biological vectors (aphids) are responsible for the secondary spread of the disease. TaqMan real-time RT-PCR assay was shown to be effective in detecting and quantifying CTV in plant materials using purified RNA targets or coupled to tissue print and squash procedure. In addition, the efficacy of DAS-ELISA and IC-RT-PCR assays was determined using purified RNA and compared with real-time RT-PCR format. The detection limit of ELISA was $1:10^3$, whereas IC-RT-nested PCR format could detect CTV targets up to 1.5×10^6 . Real-time RT-PCR assay was the most efficient in detecting CTV in field-grown trees. Of the 432 trees tested, 235 were found to be CTV-positive for tissue-print ELISA format. The results of tissue-print ELISA were confirmed by the conventional and tissue-print real-time PCR formats. Tissue-print ELISA indicated the differences in the number and intensity of immunoprecipitates localized in vascular area of imprints. Real-time RT-PCR assay was effective and efficient in detecting and quantifying CTV isolates from different hosts and origins. With this protocol, it was possible to consistently detect as few as 17 targets of purified CTV transcripts. The sensitivity of real-time RT-PCR assay was 1000 times higher than IC-RT-nested PCR and 10^6 times higher than the ELISA test. The quantitation limit ranged from 1.7×10^2 to 1.7×10^9 transcript copies. The tissue-printing and squash real-time RT-PCR formats exhibited high sensitivity, specificity, feasibility, and reliability for detection and quantification of CTV in immobilized plant materials. The results of the assay could be useful for epidemiological investigations (Bertolini et al. 2008).

The severe isolates of *Citrus tristeza virus* (CTV), including seedling yellows (SY) and/or stem pitting (SP) in grapefruit or sweet orange, are a major threat to the citrus industry worldwide. CTV isolates are composed of a population of sequence variants resulting from the error-prone nature of RNA polymerases, repeated inoculations of field trees by aphid vectors carrying different CTV variants, frequent recombination events between diverged sequences, and different selection pressures. Some CTV populations have a predominant sequence and a pool of closely related variants and others contain highly divergent variants; their ratio could alter the biological properties of the isolates. The precise identification of the CTV variants was accomplished by quantitative real-time RT-PCR, using a general primer set and three TaqMan-locked nucleic acids (LNAs) probes targeting sequences characteristic of severe, mild (nonSY, nonSP) and T36-like isolates. Specific amplification occurred in fresh or silica-desiccated CTV-infected samples, and all isolates except one reacted with one or more probes. Detection in fresh tissues was generally more suitable than in desiccated tissue. Specificity of the product amplified was checked by melting curve analyses and by agarose gel electrophoresis. For each sample, the melting curve showed a single peak, indicating a specific PCR product with no significant primer-dimer or nonspecific amplification products. Electrophoresis analysis confirmed amplification of a single DNA species for 186 bp for most isolates or 204 bp for T36-like isolates. Standard curves using RNA transcripts homologous to the three probes allowed a reproducible quantitative assay, with a wide

dynamic range of detection starting with 10^2 copies. RT-PCR assay with homologous and heterologous transcript RNA mixes demonstrated that each probe reacted only with its cognate sequence which was detected even at ratios below 2.5%. Analysis of 56 pathogenically distinct CTV isolates from 20 countries showed that mild isolates reacted with mild probe, whereas severe SP and SY isolates reacted with the severe SP or T35-like probes and often with the second probes. This protocol included three separate real-time RT-PCR reactions (one with each TaqMan LNA probe) and was found to be more rapid, sensitive, and specific than previously used methods. This method enabled estimation of the ratio of different genotypes of CTV present in infected trees in different locations (Ruiz-Ruiz et al. 2009).

The establishment of quarantine and certification programs is vital for avoiding the entry of and preventing materials infected by severe strains of *Citrus tristeza virus* (CTV) being planted to maintain and sustain zero-tolerance policies in all citrus-growing countries. In order to develop sensitive, specific, and reliable CTV-detection methods, tissue-print (TP) real-time RT-PCR assay was compared with the validated TP-ELISA format using CTV-specific MABs 3DF1 and 3CA5 for CTV detection. As there could not be any perfect diagnostic test with no false-positive and false-negative results, the diagnostic parameters of a technique (sensitivity, specificity, and likelihood ratios (LRs)) were calculated to characterize the efficacy of a diagnostic test. Samples (1395) from healthy and CTV-infected nursery and mature trees were analyzed by both methods. The total agreement between the detection methods was quite high. The diagnostic parameters of each technique were evaluated in a second test involving 658 *Citrus macrophylla* nursery plants. For TP-ELISA, a sensitivity of 0.8015, a specificity of 0.9963, and a positive and negative likelihood ratio of 216.42 and 0.199, respectively, were estimated. For TP real-time RT-PCR, a sensitivity of 0.9820, a specificity of 0.8519, and a positive and negative likelihood ratio of 6.63 and 0.021, respectively, were recorded. These comparative estimates indicated that TP real-time RT-PCR was the most sensitive technique and could be employed to monitor the sanitary status of commercial citrus trees and assist in the prevention of CTV disease spread in the nursery blocks. The combination of both techniques could accurately substitute for the bioindexing method using Mexican lime plants for detection of CTV, which previously required a long time to provide the results (Vidal et al. 2012).

The exchange and transport of plum plant materials for vegetative propagation has been the principal mode of dispersal of *Plum pox virus* (PPV). The presence of PPV in planting materials has to be tested in all kinds of planting materials intended for distribution to farmers and germplasm exchange. Detection protocol for PPV was developed for large-scale testing of field-grown peach trees (*Prunus persica*). Crude supernatants were obtained for use in a direct real-time PCR (drtPCR) procedure. The leaves from peach trees were macerated in a specially prepared buffer, referred to as direct pathogen extract buffer. Specific TaqMan primers and probes were designed for PPV detection: two sets specifically to PPV-D and PPV-M strains individually, and one for universal detection of PPV strains D, M, C, EA, and W. Using *Prunus* spp. tissue infected with 30 known fruit tree viruses, the universal primer and probe set correctly identified PPV-infected and PPV-free samples with no nonspecific cross-reaction. A threshold cycle value of 36 was suggested as the maximum threshold to declare a sample positive for PPV, based on endpoint analysis of the drtPCR reaction. Comparative efficacy of drtPCR and ELISA for detection of PPV in 12,200 field samples was assessed. The results showed that drtPCR assay was approximately 100- to 1000-fold more sensitive

than ELISA test and drtPCR assay could detect PPV at earlier stage of infection than ELISA, facilitating eradication of infected plants and identification of infected planting materials (Kim et al. 2008).

Nursery plants and planting materials are generally commercialized in winter, during the dormant period when the virus titer is low. Use of diagnostic methods which were not sensitive enough to detect the low concentrations of *Plum pox virus* (PPV) led to the certification of infected planting materials as virus-free and consequent introduction of PPV into new areas. A real-time multiplex PCR assay was applied for the detection and differentiation of PPV strains. SYBR Green I employed in this simple procedure was inexpensive and provided more reliable results rapidly, since the use of electrophoresis was not needed (Varga and James 2005). In a later investigation, four sample preparation methods, namely dilution, spot, squash, and tissue-print coupled with real-time RT-PCR assay, detected all described PPV strains using either TaqMan or SYBR Green protocols. The dilution and spot real-time RT-PCR methods were slightly more sensitive than the tissue-print and squash methods (Fig. 7.13). As PPV was unevenly distributed in infected woody hosts, the use of plant extracts was more reliable than single tissue-print or squash procedures. The dilution and spot procedures had the same detection limits, but they were 10 and 100 times more sensitive than cooperational-PCR (Co-PCR) and indirect DAS-ELISA techniques, respectively. The nylon and Whatman membranes were found to be suitable for immobilizing target nucleic acids. Spot real-time RT-PCR was validated as a reliable technique for detection of PPV in plants during the dormant period. Adult *Prunus* trees (405) were evaluated for their health status using different techniques with samples collected in the winter. Of the 405 trees tested, 201 showed symptoms of sharka disease in the following spring, indicating the prevalence of 49.6% infection by PPV. The highest sensitivity of PPV detection in winter was provided by conventional real-time RT-PCR which detected PPV in 97.5% of trees that developed sharka symptoms, the false negatives (5 of 405) being extremely low. Spot real-time RT-PCR format also had high sensitivity (93.6%), followed by IC-RT-PCR (91.5%), and indirect DAS-ELISA (86.6%). Spot real-time RT-PCR was compared with validated indirect-ELISA format in a large-scale analysis of 2919 *Prunus* samples by using the same plant extracts for both tests. Similar corroborating results were obtained from both tests in 90.8% samples (Table 7.8). The results validated the use of immobilized PPV targets and spot real-time RT-PCR as a screening method for large-scale analysis, which might facilitate production of PPV-free *Prunus* plants (Capote et al. 2009; Section 7.5.4).

Viruses infecting potatoes have been detected by RT-PCR assays for which different extraction procedures, specific RT-PCR reagents, amplification protocols, and/or virus-specific primers have been used. Standardized RT-PCR procedures were developed and validated for the detection of eleven viruses, namely *Alfalfa mosaic virus*, *Impatiens necrotic spot virus*, *Tobacco rattle virus*, *Tomato spotted wilt virus*, *Potato leafroll virus*, *Potato mop-top virus*, *Potato virus A*, *Potato virus M*, *Potato virus S*, *Potato virus X*, and *Potato virus Y* and one viroid *Potato spindle tuber viroid*. Nucleic acids were extracted from infected and healthy potato plant tissues using a modified procedure of Dellaporta. One-tube RT-PCR format was used for amplification on employing virus-specific oligonucleotide primers and the amplified PCR products were resolved by electrophoresis in 1.5 agarose gel and stained with ethidium bromide. The RT-PCR protocol provided a robust, convenient, cost-effective, and sensitive detection of 11 potato viruses, useful for potato seed tuber certification agencies and commercial diagnostic laboratories.

Figure 7.13 Detection of *Plum pox virus* (PPV) by real-time RT-PCR with (a) SYBR Green and (b) TaqMan chemistries, employing four direct sample preparation methods—dilution, spot, tissue-print, and squash methods—along with healthy GF305 peach seedlings as negative control. Dilution and spot real-time RT-PCR methods were slightly more sensitive than tissue-print and squash methods. Source: Capote et al. (2009). Reproduced with permission of International Microbiology.

Table 7.8 Comparison of levels of sensitivity and specificity of methods for detection of *Plum pox virus* (Capote et al. 2009).

Detection method	Sensitivity + SE ^a	Specificity + SE ^a
DASI-ELISA	0.866 ± 0.017	0.990 ± 0.005
IC-RT-PCR	0.915 ± 0.014	0.961 ± 0.01
Spot real-time RT-PCR	0.936 ± 0.012	0.980 ± 0.01
Conventional real-time RT-PCR	0.975 ± 0.010	0.892 ± 0.01

^a Standard error

The RT-PCR protocol involving the use of standardized conditions could detect and identify the O, European-N, North American-N, N:O, and NTN strains of PVY. The PSTVd-specific primers detected PSTVd in dry tomato tissue stored for over 30 years (Crosslin and Hamlin 2011). *Potato virus Y* (PVY) present in dormant potato tubers was detected by employing TaqMan real-time assay and its efficiency was compared with other diagnostic methods. Three pairs of primers and probes were designed and evaluated for their suitability to facilitate the real-time RT-PCR detection of PVY strain groups, including PVY^O, PVY^N, PVY^{N:O} (= PVY^{N-Wi}), and PVY^{NTN}. Among the primer and probe combinations tested, the combination of PVY-1 produced the lowest threshold cycle (Ct) value of 25.75. Various parameters including primer/probe combination, reaction volume, amplification cycles, and master mixes from different sources were adjusted for further optimization. The real-time RT-PCR was applied for the detection of PVY in dormant tubers of different cultivars and potato fields. Out of 1069 single-virus (PVY-) infected tubers tested, both RT-PCR formats detected PVY in 52 samples, ELISA on sprouts in 45 samples, ELISA on leaves in 54 samples, and visual observations in 53 samples. However, when the 61 multiple-virus-infected tubers were tested, both RT-PCR formats and ELISA test were found to be equally sensitive as they detected the viruses in both sprouts and leaves, giving similar number of positives. Nevertheless, real-time RT-PCR provided the advantage of offering results rapidly for large-scale application for detecting PVY in dormant potato tubers, whereas the grow-out test required 6–8 weeks to obtain results and remained the least-favored technique for the detection of PVY in dormant tubers (Singh et al. 2013).

7.2.5 Molecular Beacon

A novel fluorescence-based nucleic acid pathogen method of detection involves the use of a probe referred to as a molecular beacon, comprising a single-stranded DNA (oligonucleotides) with a stem-loop structure. The loop portion has a probe sequence that is complementary to a target sequence. The stem portion is formed by the annealing of the 5' and 3' arm sequences which are not related to the target sequence. A fluorescent moiety is attached to the 5' arm terminus, while a quenching moiety is attached to the 3' arm at the opposite end. The molecular beacon is added to the solution containing the target nucleic acid and the mixture is heated to 80°C, followed by cooling to 20°C. The arms associate to form a stem-loop conformation when there is no target molecule. Under this condition, the fluorescence emitted from the fluorophore is quenched by

fluorescence resonance energy transfer (FRET) via the quencher due to their close proximity to each other. On the other hand, if the target is present, the probe forms a hybrid with the target via its complementary sequence within the loop region, resulting in the displacement of the fluorescent moiety from the quenching moiety and leading to emission of fluorescent signal.

The emission of a fluorescent signal is only produced by molecular beacons when they hybridize with their complementary target nucleic acids. As the unhybridized molecular beacons do not fluoresce, there is no need to remove them from the reaction mixture. By tagging each molecular beacon with fluorescent moieties possessing different emission wavelengths, it is possible to employ multiple molecular beacons for detection of different targets. RT-PCR reaction may be performed with primers that amplify specific genomic sequences of interest, yielding targets complementary to their respective molecular beacons for subsequent detection. In addition, large number of samples up to 96 can be analyzed simultaneously, the efficiency paralleling that of RT-PCR and ELISA tests (Tyagi and Kramer 1996).

Cymbidium mosaic virus (CyMV) and *Odontoglossum ringspot virus* (ORSV), infecting orchids, were detected efficiently by employing the molecular beacon technique. Two pairs of primers were designed to target the RNA-dependent RNA polymerase (RdRp) genes and coat protein (CP) gene of CyMV and ORSV, respectively, for their simultaneous detection. RT-PCR was performed using the above primer pairs to amplify the genome targets from total RNA extracted from CyMV- and ORSV-infected *Oncidium* orchid leaves. 6-carboxyfluorescein (FAM) was used as a molecular beacon specific to CyMV, whereas ORSV was labeled with tetra-chloro-6-carboxyfluorescein (TET). The universal quenching moiety 6-carboxy-tetra methyl-rhodamine (TAMRA) was attached to the 3' ends of all molecular beacons employed. The detection limit of assay using molecular beacons was as little as 0.5 ng of viral RNA of both CyMV and ORSV simultaneously in 100 mg of coinfecting *Oncidium* orchid leaves. The tubes containing total RNA isolated from CyMV- and ORSV-infected leaves generated significant increases in fluorescence intensities upon the addition of both sets of molecular beacons. No fluorescence signal appeared in healthy control samples. The molecular beacon technique was found to be rapid and specific in providing sensitive detection of orchid viruses, and showed potential for screening plants for the production of virus-free plants by certification and quarantine programs and for selection of disease-resistant plants by screening germplasm collections (Eun and Wong 2000).

Strawberry vein banding virus (SVBV), belonging to the genus *Caulimovirus* (retroid virus), has a double-stranded circular DNA genome and is included as a quarantine pathogen by the European and Mediterranean Plant Protection Organization (EPPO/OEPP 1978). Biological indexing on indicator plants was the only method accepted by inspection services during certification procedures. It was necessary to develop a sensitive and rapid assay due to the limitations of bioindexing and immunoassays. An improved technique for the detection of SVBV in *Fragaria* spp. based on nucleic acid sequence-based amplification (NASBA) and real-time detection using molecular beacons (real-time NASBA) was developed. The coupling of NASBA and molecular beacons enabled a simultaneous amplification and detection of the specific amplicons in a sealed tube under real-time conditions. The NASBA assay was designed to amplify part of the RNA coding of the CP of SVBV. Variability within this region was determined among six different American and European isolates and the primers and molecular beacons were designed based on the conserved segments (431 bp) within this region.

The detection limit of real-time NASBA was 101 molecules of RNA per reaction in vitro, with no apparent reduction in sensitivity due to incorporation of molecular beacons into the NASBA system.

Real-time NASBA was employed for the detection of SVBV in 317 field-grown plants from the Czech Republic, the Slovak Republic, Poland, Latvia, and Italy. None of the strawberry plants was found to be infected by SVBV and the results were confirmed by a concurrent SVBV-specific RT-PCR assay. The assay was specific and sensitive for detection of SVBV and tested negative for the other common aphid-borne strawberry viruses, *Strawberry crinkle virus* (SCV) or *Strawberry mottle virus* (SMoV). The results of the NASBA assay were in good agreement with those of biological indexing. Reproducibility of the results throughout the year showed that the applicability of the assay might not be limited to the period of active plant growth. The real-time NASBA assay showed good potential for accurate, fast, and sensitive detection of *Strawberry vein banding virus* in strawberry plants. Real-time NASBA offers several advantages over standard PCR format such as reduction in contamination rates, nonrequirement of post-PCR manipulations, possibility of automation and high-throughput application of NASBA, and less expensive instruments. In addition, NASBA could be performed in standard ELISA format used commonly by several countries (Vašková et al. 2004).

7.2.6 Single-Strand Conformation Polymorphism Analysis

Differences in the genomic DNA may be determined reliably by employing single-strand conformation polymorphism (SSCP) analysis. When separated, the + and – strand of ds-DNA become metastable sequence-specific folded structures with distinct electrophoretic mobilities in nondenaturing polyacrylamide gels. Single nucleotide changes may be detected under such conditions (Magome et al. 1999). The SSCP analysis provided rapid results requiring less time than RFLP analysis and was particularly effective in detecting and differentiating serologically related strains of viruses, as in the case of isolates of *Beet necrotic yellow vein virus* (BNYVV) which could be assigned to A, B, or P groups (Koenig et al. 1995).

Apple stem grooving virus (ASGV) isolates from apple, European pear, and Japanese pear were found as at least two to four sequence variants within a single tree and were characterized by employing a combination of an IC-RT-PCR and SSCP analysis of the PCR products from ASGV-infected trees. Two to four bands were detected in samples from all trees, indicating ASGV existed as a mixture of sequence variants. The composition of sequence variants (the number of bands and their relative quantity) differed among leaf samples from different branches, showing that each sequence variant might be distributed unevenly within an individual tree. Since ASGV was spread only by graft transmission, sequence variation within a single tree might occur by means of successive accumulation of nucleotide substitutions into the pre-existing genome and/or by mixed infection of each sequence variant originally contained in the rootstock or scion by graft transmission. In contrast, the SSCP analyses of P-209 and Li-23-infected *C. quinoa* leaves showed only a single band in each isolate, indicating that the genomes of these isolates appeared to be homogenous. Repeated passages of these isolates by sap transmission changed the composition of sequence variants originally contained in ASGV isolates, indicating that some sequence variants rapidly multiplied and dominated, whereas other variants decreased to undetectable concentration in leaves of *C. quinoa* (Magome et al. 1999).

The SSCP analysis was applied for the detection and differentiation of isolates of *Citrus tristeza virus* (CTV). The CTV isolates collected from diverse locations were investigated to assess the differences in their coat protein (CP) gene sequences. The amplicons from CP genes of 17 CTV isolates after RT-PCR amplification were cloned and sequenced. Sequences of the clones showed sequence homology between 91.7% and 99.8%. After clone amplification and denaturation of PCR products, they were compared based on the results of SSCP analysis in 8% polyacrylamide gels. The patterns of 16 or 17 clones exhibited variations under two different electrophoretic conditions. The SSCP analysis with combination of two electrophoretic conditions and restriction of eight clones with *Eco9II* allowed discrimination between 21 of 22 CP gene clones selected for comparison. SSCP analysis, not dependent on the availability of full sequence data for comparison, was found to be rapid and inexpensive. In addition, the result of SSCP might be used as a sound basis for identification and differentiation of several genes or gene regions of viral genomes (Rubio et al. 1996).

Biologically characterized isolates (19) of *Citrus tristeza virus* (CTV) covering a wide range of symptom expression and geographic origin were compared by SSCP analysis of cDNA of the four 3' terminal genes, *p13*, *p18*, *p20*, and *p23*. There was no profile of any of the four genes that was conserved in all isolates within the biogroup. Many of the mild isolates of CTV (biogroups 0–2) showed just two DNA bands, whereas the most severe isolates (biogroups 4–5) usually showed four or more bands. The electrophoretic profile of cloned DNA fragments sometimes showed three instead of two bands, due to the presence of two stable conformations for one of the two strands. However, the presence of multiple DNA bands in the SSCP profile of an RT-PCR product generally indicated that the cDNA analyzed contained more than one sequence variant. The set of SSCP profiles of the four genes allowed identification of individual isolates, but no profiled characteristic of a geographic location was observed. Sweet orange plants singly inoculated with a mild or severe isolate yielded the SSCP profile characteristic of each isolate. On the other hand, the SSCP profile of plants successfully inoculated with both isolates (mild and severe) was a composite of the two individual profiles. The SSCP profile of singly inoculated plants remained constant, but the profile of doubly inoculated plants varied with time. Changes in the SSCP profiles of plants preinoculated with mild isolate T11 or T32 and challenge-inoculated with severe isolate T318 were monitored. The plants in which the p20 SSCP profile characteristic of T318 became predominant showed symptoms, whereas plants in which the predominant SSCP profile was characteristic of the mild isolate remained symptomless. The virulent RNA population usually out-competed and reached higher titer than the pre-existing mild RNA populations. The results indicated the usefulness of SSCP analysis to study the changes in the RNA populations of doubly inoculated plants and to monitor the effectiveness of cross-protection between mild and severe isolates of *Citrus tristeza virus* (Sambade et al. 2002).

7.2.7 Reverse-Transcription Loop-Mediated Isothermal Amplification

Loop-mediated isothermal amplification (LAMP) is a novel nucleic acid amplification procedure developed by Eiken Chemical Co., Tokyo, Japan. Because of its simplicity, rapidity, specificity, and cross-effectiveness, RT-LAMP method is likely to replace PCR-based assays. RT-LAMP technique is based on the principle of standard displacement reaction and stem-loop structure that amplifies the target with high specificity, selectivity, and rapidity under isothermal conditions, and this technique does not

require an expensive thermocycler. The amplification efficiency of LAMP method is extremely high due to continuous amplification under isothermal conditions, producing a large amount of the precipitate of magnesium pyrophosphate as a byproduct leading to turbidity. Using four specially designed primers that include six short sequences matching the target DNA fragment, the DNA is amplified under isothermal conditions within a short period of time. The reactions can be monitored unambiguously by detecting the turbidity, using an inexpensive turbidimeter. In addition, the higher amplification efficiency of the LAMP technique enables simple visual observation of amplification via the naked eye by using a UV-lamp in the presence of an intercalating dye such as SYBR Green I or ethidium bromide (Notomi et al. 2000; Parida et al. 2004). The reaction is carried out in a single tube by mixing of the buffer, primers, reverse transcriptase, and DNA polymerase, and incubating the mixture at 63°C for 60 min. The increase in the turbidity of the reaction mixture correlates with the amount of DNA synthesized. The measurement of turbidity is extremely simple and no expensive equipment is required for the LAMP procedure, as in real-time PCR format. In addition, the time required for the RT-LAMP assay is just 30 min compared with 3–4 h needed for RT-PCR based assays (Notomi et al. 2000; Parida et al. 2004).

Detection of *Japanese yam mosaic virus* (JYMV) in infected Japanese yam plants was achieved by employing reverse-transcription loop-mediated isothermal amplification (RT-LAMP) technique which was simple and provided results rapidly. Neither elaborate RNA extraction steps nor precise thermal cycling and gel electrophoresis was needed as in standard and other PCR formats. JYMV was effectively detected in leaves, propagules, and roots of Japanese yam plants. The intensity of turbidity determined using a turbidimeter indicated the virus concentration in the infected plant extracts (Fukuta et al. 2003). For the detection of *Potato virus Y* (PVY), a set of four primers matching a total of six sequences of CP gene of PVY was designed in such a way that a loop could be formed and elongated during DNA amplification. PVY CP complementary DNA clones were employed as templates and the LAMP reaction was optimized by adjusting the concentrations of $MgSO_4$, dNTPs, and Bst DNA polymerase. A positive reaction is indicated by the formation of a visible precipitate of insoluble magnesium pyrophosphate as a byproduct of LAMP reaction. Absorbance values recorded at 405 and 600 nm using a microplate reader and/or a spectrophotometer reflected the virus titer in the plant tissue samples. Assessment of turbidity visually and spectrophotometrically could save time and significantly reduce the cost of data analysis. The determination of comparative efficacy of the one-step RT-LAMP and two-step RT-PCR assays showed that both methods provided equally efficient detection of PVY in leaf and tuber samples, each one diagnosing PVY infection in 234 of 240 samples tested. The advantages of one-step RT-LAMP technique were the relative simplicity in reaction setup and detection of amplified products with high efficiency. In addition, isothermal conditions required for performing RT-LAMP analysis could be obtained easily using a water bath, whereas an expensive thermocycler would be needed to obtain the accurate temperature conditions required for RT-PCR assays. Furthermore, use of hazardous chemicals such as ethidium bromide for staining gels after electrophoresis as required for PCR-based assays could be avoided, and the positive reaction could be inferred by observing the formation of a precipitate in RT-LAMP assay (Nie 2005).

A one-step, accelerated reverse-transcription loop-mediated isothermal amplification (RT-LAMP) procedure was developed for the detection and identification of *Plum pox virus* (PPV). Six primers based on the sequences of a conserved region in the

C-terminus of the CP coding region of PPV were designed and employed in RT-LAMP assay. The isolates of five strains of PPV including the strains D, M, EA, C, and W were detected and precisely identified. The virus could be detected reliably in both herbaceous and woody host plant species infected by PPV. The relative sensitivity levels of RT-LAMP and real-time RT-PCR with SYBR Green I and melting curve analysis were evaluated using serially diluted total RNA extracts. RT-LAMP assay was as sensitive as the real-time RT-PCR formats except at lower template concentrations, when the latter technique gave more consistent results. A longer incubation period was required for detecting lower template concentration of PPV by RT-LAMP assay. The optimal temperature of incubation was 60°C for 30 min for successful detection of PPV by RT-LAMP procedure. RT-LAMP assay was found to be a highly sensitive and cost-effective tool with potential for large-scale application for assessing the disease incidence and restricting the subsequent spread of *Plum pox virus* (Varga and James 2006).

The RT-LAMP assay was developed for the reliable and sensitive detection of *Banana streak virus* (BSV), a significant constraint impacting banana production. Four primers matching a total of six sequences of the concerned ORF III polyprotein genes were designed. DNA extracts from field-infected banana plants were used as template for the detection of BSV. The LAMP assay could detect as low as 1 pg μL^{-1} template DNA. Test results of all field samples collected from different regions of South China showed that LAMP was found to be more sensitive than PCR assay. This relatively simple procedure could be applied for the detection of BSV in field-grown banana plants and showed potential for routine screening of tissue culture materials raised for the production of virus-free stocks (Peng et al. 2012).

Potato virus Y (PVY) exists in the form of many strains and recombinant variants with differing levels of virulence on potatoes. Potato seed certification systems operating in different countries require efficient methods for accurate identification and quantification of the strains of PVY. Immunoassays and RT-PCR assays have limitations that affect the cost and time required for diagnosis of PVY infection. Methods based on reverse-transcription (RT-) isothermal amplification (LAMP) of DNA facilitate fast, sensitive, and specific detection of target RNA. A closed-tube real-time RT-LAMP assay was developed for fluorescent detection of PVY in potato. A set of primers for RT-LAMP assay was designed by aligning 40 sequences of the coat protein genes of different isolates of PVY to amplify the conserved region of CP gene. The specificity of the designed primers was confirmed by amplifying RNA extracted from leaves of virus-free plants inoculated with PVY, *Potato virus M* (PVM), *Potato virus S* (PVS), and *Potato virus X* (PVX). The primers only amplified the expected amplicons from plants infected by PVY, but not from plants infected by other viruses tested. The RT-LAMP assay provided specific and sensitive detection of PVY in a single tube at 65°C. The closed-tube format eliminated the risk of carry-over contamination. The RT-LAMP format provided very fast detection of PVY in 11–30 min, depending on the virus concentration. Under the conditions of experimentation, the RT-LAMP assay was 1000-fold more sensitive than RT-PCR format. Further, RT-LAMP assay might be applied for quantitative or semi-quantitative estimation of viral RNA, as for real-time RT-PCR format. The effectiveness of RT-LAMP assay was equivalent to that of DAS-ELISA and RT-PCR techniques for testing field-grown potato plants. RT-LAMP assay combines the high-throughput advantage of DAS-ELISA test and sensitivity of RT-PCR format. RT-LAMP procedure therefore has the potential to become an alternative to methods currently employed for routine detection of *Potato virus Y* in potatoes (Przewodowska et al. 2015).

7.2.8 DNA Array Technology

DNA array technology is a promising multipathogen detection system, useful for detecting two or more pathogens (viruses) present in propagules. DNA technology aims to miniaturize traditional bioanalytical detection system so that hundreds of biomolecules with unique identity can be detected simultaneously in one single experiment. In a microarray platform (glass slide), thousands of diagnostic probes can be spotted and hybridized with labeled targets such as nucleic acids extracted from specimens and chemically modified with a fluorescent or other reporter (compound/molecule). DNA microarray provides a medium for hybridization of the known with unknown DNA samples based on base-pairing rules and automating the process of identifying the unknowns. Microplates or standard blotting membranes may be used in the assays, based on the size of the deposited sample spotted designated as microarrays (<200 µm in diameter) or macroarrays (>300 µm in diameter) (Wang et al. 2003; Morais et al. 2006). The microarray has been applied less frequently for the detection of plant viruses compared to fungal or bacterial pathogens infecting crop plants. The DNA arrays contain gene sequences from each target virus in a single assay. The microarray is exposed to fluorescently labeled cDNA from the sample to be tested, followed by scanning with a microarray scanner to detect the targets in the test samples. Commercial kits such as Qiagen are available, variously referred to as DNachip, Biochip, genechip, and gene array (Shi et al. 2003).

Compact discs (CDs) made from a 1.2 mm thick disc of polycarbonate (PC) plastic coated with a 100 Å reflective layer of aluminum, silver, or gold protected by a transparent polymeric layer were used to detect *Plum pox virus* (PPV) and also for the analysis of single nucleotide polymorphisms (SNPs) in PPV. Samples from different serogroups SER1, SER2, and SER3 of PPV were used in macroarray assay. Identification of virus types and SNP tests were carried out on polycarbonate CD. Samples of PPV type Dideron (D) were specifically hybridized with both universal (P21) and D-specific probes. On the other hand, type Marcus (M) hybridized with both universal and M-specific probes which implied a full score for discriminating different types of *Plum pox virus*. The match/mismatch ratio reached was 17 and 18 for type M and D, respectively. The results indicated that the CD array could be an effective alternative technique for rapid and reliable detection of plant viruses. The SNP analysis showed that SER1 samples hybridized with probes SNP3B and SNP1A and SER2 samples hybridized with SNP1B and SNP3A, while samples of SER3 specifically hybridized with SNP1B and SNP3B. The match/mismatch ratios were 3.7 and 4.5 for SER1 and SER3, respectively. On the other hand, SER2 was better scored with a match/mismatch ratio of 11.8. These values confirm the ability to analyze nucleotide polymorphisms which were associated with different serotypes within PPV type D. This investigation revealed the advantage of using compact disc (CD) surfaces as high-throughput screening platforms to perform a wide range of experiments for detection and differentiation of plant viruses and their strains (Morais et al. 2006).

The microarray technique was found to be effective in detecting *Potato virus Y* (PVY), *Potato virus X* (PVX), *Potato virus A* (PVA), and *Potato virus S* (PVS) in plants infected by individual or a mixture of viruses. Closely related viruses or strains of these viruses could be detected and differentiated even when the sequence identity was less than 80%. Sequence variants with greater than 90% sequence identity could be selected and distinguished by the microarray method. Discrimination of virus species within the same genus was also achieved and discrimination could be effected where the sequence

identity was less than 80%. The potyviruses PVY and PVA were effectively discriminated, as were the quite distinct strains of PVS (the ordinary and Andean). The results of microarray were in good agreement with those of ELISA format with equivalent sensitivity (Boonham et al. 2003).

Short synthetic single-stranded oligomers (40-nt) were used as capture probes instead of PCR products. Using a microchip array, *Potato virus X*, *Potato virus A*, *Potato virus S*, *Potato virus Y*, *Potato virus M*, and *Potato leafroll virus* were efficiently detected in both single and mixed infections. The oligonucleotide-based microarray was able to efficiently detect and differentiate the principal strains of PVY and PVS (Bystricka et al. 2005). Potato-infecting viruses *Potato virus Y* (PVY), *Potato leafroll virus* (PLRV), and *Cucumber mosaic virus* (CMV) were detected using nonradioactive microarray system. Oligonucleotide (70-mer) probes specific to the target virus were immobilized on nylon membranes. Total plant RNA extracts were used for cDNA and second-strand synthesis, employing an anchor primer sequence with random pentamers coupled at the 3' end. Subsequent synthesis by PCR using the anchor primer alone led to a relatively unbiased amplification of plant and viral RNAs. After chemically labeling the cDNAs, the product was used as a target in hybridization. CMV, PVY, and PLRV were detected by employing this protocol. Viral RNAs were amplified by a factor of 100–1000 and could therefore be detected in single and multiplex infections. The labeled target DNA hybridization was specific to the infecting virus and there was no cross-hybridization to probes for heterologous viruses. The limit of detection of the macroarray was similar to that of DAS-ELISA test. The macroarray protocol developed in this investigation was less sensitive by 10^3 and 10^5 times relative to conventional RT-PCR and real-time RT-PCR assays respectively (Agindotan and Perry 2007).

Multiple pathogen detection of 11 potato viruses and a viroid *Potato spindle tuber viroid* (PSTVd) was achieved by employing a macroarray procedure. The viruses commonly occurring in North America include *Alfalfa mosaic virus* (AMV), *Cucumber mosaic virus* (CMV), *Potato mop-top virus* (PMTV), *Potato leafroll virus* (PLRV), *Potato latent virus* (PotLV), *Potato virus A* (PVA), *Potato virus M* (PVM), *Potato virus S* (PVS), *Potato virus X* (PVX), *Potato virus Y* (PVY), and *Tobacco rattle virus* (TRV) for which seed tubers were tested for the presence of the virus(es) in potato seed tuber certification programs. Oligonucleotide probes (70-mer) and labeled targets were prepared in a random primer amplification method. Samples from 12 reference virus stocks and 36 field isolates from potato plants were analyzed. All eleven viruses were consistently detected by the macroarray procedure and the results were similar to those obtained with standard ELISA tests. Four isolates of PSTVd in mixed infections with one or more viruses were also detected in the array, although strong hybridization signals could only be obtained with viroid-specific primers in combination with anchored-random primers. Up to four viruses, or a viroid plus two viruses, were detected in individual plants with no apparent competition or inhibition. The macroarray procedure might compliment available diagnostic methods such ELISA, and holds promise in the reliable and sensitive detection of viruses in dormant and sprouted tubers. The cost-effectiveness of the macroarray approach for simultaneous detection of as many as 11 viruses and one viroid in infected potatoes could be an important factor when choosing diagnostic tests for large-scale application (Agindotan and Perry 2008).

A complementary DNA (cDNA) macroarray was developed for the simultaneous detection of 12 viruses infecting potatoes since there was cross-hybridization between

viruses in the previously available macroarray, making the interpretation of results difficult. In addition, the procedures required expensive tools such as an imaging system for chemiluminescence. Virus-specific capture probes and biotin-labeled target amplification were therefore used to enhance sensitivity and to reduce cross-hybridization. A suitable region in the viral genome was selected for each of following viruses to be detected: *Alfalfa mosaic virus*, *Cucumber mosaic virus*, *Potato acuba mosaic virus* (PAMV), *Potato leafroll virus*, *Potato mop-top virus*, *Potato virus A*, *Potato virus M*, *Potato virus S*, *Potato virus X*, *Potato virus Y*, *Tomato ringspot virus* (ToRSV), and *Tomato spotted wilt virus* (TSWV). The viruses and their respective cDNAs were cloned into plasmid vectors. Capture probes for each virus ranging from 290 to 577 bp were generated by PCR and immobilized on a nylon membrane. Total RNAs were extracted from plants infected by each virus and cDNAs were synthesized from the RNA extracts using a random 9-mer primer. Subsequently PCR reactions were performed, using one primer pair specific to each of the 12 potato viruses. During PCR, amplified cDNAs were labeled with biotin and used as a target for hybridization analysis on a macroarray membrane. Hybridization signals between capture probes for the 12 viruses and their respective target cDNAs were observed using chemiluminescent or colorimetric detection. Hybridization signals with capture probes were only detected when homologous virus targets were examined and no hybridization to healthy plant extract was observed, facilitating identification of each virus. For example, when an AMV-infected plant was used as template, PCR was performed using primer pair AMVF2/AMV1R and biotin-labeled cDNA was hybridized on a macroarray. Clear signals were observed in the positions of capture probes for AMV and there was no signal from other viruses in chemiluminescent detection, indicating the absence of cross-hybridization with any other viruses tested. The results of colorimetric detection were in complete agreement with those obtained using chemiluminescence detection, indicating that inexpensive colorimetric procedure could be used with no compromise in the sensitivity of detection. The microarray protocol was 5×10^2 to 4×10^6 times more sensitive than ELISA test and 5 to 5×10^4 times more sensitive than RT-PCR assay except for AMV detection. The efficacy of the macroarray technique was demonstrated to have practical application by testing field samples. Further, the protocol showed potential for use in breeding, quarantine, and foundation seed potato production programs, contributing to effective management of virus diseases affecting potatoes (Maoka et al. 2010).

7.2.9 Small-RNA Deep-Sequencing Analysis

Universal detection of several viruses in infected plants is possible by analyzing virus-derived small interfering RNAs (siRNAs) that accumulate in infected plant tissues due to the activation of antiviral defense mechanism based on RNA silencing (Llave 2010). The occurrence of a severe grapevine vein clearing and vine decline syndrome was observed in grapevine orchards in the Midwest USA. In order to establish the nature of the possible virus causing the disease, deep sequencing of sRNAs enriched from symptomatic and asymptomatic grapevine plants was performed. A large number of viral small RNAs that share identical nucleotide sequences with the genomes of 27 plant viruses was profiled. Two cDNA libraries were constructed from a symptomatic and an asymptomatic grapevine plants. Deep sequencing of the two cDNA libraries showed that the most abundant viral small RNAs aligned with the genomes of viruses in the genus *Badnavirus*, family *Caulimoviridae*. Amplification of the viral DNA by PCR

allowed the assembly of the whole genome sequence of a grapevine by a DNA virus for the first time in the USA, closely associated with vein clearing symptoms; the virus was provisionally designated *Grapevine vein clearing virus* (GVCV). RT-PCR assays were performed on samples from grapevine cultivar Chardonnay in a commercial vineyard using the primer set GVCV-F1/GVCV-R1. The results indicated that the GVCV-specific fragment of 530bp was present in the extracts of infected young leaves with vein clearing symptoms. Other grapevine cultivars infected by GVCV included Chardonnay, Vidal Blanc, and Chardonnay in Illinois and Indiana. The results showed that GVCV was present in six cultivars in three states in the Midwest USA and these cultivars exhibited vein clearing symptoms (Zhang et al. 2011).

Infection of cherry trees in Italy and plum trees in Azerbaijan by a new virus was observed. Double-stranded RNAs purified from the infected trees were analyzed by deep sequencing. Contigs showing weak, but significant, identity with various members of the family Betaflexiviridae were constructed. A comparison of nucleotide sequences led to the conclusion that viral isolates present in the *Prunus* plants belonged to the same viral species. The genomic organization of the isolates was similar to that of some members of Betaflexiviridae, with three overlapping open reading frames (RNA polymerase, movement protein, and capsid protein). Phylogenetic analyses of the deduced encoded proteins showed a clustering with the sole members of the genus *Tepovirus*, *Potato virus T* (PVT). Based on the results, the new virus designated *Prunus virus T* (PrVT) was considered as a new member of the genus *Tepovirus*. An RT-PCR assay was developed for the detection and identification of two other PrVT isolates and the prevalence of the PrVT isolates was estimated to be 1% in the large *Prunus* collection (Marais et al. 2015).

The approach based on small-RNA deep-sequencing (SRDS) was applied to detect viruses in a single sweet potato plant inoculated with *Sweet potato chlorotic stunt virus* (SPCSV-EA) and *Sweet potato feathery mottle virus* (SPFMV) (Kreuze et al. 2009). Analysis of its siRNA revealed the presence of three additional previously unknown viruses which included the strains A and B of *Sweet potato pakakuy virus* (SPPV, genus *Badnavirus*, family *Caulimoviridae*) and *Sweet potato symptomless virus 1* (SPSV1, genus *Mastrevirus*, family *Geminiviridae*). SRDS was shown to be a novel technique capable of detecting both RNA and DNA viruses. This technique was applied for field surveys for assessing the incidence of grapevine virus associated with grapevine vein clearing and vine decline syndrome (Zhang et al. 2011).

Small-RNA deep-sequencing (SRDS) procedure was applied to determine the nature of viruses infecting sweet potato grown in Honduras and Guatemala, which are within the main center of domestication of sweet potato, and the Galapagos Islands (Ecuador), which are within the secondary center of domestication. SRDS on the pooled RNA (10 µg) from 11 sweet potato plants from Guatemala and Honduras resulted in 4,155,175 reads (size range 10 to 27-nt) and a total of 132,965,600 bases. The viruses detected by SDRS procedure included *Sweet potato feathery mottle virus* strain RC and *Sweet potato virus C* (*Potyvirus* spp.), *Sweet potato chlorotic stunt virus* strain WA (SPCSV-WA, *Crinivirus* sp.), *Sweet potato leaf curl Georgia virus* (*Begomovirus* sp.), and *Sweet potato pakakuy virus* strain BC (= *Sweet potato badna virus* B). The identity established by SRDS method was confirmed by PCR assay and sequencing of the amplicons. Four viruses were detected in a sweet potato sample from Galapagos Islands. NCM-ELISA and TAS-ELISA formats using the virus-specific antibodies detected SPFMV and SPCSV-WA, respectively, and other viruses were not detectable by these immunoassays.

This investigation showed that 4 million small RNA reads might be readily obtained by SRDS, using 10µg of total RNA from each sweet potato sample. SRDS might be widely applicable and useful for simultaneous detection of several viruses in crop plants infected with a wide range of unrelated viruses, about which little information may be available (Kashif et al. 2012).

7.3 Detection of Viroids in Seeds

Among the disease-causing pathogens of plants, viroids are the smallest in size and simplest in structure; however, they are capable of inducing distinct symptoms when they gain entry into the susceptible host plant tissues. They have small, single-stranded covalently closed circular RNAs with a highly base-paired rather stiff rod-like conformation. None of the viroids has the ability to code for any viroid-specific protein, and they have to depend on the host’s enzyme systems entirely for the replication of their genomic RNAs. It has been suggested that the viroids have shed all the dispensable processes of viral pathogens to make use of the host in the most sophisticated manner to become highly gifted modern RNA parasites (Tabler and Tsagris 2004). Viroid RNAs carry the essential information for their independent replication when introduced into cells/tissues of susceptible plants, attaining required concentrations for production of characteristic symptoms or remaining latent in seeds and/or propagules. The infected symptomatic or asymptomatic seeds and propagules are the primary sources of inoculum for their dispersal to subsequent generations and to different geographical locations. Contaminated tools and propagation practices may also aid in the viroid transmission from infected to healthy plants.

7.3.1 Classification of Viroids

The genomes of viroids are GC-rich and consist of 260–402 nucleotides. Biological, biochemical, and structural characteristics have been used for the classification of viroids into two families (Góra-Sochaka 2004; Mayo and Brunt 2007) as detailed in Table 7.9. Viroids with a central conserved region (CCR) and without hammerhead ribozymes are included in the family of *Pospiviroidae*. In contrast, viroids lacking CCR

Table 7.9 Viroids belonging to different families and genera transmitted through seeds/propagules of infected plants (Mayo and Brunt 2007).

Family	Genus	Viroid
Pospiviroidae	<i>Pospiviroid</i>	Potato spindle tuber viroid, Citrus exocortis viroid, Tomato planta macho viroid
	<i>Hostuviroid</i>	Hop stunt viroid
	<i>Cocaviroid</i>	Citrus viroid IV, Hop latent viroid
	<i>Apscaviroid</i>	Apple scar skin viroid, Australian grapevine viroid, Citrus bent leaf viroid, Citrus viroid II, Citrus viroid III
Avsunviroidae	<i>Avsunviroid</i>	Avocado sunblotch viroid
	<i>Pelamoviroid</i>	Peach latent mosaic viroid

have the ability to self-cleave through hammerhead ribozymes and are assigned to the family *Avsunviroidae*. Furthermore, the site of viroid replication is different for the members of these two families. The nucleus is the site of replication for the members of *Pospiviroidae*, whereas the members of *Avsunviroidae* replicate in the chloroplasts (Flores et al. 2003, 2005). Similarity to viruses in the type of symptoms induced and modes of transmission of viroids has contributed to the failure of viroids being recognized as a separate group of disease-causing entities until the second half of the twentieth century. Diener (1971) demonstrated for the first time that potato spindle tuber disease was caused by a single-stranded RNA with no protein coat as in the case of viruses, and the causative agent was designated *Potato spindle tuber viroid* (PSTVd).

7.3.2 Biological Methods

Symptoms induced by viroids vary depending on the host-plant–viroid combinations after varying periods of incubation. However, specific and characteristic symptoms with diagnostic value are observed in particular organs of infected plants. *Potato spindle tuber viroid* (PSTVd) causes abnormally elongated tubers which assume a spindle or cylindrical shape with prominent eyes (Diener 1979). Apple fruits exhibit recognizable symptoms induced by *Apple scar skin viroid* (ASSVd) (Koganezawa et al. 2003). Citrus viroids, *Citrus exocortis viroid* (CEVd), *Citrus bent leaf viroid* (CBLVd), *Hop stunt viroid* (HSVd), *Citrus viroid III* (CvD-III), and *Citrus viroid IV* (CvD-IV), produce distinguishable symptoms in citrus plants (Duran-Vila et al. 2000). However, most viroids induce symptoms in their natural hosts which are not clearly distinguishable, and it is difficult to identify the viroids based on the type of symptoms caused in their primary host plant species. Biological indexing by grafting infected citrus samples (scions) onto Arizona 861-S1 Etrog citron plants was useful for detecting *Citrus exocortis viroid* (CEVd), *Hop stunt viroid* (HSVd), and *Citrus viroid III* (CvD-III) (Malfitano et al. 2005). Diagnostic/assay/bioindicator plants that exhibit clear symptoms rapidly have been used for differentiating viroids, and include tomato cultivar Rutgers, *Citrus medica* cultivar Etrog, *Gynura aurantica*, *Chrysanthemum morifolium* cultivar Mistletoe, *Cucumis sativa* cultivar Sporu, and *C. sativus* (Narayanasamy 2011).

The grow-out method has been applied for the detection of viroids in seeds as in the case of viruses under greenhouse conditions. Specific numbers of seeds collected from infected plants are sown in pots, the development of symptoms is recorded in growing seedlings, and percentages of infected seeds are calculated. The transmission of *Potato spindle tuber viroid* (PSTVd) via pollen, true seeds of potato (Fernow et al. 1970), and also through tomato seeds (Benson and Singh 1964) was observed. *Peach latent mosaic viroid* (PLMVd) was shown to be transmitted through pollen by pollinating healthy plants with pollen from infected plants. Two peach, cultivars Velvel C and Vivian C, were infected when pollinated with pollen from infected peach cultivar Nectaross (Barba et al. 2007). *Citrus exocortis viroid* (CEVd) was shown to be transmitted through seeds of *Impatiens walleriana* and *Verbena* x hybrid by visual examination of developing seedlings emerging from seeds collected from commercial sources. All 19 samples showed infection by CEVd, with a seedling transmission rate of 66% in *I. walleriana* and 28% in *V x hybrida*. The presence of viroid in nongerminated seed was 21%. Storage of seeds for 2 years significantly reduced the percentage of seed transmission in these host plant species (Singh et al. 2009). *Pepper chat fruit viroid* (PCFVd) belonging to the genus *Pospiviroid* was detected in tomato seed in Australia. Other viroids detected

in tomato seed were *Potato spindle tuber viroid* (PSTVd), *Citrus exocortis viroid* (CEVd), and *Tomato chlorotic dwarf viroid* (CDVd). PCFVd causes disease in *Capsicum*, potato, and tomato. It is known to be transmitted through seed of *Capsicum* (Verhoeven et al. 2009; Reanwarakorn et al. 2011).

7.3.3 Physico-Chemical Methods

The presence of viroids in seeds/propagules has to be detected unambiguously and rapidly to eliminate the infected plants. The biological diagnostic methods require a long time to obtain results, in addition to being cumbersome and inconsistent; alternative diagnostic procedures based on physico-chemical properties of the viroids have therefore been developed. Nucleic acid molecules could be separated based on the differential mobility in an electrical field. The viroid molecules differ distinctly from normal host RNAs in their electrophoretic mobility in nondenaturing and partially denaturing gels. Polyacrylamide gel electrophoresis (PAGE) technique utilizes this property of viroid nucleic acids. *Potato spindle tuber viroid* (PSTVd) was detected in potato and tomato plants by extracting the cellular nucleic acids from healthy and infected potato plants by employing PAGE procedure. PSTVd only appeared as a distinct band in the extracts from infected plants, but not in healthy plant extract. Further, PAGE technique was applied to differentiate mild and severe strains of PSTVd. PAGE procedure was employed to eliminate infected seed tubers of several elite or basic potato seed stocks and viroid-free seed stocks were developed in certification programs (Morris and Wright 1975). The PAGE technique was shown to be efficient in detecting viroid and viroid-like RNAs in grapevine plants.

A band with faster mobility than that of *Citrus exocortis viroid* (CEVd) under non-denaturing conditions was detected by PAGE procedure. Two bands were visualized under fully denaturing conditions, one co-migrating with circular forms of CEVd and a second band migrating at a faster rate than the linear forms of this viroid. This RNA species did not hybridize with cDNA probe to CEVd. The identity of the viroid was confirmed by its reaction on the bioindicator *Gynura aurantica* plants (Flores et al. 1985). The detection of *Potato spindle tuber viroid* (PSTVd) in true seeds of potato was more effectively achieved by return gel electrophoresis. This procedure was comparable with or superior to the nucleic acid hybridization method (Singh et al. 1988). Return gel electrophoresis provided more sensitive detection of *Apple scar skin viroid* (ASSVd) in apple leaf tissue, *Hop stunt viroid* (HSVd) in plum bark, and *Citrus exocortis viroid* (CEVd) in citrus leaves (Asai et al. 1998). *Citrus exocortis viroid* (CEVd), *Hop stunt viroid* (HSVd), and *Citrus viroid III* (CV-III) were most widely distributed in the citrus orchards of Campania region in southern Italy. Sequential (s)PAGE analysis of nucleic acid extracts of 112 citrus field-grown trees revealed that 8 source trees did not contain any viroid-like RNA, whereas 12 trees contained single RNA band with the molecular size of HSVd (7 samples), CEVd (2 samples), or CVd-III (3 samples). The remaining source trees showed the presence of 2 or more viroid-like RNAs with the electrophoretic mobility of CEVd, *Citrus bent leaf viroid* (CBLVd, formerly known as *Citrus viroid I*), HSVd, CVd-III, and/or CVd-IV, revealing the occurrence of mixed infections by two viroids in the same tree. The results of sPAGE procedure were consistent with those of Northern and dot-blot analyses using DIG-labeled probes specific to CEVd, CBLVd, HSVd, CVd-III, and CVd-IV. The results of sPAGE procedure performed on 112 field trees over 3 years were confirmed by molecular hybridization analyses. Infection by

CEVd, HSVd, and CV-III accounted for 68%, 87%, and 85% respectively, whereas CVd-IV and CBLVd infections were detected in 24% and 13% of the field trees tested. The results emphasized the urgent need to establish effective certification programs to prevent further spread of the viroid diseases affecting citrus plants (Malfitano et al. 2005). Return (R-) PAGE technique was employed as an adjunct procedure to reverse-transcription (RT-) PCR assay for the detection of viroids. RT-PCR assay was employed for the detection of *Potato spindle tuber viroid* (PSTVd) and *Chrysanthemum stunt viroid* (CSVd) in 6 of 891 potato tubers and 2 of 154 chrysanthemum samples, respectively. The amplified product of 199bp was detected by R-PAGE technique. The virus-specific band could be visualized by R-PAGE procedure. The expected band location for PSTVd and CSVd in R-PAGE gel was adjacent to each other (Bostan et al. 2010).

7.3.4 Nucleic Acid-Based Techniques

Nucleic acid hybridization techniques using viroid-specific probes and reverse-transcription (RT) polymerase chain reaction (PCR) assay, using appropriate primers targeting specific regions of the viroid genome, have been applied for the detection of viroids present in seeds and propagules. Different hybridization procedures have been shown to be useful in detecting the viroids in seeds. Dot-blot hybridization using digoxigenin (DIG-) labeled cRNA probes was found to be effective for routine detection of *Chrysanthemum stunt viroid* (CSVd) (Mumford et al. 2000b). Northern and dot-blot analyses using viroid-specific DIG-labeled probes were useful for efficient detection of *Citrus exocortis viroid* (CEVd), *Citrus bent leaf viroid* (CBLVd = *Citrus viroid I*), *Hop stunt viroid* (HSVd), *Citrus viroid III* (CVd-III), and *Citrus viroid IV* (CVd-IV). The results obtained with hybridization assays corroborated those of sPAGE procedure (Malfitano et al. 2005). Simultaneous detection of four viroids infecting grapevine was achieved by employing polyprobe and nonisotopic dot-blot hybridization technique. A polyprobe was constructed by cloning tandem full-length sequences of *Hop stunt viroid* (HSVd), *Australian Grapevine viroid* (AGVd), and *Grapevine yellow speckle viroid-1* and *-2* (GYSV-1, -2) into a single vector. The cRNA probe detected all four viroids with sensitivity similar to that obtained using individual probes. The grapevine samples collected during a field survey in Beijing, Xinjiang, China from 78 varieties showed the presence of grapevine viroids in 56 varieties (71.8%). The protocol developed in this investigation was found to be rapid, reliable, and cost-effective for detection of infection by four viroids in grapevine (Zhang et al. 2012b).

Peach latent mosaic viroid (PLMVd) infection was found to be widely distributed in the peach germplasm from Europe, Asia, North America, and South America. The cherry isolate of PLMVd has 377 nucleotides (nts) which are 91–92% homologous to PLMVd isolates of peach. Dot-blot and Northern blot hybridization analyses of total nucleic acids extracted from plum, apricot, cherry, and peach samples resulted in hybridization signal only from infected stone fruit samples. PLMVd from peach had an electrophoretic mobility similar to the viroid from plum (Hadidi et al. 1997). Dot-blot hybridization procedure using DIG-labeled viroid-specific probes was effective in detecting PLMVd and *Hop stunt viroid* (HSVd) infection in peach trees. The single or mixed infection by PLMVd and HSVd were high, reaching 77% and 69% respectively, in different orchards of Czech Republic (Hassan and Ryšánek 2004).

The natural mode of transmission of *Peach latent mosaic viroid* (PLMVd) was investigated since a high incidence of field infections and rate of natural spread (5–10% new infections/year) were observed. Under experimental conditions, a low percentage of transmission by the aphid *Myzus persicae* was recorded (Flores et al. 1992), but natural spread of PLMVd was not documented. Pollen from 9 peach trees of 3 cultivars (3 plants/cultivar) infected with an Italian isolate of PLMVd were used to pollinate 18 virus-free 5 year old peach trees of 6 cultivars (3 plants/cultivar). Pollen collected from pollinated trees was tested for the presence of PLMVd by spot-blot hybridization and RT-PCR procedures. Both tests detected PLMVd in all samples (100%) tested from peach trees used as donors. Positive signals from hybridization and RT-PCR were obtained both in the supernatant of pollen and in washed pollen of PLMVd-infected trees, indicating that PLMVd was located both externally and internally. Of the 18 trees pollinated with pollen from infected donors, five trees showed the presence of PLMVd. PAGE procedure confirmed the presence of the viroid by revealing viroid-specific band. Seed transmission of PLMVd was investigated by testing 1000 seeds from PLMVd-infected plants of 10 cultivars (100 seeds/cultivar) using dot-blot hybridization and RT-PCR techniques. The viroid was detected in the teguments of 242 of 500 (c. 49%) seeds tested and in 224 of 500 (c. 45%) peeled kernels. The seedlings from seeds of PLMVd-infected plants were negative by RT-PCR and hybridization techniques, indicating a lack of transmission of PLMVd through seeds. The results showed that PLMVd was pollen-borne but was not transmitted from seeds to seedlings, although the viroid was present in the seed (probably PLMVd could not infect the embryo of the seed). Further, PLMVd could be detected in peach roots. However, root infection may not have a significant role in the spread of the viroid from infected plant to healthy plants (Barba et al. 2007).

Hop latent viroid (HLVd) could be readily detected by RT-PCR in hop anthers from small buds and practically mature anthers. However, HLVd was eliminated from hop pollen during the process of pollen maturation and germination. Transmission of HLVd through pollen was investigated during different stages of pollen and seed development. HLVd was readily detectable in mature pollen, but the intensity of amplified cDNA dramatically decreased in pollen maturation stages and no viroid was detected in germinating pollen. HLVd could propagate in uninucleate microspores and was still abundant in young pollen. However, in later stages during pollen vacuolization and maturation, HLVd was effectively eliminated. Traces of HLVd were still detectable by RT-PCR in mature pollen, but disappeared during pollen germination. It appeared that viroid RNA was intensively degraded by endonucleolytic cleavage of circular RNA and subsequent linear RNA degradation during pollen development. The interval when rapid viroid degradation occurred was therefore determined. HLVd monomeric circular and linear forms could still be detected by Northern blotting in stages following postmitotic young bicellular pollen during initial vacuolization, but was detectable only by RT-PCR in mature pollen. HLVd cleavage products, including RNA fragments shorter than unit-length HLVd, were detected in young bicellular pollen. HLVd degradation in hop pollen was found to be a selective process that efficiently eliminated HLVd during pollen maturation and germination. The majority of the degraded HLVd RNA in mature pollen included discrete products in the range of 100–230 nucleotides which did not correspond to siRNAs (small interfering RNAs). HLVd eradication from pollen correlated with developmental expression of a pollen nuclease and specific RNases. Activity of the pollen nuclease HBN1 was maximal during the vacuolization step and decreased in mature pollen. Total RNase activity increased continuously up to the final

steps of pollen maturation. The developmentally activated HBN1 and pollen ribonucleases could participate in the mechanisms of HLVD recognition and degradation (Matoušek et al. 2008). Pollen transmission of *Hop stunt viroid* (HSVd) was investigated by collecting closed flowers of plum trees and the pollen grains were mechanically separated from anthers and stored in petridish. RT-PCR assay was used to detect HSVd in pollen from parental donor plants of cultivars Black Sunrise and Black Glow. HSVd was detected both inside and outside the granules, suggesting the possibility of transmission of HSVd to seed and subsequently to plants (Luigi et al. 2010).

Citrus exocortis viroid (CEVd) infects *Impatiens walleriana* and *Verbina x hybrida* plants, seriously affecting production of flowers. RT-PCR assay was applied to detect CEVd in the seeds of these flower crops. The viroid was detected in the nongerminated seeds and also in the seedlings growing from the infected seeds. The rate of detection of CEVd in the seeds was at a lower level than in the seedlings because the seeds had a smaller amount of tissue compared to the seedlings which could allow virus replication after seed germination, attaining a detectable level of viroid titer. The seedlings were grown in separate plots. In three RT-PCR tests, CEVd was detected in leaves and petals of *Impatiens* and *Verbena* from all CEVd-positive plants, but not from healthy plants. The presence of CEVd in commercially distributed seeds and its seed transmission in these two species of ornamental plants could be conclusively established by the RT-PCR assay (Singh et al. 2009).

A viroid disease observed in the glasshouse crop of sweet pepper (*Capsicum annuum*) in the Netherlands was investigated to establish the identity of the viroid pathogen. The viroid induced vein necrosis and reduced fruit and tuber size in tomato and potato, respectively. The viroid designated *Pepper chat fruit viroid* (PCFVd) was detected in pepper plants cultivar Yolo Wonder at 6 weeks after inoculation, by employing RT-PCR assay using the primer pair AP-FW1/RE2. Based on the biological and molecular properties of the viroid infecting sweet pepper, the pathogen was named *Pepper chat fruit viroid* and proposed as a new species in the genus *Pospiviroid*. The presence of PCFVd in inoculated plant species (7) including tomato and potato was also detected using the primer pair. The seeds (72) collected from pepper fruits in artificially inoculated plants were sown and at 2 weeks after emergence the seedlings were tested by RT-PCR assay in groups of 6 plants. Groups that reacted positively were tested individually, and RT-PCR products of 3 plants were sequenced. The predominant nucleotide sequence of the viroid had not changed during seed germination and seedling formation. The results indicated that PCFVd was transmitted through seeds of infected pepper plants. The genome of PCFVd consisted of 349 nucleotides and the primary structure showed high similarity to the members of *Pospivirus* genus (Verhoeven et al. 2009).

7.4 Detection of Viroids in Propagules

7.4.1 Nucleic Acid-Based Techniques

In addition to seeds, propagules form the primary sources of inoculum, spreading the disease to different geographical locations as well as to subsequent generations of crops. Viroids may also spread through contaminated tools and propagation practices, whereas the involvement of biological vectors as in the virus disease is only known in a few cases such as *Peach latent mosaic viroid* (PLMVd) to a limited extent (Flores et al. 1992).

The importance of sensitive, reliable, and rapid techniques for detection of viroids in propagules must therefore be emphasized. As conventional biological methods are time-consuming and inconsistent, modern molecular techniques seem to be the choice of researchers in accomplishing the task of producing viroid-free stocks to restrict the initial incidence and subsequent spread of the viroid diseases. However, nucleic acid-based techniques have to be validated by testing them at several locations other than the laboratory where the protocol was developed for their reliability, reproducibility, and cost-effectiveness. Further, the feasibility of the technique for large-scale application under field conditions and for the certification and quarantine programs also has to be demonstrated.

7.4.1.1 Nucleic Acid Hybridization

Citrus viroid V (CVd-V) has a G + C-rich genome of 293–294 nucleotides and its predicted secondary structure of minimum free energy is a rod-like conformation with 68.7% paired nucleotides. A new variant of CVd-V was detected in California, Spain, and Nepal. The viroid-like RNA was inoculated onto Etrog citron, which was used as a secondary bioamplification host. Northern blot hybridization procedure was applied using DIG-labeled viroid-specific probes. Northern blot hybridization with full-length CVd-V-specific probe corroborated the sequence similarity of CVd-V with the viroid-like RNA, but not with HSVd or CVd-V included as controls. Nucleic acid extracts from Etrog citrons graft-inoculated with 62 field isolates collected in different citrus-growing countries and one sweet orange sample from Nepal were analyzed by Northern hybridization with CVd-V-specific DIG-labeled DNA probe. CVd-V was identified in a single source of Seminoletangelo (*C. paradise* x *C. tangerine*) from Spain, in the sweet orange from Nepal, and in six isolates of sweet orange from Sultanate of Oman. CVd-V could also be detected by slot-blot hybridization with CVd-V-specific probe. RT-PCR assay using CVd-V-specific primers was able to provide confirmatory results for the presence of the new variant of CVd-V in *Citrus* spp. (Serra et al. 2008).

Citrus plants are natural hosts of several viroids belonging to the family *Pospiviroidae*. Detection of the viroids directly in citrus plants by diagnostic methods yielded erratic results. Etrog citron had to be used as a secondary bioamplification host, which allowed rapid multiplication of the viroids to reach detectable concentrations. To avoid the use of Etrog citron, an easy-to-use Northern hybridization protocol was developed for the detection of *Citrus exocortis viroid* (CEVd) directly in samples collected from field-grown *Citrus* spp. and cultivars. The Northern hybridization protocol involved: (i) use of nucleic acid preparations from bark tissue samples collected from the field-grown trees, regardless of the growing season and storage conditions; (ii) separation on 5% PAGE or 1% agarose blotting membrane and fixing; and (iii) hybridization with viroid-specific DIG-labeled probes and detection with anti-DIG-alkaline phosphatase conjugate and autoradiography with the chemiluminescence substrate disodium 3-(4-methoxyspiro (1,2-dioxetane-3,2-(5-chloro) tricyclodecan)-4-yl) phenyl phosphate (CSPD) (Roche). The protocol was tested with viroid-infected trees of sweet orange, lemon, mandarin, grapefruit, sour orange, Swingle citrumello, Tahiti lime, and Mexican lime (Fig. 7.14). The Northern hybridization protocol did not require the use of Etrog citron for bioamplification of the target viroid and provided an alternative for reliable viroid indexing. The procedure and synthesis of probes were easy for viroid detection in *Citrus* spp. in commercial orchards. The Northern hybridization protocol was highly specific and sensitive for viroid detection (Murcia et al. 2009).

(2009). Reproduced with permission of Elsevier BV, USA.

Potato spindle tuber viroid (PSTVd) is an A2 quarantine pathogen as declared by EPPO and is transmissible by true seed, pollen, and seed tubers, as well as through contaminated tools. DIG-labeled cDNA probes were found to be effective in detecting PSTVd in the extracts of potato tubers and leaves (Nakahara et al. 1997). The incidence of PSTVd in ornamental solanaceous plants was assessed in Italy. *Solanum jasminoides* and *S. rantonnetti* showed symptoms of infection by viroid-like agents. In order to evaluate the possibility of detecting PSTVd in the infected ornamental Solanaceae, the simple, fast, and economic detection procedure of tissue-printing hybridization (TPH) was employed. Tissue prints were prepared by directly pressing freshly cut herbaceous stems of *S. jasminoides* and *S. rantonnetti*. Strong signals that perfectly matched those obtained with dot-blot hybridization were generated, while healthy controls showed consistently negative reaction. PSTVd diagnosis in potato using DIG-labeled probes should be confirmed by another technique such as RT-PCR and sequencing of the generated amplicon (Di Serio 2007).

Hybridization techniques have been applied for the detection of viroids infecting potato and fruit crops. The usefulness of labeled cDNA specific to *Peach latent mosaic viroid* (PLMVd) was demonstrated for detection of PLMVd efficiently in stem pieces and dormant buds of peach (Skrzeczowski et al. 1996). The sanitary status of the Clonal Genebank of stone fruit in Canada was evaluated by applying molecular methods. Tissue-printing hybridization (TPH) technique was employed to test a total of 336 trees comprising 116 peach and nectarine, 84 sweet and sour cherries, 54 plums, and 44 apricots for the presence of *Peach latent mosaic viroid* (PLMVd) and *Hot stunt viroid* (HSVd).

Infection of 28 of 30 peaches and nectarines by PLMVd and two apricots by HSVd was revealed by TPH assay. Viroid-free mother trees were identified by TPH procedure and were used for vegetative propagation (Michelutti et al. 2005). Tissue-printing hybridization (TPH) assay was employed to detect *Apple scar skin viroid* (ASSVd), *Apple dimple fruit viroid* (ADFVd), and *Pear blister canker viroid* (PBCVd) in about 1000 trees in the commercial orchards and nurseries located in Bosnia Herzegovina, Malta, Lebanon, Morocco, and Turkey. High rates of infection by PBCVd (5.4–13%) were observed. Of the 398 pear trees assayed by TPH, 35 tested positive for PBCVd. The Northern blot hybridization assay and/or RT-PCR procedure also confirmed the results of TPH method. By cloning and sequencing of the amplified cDNA products, the identity of PBCVd was confirmed for some isolates. TPH procedure was employed for testing samples from more than 800 trees during a survey undertaken in different countries indicated above. ASSVd was not detected in any of the apple trees in Morocco, Lebanon, and Bosnia Herzegovina or in pear trees (194) in Morocco and Lebanon. PBCVd was detected in one quince tree. The results of the investigation using TPH assay indicated that viroid-free germplasm should be imported and viroid-indexed mother trees alone have to be used for producing propagation material. TPH was found to be an easy and valuable tool for identifying viroid-free mother plants of pome fruit crops (Di Serio et al. 2010).

The viroids *Apple scar skin viroid* (ASSVd), *Apple dimple fruit viroid* (ADFVd), *Apple fruit crinkle viroid* (AFCVd), *Pear blister canker viroid* (PBCVd), *Hop stunt viroid* (HSVd), and *Peach latent mosaic viroid* (PLMVd) are well distributed worldwide, causing significant adverse impact on fruit production. These six viroids belong to two different families; with the exception of PLMVd, which is included in *Avsunviroidae*, five belong to *Pospiviroidae*. A simple and sensitive dot-blot hybridization assay using a digoxigenin (DIG-) labeled cRNA polyprobe was developed for the simultaneous detection of these six viroids infecting pome and stone fruit trees. The poly6 probe was constructed by cloning sequentially partial sequences of each viroid into a single vector, with run-off transcription driven by the 17 promoter. All six viroids could be detected with a dilution range of 5^{-3} to 5^{-4} in total nucleic acid extracts from infected trees. Two viroids PBCVd and PLMVd were detected in the 5^{-4} diluted samples. The other four viroids –ASSVd, ADFVd, AFCVd, and HSVd– were detected in the 5^{-3} diluted samples (Fig. 7.15). The respective detection limits of the poly6 probe for detecting each of the six viroids were similar to those of the single probes, indicating that the poly6 probe was reliable for the detection of its homologous viroids in the dot-blot hybridization assay. Nucleic acid extracts were prepared from the three apple and three pear trees inoculated with ADFVd, AFCVd, ASSVd, and PBCVd approximately 1 year after grafting. The dot-blot hybridization assay using the poly6 probe yielded intense hybridization signal in all six trees, and the identity of each viroid was confirmed using the viroid-specific primers. Combinations of the three apple viroids ASSVd, ADFVd, and AFCVd were found in the inoculated apple trees, and all four viroids were detected in the inoculated pear trees. Poly6 probe was found to be able to detect in six peach and six plum plants coinoculated with PLMVd and HSVd at different periods after inoculation. Of the 12 pooled samples, mixed infections of PLMVd and HSVd were present in 6 GR305 pooled peach samples and HSVd alone was detected in 5 plum samples. Of the remaining pooled sample, a myrobalan plum was not infected by either PLMVd or HSVd. Field samples (725) representing a diverse collection of germplasm accessions from throughout the world and commercial orchards were tested by dot-blot hybridization using poly6 probe. Most of the samples were free of the six target viroids. The hybridization

Figure 7.15 Detection of six viroids in mixed infections by dot-blot hybridization assay using DIG-labeled probes in extracts of pome and stone fruit trees. A1–11: extracts from plants infected by *Apple scar skin viroid* (ASSVd); B1–11: extracts from plants infected by *Apple dimple fruit viroid* (ADFVd); C1–11: extracts from plants infected by *Pear blister canker viroid* (PBCVd); D1–11: extracts from plants infected by *Apple fruit crinkle viroid* (AFCVd); E1–11: extracts from plants infected by *Hop stunt viroid* (HSVd); F1–11: extracts from plants infected by *Peach latent mosaic viroid* (PLMVd); G1–11: extracts from healthy plants. Single probes tested: row 1 (ASSVd); row 2 (ADFVd); row 3 (PBCVd); row 4 (AFCVd); row 5 (HSVd); and row 6 (PLMVd). Polyprobes tested: poly2-A (ASSVd and ADFVd, row 7); poly2-B (PBCVd and AFCVd, row 8); poly2-C (HSVd and PLMVd, row 9); poly4-AB (ASSVd, ADFVd, PBCVd, and AFCVd, row 10) and poly6 (row 11). Source: Lin et al. (2011). Reproduced with permission of Elsevier BV, USA.

assay using poly6 probe capable of detecting six viroids infecting pome and stone fruit trees in a single test could be particularly beneficial as an alternative to the single-probe assays, reducing cost, time, and labor requirements for diagnostic assays, especially for quarantine and certification programs (Lin et al. 2011).

7.4.1.2 Reverse-Transcription (RT-) PCR Techniques

Reverse-transcription (RT-) PCR-based methods have been applied for the detection of several viroids infecting a range of crop plant species, asexually propagated by different plant parts obtained from mother plants whose freedom from viroid infection has to be ensured. The effectiveness of detection of *Chrysanthemum stunt viroid* (CSVd) and *Potato spindle tuber viroid* (PSTVd) by dot-blot hybridization, RT-PCR, and TaqMan assays was compared using a wide range of isolates obtained from various locations and cultivars. Dot-blot hybridization and TaqMan assays efficiently and specifically detected CSVd and CSVd/PSTVd, respectively. On the other hand, RT-PCR alone was unable to differentiate CSVd and PSTVd. However, a combination of RT-PCR assay and RFLP analysis could be employed to differentiate these two viroids. The detection limits of dot-blot hybridization, RT-PCR, and TaqMan assays for CSVd were 1:100, 1:1000, and 1:100,000 respectively. When CSVd-primer-probe set and PSTVd-primer-probe set were employed, TaqMan amplification of the viroid genomes resulted in two distinct patterns based on which respective viroids could be detected in the RNA extracts from infected plants (Fig. 7.16). The TaqMan assay provided a high level of sensitivity, reduction in the risk of false-negative results, and elimination of contamination by using closed-tube format (Mumford et al. 2000b).

RT-PCR assay was effective in detecting *Potato spindle tuber viroid* (PSTVd) in tree potato pollen and seeds. Total nucleic acid (TNA) extracts or Gene ReleaserTM-treated extracts of plant tissues were subjected to PCR amplification. An amplified full-length

Figure 7.16 Detection of (a) *Chrysanthemum stunt viroid* (CSVd) and (b) *Potato spindle tuber viroid* (PSTVd) by real-time TaqMan assay using viroid-specific probes. TaqMan amplification plots for specific detection of CSVd and PSTVd. Source: Mumford et al. (2000a). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

PSTVd cDNA could be produced by treating as few as five pollen grains with Gene ReleaserTM (Shamloul et al. 1997). RT-PCR assay was employed to detect PSTVd using the primer pair PSTVd-321/PSTVd-323 which were complementary and identical to positions 156–179 and 180–203, respectively, of the PSTVd reference variant. The region covered by these adjacent primers was highly conserved in most known PSTVd variants. Using this primer set, a cDNA of about 360 bp corresponding to the full-length PSTVd RNA could be amplified from infected samples. PCR analyses showed that all samples testing positive by dot-blot hybridization generated an RT-PCR amplicon of this size, indicating the infection of the sample by PSTVd (Di Serio 2007).

Efficient methods have to be employed for the successful detection of viroids in plant tissues. In order to recover viroids, different extraction procedures and RT-PCR formats and other molecular techniques have been employed. Four extraction protocols were

compared for their efficiency to obtain RNAs of high concentration and purity from bark tissues sampled from *Citrus limon* plants infected by *Citrus exocortis viroid* (CEVd). The concentration of CEVd in the bark was 10 times higher than in the leaves of Etron citron, which was used as a bioamplification host for CEVd. RT-PCR assay provided a sensitive detection of CEVd by amplifying the entire viroid genome (Umaña et al. 2001). Detection of three citrus viroids, namely *Citrus exocortis viroid* (CEVd), *Citrus viroid II* (CVd-II) (*Hop stunt viroid*), and *Citrus viroid III* (CVd-III), in field-collected citrus plants in Florida was accomplished by employing RT-PCR assay. The PCR amplification products were analyzed by agarose gel electrophoresis. CEVd, CVd-II, and CVd-III were consistently detected in tissues from experimentally infected orange, lemon, and lime cultivars, but detection of viroids in the tissues of grapefruit and mandarins was less consistent, possibly due to low concentration and uneven distribution of the viroids in this host plant species. Bark tissues from woody, budwood-sized twigs were the best tissue sources for viroid detection. Samples collected in warm weather yielded better results than those obtained in winter. A collection of 55 viroid isolates derived from 44 different sources representing different hosts and locations in Florida was tested by RT-PCR assay. CEVd was detected in 22 sources infected by 20 isolates of CEVd, whereas 45 isolates of CVd-III were found in different source plants. The correlation between results of RT-PCR assay and biological indexing exceeded 90%. Several isolates causing moderate symptoms in Etron citron were not amplified by the primers specific to CEVd, CVd-II, and CVd-III. One of the isolates was identified as *Citrus viroid IV* which was found for the first time in Florida. The protocols developed in this investigation were successfully used in three different laboratories (Garnsey et al. 2002).

Citrus cuttings collected from field-grown plants were forced to sprout in a growth chamber in sterilized agriperlite and grown under artificial illumination (1000 lux and photoperiod for 16h) at a temperature of 27–32°C. Leaves from forced cuttings were tested at 15 or 30 days after sprouting by one-step RT-PCR. In forced cuttings, *Hop stunt viroid* (HSVd) and *Citrus viroid III* (CVd-III), but not CEVd, were readily detected in the leaves collected at 15 days after sprouting. However, leaves collected at 30 days after sprouting yielded amplicons of expected size for CEVd (371 bp), HSVd-cit (300 bp), and CVd-III (296 bp). Forced cutting method allowed citrus viroid detection when field conditions were unfavorable for their detection and identification from samples directly from the groves. Forcing cuttings to sprout in growth chamber at temperatures around 30°C seemed to promote viroid replication without the need for Etron 861-S1 citron for their amplification. The forced cuttings technique was applied routinely for indexing citrus plants along with sequential (s-) PAGE and bioindexing methods for the presence of citrus viroids in Italy (Guardo et al. 2005).

A one-tube RT-PCR assay was developed for the detection of *Citrus exocortis viroid* (CEVd) and *Hop stunt viroid* (HSVd) in citrus samples (105) collected during the survey in citrus fields in central Italy. The assessment of frequency of viroid presence in this region showed that CEVd and HSVd infections were present in 71% and 19% of the citrus samples. Both viroids were more widespread in citrus germplasm from Lazio than from Tuscany regions. Of the 21 cultivars belonging to 9 *Citrus* spp. and 1 hybrid, 12 cultivars and the hybrid were infected with CEVd, one cultivar was infected with HSVd, and 3 cultivars showed infection by both viroids. The cultivars that showed no visible symptoms were grafted onto tolerant rootstocks. HSVd-positive samples were also asymptomatic. The one-tube RT-PCR format in a single PCR reaction detected both CEVd and HSVd, widely distributed and economically important viroids, in citrus

germplasm collections. The one-step RT-PCR protocol provided an earlier and more rapid detection and identification of the citrus viroids compared with the procedures employed earlier. Biological tests confirm the results obtained using one-step RT-PCR format developed in this investigation. Use of the one-step RT-PCR might reduce the number of biological tests required, since these tests need to be carried out only on viroid-negative samples (Ragozzino et al. 2005).

The yellow corky variant of *Hop stunt viroid* (HSVd-sycV) and *Citrus exocortis viroid* (CEVd) infecting Washington Navel orange was detected using a combination of RT-PCR and dot-blot hybridization (DBH) techniques. The RT-PCR products were subjected to DBH assay. Southern blot hybridization could detect HSVd only at a dilution of 1:100. RT-PCR assay was 10-fold more sensitive than Southern blot hybridization. Detection of DIG-labeled HSVd and CEVd cDNA products by probe capture hybridization was 100 to 1000 times more sensitive than detection by PAGE analysis. RT-PCR-DBH combination was sensitive and specific for the detection of targeted viroids (Fig. 7.17). RT-PCR-DBH showed two levels of specificity based on internal hybridization probe. RT-PCR-DBH assay, with a higher level of sensitivity, specificity, visual indication, adaptation to automation, and rapidity of providing results, could become a preferred diagnostic tool for diagnosis of viroids infecting citrus, especially for certification and quarantine programs (Bagherian et al. 2009).

RT-PCR assay was applied to assess the sanitary status of citrus varieties and/or clones with respect to the extent of viroid infection, in order to select elite mother plants of citrus for vegetative propagation. The results of RT-PCR assay indicated that all mother plants tested were infected by *Citrus exocortis viroid* (CEVd) and *Citrus bent leaf viroid* (CBLVd), although they were free of *Citrus tristeza virus* (CTV) and *Citrus variegation virus* (CVC). The viroids could be successfully eliminated from 3 lemon, 6 mandarin, and 20 “Jaffa” orange plants by adopting micrografting technique. These virus- and viroid-free plants formed the nuclear stock for government plantations, private nurseries, and growers in Cyprus (Kaparia-Isaia et al. 2007).

Figure 7.17 Comparative levels of sensitivities of electrophoresis, Southern blot hybridization, and RT-PCR dot-blot hybridization (DBH) for the detection of *Hop stunt viroid* (HSVd) and *Citrus exocortis viroid* (CEVd) in citrus. The presence of citrus viroid in citrus collections from eight provinces maintained in the greenhouse of National Citrus Virus Exclusion Center, China was tested. A simple, one-step multiplex RT-PCR protocol was applied for the detection of five viroids, *Citrus exocortis viroid* (CEVd), *Citrus bent leaf viroid* (CBLVd), *Hop stunt viroid* (HSVd), *Citrus viroid III* (CVd-III), and *Citrus viroid IV* (CVd-IV). Total nucleic acids (TNAs) were extracted using a micro and rapid nucleic acid extraction procedure. A cocktail of primer pairs specific to all five viroids was employed for simultaneous detection of these viroids by the one-step multiplex RT-PCR assay. Most of the plants showed infection by more than one viroid species, and a few of them were found to be infected by up to four citrus viroids. The protocol developed in this investigation revealed the extensive incidence of citrus viroids in many provinces of China, and the need for careful selection of viroid-free mother plants for vegetative propagation to establish viroid-free nuclear stock by employing sensitive and reliable diagnostic technique(s) (Wang et al. 2009).

The possibility of citrus budlings originating in the Middle East as the potential sources of citrus viroid inoculum was investigated. Citrus budlings (101) belonging to 9 citrus cultivars which originated from 5 countries collected from commercial nurseries were tested by the multiplex RT-PCR assay for the detection of *Citrus exocortis viroid* (CEVd), *Citrus bent leaf viroid* (CBLVd), *Hop stunt viroid* (HSVd), *Citrus dwarfing viroid* (CDVd), and *Citrus bark cracking viroid* (CBCVd). Multiplex RT-PCR analysis, followed by sequencing of representative isolates, indicated that 29, 28, 54, 68, and 79% of the citrus budlings from Oman, Lebanon, Syria, Egypt, and Jordan showed positive reactions for CEVd, CBLVd, HSVd, CDVd, and CBCVd, respectively. Nucleotide sequence similarity of viroids from Oman was high (94–100%) with the citrus viroids from other countries. The results revealed that the citrus viroids could spread through budlings to other geographical locations (Al-Harthi et al. 2013).

Infection levels of *Hop stunt viroid* (HSVd), *Hop latent viroid* (HLVd), and *Apple fruit crinkle viroid* (AFCVd) in commercial hop (*Humulus lupulus*) plantings in three regions of intensive hop production in Washington State were assessed using RT-PCR formats. A one-tube duplex RT-PCR assay was employed for the detection of HLVd and HSVd, using viroid-specific primers, and a separate RT-PCR assay was applied for the detection of AFCVd using primers that reacted with a wide range of ascapiviroids. RT-PCR performed using the SuperScript III One-Step RT-PCR System with Platinum Taq High Fidelity (Invitrogen, CA). Higher-molecular-sized bands frequently appeared in assays for HSVd and HLVd. HSVd was detected in 10 of 33 hop gardens sampled. Samples in which HSVd was detected in 2004 originated from all three regions of hop production. The results suggested that HSVd could have remained undetected for a significant period of time, leading to its widespread incidence. HLVd was also widely distributed in Washington hop production, as it was detected in all three regions and in all gardens except one sampled. None of the plants tested yielded positive results for AFCVd, reported in hops in Japan. *Hop latent viroid* was frequently associated with high frequency (98 of 126 hop plants tested), indicating the need for use of sensitive and reliable techniques for testing the hop plant materials (Eastwell and Nelson 2007).

The association of *Hop stunt viroid* (HSVd), and other viroids and viruses, with plum dapple fruit and fruit rugosity was investigated using RT-PCR assay. Among the viruses, *Apple chlorotic leaf spot virus* (ACLSV) was the only virus that could be detected in the plants tested; *Plum latent mosaic viroid* (PLMVd) was also detected by RT-PCR assay. HSVd was detected in all symptomatic samples, but asymptomatic samples did not show the presence of HSVd. Sequencing of the cloned HSVd isolates showed a high

homology (99–100%) among clones except F20.2 with 92% homology. The parental pollen donor plants “Black sunrise” and “Black glow” were found to be infected with the same HSVd isolate of the fruit seedlings. The pollen collected from the parental plants was also positive for the RT-PCR assay, indicating the presence of the viroid both inside and outside of pollen granules. The results indicated the possibility of infected pollen being the reservoir of HSVd inoculum, in addition to the infected plum plants (Luigi et al. 2010).

The extent of incidence of *Apple scar skin viroid* (ASSVd) in Xinjiang Province of China was assessed by applying RT-PCR and in situ RT-PCR assays. ASSVd-specific primers amplified fragments of about 330bp from extracts of samples from infected apple, pear, apricot, and peach trees. The RT-PCR assay detected 15 strains of ASSVd from apple, 13 strains from pear, 11 strains from peach, and 12 strains from apricot samples. Sequence analysis of the selected clones showed that the full-length of ASSVd contained 330-nt. The detection rates for ASSVd were 2.1%, 2.1%, 2.8%, and 3.3% in apple, pear, peach, and apricot, respectively. The extent of incidence of ASSVd in different countries varied over 0.4–8.5%. The in situ RT-PCR assay revealed the blue-purple positive signals in the nucleus of palisade tissues of ASSVd-infected plants, but not in healthy plant tissues. The presence of ASSVd-specific plant tissues and ASSVd-specific nucleotide sequences was detected in infected tissues confirming the infection by *Apple scar skin viroid* (Wang et al. 2012).

A duplex RT-PCR assay in combination with a plant mRNA as internal control was developed to evaluate the quality of RNA extracted from a dormant potato tuber, and the effectiveness of detection of *Potato spindle tuber viroid* (PSTVd) by the duplex RT-PCR was also assessed. Furthermore, a noninfectious RNA based on the PSTVd sequence, was generated in vitro as a readily available positive control to prevent false-negative results. This noninfectious RNA was distinguishable from the true positives in PSTVd infection. This protocol provided an accurate and reliable system that could be useful for routine application in plant quarantine and phytosanitary certification programs (Hataya 2009).

The members of the genus *Pospiviroid* infect potato, tomato, and ornamental plants and nine species, namely *Potato spindle tuber viroid* (PSTVd), *Tomato chlorotic dwarf viroid* (TCDVd), *Mexican papito viroid* (MPVd), *Tomato planta macho viroid* (TPMVd), *Chrysanthemum stunt viroid* (CSVd), *Citrus exocortis viroid* (CEVd), *Tomato apical stunt viroid* (TASVd), *Iresine viroid* (IrVd), and *Columnnea latent viroid* (CLVd) (Hadidi and Candresse 2003). RT-PCR assay was employed to detect the viroids in a total of 1766 samples consisting of 891 potato tubers, 156 potato leaves, 258 tomato leaves, and 461 ornamental plants. PSTVd was detected in 4 of 891 tubers, and CSVd in 2 of 154 chrysanthemums grown in greenhouses. Samples of tomato and ornamental plants did not show infection by any viroids belonging to *Pospiviroid* in Turkey, except CSVd which was detected for the first time. Amplification of a 199bp fragment for both PSTVd and CSVd occurred in the infected plants, but not in healthy control plants. The amplified RT-PCR product was visualized as the distinct band by return (R-) PAGE procedure. The results indicated that potato seed tuber and ornamental plant should be rigorously tested by sensitive diagnostic assays to prevent the introduction of *Pospiviroid* spp. which may be transmitted through seeds and vegetatively propagated planting materials (Bostan et al. 2010).

As potato is infected by several viruses and viroids, the need for standardization of RT-PCR procedures was realized; a standardized amplification protocol was therefore

Figure 7.18 Detection of *Potato spindle tuber viroid* (PSTVd) in potato, tomato, and petunia by RT-PCR assay. M: DNA size standards; lanes 1, 2, and 7: healthy tomato, petunia, and potato; lane 3: dry tomato infected with Cornell severe PSTVd strain; lane 4: freshly infected petunia; lanes 5 and 6: dry tomato infected with PSTVd-S; lane 8: water control. Source: Crosslin and Hamlin (2011). Reproduced with permission of Springer Science, Heidelberg, Germany.

developed for the detection of PSTVd and 11 important viruses of potatoes. Further, the same RT-PCR conditions could be effectively adopted for the detection and differentiation of major strains of *Potato virus Y* (PVY). The validated primers and the standardized RT-PCR conditions could provide a robust, convenient, and cost-effective detection useful for potato seed tuber certification agencies and commercial diagnostic laboratories. The ability to test for the presence of these diverse pathogens with the same reagents, thermal cycling parameters, and gel electrophoretic conditions might simplify the diagnostic testing for these important potato pathogens (Fig. 7.18) (Crosslin and Hamlin 2011).

Peach latent mosaic viroid (PLMVd), belonging to the *Avsunviroidae* family, remains latent in orchards for several years and it is transmitted via propagation materials and the cutting and grafting tools commonly used in production areas (Flores et al. 2004). Rapid, reliable, and sensitive techniques are therefore required to avoid the uncontrolled spread of PLMVd and certification of false-negative planting materials/plants. Use of endpoint RT-PCR and molecular hybridization assays were found to be insufficient to avoid false negatives. A complete detection procedure based on reverse transcription (RT) followed by a quantitative real-time PCR format was developed. Initially dimeric PLMVd clones were employed to avoid the difficulties of reverse transcription and inhibitory effects of total extract. Five reverse primers were selected in conserved regions of the PLMVd highlighted by a multiple sequence alignment of 119 PLMVd sequences. In order to avoid selecting nonspecific primers amplifying plant DNA or RNA, the reverse primers R14, R12, R7, R3, and R2 combined with the forward primer (F-PLMVd) were tested by RT-PCR on crude sap extract from peach tree leaves. Three PLMVd-specific primers identified in this manner yielded amplicons of 65 to 135 bp, as recommended for real-time RT-PCR (qPCR). Based on the higher determination coefficient of primers, the F-PLMVd/R7 pair ($R^2 = 0.991$) was selected for further optimization. The comparative effectiveness of reference RT-PCR and RT-qPCR assays was determined. RT-PCR only detected PLMVd at a dilution of 1:100. On the other hand, RT-qPCR assay proved to be 10^5 times more sensitive than the conventional RT-PCR format. The reproducibility of the qPCR assay was checked by independent amplifications from the same extract. The melting curve confirmed specific

amplification of PLMVd even in the most diluted samples (10^{-7}). In order to determine the suitability of RT-qPCR assay for certification programs, the assay was performed using the extracts from two young peach seedlings inoculated at three months after emergence. The reference RT-PCR format did not detect PLMVd in the samples harvested until 8 months postinoculation. The optimized RT-qPCR assay detected PLMVd from 3 months after postinoculation and quantified the viroid concentration in the infected seedlings. The optimized RT-qPCR protocol developed in this investigation incorporates quick, low-cost extraction procedure and efficient primers, making the procedure suitable for routine testing in certification and quarantine programs (Parisi et al. 2011).

7.4.1.3 Reverse-Transcription Loop-Mediated Isothermal Amplification

Reverse-transcription (RT-) loop-mediated isothermal amplification (LAMP) technique is a simple, robust, and rapid method that has been applied for the detection of different kinds of microbial plant pathogens in infected plants. Because of its isothermal nature, RT-LAMP method has the potential for deployment in the field tests. RT-LAMP method was developed and validated for the detection of *Potato spindle tuber viroid* (PSTVd) in potatoes and tomatoes along with RT-PCR format in order to assess the relative sensitivity, rapidity, and reliability of the methods. RT-LAMP procedure was employed to detect PSTVd in total nucleic acid (TNA) extract from infected tubers and tomato leaves using the primers PSTVd-F3, -B3, FIP, -BIP, -LE, and -LB. An increase in the turbidity (formed as white precipitate in the RT-LAMP mixture) began to appear in about 30 min and reached the highest concentration in about 45–60 min. The specific amplifications of the target PSTVd RNA were confirmed by agarose gel electrophoresis. The detection sensitivity of RT-LAMP was about 10 times greater than that of RT-PCR format. RT-LAMP assay was applied to detect PSTVd in the extracts of a potato tuber, 400 potato seeds, and 400 tomato seeds. The viroid was detected stably in all infected samples. PSTVd was detected in the clarified crude sap from PSTVd-infected potato leaves and tomato leaves within 60 min. Further, PSTVd could be detected in the extracts of one tomato seed, but not in any of the 400 potato seed samples tested by RT-LAMP method. The RT-LAMP procedure was simplified by using clarified crude sap and an insect pin. Potato leaves and tomato leaves were struck with insect pins (No. 5) several times and the pins were dipped into 25 μ L of RT-LAMP reaction mixture. PSTVd could be stably detected from infected leaves of tomato. However, detection of PSTVd in potato leaf extracts was inconsistent. The time needed for detection of PSTVd for RT-LAMP method was about one-third of the time required for performing the RT-PCR assay, since PSTVd could be detected by RT-LAMP method under isothermal conditions without gel electrophoresis. Consequently, RT-LAMP method could detect PSTVd rapidly and with high sensitivity compared with RT-PCR assay with these advantages. RT-LAMP procedure might become an alternative for efficient and reliable detection of PSTVd in potatoes and tomatoes (Tsutsumi et al. 2010; Section 7.5.5).

In order to improve the effectiveness of detection of *Potato spindle tuber viroid* (PSTVd) in a single potato tuber, real-time reverse-transcription (RT-) loop-mediated isothermal amplification (RT-LAMP) technique was developed. Amplification was followed in real-time and the specificity of the final product was confirmed by its melting temperature. Total RNA was extracted from fresh leaves, tuber tissue, or lyophilized plant material using the RNeasy Plant Mini Kit (Qiagen) following the manufacturer's instructions with minor modification. The sequences of 173 PSTVd isolates were

aligned and the consensus sequence was used for LAMP primer design. The analytical specificity of RT-LAMP was tested experimentally against a collection of 16 PSTVd isolates and 42 isolates belonging to 6 other species of the genus *Pospiviroid*. The specificity of the RT-LAMP assay was compared with that of the single-step real-time RT-PCR format. Both methods detected PSTVd and *Tomato planta macho viroid* (TPMVd), which are closely related. However, the signals from RT-LAMP assay could be distinguished from the PSTVd signal by melting temperature analysis. The specificity of the RT-LAMP assay was also compared with that of Tsutsumi RT-LAMP procedure (Tsutsumi et al. 2010) which was able to detect only 14 of 16 PSTVd isolates, 2 of them only with late signals (after 31 min). The analytical sensitivity of RT-LAMP assay for PSTVd was estimated to be between 100 and 1000 viroid copies per reaction, a 10-fold greater sensitivity than that of the RT-PCR and 100 times lower than that of real-time RT-PCR assays. Further, RT-LAMP assay was more sensitive (10-fold) than the Tsutsumi RT-LAMP method.

Another format of the assay was developed, based on formation of turbidity in the PCR reaction mixture. RT-LAMP assay required about 10 min less than that needed for the optimized Tsutsumi RT-LAMP format. The one-step RT-LAMP assay could be a simple first-line screening of potato PSTVd RNA, allowing real-time detection of this pathogen of quarantine importance. A few cross-reactions observed in the RT-LAMP assay might be resolved from the signals observed. *Tomato chlorotic dwarf viroid* (TCDVd), *Tomato planta macho viroid* (TPMVd), *Chrysanthemum stunt viroid* (CSVd), and *Columnea latent viroid* (CLVd) could be differentiated from PSTVd based on melting curve analysis. This RT-LAMP protocol could be employed to detect PSTVd in potato tuber and leaves and also in tomato and ornamental hosts of PSTVd. The speed, lower screening time, and cheaper reagents and consumables required for the RT-LAMP assay may significantly reduce the cost of testing (Fig. 7.19) (Lenarčič et al. 2012).

Figure 7.19 Comparative sensitivity of RT-LAMP and Tsutsumi RT-LAMP assays for detection of *Potato spindle tuber viroid* (PSTVd) using different dilutions of total potato plant RNA. Dilutions of total RNA: 1×10^{-2} ; 1×10^{-3} ; 1×10^{-4} ; control: water (without template). Source: Lenarčič et al. (2012). An outbreak of *Potato spindle tuber viroid* (PSTVd) occurred in commercial glasshouse-grown tomato crops in Queensland, Australia. Phylogenetic analysis revealed that the genotype of this isolate grouped in a cluster of PSTVd genotypes from tomato and *Physalis peruviana* and had a mutation ($U_{257} \rightarrow A$) that was earlier linked to lethal symptom expression in tomato. The viroid could be mechanically transmitted from crushed fruit sap but not from undamaged fruits. A low rate of asymptomatic infection was recorded among the affected plants in the glasshouse. None of the solanaceous weed species present outside the glasshouse was infected by PSTVd, indicating that the weeds were not likely to have a role in PSTVd epidemiology. Monitoring and subsequent testing of new tomato crops grown in the glasshouse showed that viroid infection had been successfully arrested. The trace-back analysis linked the outbreak of PSTVd to an infected tomato seed lot, indicating that PSTVd was transmitted internationally through contaminated seeds (van Brunschot et al. 2014).

7.4.1.4 Single-Strand Conformation Polymorphism Analysis

Six isolates of *Peach latent mosaic viroid* (PLMVd), inducing three different symptoms under field conditions, were examined by using single-strand conformation polymorphism (SSCP) and nucleotide sequence analyses. Each of the PLMVd isolates was found to be composed of a population of genetically related variants (haplotypes), one being predominant with frequencies of 32–57% and most of the others having a low frequency of 4–5%. Each predominant haplotypes was selected randomly to compare the nucleotide sequences. The predominant haplotype displayed a wide representative of sequence for others in a PMLVd isolate. The similarities and genetic distance between the predominant sequences from peach showing the same symptoms were higher than that with different symptoms: >98.8% and <1% between the predominant sequences with different symptomatic source, respectively. The results suggested that some correlations might exist between the genetic diversity and symptoms, but whether change in the bases are crucial factors in deciding the type of symptoms induced by the isolates of PLMVd has still to be determined by further investigation (Xu et al. 2008b).

7.5 Appendix

7.5.1 Detection of *Citrus Tristeza Virus* by Improved Direct Tissue-Blot Immunoassay (I-DTBIA) in Citrus Plants (Lin et al. 2000, 2006)

7.5.1.1 Preparation of Antibodies

- i) Use purified IgG as antibody sources for polyclonal antibody PCA1212 and MAb MCA 13; use undiluted cell culture fluid as source for MAb 17G11.
- ii) Use goat antimouse Ig (H + L) -alkaline phosphatase conjugate (GAM-AP) as secondary antibodies to react with CTV MAbs and goat antirabbit IgG alkaline phosphatase conjugate (GAR-AP) to react with CTV PCA (GAM-AP and GAR-AB) supplied by Southern Biotechnologies Assoc Inc., AL and Sigma Chemical Co, MO, USA.
- iii) Prepare prereaction solutions using PBS buffer containing 0.15 M sodium chloride, 0.015 M sodium phosphate, pH 7.0 or PBS-B buffer containing 1% fetal bovine serum (BS); prepare prereaction solutions for MAbs by directly adding GAM-AP into MAb17G11 cell culture fluid; maintain the concentrations of PCA1212 and MCA13 at $1.0 \mu\text{g mL}^{-1}$ and dilutions of GAM-AP were 1/1000 to 1/4000 and dilutions of GAR-AP at 1/5000 to 1/10000.

7.5.1.2 Improved DTBIA Procedure

- i) Cut sections (100–200 μm thick) using a new razor blade from fresh stems, petioles, or veins from healthy or infected plants; maintain 4–6 replicates for each sample; gently and evenly press the fresh-cut surface of the stems onto nitrocellulose membrane.
- ii) Incubate with prereaction solutions of CTV-specific antibodies ($1.0 \mu\text{g mL}^{-1}$) mixed with labeled secondary antibodies (1/1000 for GAM-AP, 1/5000 dilution for GAR-AP) for 20 min and rinse with PBST buffer (0.15 M sodium chloride, 0.015 M sodium phosphate, pH 7.0, 0.05% Tween-20) for 5 min.
- iii) Incubate the blots with 300–500 μL of a freshly prepared NBT-BCIP substrate mixture (66 μL of nitroblue tetrazolium at 0.3 mg mL^{-1} and 33 μL of 5-bromo-4-chloro-3-indolyl phosphate at 0.15 mg mL^{-1} in 10 mL of 0.1 M sodium carbonate buffer, pH 9.8) for 5–15 min; stop the reaction by removing the substrate solution and adding 500–1000 μL of water.
- iv) Record the results by observing under a light microscope at $\times 10$ to $\times 25$ magnification; positive reaction is indicated by development of purple color in blots.

7.5.2 Detection of Tomato Spotted Wilt Virus (TSWV) in *Ranunculus* Tubers by Tissue-Blot Immunoassay (Whitfield et al. 2003)

7.5.2.1 Preparation of Plant Tissue Samples

- i) Roll leaf samples into tight bundle; slice with a razor blade and gently blot the oozing sap onto 0.45 μm Nitro ME nitrocellulose membranes (Micron Separations, Inc., MA) for 3–5 s.
- ii) Incubate the rootlets sampled from dried tubers (*Ranunculus*) for 16–20 h in deionized (DI) water in 24-well microtitre plates at room temperature (RT); cut cross-sections of each rootlet using a razor blade and press the cut surface gently into nitrocellulose membrane.

7.5.2.2 Tissue-Blot Immunoassay (TBIA)

- i) Air-dry the blotted membranes at RT; place them in hybridization tubes and allow them to react with reagents as indicated in the following.
- ii) Carry out all incubations and wash steps at RT in a hybridization oven (Lab-Line, Barnstead, IA) at 16 rpm; expose membranes to reagents sequentially and pour in and out the reagents from the tubes without removing the membrane.
- iii) Block the membranes with 10 mL of 1% bovine serum albumin (BSA) in phosphate buffered saline (PBS) (0.14 M sodium chloride, 1.0 M potassium phosphate, 8.0 mM sodium phosphate and 2.5 mM potassium chloride at pH 7.5) for 1 h.
- iv) Treat the membranes with appropriate dilution of anti-NSs monoclonal antibody from a stock solution (MAb at 1 mg mL^{-1}) by diluting in 4 mL of antibody dilution buffer (PBS, 0.1% Empigen BBe (Calbiochem La Jolla, CA) and 0.1% BSA); incubate the antibody for 2 h; wash three times in PBS with 0.5% Tween (PBST) for 5 min/wash followed by incubation in 4 mL of a 1:2000 dilution (in antibody dilution buffer) of rabbit antimouse alkaline phosphatase conjugate (Biorad, Richmond, CA) for 1 h.
- v) Wash the membranes again in PBST (3 times, 5 min/wash); add alkaline phosphate substrate (Sigma Fast BCIP/NBT tablets, b5655); incubate the membranes for 5–15 min; rinse in water and examine after air drying at RT.
- vi) Observe for the development of purple color, indicating the positive reactions.

7.5.3 Detection of *Citrus Tristeza Virus* (CTV) by Hybridization Assays (Narváez et al. 2000)

7.5.3.1 Preparation of Nucleic Acid Extracts

- i) Pulverize young bark of CTV-inoculated and healthy sweet orange plants with liquid nitrogen; extract with 4 mL g⁻¹ tissue of 2 × STE (10 × STE = 0.5 M Tris-HCl, 1 M NaCl, 10 mM Na₂EDTA, pH 6.8), 1% SDS, 50 μL of a bentonite suspension (32 mg mL⁻¹) and 12 mL g⁻¹ tissue of STE-saturated phenol/chloroform (1:1 v/v) and centrifuge at 10,000 g for 15 min.
- ii) Collect the supernatant containing total nucleic acids; precipitate with cold ethanol and sodium acetate and resuspend in 50 μL distilled water (concentrated RNA).
- iii) Purify ds-RNA from the total nucleic acid extract by nonionic cellulose (CF-11, Whatman) column chromatography in the presence of 16% ethanol.
- iv) Denature aliquots of 2 μL of nucleic acid extract with an equal volume of formamide at 94°C for 3 min; chill on ice and spot the solutions to nylon membranes (Hybond, Amersham) or polyvinylidene difluoride (PVDF) (Immobilon-N, Milipore) and bake the membrane at 80°C for 2 h in a vacuum oven or irradiated with UV light (50 mJ) in cross-linking oven.
- v) Prepare tissue prints by cutting transversely tender shoots or leaf petioles, gently pressing the cut surface to the membrane and air dry.

7.5.3.2 Hybridization

- i) Prehybridize the membranes for 2 h in 6 × SSC (20 × SSC = 3 M NaCl, 0.3 sodium citrate, pH 7.0), 5 × Denhardt's solution (50 × Denhardt's = 1% Ficoll, 1% bovine serum albumin, 1% polyvinylpyrrolidone), 1% sodium dodecylsulfate (SDS) and 100 μg mL⁻¹ denatured Salmon sperm DNA at 60°C for nonradioactive detection.
- ii) Perform hybridization at 60°C overnight, adding 25 ng of the DIG-labeled probe; wash the membranes twice (15 min each) in 2 × SSC and 1% SDS at room temperature twice in 0.1 × SSC and 0.1% SDS at 60°C.
- iii) For differentiation of CTV isolates using tissue prints, hybridize the membranes as per the Labelling and Detection Kit (Boehringer) instructions at 60°C in 50% formamide; wash twice with maleate buffer plus 0.3% Tween-20, after incubation with anti-DIG antibody.
- iv) Detect positive hybridization with the chromogenic substrate 5-bromo-4 chloro-3-indolyl phosphate (BCIP)/nitroblue tetrazolium (NBT) or with the chemiluminescent substrates LPPD or CSPD (Boehringer Mannheim), as per manufacturer's instructions.

7.5.4 Detection of *Plum Pox Virus* (PPV) by Real-Time RT-PCR and Its Variants (Capote et al. 2009)

7.5.4.1 Preparation of Crude Extracts of Plant Tissues

- i) Collect samples from adult *Prunus* trees (dormant or swelling buds) in winter; grind in plastic bags containing a heavy net (Plant Print Diagnostics, Valencia) using a hammer in the presence of 1:20 PBS buffer, pH 7.2 supplemented with 2% polyvinylpyrrolidone and 0.2% sodium diethyl dithiocarbamate, and use the same extracts for all detection procedures.

- ii) Prepare serial dilutions (1:10 to 1:10¹¹ v/v) of the extract from PPV-infected and healthy peach seedling (GF305).
- iii) Use sections of leaf petioles and sectors of expanded leaves for GF305 peach seedlings to prepare imprints and squashes on membranes.

7.5.4.2 Real-Time RT-PCR and Dilution, Spot, Tissue Print, and Squash Variants

- i) For conventional RT-PCR, extract total RNA from 200 µL of crude extracts using RNeasy Plant MiniKit (Qiagen) or Ultraclean Plant RNA isolation kit (MoBio).
- ii) For real-time RT-PCR, use 5 µL of total RNA as template with plant crude extract; dilute 5 µL in 100 µL of conventional extraction buffer and use 5 µL of the diluted sample.
- iii) For spot procedure, load 5 µL of plant crude extract onto 0.45 µm positively charged nylon membrane (Roche) or on Whatman 3 MM paper filter.
- iv) For tissue print, gently press fresh sections of tender shoots or leaves on the membranes to make one or several prints; combine leaf petiole imprints from a PPV-infected GF305 peach seedling with overlapping petiole imprints of a healthy GF305 in the same site of the membrane in different ratios (infected:healthy) of 0:8, 1:7, 2:6, 3:5, 4:4, 5:3, 6:2, 7:1, and 8:0.
- v) Squash fresh tissues on the membrane with the bottom portion of the Eppendorf tube; insert sections of membranes with immobilized samples (spotted, tissue-printed, or squashed plant materials) into Eppendorf tubes or placed inside ELISA plate wells for large-scale assays and extract RNA targets with 0.5% Triton X-100 or glycine buffer (0.1 M glycine, 0.05 M NaCl, 1 mM EDTA, pH 8.0).
- vi) Prepare reaction cocktail for SYBR Green Chemistry containing 1 × Power SYBR Green PCR Master Mix (Applied Biosystems), 10 units of RNase inhibitor (Applied Biosystems), 0.3 µM primer P₁ and 0.05 µM primer P₂.
- vii) Provide the RT-PCR conditions as follows: 48°C for 30 min, 95°C for 10 min and 45 cycles of amplification (95°C for 15 s, 60°C for 1 min); prepare a melting curve for temperatures between 60 and 95°C in all cases to verify the specificity of reactions and perform data acquisition and analysis using an ABI Prism 700 and StepOnePlus software packages (Applied Biosystems).

7.5.5 Detection of *Potato Spindle Tuber Viroid* by Reverse-Transcription Loop-Mediated Isothermal Amplification (LAMP) (Tsutsumi et al. 2010)

7.5.5.1 Extraction of Total Nucleic Acid from Potato Leaf, Tuber, and Tomato Leaf Tissues

- i) Extract total nucleic acid from infected plant tissue by sodium dodecylsulfate (SDS-) potassium acetate method; grind the samples (50 mg/sample) in 2 mL buffer solution (0.1 M Tris-HCl (pH 8.0), 0.5 M NaCl, 1% 2-mercaptoethanol, 0.005 EDTA (pH 8.0), 1.25% SDS, 3.3% PVP and 1.25 M potassium acetate (40 v/w)) and stir thoroughly.
- ii) Centrifuge for 10 min at 15,000 g and separate the supernatant.
- iii) Add half volume of 2-propanol to the supernatant; mix and centrifuge for 10 min at 15,000 g.
- iv) Add equal volumes of 99.5% ethanol and 1/10 volume of 3 M sodium acetate to the supernatant and mix well; dissolve the precipitate containing total nucleic acid in 50 µL of 0.1 TE (pH 8.0) and use 1 µL of total nucleic acid as the template for the LAMP reaction.

7.5.5.2 RT-LAMP Reaction

- i) Perform RT-LAMP reaction with a LoopampRNA amplification reagent kit (Eiken Chemical co) in 25 μ L of the mixture containing 1 $\times$ reaction mix (40 mM Tris-HCl (pH 8.8), 20 mM KCl, 16 mM MgSO₄, 20 mM (NH₄)₂ SO₄, 0.2% Tween-20, 1.6 M Betain, 2.8 mM each dNTPs), 0.2 μ M each of F3 and B3 primers, 1.6 μ M each of FIP and BIP primers, 0.8 μ M each of LF and LB primers, 1 μ L Enzyme mix (AMV reverse transcriptase and *Bst* DNA polymerase) and 1 μ L of total nucleic acid.
- ii) Measure turbidity indicating target gene amplification by a real-time turbidity meter (LA-2003 Termecs Co) and carry out the reactions at 65°C for 80 min.
- iii) An increase in turbidity within 60 min indicates positive reaction.

Biology and Infection Process of Viruses and Viroids

Viruses are ultramicroscopic and intracellular obligate pathogens, capable of infecting all living organisms from primitive prokaryotes to highly evolved human beings. Although infection of tulips resulting in tulip break disease was known of for a long time, it was not until the late nineteenth century that viruses were proven to be the causative agents of plant diseases. As viruses are obligate pathogens, requiring the presence of living cells for their existence, their presence in the plants and vectors involved in their transmission from infected plants to healthy plants has to be detected at the earliest possible time by employing sensitive, specific, rapid, and reliable techniques to identify the sources of inoculum. The management of plant virus diseases is largely limited to preventive methods by eliminating infected seeds and propagules and establishing virus-free seed stocks. If seeds and planting materials are not assessed for virus infection they may ruin crops within a short period of time due to the rapid increase in infection levels through subsequent generations. It is imperative to monitor the movement of seeds and planting materials, as globalization facilitates unrestricted exchange of seed materials between countries and regions in a country. Knowledge of various factors that influence virus infection and the development of disease in individual plants, and the spread of disease in individual plants and in plant populations, is required to develop short- and long-term strategies to restrict disease incidence and subsequent spread in the field. Furthermore, the biology of viruses has to be studied to understand their pathogenic potential (virulence), genetic variability, host range, virus–vector relationship, and their survival in the absence of primary host (crop) plant species in order to target the weak link in the disease cycle for the eradication of the virus disease(s).

8.1 Characteristics of Plant Viruses

Plant viruses have simple morphological characteristics with limited variations in the particle morphology that are useful for their reliable identification and differentiation. All viruses have a protein coat (covering) to protect viral genomic nucleic acid from inactivation. The viral nucleic acid may be of either ribonucleic acid (RNA), as in the majority of plant viruses, or deoxyribonucleic acid (DNA) molecules. The viral genome may be encapsidated either in one type of particle (monopartite) or in two (bipartite) or more types of particles (multipartite). There is no evidence for the production of any virus-specific enzyme present in the virus particle or in their capacity

for producing any enzyme of their own during the infection process (pathogenesis). They have to depend entirely on the synthetic machinery of the susceptible host plant for their replication, leading to the development of various types of external and internal symptoms depending on the virus–host interactions. The virus replication process is distinct from other cellular pathogens. Viruses represent particulate entities which are similar to cellular constituents and do not possess any organelle of cellular organisms. The viral components – coat protein (CP) and genomic nucleic acid – are synthesized separately in different sites in susceptible host cells. Viral genomic nucleic acids carry the required information for synthesizing viral components, taking command of the host's synthetic systems and directing the synthesis of the required amino acids and nucleotides for viral coat protein and genomic nucleic acid. When the viral coat protein and nucleic acid reach required concentrations, they are assembled to form infective mature virions (Narayanasamy 2011). The nature of viral genomic nucleic acid, particle morphology, presence of membranous envelope, immunological properties, nucleotide sequences of genomic nucleic acid and amino acid sequences of viral coat (capsid) protein, and the presence of virus-associated protein are the major characteristics used for the identification, classification, and differentiation of plant viruses and their strains (Chapter 7).

8.2 Biological Properties of Viruses

8.2.1 Types of Symptoms Induced by Viruses

The pathogenic potential (virulence) is the basic requirement of any organism to be considered as a pathogen. Plant viruses may infect one or more plant species which may produce visible external symptoms or may remain latent without inducing any recognizable symptoms of infection. The plant species that are asymptomatic can be potential reservoirs of virus inoculum which may be spread by the natural biological vectors or by other means. The symptoms induced by viruses may be macroscopic (externally visible) and/or microscopic (internal) symptoms characteristic of virus infection. The severity of symptoms may differ depending on the levels of susceptibility/resistance of the cultivars to the virus concerned. Likewise, the ability to allow the transmission of the virus(es) through seeds varies depending on the cultivars of the crops. The mechanism of virus transmission through seed was investigated by inoculating *Arabidopsis thaliana*, the model plant, with *Turnip yellow mosaic virus* (TYMV) and *Tobacco mosaic virus* (TMV). Serological and biological tests (grow-out) were conducted to identify the route by which the viruses could reach the seed and their locations in the seed. Both TYMV and TMV were detected in seed from infected plants. However, only TYMV was transmitted from infected seed to seedlings that grew from infected seed as revealed by the grow-out test and enzyme-linked immunosorbent assay (ELISA) test. The mere presence of the virus in the seed coat did not result in seedling infection. Embryo infection was shown to be necessary for seed transmission, which was inferred from the successful seed transmission of TYMV in *A. thaliana* (de Assis Filho and Sherwood 2000). Natural seed transmission of *High Plains virus* (HPV) to the seedlings grown from infected corn seeds was confirmed by the production of mosaic and broad chlorotic streaks in leaves similar to those on HPV-infected mature plants in the field (Forster et al. 2001).

Figure 8.1 Influence of *Bean pod mottle virus* (BPMV), *Soybean mosaic virus* (SMV), and mixed infections on the percentage of seeds of soybean lines with mottling symptoms under field conditions in 2001. Mean percentages of mottled seeds (columns) followed by the same letter are not significantly different as per the Student's test ($P=0.05$). Source: Hobbs et al. (2003). Reproduced with permission of the American Phytopathological Society, MN, USA.

Plant viruses may cause systemic or localized infections. If the virus is able to move from the site of infection to other organs of plants, the virus is said to be systemic, inducing various kinds of discoloration of leaves such as mosaic, vein clearing and chlorosis, and deformation of affected leaves and other plant parts. Dwarfing of plants and smalling of leaves due to virus infection may also be observed. Seeds may also exhibit discoloration, reduction in seed size, and seed germination. Seed infection may result in seed coat mottling, which may pose problems for marketing. *Bean pod mottle virus* (BPMV) and *Soybean mosaic virus* (SMV) alone or in combination produced seed coat mottling to different intensities. A significant level of seed coat mottling was seen in a virus-isolate-soybean line combinations. Percentages of seed coat mottling were significantly higher in BPMV and SMV doubly infected soybean plants than in both BPMV and SMV singly infected plants for cultivars Williams in 2000 and Williams *Im* in 2001 (Fig. 8.1). SMV-resistant line 3 and cultivar Williams-*Rsv1* exhibited negligible percentages of seed coat mottling when challenged with SMV alone. The percentages of seed coat mottling observed in these two lines were therefore probably due to BPMV only. Seed coat mottling of seed from individual parent plants (+ or -), as determined by ELISA tests, were significantly correlated ($P=0.01$). SMV resistance in line 3 and Williams-*Rsv1* offered high levels of protection against SMV infection. The results showed that BPMV induced significant seed coat mottling which could adversely affect the marketability of bean seed (Hobbs et al. 2003). When the virus infection is localized in some plant species, countable chlorotic or necrotic lesions may be produced on inoculated leaves. In such plant species the virus is restricted to the lesions and it is not detectable in other plant parts. The number of local lesions formed on the inoculated leaves may reflect the concentration of the virus inoculum used for inoculation. As the local lesions are considered to be initiated by a single virus particle, the host plant species reacting with local lesions are used as diagnostic or indicator host for detecting and quantifying the virus titer in different systemic host

plants or samples. Furthermore, single lesion isolations are made to differentiate strains of a virus which may differ in some biological properties. Some of the plant species employed as diagnostic hosts are *Nicotiana glutinosa*, *Phaseolus vulgaris*, *Vigna unguiculata*, *Gomphrena globosa*, *Chenopodium amaranticolor*, and *C. quinoa*. Citrus cultivars/species used as diagnostic hosts such as Mexican lime, Dweet tanger, and *Citrus excelsa* have been useful to detect infection by *Citrus tristeza virus*, *Citrus vein enation mosaic virus*, and *Citrus psorosis virus* (Vidalakis et al. 2004; Narayanasamy 2011).

Tobacco mosaic virus (TMV), infecting tomato, is transmitted through tomato seed. The strain of TMV occurring in Sapopena-PR Brazil could not infect *Petunia hybrida*, described as a host for TMV and *Tomato mosaic virus* (ToMV). However, TMV induced severe mosaic symptoms in tomato cultivars Santa Clara and Avansus, while TMV-Sapopena caused only mild symptoms in cultivar Carmen. The TMV-Sapopena strain could be differentiated based on the differences in the type of symptoms induced on tomato cultivars and by its inability to infect *P. hybrida* (da Silva et al. 2008). The biological characterization of 10 isolates of *Cucumber mosaic virus* (CMV) associated with banana mosaic disease (BMD) in Taiwan were compared following inoculation of Cavendish banana plantlets using the cotton aphid (*Aphis gossypii*). The isolates were classified into four pathotypes based on the symptom types induced on banana, *Nicotiana glutinosa*, and cowpea (*Vigna unguiculata*) inoculated by sap inoculation. Three symptom types A, B, and C were distinguishable using *N. glutinosa* as a differential host plant. Two isolates infected systemically inducing mosaic symptoms on newly expanded leaves, while other isolates caused local lesions on inoculated leaves. Satellite RNA associated with CMV did not have any significant effect on symptom intensity induced in banana or in *N. glutinosa* (Chou et al. 2009).

Among the seedborne viruses, members of the genus *Potyvirus* form the largest group and induce characteristic inclusion bodies in the infected cells. The ultrastructural investigations revealed the presence of cylindrical or pinwheel inclusions in their respective host plants. The pinwheel inclusion has a central core from which rectangular or triangular curved plates radiate. In addition to pinwheel inclusions, they produce complex amorphous cytoplasmic inclusion bodies and secondary vacuolation of cytoplasm (Martelli and Russo 1984). *Artichoke yellow ringspot virus* (AYRSV), belonging to the genus *Nepovirus*, was found to be transmitted via onion seeds by up to 20%. *Nicotiana benthamiana*, the indicator plant species, was inoculated by sap inoculation. Cytopathological investigation showed that large cytoplasmic inclusions were produced in the mesophyll cells. These inclusions comprised voluminous accumulations of entangled membranous elements, more or less developed and specifically arranged particle aggregates and conspicuous globules of a possible lipid nature. A very characteristic and apparently specific cytopathologic structure occurred in many infected cells and in different stages of development and localization. This cytopathologic structure mainly contained complexes of two cisternae of rough endoplasmic reticulum (ER) in a parallel arrangement. In addition, a high proportion of infected cells showed the presence of virus particles. On the other hand, in the infected onion leaves extremely vacuolated cells with very low concentrations of cell constituents and AYRSV-induced cytological alterations were observed. AYRSV-On strain predominantly induced particle aggregates in the form of crystal-like arrays, either in particle monolayers enclosed between specially arranged ER cisternae or in double layers not enclosed between membrane elements (Maliogka et al. 2006).

8.2.2 Host Range of Viruses

Plant viruses may be able to infect a large number of plant species which may be other crops grown in the same farm or wild species growing in the vicinity of the cultivated fields. Viruses such as *Potato virus Y* (PVY) and *Alfalfa mosaic virus* (AMV) have wide host ranges including several crop plant species. AMV has been reported to naturally infect many herbaceous and woody plant hosts belonging to 150 species in 22 families. In addition, AMV could be experimentally transmitted to over 430 species in 51 dicotyledonous families (Jaspars and Bos 1980). *Potato virus Y* (PVY) belongs to genus *Potyvirus* to which more than 30 plant species are susceptible, including several crop plants such as potato, bean, peanut, pepper, soybean, lettuce, and watermelon (Narayanasamy 2001). On the other hand, some viruses have the ability to infect only a few wild plant species, in addition to the primary crop plant species. *Rice yellow mottle virus* (RYMV) infected wild rice species *Oryza barthii* and *O. longistaminata* and the presence of RYMV could be detected in the scales of these wild rice species by ELISA tests. RYMV also infected the other grass species *Dactyloctenium aegyptium*, *Eragrostis ciliaris*, *E. tenella*, and *E. tremula*. However, the virus could not be detected in the seeds of these grass species (Allarangaye et al. 2006).

Artichoke yellow ringspot virus (AYRSV), infecting onion crops, was inoculated onto 44 plant species belonging to eight families and 28 species were found to be infected by the virus. The host range of AYRSV included *Cucumis sativus*, *Phaseolus vulgaris*, *Vicia faba*, *Capsicum annuum*, *Nicotiana tabacum* cultivars Samsun, White Burley, and Xanthi which were systemically infected with the virus (Maliogka et al. 2006). *Indian peanut clump virus* (IPCV) infected peanut and was transmitted through seeds of finger millet (5.2%), foxtail millet (9.7%), and pearl millet (0.9%), but the virus did not infect sorghum. Transmission of IPCV in seeds of millets which are often grown in rotation with peanut is important because of the possibility of the infected millet plants being potential sources of inoculum that may be spread by the fungal vector *Polymyxa* sp. Millets in which the Hyderabad isolate of IPCV was seed-transmitted were also found to be the hosts of the vector *Polymyxa* sp. (Reddy et al. 1998).

8.2.3 Genetic Variability of Viruses

Biological, serological, and molecular properties of viruses have been used as the basis of differentiating strains of the viruses transmitted through seeds and propagules. *Plum pox virus* (PPV), causing plum pox or Sharka disease, infects stone fruit trees such as plum, peach, and apricot. Four groups of PPV, namely D, M, EA, and C, were differentiated based on the disease severity on natural hosts, geographical distribution, and latency period. The two most frequently observed groups – PPV-D in apricot and plum and PPV-M in peach – were investigated for their ability to be transmitted through seeds by testing the seeds obtained from infected plants and the seedlings developing from these seeds using immunocapture (IC-) RT-PCR assay. Although PPV was detected in seed coats and cotyledons, none of the seedlings showed symptoms or were PPV-positive in IC-RT-PCR assay, indicating lack of seed transmission of the virus (Pasquini et al. 2000). *Potato virus Y* (PVY) strains were differentiated based on the type of symptoms induced on potato cultivars and other plant species. The strain PVY^O causes mosaic symptoms on most potato cultivars. The induction of veinal necrosis in indicator plants (tobacco) forms the criterion for biological differentiation of PVY isolates. Necrotic ringspot symptoms in potato and tobacco are induced by the strain PVY^{NTN}.

Some isolates of PVY^{NTN} have been shown to be recombinants between PVY^O and PVY^N strains, where other strains might have arisen by point mutation. The potato cultivar Yukon Gold develops necrosis when inoculated with isolates of PVY^N (Chrzanowska 1994; Boonham et al. 2002; Nie and Singh 2002; Baldauf et al. 2006).

A one-step fluorescent RT-PCR assay on a single nucleotide polymorphism (SNP) was developed to examine the relationship between biological and molecular properties of PVY isolates. PVY isolates (42) could be assigned to their respective groups based on this approach. In addition, mixed infection of PVY^N and PVY^O strains could also be resolved, indicating the potential of the one-step fluorescent RT-PCR format for reliably classifying PVY isolates without the requirement of inoculating tobacco cultivar Xanthi plants in the greenhouse (Glais et al. 2002; Jacquet et al. 2005). *Potato virus Y* (PVY) strain PVY^{NTN} causes potato necrotic ringspot disease (PTNRD). The strain PVY^{NTN} was differentiated by applying strain-specific restriction endonucleases that cleave their respective PCR products. Single cleavages of PCR products derived from the 5' end of PVY^{NTN} genome by *Nco*I and that of the PVY^N by *Bgl*II were accomplished. The digests were then resolved by PAGE analysis. The strains of PVY were differentiated based on RFLP profiles. The components of mixed infections in potato by PVY strains could be identified and differentiated reliably and precisely (Rosner and Maslenin 1999; Lorenzen et al. 2006).

Variations in symptomatology, host range, and pathogenicity of strains/isolates of *Zucchini yellow mosaic virus* (ZYMV) have been indicated by Antignus et al. (1989) and Lecoq and Purcifull (1992). The reliability of differentiating isolates of ZYMV based on variation in biological characteristics was examined by inoculating different plant species and also sequencing of genomic portion of the C-terminal part of Nib and N-terminal part of the CP gene of ZYMV. All isolates (12) infected *Chenopodium amaranticolor* which reacted by producing necrotic local lesions, whereas *Gomphrena globosa* was infected only by four isolates. The inability of 8 of 12 isolates to infect *G. globosa* was confirmed by DAS-ELISA test which could not detect these isolates in inoculated *G. globosa* plants (Bananej et al. 2008). Strains of *Soybean mosaic virus* (SMV) were identified based on their pathogenicity on differential soybean cultivars. Use of differential cultivars was widely adopted since it was difficult to differentiate SMV strains by serological methods; most SMV strains were found to be serologically homogenous. A RT-PCR/RFLP procedure was therefore employed successfully for detection and identification of SMV strains. A primer pair amplifying a 1385 bp fragment of the cylindrical inclusion (CI) coding region was used for RT-PCR. The RFLP profiles of the RT-PCR products were compared after restriction digestion with restriction endonuclease enzymes *Rsa*I, *Eco*RI, or *Acc*I. Five strains, as well as the seedborne SMV isolates from local soybean cultivars grown in Korea, could be differentiated by RT-PCR/RFLP analysis (Kim et al. 2004).

Strains of *Citrus tristeza virus* (CTV) were distinguished based on the reactivity with monoclonal antibodies (MAbs), and were placed into two serogroups which were correlated with groups differentiated by sequencing of their coat protein (CP) genes (Shalitin et al. 1994). CTV strains inducing stem-pitting symptoms have to be differentiated from other strains, since the stem-pitting-inducing strains cause serious damages to citrus production. Different combinations of polyclonal antibodies (PAbs) and monoclonal antibodies (MAbs) were used in indirect DAS-ELISA format to identify stem-pitting-inducing strains so that the infected citrus trees could be eradicated to prevent the subsequent spread of these CTV strains (Nikolaeva et al. 1998). The decline-inducing

strains of CTV could be differentiated from non-decline-inducing strains by employing the RT-PCR assay. Two internal primers, one (CP4) specific for non-decline-inducing strains of CTV and two terminal primers HCP1 and HCP2 for the ends of the capsid protein gene, were employed. This RT-PCR protocol was able to detect and also differentiate decline-inducing and non-decline-inducing strains of CTV accurately, since the 320 bp fragments were only amplified from the decline-inducing strains of CTV (Huang et al. 2004). Genetic variations in two groups of CTV isolates (Spanish and Japanese sources) were investigated. Single-strand conformation polymorphism (SSCP) analysis of genes *p18* and *p20* was performed. The genetic diversity was estimated within and between isolates, and the genetic differentiation between populations was evaluated based on nucleotide sequences of representative haplotypes of each isolate and gene. In some isolates, within-isolate diversity was greater than diversity with other isolates because their populations contained distinctly related sequence variants. The genetic variation of different genes, repeated inoculation in the field, homologous RNA recombination between sequence variants, and the presence of different defective RNAs were found to be some of the factors that may contribute to biological variability of CTV isolates (Ayllón et al. 2006).

Isolates of *Citrus tristeza virus* (CTV) collected from different geographical locations were investigated for their differentiation based on the polymorphism in the coat protein (CP) gene by cleavase fragment length polymorphism (CFLP) and single-strand conformation polymorphism (SSCP) analyses. CTV sources were initially biologically characterized, followed by IC-RT-PCR and CFLP analysis targeted to CP gene. All CTV isolates (except one) formed different clusters which frequently shared some kind of geographical or biological relationship. SSCP analysis grouped the clones in a different way, however. The CP gene products of CTV isolates (12) obtained after RT-PCR amplification were analyzed by CFLP procedure. It was possible to group most of the isolates accurately by CFLP analysis according to the sequences of the variants constituting the isolates. The plant inoculated with a mixture of mild and severe isolates showed patterns that were more closely related to those of severe isolates, suggesting that severe isolates could multiply more rapidly and become more predominant in plants inoculated with the mixture of mild and severe isolates. The results indicated that CFLP procedure might be effective for identification and differentiation of CTV isolates more reliably and accurately (Marques et al. 2006).

Genetic diversity of isolates of *Citrus tristeza virus* (CTV) collected from 20 citrus growing countries was assessed using single-strand conformation polymorphism (SSCP) analysis. RT-PCR assay was employed for amplification of CP gene of these isolates followed by cloning and subjecting to SSCP analysis. Haplotypes that produced different patterns within each geographic region were sequenced and a database of 153 accessions of CTV was assembled. The existence of seven well-defined clusters with a coefficient of differentiation of 0.78 was revealed by phylogenetic analysis. An asymmetric PCR-ELISA typing (PET) assay was developed in the frame of this clustering pattern, using a set of eight hybridization probes. The results could be interpreted objectively through a visual basic application that could be compared to the rates of hydrolysis of the ELISA substrate of an assayed isolate to a matrix of rates of hydrolysis obtained from standard haplotypes. An additional notable factor is the possibility of automation as the ELISA test (Nolasco et al. 2009). Severe strains of CTV causing seedling yellows (SY) and/or stem-pitting symptom are potentially dangerous, being responsible for the destruction of citrus plants in several countries. The plants infected by the severe

isolates therefore have to be identified rapidly by employing sensitive and reliable diagnostic methods. Real-time RT-PCR assay was applied by employing a general primer set and three TaqMan locked nucleic acid (LNA) probes targeting sequences characteristic of severe, mild (non-SY, non-SP), and T-36-like isolates. It was possible to amplify expected DNA fragment from fresh or silica-desiccated CTV-infected samples and all isolates except one, which reacted with one or more probes. RT-PCR assays with homologous and heterologous transcript RNA mixes demonstrated that each probe reacted only with its cognate sequence which was detected even at ratios below 2.5%. In a test with 56 CTV isolates from different countries analyzed by real-time RT-PCR format, mild isolates reacted only with the mild probe. In contrast, severe SP and SY isolates reacted with severe SP or the T36-like probes, respectively. The real-time RT-PCR protocol could be effective in differentiating the severe strains of CTV from the mild strains, facilitating the development of required systems for the eradication of citrus plants infected by severe strains of CTV (Ruiz-Ruiz et al. 2009).

Monoclonal antibodies (MAbs) generated against coat protein (CP) of *Grapevine leafroll-associated virus 1* (GLRaV-1) exhibited variations in their levels of specificity of reactions with different isolates of GLRaV-1, as indicated by the results of DAS-ELISA and Western blot analysis. Two MAbs IC4 and IB7 reacted positively with 25 and 32 isolates of GLRaV-1 obtained from infected grapevine plants, but not with GLRaV-3 coat proteins. The MAb IG10 reacted with both GLRaV-1 and GLRaV-3 coat proteins, indicating that these two viruses had some antigenic determinants (epitopes) in common (Seddass et al. 2000). The MAb specific to *Grapevine virus D* (GVD) could react differentially with GVD when tested by ELISA test (Boscia et al. 2001). In order to determine the variability of CP gene of *Citrus psorosis virus* (CPsV), isolates from 50 field sources were analyzed by immunoassay. By employing 23 MAbs and 9 serogroups, at least 10 different epitopes on CPsV coat protein were recognized. The reaction patterns of field sources were determined using triple-antibody sandwich (TAS-) ELISA format. The field sources were grouped into more patterns named A to I. Pattern A was the most frequent, accounting for 39.6% of the field sources. Different *Citrus* species and cultivars growing in the same plot frequently showed distinct reaction patterns. By using TAS-ELISA to analyze 40 isolates from different countries with 24 MAbs, 14 reaction patterns and at least 17 different epitopes of CPsV coat protein were identified (Alioto et al. 2003).

Several strains of *Plum pox virus* (PPV) infecting plum trees have been identified. Serotypes of PPV designated PPV-D and PPV-M could be differentiated by employing specific MAbs in DAS-ELISA tests (Candresse et al. 1998). In a later investigation, two more serotypes C and EL Amar were identified in addition to the serotypes D and M (Myrta et al. 1998). Triple-antigen sandwich (TAS-) ELISA format with MAbs specific to PPV-M and PPV-D serotypes was employed for assessing the reactivity of 43 isolates collected from orchards in Romania. All isolates reacted positively to at least one of the two MAbs, as well as to PPV-D- and/or PPV-M-specific primers in PCR assays. Using TAS-ELISA test 21 isolates were identified as PPV-D (48.8%), 17 isolates as PPV-M (39.6%), and 5 isolates as a mixture of D and M strains (11.6%). The results were corroborated by those of immunocapture (IC-) RT-PCR format (Zagarai et al. 2008).

The need to assess the extent of genetic diversity of *Plum pox virus* (PPV) was emphasized because of the destructive nature of Sharka or plum pox disease infecting *Prunus* spp. all over the world. The serologically distinct strains PPV-D and PPV-M could be differentiated by *RsaI* polymorphism in RFLP analysis. The unique 243bp DNA

fragment was amplified by P1 and P2 primers located at the C-terminus of PPV CP gene or by direct IC-RT-PCR typing using PD- and PM-specific oligonucleotides (Olmos et al. 1997). RT-PCR was performed using primers capable of amplifying the 243 bp fragment in the C-terminus of the CP coding region. Restriction fragment length polymorphism (RFLP) analysis applied to the amplified 243 bp fragment showed that restriction sites of *AluI* and *RsaI* were present in the samples extracted from plum and apricot. An amplified 836 bp cDNA fragment derived from the P3-6 K coding regions of both isolates had restriction profiles typical of PPV-D strain. Nucleotide identities of 99–100% were observed for the 243 bp fragments of the Kazakhstan isolates when compared to the corresponding regions of strain D, and the similarity of identity with strain M was 94–95%. Nucleotide sequence analysis of the entire CP coding region of the plum and apricot isolates resulted in the identification of a unique deletion of six nucleotides in the N-terminal region of the plum isolate. Several nucleotide substitutions in the CP coding region were commonly seen in plum and apricot isolates and they seemed to be unique to the Kazakhstan isolates (Spiegel et al. 2004).

Pepino mosaic virus (PepMV) induced two types of yellowing symptoms, namely interveinal leaf yellowing and yellow mosaic, in glasshouse tomatoes. After several weeks, the interveinal yellowing symptoms gradually disappeared and leaves in the apical portions became green (green heads) again, with yellow mosaic patterns on the leaves as intermediate stage. The sequencing of multiple isolates causing interveinal leaf yellowing identified two point mutations, occurring in positions 155 and 166 of coat protein (CP), as unique to the yellowing pathotype. Site-directed mutagenesis of infectious clones confirmed that both CP mutations are determinants of the interveinal leaf yellowing symptoms. Sequencing of CP clones from plants or plant parts with yellow mosaic symptoms resulted in a mixture of wild-type and mutated sequences, whereas sequencing of CP clones from the green heads of recovered plants resulted in only wild-type sequences. Yellow mosaic symptoms could be reproduced by inoculation of an artificial 1:1 mixture of RNA transcripts from wild-type and mutated infectious clones. The results showed that the ratio of mutated versus wild-type sequences could determine the nature and severity of symptom development. The gradual recovery of the plants, which coincided with disappearance of the yellowing mutations, suggested that selection pressure might act to the advantage of the wild-type virus. Experiments with wild-type and mutated infectious clones showed that reverse mutation events from mutants to wild-type occurred and the wild-type virus did not have a replicative advantage over the mutant (Hasiów-Jaroszewska et al. 2013).

8.2.4 Modes of Transmission of Viruses

Plant viruses, being obligate pathogens, cannot exist in a free state except in the case of a few viruses. In contrast, most of the fungal or bacterial pathogens are dispersed freely as spores, sexual spores, or other structures which may be resistant to adverse conditions. Further, like fungal or bacterial pathogens, plant viruses do not produce any enzymes or toxins that may aid in the penetration of or ingestion through unwounded plant surfaces. Plant viruses therefore cannot infect unwounded plant surfaces and have to be introduced and deposited inside the susceptible cells of the host plants. Transmissibility of plant viruses via pollen, seed, and propagules has been discussed already (Chapter 7). Another important characteristic of viruses is their natural dissemination through vectors such as insects, mites, nematodes, or fungi. In a few

cases such as *Tobacco mosaic virus* (TMV) and *Potato virus X* (PVX), transmission through leaf contact may be possible under field or glasshouse conditions. Potato viruses are known to be transmitted through cutting knives and other handling equipments. Transmission of viruses may be accomplished under in vitro conditions, by mechanical inoculation, or sap inoculation. Grafting and budding operations and other nursery practices have been shown to be responsible for significant spread of viruses infecting fruit crops. Transmission of some viruses through parasitic dodder (*Cuscuta* spp.) and natural root grafts may also occur.

Plant viruses are transmitted by different types of vectors with varying efficiency. The nature of relationship between the virus and the vectors is determined by the virus concerned. Three kinds of major virus–vector relationships have been recognized. The viruses may be grouped as nonpersistent (styletborne), semipersistent (circulative), and persistent (propagative) viruses based on the nature of their relationship with the vectors. Nonpersistent viruses are acquired by their vectors after a short acquisition feeding period (a few minutes) on the infected source plants, and can be transmitted to healthy plants immediately after acquisition of the virus from the infected plants. There is no demonstrable latent (incubation) period in the vectors. The vectors of nonpersistent viruses lose their infectivity after moulting. These viruses are also known as styletborne viruses. The semipersistent viruses are acquired by their vectors after several hours of acquisition access period on the infected source plants. A latent period of few hours or days may be required after the acquisition access period on the infected source plants before the vectors become infective and are able to transmit the viruses to healthy plants. These viruses are called semipersistent or circulative viruses. The vectors remain infective for a long time (several days) and even after moulting. The third type of viruses is designated persistent or propagative viruses. These viruses are acquired by their vectors after a long feeding period (several days) on infected source plants and can be transmitted after a long latent period (several days or weeks) to healthy plants. Some of the persistent viruses are able to multiply in their vectors and may be transmitted to the next generation through eggs. This type of transmission is known as transovarial transmission or congenital transmission. Viruses transmitted via seeds have predominantly different aphid species as vectors. Some of the aphid-transmitted viruses such as *Alfalfa mosaic virus*, *Cucumber mosaic virus*, *Pea enation mosaic virus*, *Barley stripe mosaic virus*, *Potato virus Y*, and *Lettuce mosaic virus* are also transmitted through seeds. Viruses infecting citrus, stone fruits, strawberry, and banana are transmitted by different species of aphids and these viruses are also transmitted through propagules. The vector efficiency differs with species of vectors, virus, and the environmental conditions that influence vector population and movement. Nematodes and fungi function as vectors of members of the genera *Nepovirus* and *Furovirus*, respectively. The nature of virus–vector relationship and vector specificity may be useful for putative identification of plant viruses to some extent. However, the identity of the virus concerned has to be conclusively established using immunoassays and/or nucleic acid-based techniques.

8.2.5 Cross-Protection of Viruses

The phenomenon of cross-protection of plants by mild strain against severe strain of the same virus or related virus was demonstrated in tobacco against *Tobacco mosaic virus* (TMV) (McKinney 1929) and *Potato virus X* (PVX) (Salaman 1933). No additional symptom due to inoculation with severe strain was observed in plants already

inoculated with the mild strain. Cross-protection is one of the biological properties of viruses used to establish relationships among viruses and their strains. The degree of cross-protection, as a measure of relatedness of strains, may be determined quantitatively by inoculating a systemically invading strain and a local lesion-forming strain on an appropriate host plant species. For example, relationships between TMV strains could be determined by inoculating *Nicotiana sylvestris* with the type strain causing systemic infection; when these plants were inoculated with aucuba mosaic strain of TMV, the number of local lesions formed by the challenging strain was significantly reduced (Kunkel 1934). The phenomenon of cross-protection by mild strains against severe strains of viruses has been exploited for protecting plants as an effective disease management strategy. Cross-protection between virus strains as a practical disease management strategy was assessed.

CM95, an attenuated isolate of *Cucumber mosaic virus* (CMV), was evaluated for its ability to protect plants against severe isolates of CMV under field conditions. RT-PCR-RFLP procedure was used to rapidly detect and differentiate CMV-95 from severe isolates. Preimmunized plants were challenge-inoculated at 14 days after inoculation with CMV-95 isolate. The appearance of symptoms on newly formed upper leaves was monitored at 30 days after inoculation. RT-PCR-RFLP technique rapidly revealed the presence or absence of the severe isolates in the preimmunized plants much earlier than assessment of cross-protection based on symptoms expression which required 30 days after inoculation (Nakazono-Nagaoka et al. 2005).

The degree of protection varied with *Citrus tristeza virus* (CTV) isolate and climatic conditions at a given location. Preimmunization with mild CTV isolate (PB61) protected Marsch grapefruit trees against stem-pitting strain for 35 years. However, a gradual increase in CTV severity occurred in the preimmunized trees used as budwood sources, commencing 17 years after planting. Nevertheless, the preimmunized trees remained vigorous and productive with only 6 of 64 trees showing mild trunk-pitting. Breakdown in mild strain protection was seen more significantly in subpropagations from trees with mixed infections (Broadbent et al. 1995). Mild strains of CTV have been shown to have the potential to protect grapefruit plants against severe strains. Grapefruit cultivar Ruby Red plants on sour orange rootstock were graft-inoculated with three mild isolates of CTV whose ability to protect the plants was determined at 16 years after inoculation with mild isolates. The mild isolate DD102 protected the grapefruit plants most effectively against severe strains of CTV (Powell et al. 1999). Kagzi lime plants inoculated with mild strain showed a significantly reduced incidence of decline due to severe strain of CTV. The presence/absence of severe strain of CTV was checked by employing enzyme-linked immunosorbent assay (ELISA) tests (Chakraborty and Ahlawat 2001).

The efficacy of preimmunization against superinfection was influenced by the inoculation method, the challenge isolate involved, and the host and its physiological status. The protective capacity of a mild strain (PB61) of *Citrus tristeza virus* (CTV) to protect Marsh grapefruit seedlings against superinfection with the severe grapefruit stem-pitting (OSP) isolates (PB155 or PB235) was assessed. Symptom development in the test plants was monitored by applying isolate-specific RFLP analysis of amplicons generated by RT-PCR and multiplex RT-PCR assays. Only 1 of 15 Symons sweet orange (SSwO) seedlings preimmunized with PB61 (mild strain) and challenged with PB235 by aphid inoculation was superinfected by 90 days postinoculation, compared to 14 of 15 days in non-preimmunized control plants. Preimmunization with PB61 did not ameliorate the

expression of OSP symptoms once superinfection with OSP-inducing isolates was initiated, and the mild strain could not prevent movement of challenge virus. Preinoculation with a severe OSP isolate (PB155) did not delay superinfection by PB61 when introduced via grafting. Preimmunization with PB61 isolate protected plants more effectively against OSP isolate PB235 than against OSP PB155. The higher level of protection provided against PB235 isolate might be due to its closer nucleotide sequence homology to PB 61 (97.6%) than to the PB155 isolate (91.2%). The more effective protective capacity of PB61 against the isolate PB235 might be a direct function of the sequence homology between them. A model of RNA-mediated defense was suggested whereby infection with the preimmunizing isolate might trigger the host to produce a ds-RNA-specific nuclease which targets the viral RNA for degradation to low levels. This might result in the appearance of small nucleotide fragments such as those observed during posttranscriptional gene silencing (PTGS) process. Once PTGS is established other transcripts homologous, or nearly so, to the silenced gene are also subsequently degraded if they infect the plant. The mechanism of development of cross-protection appeared to be through operation of the PTGS in citrus plants inoculated with the challenged strain (mild strain) (Zhou et al. 2002).

Changes in the populations of sequence variants of *Citrus tristeza virus* (CTV) isolates from different geographic origins and pathogenicity properties were followed using single-strand conformation polymorphism (SSCP) analysis of cDNA of the genes *p18*, *p13*, *p20*, and *p23*. RT-PCR with primers specific for selected genes yielded DNA fragments of the expected sizes: 425, 438, 520, and 698 nucleotides for genes *p18*, *p13*, *p20*, and *p23*, respectively. The mild isolates of CTV used in this investigation generally yielded a SSCP profile with two DNA bands, indicating that their viral populations might be more complex. The set of SSCP profiles of the four genomes allowed identification of individual isolates, but no profile characteristic of a geographic location or a biogroup could be recognized. The SSCP profiles of the mild isolate T425 for genes *p18* or *p20* differed from the corresponding profiles of the severe isolates T388 or T305 and provided a convenient system to discriminate between the predominant sequence variants of these isolates in mixed infection (Fig. 8.2). Sweet orange plants singly inoculated

Figure 8.2 Differentiation of *Citrus tristeza virus* (CTV) isolates in individual and mixed infections of sweet orange plants based on SSCP profiles characteristic of *p18* gene. SSCP profiles of mild isolate T425, severe isolates T388 or T305, or a mixture of T425 and T388 or T425 and T305 in the extracts of inoculated plants determined at 3 years after challenge inoculation with T388 or T305 isolates. Source: Sambade et al. (2002). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

with a mild or with a severe isolate yielded the SSCP profile characteristic of each isolate, whereas the SSCP profile of plants successively inoculated with both mild and severe isolates was a composite of two individual profiles. In these plants, the DNA bands characteristic of the mild isolate T425 were often less intense than those characteristic of T388 or T30 (severe isolates challenge inoculated). The SSCP profile of plants singly inoculated remained constant, but the profile of doubly inoculated plants varied with time. Plants in which the SSCP profile of the severe isolates became predominant showed stem-pitting symptom. On the other hand, the plants in which the predominant profile corresponded to the mild isolate remained asymptomatic. In cross-protection experiments, the virulent RNA population usually out-competed and reached a higher titer than the pre-existing mild RNA population. The shift in population could be efficiently monitored (during 3–6 months after challenge inoculation) by periodical SSCP analysis of gene *p20*. The observation that DNA bands characteristic of T425, T11, or T32 were always present in the SSCP profile of the doubly inoculated plants indicated that the population of the mildly pathogenic isolates were overgrown by populations of the severely pathogenic isolates, but they were not totally displaced. Periodical SSCP analysis of the budwood sources could be a simple and reliable procedure to check the authenticity of the mild protecting isolate and to detect a potentially dangerous change in its RNA population before bud propagation to produce new cross-protected plants (Sambade et al. 2002).

Citrus psorosis disease has been presumed to be due to *Citrus psorosis virus* (CPsV), the type member of the genus *Ophiovirus* (Milne et al. 2000). CPsV was generally detected by biological assay on sensitive sweet orange seedlings (*Citrus sinensis*) grown in a temperature-controlled (18–26 °C) greenhouse. Later, specific diagnosis of psorosis was performed by cross-protection tests or immunoassays. Direct tissue-blot immunoassay (TBIA) and enzyme-linked immunosorbent assay (ELISA) were employed for the detection of CPsV in field-grown *Citrus* spp. Field samples of different varieties of sweet orange, grapefruit, lemon, clementine, Satsuma, and sour orange (*Citrus aurantium*) showing psorosis symptoms from different citrus growing areas in Spain and Italy were tested. For biological indexing of field sources, two seedlings each of sweet orange and *C. excelsa* were graft-inoculated with bark pieces from each candidate tree. Pineapple sweet orange plants were challenge-inoculated with the isolate PB108 and evaluated for cross-protection at 3 and 6 months later. A cross-protection test was performed for the diagnosis of CPsV. Sweet orange seedlings preinoculated with candidate psorosis isolate A were challenge-inoculated with psorosis B. Plants already inoculated with psorosis A did not develop leaf pustules and twig blisters characteristic of psorosis B. Healthy sweet orange seedlings inoculated with psorosis B exhibited characteristic symptom within 6 months, whereas plants already infected with psorosis A were protected and did not exhibit the symptoms of psorosis B. Cross-protection against psorosis B was observed in 41 of 47 citrus plants, as indicated by the absence of symptoms induced by psorosis B.

As this procedure was found to be slow and expensive in terms of trained personnel and large greenhouse space with temperature-controlled facilities, detection of CPsV by ELISA, RT-PCR, molecular hybridization, and ISEM techniques was compared with the results of cross-protection tests. CPsV was detected by the four techniques in plants inoculated with all isolates of psorosis A and B and two of the ringspot type isolates (RS-108 and RS-ALM). The presence of biologically characterized CPsV isolates was detected by ELISA, RT-PCR, dot-blot hybridization, or ISEM, and the results were

correlated with psorosis diagnosis by biological indexing and cross-protection tests. The results suggested that CPsV was the causal agent of psorosis, as defined by the cross-protection test against psorosis B and that rapid diagnosis of CPsV disease could be accomplished by employing one or more of the rapid tests employed in these investigations (Martin et al. 2002, 2004).

8.3 Infection Process of Plant Viruses

8.3.1 Virus Replication

Plant viruses have structural features distinctly different from those of cellular bacterial pathogens and multicellular fungal pathogens. Plant viruses constitute a group of obligate intracellular and molecular pathogens resembling the host cellular constituents rather than the cells. As the requirements of viral replication are different, their strategies for successful infection and development of symptoms (pathogenesis) are also different and unique. As no known physiological functions and enzymatic activities of viruses are known, the viruses depend on the wounds created by mechanical damage on the plant surface or feeding injuries made by the vectors of viruses. The viruses have to be deposited directly into the susceptible host cells because of their inability to enter through the intact host cells. Viral infection of susceptible hosts is a complex process. Four principal stages in the process of infection by viruses have to be completed for successful infection of the natural host plant species: (i) entry into plant cells; (ii) replication in the primarily infected cells; (iii) cell-to-cell movement through plasmodesmata (PD); and (iv) long-distance movement through vascular system. As the animal cells lack a cell wall, animal viruses are able to enter the cells through a receptor-mediated endocytosis. In contrast, plant cells have cell walls forming a formidable barrier to the entry of the viruses and there is no receptor-mediated mechanism operating for effecting initial transfer of the plant virus into a plant cell. The cell-wall barrier has to be breached and the virus particle needs to be placed inside the cell through wounds or injuries by feeding vectors.

Soon after the entry of the virus particle into the susceptible plant cell, uncoating of viral coat protein is initiated and the viral genome is released into the cell cytoplasm. The infecting viral genome is translated directly if it is + sense RNA. Single-stranded (ss) RNA or mRNAs are formed and translated to produce early products such as virus replicase and perhaps other virus-specific proteins. The viral replicase or replicase-associated protein(s) required for the synthesis of subgenomic mRNAs are formed. The new viral RNA genomes are synthesized by the viral replicase or replication-associated proteins. Proteins needed relatively late in the viral replication cycle, such as coat protein (CP) and movement protein (MP) essential for cell-to-cell movement of the viruses, are synthesized. When they reach sufficient concentrations, coat protein subunits and viral genomes are assembled together for the production of new progeny virions, usually in the cytoplasm. The mature virions move from the initially infected cell to adjacent cells. If the virus has the capacity to move to other cells, different plant organs are infected in systemic infection. If the cell-to-cell movement is restricted by the host defense system the virus is localized, leading to local infection and giving rise to a relatively small zone of infected tissue which may be recognized as chlorotic or necrotic local lesions on the inoculated leaves. The principal stages in virus replication may vary depending on the nature of host–virus combinations.

For the successful infection of plants, viruses need to overcome a series of pre-existing physical and chemical barriers in plants. If the virus succeeds in overcoming this first line of defense, it has to face the nonspecific defensive reactions with which the plant responds to some molecular patterns that are common to different pathogens. Plants are able to recognize virulence factors of viruses and create a new, more specific resistance layer that is induced only when faced with viruses expressing the virulence factor(s). A virus can cause productive infection only in plants that are unable to develop specific defense responses to its virulence factors (Jones and Dangl 2006). Viral RNA induces specific plant defense responses in which a large number of plant proteins participate. Dicer-type ds-RNases, ss-RNases belonging to the Argonaute-type protein family, assemble in RNA-induced silencing complex (RISC), RNA polymerases, and RNA helicases (Dunoyer and Voinnete 2005). This antiviral response, which is one of the manifestations of a complex set of cellular proteases known as RNA silencing, is apparently universal and the virus not only needs to escape the defenses that are host-produced obstacles but must also successfully accomplish all stages in its life cycle. The initiation of this cycle depends on the nature of the genetic material of the virus concerned. The induction of plant defense mechanisms, their suppression by counteracting viral strategies, and the cooperation of host factors required for virus replication and movement may confer a pathological condition upon successful virus infection (Pallás and García 2011).

RNA silencing is a potent surveillance system targeting parasitic RNA in a highly sequence-specific manner, manifesting as posttranscriptional gene silencing (PTGS) in plants. The RNA silencing pathway in plants constitutes a formidable defense against viral pathogens. Most plant viruses have adopted counter-defensive strategies to overcome the host silencing pathway. RNA silencing has two distinct stages: initiation and maintenance. At the initiation stage, the host cells sense the presence of ds-RNA as abnormal and employ a ds-RNA-specific RNase called Dicer or Dicer-like (DCL) to digest the ds-RNA into small RNA species of 21–24 nucleotides known as small interfering RNAs (siRNAs). The viral RNA may also be converted into a ds-RNA target by one of the RNA-dependent RNA polymerases (RdRps) encoded by the plant host (Yu et al. 2003; Molnar et al. 2005). The siRNA produced by the action of DCLs is then recruited into a RNA-induced silencing complex (RISC) where it mediates the sequence-specific digestion of homologous RNA by RISC. At the maintenance stage, silencing of homologous RNA persists in the absence of the ds-RNA trigger. This is accomplished through a siRNA amplification process in which host RdRp synthesizes new ds-RNA, using siRNA as a primer and the homologous cellular RNA as template (Vaistij et al. 2002). Local induction generating sequence-specific signals that spread systemically throughout the plant is the unique characteristic of RNA silencing in plants (Voinnet 2005).

Plant viruses encode suppressors of RNA silencing to specifically counteract the RNA-silencing-based defense mechanisms to ensure successful systemic infection of the host plant. Virus-encoded silencing suppressors have been investigated in some host–virus interactions. In potyviruses, the protein P1/HC-Pro has been shown to be multifunctional in that it influenced aphid transmission, polyprotein processing, genome amplification, and long-distance virus movement (Kasschau et al. 1997). The P1/HC-Pro was also able to act as a broad range pathogenicity enhancer causing increased viral RNA accumulation and dramatically more severe viral symptoms in many unrelated viral functions (Pruss et al. 1997). P1/HC-Pro has been shown to strongly suppress RNA

silencing most likely acting on a maintenance step affecting the assembly and/or targeting of RISC complex (Chapman et al. 2004). The role of P1/HC-Pro in genome amplification and long-distance movement was found to be highly correlated with its silencing suppressor activity. Mutant viruses that lacked suppressor activity were able to initiate the replication process but unable to sustain robust amplification; consequently, long-distance movement was significantly reduced. The results indicated that suppression of the RNA silencing-based on host defense was crucial for vigorous viral RNA replication followed by efficient systemic spread of the virus (Kasschau and Carrington 2001). The 2b protein of cucumoviruses was demonstrated to have silencing suppressor activity, as the P1/HC-Pro of potyviruses. This protein enhanced long-distance movement of *Cucumber mosaic virus* (CMV) in a host-dependent manner. CMV 2b mutants invaded tobacco systemically, but not cucumber plants (Ding et al. 1995). Systemic infection of plants containing a silenced GFP transgene by either CMV or a PVX vector expressing 2b protein restored GFP expression in the leaves emerging after infection, but not in leaves where GFP silencing had already established. The results suggested that CMV 2b might function to prevent the systemic spread of RNA silencing signals (Brigneti et al. 1998; Guo and Ding 2002).

8.3.2 Movement of Plant Viruses

Plant viruses replicate in initially infected cells, attaining the required concentration for infecting neighboring cells and sustaining their subsequent pathogenic activities. The progeny virus particles have to move out of the initially infested cells to infect adjacent cells or plant tissues away from the initially infected. Two phases of virus movement within the host plant, namely cell-to-cell or short- and long-distance, have been distinguished. When a virus is unable to move to neighboring cells after replication in the initially infected cells, the infection is referred to as subliminal infection of the plant species. Such plants show a high form of resistance (extreme sensitivity) restricting the virus movement, resulting in necrosis of infected cells and subsequent inactivation of virus particles which cannot survive in the absence of live cells (Cooper and Jones 1983). Viruses differ in their ability to become systemic or confined to local lesions depending on the nature and level of resistance/susceptibility of plant species.

8.3.2.1 Cell-to-Cell Movement

Plant viruses utilize host plant proteins generally required for host-specific activities during the life cycles commencing from deproteinization of virus particles to intracellular, local, and systemic movement, leading to development of various symptoms induced by different viruses. The movements from one cell to another adjacent cell via plasmodesmata (PD) are modified to a lesser or greater extent and to other distant plant organs, including flowers and seeds, through the vascular system. Plasmodesmata function as cytoplasmic bridges and establish membrane (endoplasmic reticulum (ER) and plasma membrane) as well as cytoplasmic continuity between adjacent plant cells. The plasmodesmata form an important route for communication between plant cells, regulating cell-to-cell communication. As such, PDs are too small to allow free passage of mature virus particles or viral genomes which are far larger than the size exclusion limit (SEL) of plasmodesmata. The viruses first move from replication sites to PD at the cell periphery and then traverse the intracellular channels to enter the neighboring cells (Nelson and Citovsky 2005).

In the case of many plant viruses, cell-to-cell transport is mediated by specific virus-encoded factors known as movement proteins (MPs). The function of MPs may be augmented by other viral proteins. The involvement of MPs in the modification of the size exclusion limit (SEL) of plasmodesmata (PD) has been shown by the investigation using *Tobacco mosaic virus* (Wolf et al. 1989). Many viral MPs may be delivered to PD via endoplasmic reticulum (ER), whereas actin/myosin filaments may regulate the flow of proteins in the ER membrane (Boevink and Oparka 2005). Many viruses form replication centers enriched in endoplasmic reticulum (ER) and many viral proteins are translocated to ER. The role of ER translocation and plasmodesmatal targeting was explored using calreticulin, a cellular protein that localizes to PD. The N-terminal signal peptide critically influenced the ability of calreticulin to accumulate within plasmodesmata (Chen et al. 2005). Coat protein (CP) has a role in virus movement, in addition to providing protection to the viral genome against inactivation. The requirements of *Cucumber mosaic virus* (CMV) for cell-to-cell movement seemed to be different. Both MP and CP were found to be necessary for the cell-to-cell movement. CMV variants lacking CP could not move from infected cell to adjacent cells (Canto et al. 1997). Virion assembly was not found to be a prerequisite for CMV movement, since assembly-defective CMV variants efficiently spread and induced local lesions (Kaplan et al. 1998).

During infection of plants by tobamoviruses such as *Tomato mosaic virus* (TMoV), viral replication complexes containing a viral 126 kDa replicase component (126 K) are generated temporarily in association with a viral movement protein (MP) that is indispensable for viral intracellular movement. The *Tobamovirus* 126 K protein has been shown to play an important role not only in virus replication, but also in intercellular transport of viral RNAs. Transient expression of the 126 K protein was shown to result in the formation of cytoplasmic bodies with shapes similar to those of the replication complexes. Roles of TMoV MP in the formation, localization, and dynamics of cytoplasmic bodies of 126 K protein were investigated by using confocal microscopy for visualizing fluorescently tagged 126 K and MP that were transiently and simultaneously expressed in *Nicotiana benthamiana*. The 126 K protein was evenly distributed in the cytoplasm with occasional formation of small 126 k bodies, when MP was not expressed. These small 126 K bodies moved in the cytoplasmic stream and along the endoplasmic reticulum (ER) network. In contrast, the coexpression of MP markedly promoted the formation of larger MP-associated 126 K bodies which were generally static, but moved occasionally in the cytoplasmic stream. Further, small mobile 126 K bodies were captured at the terminal part of the MP-derived filamentous structures, resulting in the formation of 126 K-MP complexes and their translocation to another cellular site (Sasaki et al. 2014).

Barley stripe mosaic virus (BSMV), a seedborne virus in the seeds of barley, has RNA B genome which contains a series of overlapping open reading frame (ORF) known as triple gene block (TGB). The three most abundant proteins, β b, β c, and β d, have essential roles in infectivity. The involvement of each of these proteins in cell-to-cell movement of BSMV in planta was studied by engineering fusions of the green fluorescent protein designated γ b. Microscopic examination of inoculated and systemically infected barley and oat leaves revealed high levels of fluorescence that moved rapidly through the compact striate vascular tissue without infecting epidermal cells. In contrast, a radial pattern of fluorescence spread through a large number of epidermal and mesophyll cells before entry into the reticulate vascular tissue of the dicotyledonous plants *Nicotiana benthamiana* and *Chenopodium amaranticolor*. Mutational analysis indicated that the

β b, β c, and β d proteins were essential for cell-to-cell movement in local lesion and systemic hosts, whereas the β d' protein was dispensable. The results demonstrated that the three major triple gene block-encoded proteins could act in concert to mediate cell-to-cell movement of *Barley stripe mosaic virus* (Lawrence and Jackson 2001).

The cell-to-cell movement of several groups of viruses is mediated by proteins translated from a set of three overlapping ORFs known as triple gene block (TGB). Two classes of triple gene blocks have been distinguished: class 1 TGB1 includes hordeiviruses having a 42–63 kDa protein and class 2 TGB2 contains potexviruses and carlaviruses with TGB1 encoding a product of 25 kDa (Solovyev et al. 1996). The transport component ribonucleoprotein (RNPs) or virions involved in the cell-to-cell movement of *Potato virus X* (PVX) genome include TGBp1 and CP. Both proteins are able to move through plasmodesmata (Batten et al. 2003; Howard et al. 2004). The PVX TGBp1 is able to modify plasmodesmata (PD) and move between cells. In rod-shaped viruses, TGBp2 and TGBp3 move to PD and act in concert to transport TGBp1 to and through PD (Schepetilnikov et al. 2005). In virus-infected plants, RNA silencing involves a mobile silencing signal that has the ability for cell-to-cell movement and also systemic movement through plants. The silencing signal may be linked to the defense activity if it moves through the plant either with or ahead of an invading virus. Many plant viral genomes encode suppressors of RNA silencing that are also effectors of long-distance virus movement through phloem. The protein P19 from *Cymbidium ringspot virus* is a suppressor of silencing not required for virus replication in isolated cells, but it is necessary for invasion of leaves systemically (Havelda et al. 2003).

The two groups of viruses containing TGB have the major difference in their requirement of coat protein (CP) for Group 2 and dispensability of CP for Group 1 viruses for cell-to-cell movement. Studies on subcellular localization of TGB proteins of *Potato mop-top virus* (PMTV) show that, when expressed as N-terminal fusions to GFP from a TMV-based vector, both the PMTV GFP-TGB2 and GFP-TGB3 fusions were associated with cellular endomembranes, particularly the ER network and membranes surrounding the nucleus. The GFP-TGB3 labeled opposing pairs of fluorescent spots across neighboring cell walls that suggested localization at or near plasmodesmata were present (Cowan et al. 2002). The TGB1 protein interaction with RNA and its transport as a part of the RNP complex out of the cell and long distance throughout the plant appears to be possible. The fluorophore-labeled TGB2 and TGB3 proteins of PMTV showed an early association with ER and colocalized in mobile granules that used the ER-actin network for intracellular movement. Both proteins were able to increase size exclusion limit (SEL) of plasmodesmata. TGB3 accumulated at PD in the absence of TGB2. Both fusion proteins were incorporated into vesicular structures during expression cycle. TGB2 was associated with its structures independently, while TGB3 required TGB2 for its incorporation into vesicles. Furthermore, in addition to localization to ER and motile granules, mRFP-TGB3 was incorporated into vesicles when expressed in PMTV-infected epidermal cells, indicating recruitment by virus-expressed TGB2. The experiments involving labeling of the TGB fusion of protein-containing vesicles with FM4-64 indicated that the endocytic pathway was involved in viral intracellular movement (Haupt et al. 2005).

Members of *Potyvirus* group cause the most numerous and devastating diseases among plant viruses, negatively impacting production of agricultural, horticultural, and floricultural crops. The viral genome has about 10,000 nucleotides, encoding a polyprotein that is processed by three proteinases to synthesize 10 mature viral proteins.

The proteinases are P1, HC-Pro, and NIa and mature proteins are P1, HC-Pro, P3, 6K1, CI, 6K2, VPg, NIa-Pro, NIb, and CP. All viral proteins are involved at one or other stages of the viral cycle. Three essential HC-Pro regions responsible for different functions have been identified. The N-terminal part controls virus transmission by aphids, virulence (symptom severity), genome amplification, and virus accumulation. The central region controls both long-distance movement and replication maintenance functions. The C-terminal region of HC-Pro is a cysteine-type proteinase and has a role in virus cell-to-cell movement. HC-Pro has also been shown to be a pathogenicity determinant (Revers et al. 1999; Redondo et al. 2001; Syller 2003). The coordinate activity of HC-Pro with capsid protein (CP) for transmission of potyviruses by aphid vectors and virus movement appears to indicate a direct interaction between these proteins. By using HC-Pro-specific monoclonal antibodies in a two-site triple-antibody sandwich (TAS-) ELISA format, an interaction between HC-Pro and CP of *Lettuce mosaic virus* (LMV) was demonstrated in extracts of LMV-infected leaves, as well as for two other potyviruses *Plum pox virus* (PPV) and *Potato virus Y* (PVY) (Roudet-Tavert et al. 2002). The cell-to-cell movement of two potyviruses *Bean common mosaic necrosis virus* (BCMNV) and *Lettuce mosaic virus* (LMV) was demonstrated to be dependent on HC-Pro. The interaction of this protein with viral CP was revealed by microinjection techniques using *Escherichia coli*-expressed proteins. Both proteins trafficked from cell to cell induced an increase of plasmodesmatal SEL and facilitated cell-to-cell movement of viral RNA, as a mutation in the C-terminal part of HC-Pro appears to have a role in short-distance movement of potyviruses (Rojas et al. 1997).

In addition to the cell-to-cell movement, the involvement of HC-Pro in different steps of the viral cycle such as aphid transmission, replication, systemic movement and as a suppressor of posttranscriptional gene silencing (PTGS) has also been indicated by various investigations (Plisson et al. 2003). Increasing the size exclusion limit (SEL) of the plasmodesmata (PD) is a critical factor affecting cell-to-cell movement and subsequent long-distance movement of viruses. The viral movement protein (MP) is involved in the process of enhancement of SEL of PD which is known as gating (Wolf et al. 1989). The movement complexes, comprising many proteins, function in a coordinated manner with different roles for the protein components of the complex. Gating appears to be a basic requirement for cell-to-cell movement of non-tube-forming viruses. Actin is involved in depolymerizing the actin, leading to an increase in SEL. In contrast, deposition of callose in response to defense and wound responses may lead to closure of plasmodesmata (Roberts and Oparka 2003). The interaction between PVX TGB2 and proteins that interact with β -1,3-glucanase, a callose-degrading enzyme, has been suggested to be a strategy of PVX employed to gate PD to accelerate callose degradation (Fridborg et al. 2003). The interaction of *Tobacco mosaic virus* (TMV) MP with pectin methyl esterase (PME) may regulate the activity of PME, loosening the cell wall around PD and allowing the PD to open more easily. Alternatively the MP may recruit additional PME to PD to assist gating rather than relying on PME for targeting (Chen et al. 2005).

8.3.2.2 Long-Distance Movement of Viruses

Plant viruses have to move from the initial site of infection or inoculations and travel long distances to infect other plant organs such as petiole, stem, roots, flowers, and seeds. The majority of plant viruses depend on the phloem for long-distance movement, whereas a few viruses such as *Lettuce necrotic yellows virus* (LYNV) and *Rice yellow mottle virus* (RYMV) can move through xylem (Hull 2002). Different mechanisms may

operate singly or in combination depending on the virus concerned. A host defense system silencing signal spreads between cells and also long distances from the lower to upper leaves. The movement of viruses to other plant organs depends on an RNA-dependent RNA polymerase (RDR), whereas the signal for cell-to-cell movement does not depend on RDR (Himber et al. 2003). Systemic infection by plant viruses entails cell-to-cell movement into, through, and out of various cell types of the vascular system, in addition to long-distance transport through sieve elements. A barrier formed as constitutive or postinfectious responses may block the systemic spread of the virus at different stages.

The long-distance movement of *Potato leafroll virus* (PLRV) was investigated using two potato clones showing resistance to virus multiplication and accumulation. These clones were graft- or aphid-inoculated with PLRV and grown in the greenhouse along with a moderately susceptible cultivar for comparison. A high concentration of aphid-borne PLRV inoculum was used to ensure strong inoculum potential. Clones M62759 and PS1706 were highly resistant and susceptible to PLRV, respectively. Both clones expressed a high level of resistance to virus multiplication when primary or secondary infection was assayed by ELISA test. In addition, PLRV could only be detected in a few or none of the progeny plants of clone M62579, therefore indicating strong inhibition of virus transport to tubers. Translocation of PLRV from aphid-inoculated shoots to uninoculated shoots sprouted from the same tubers was monitored. No specific mechanism appeared to impair PLRV movement through tubers of the resistant genotypes. The results indicated that three valuable components of resistance to PLRV seemed to be closely linked in the genotype, a combination occurring rather rarely in potato clones (Syller 2003). Reduction in the rate of cell-to-cell movement in inoculated leaves resulted in inhibition of systemic infection of zucchini squash (*Cucurbita pepo*) by M strain of *Cucumber mosaic virus* (M-CMV) (Shintaku and Palukaitis 1990). However, coinfection of zucchini plants with M-CMV and *Zucchini yellow mosaic virus* strain A (ZYMV-A) facilitated M-CMV to move systemically, as revealed by tissue-print hybridization analysis. Gel analysis of RT-PCR products obtained from nucleic acids extracted from the upper leaves of plants doubly inoculated with M-CMV and ZYMV showed that M-CMV CP gene-specific production was absent from extracts of plant inoculated with M-CMV alone. On the other hand, the expected size band for M-CMV CP was detected in plants doubly inoculated with M-CMV and ZYMV. ZYMV-encoded HC-Pro or other proteins of ZYMV involved in the systemic movement of M-CMV into uninoculated leaves away from the site of inoculation (Choi et al. 2002).

Transcriptional gene silencing (TGS) is recognized by the absence of transcription from silenced gene and occurs where homology exists between promoter sequences of the affected genes. In contrast, PTGS genes contain a homologous sequence within the coding region. Although PTGS genes are actively transcribed, only low levels of steady-state mRNA can be detected. PTGS is a homology-dependent RNA degradation process that may target RNA exclusively in the cytoplasm of host cells. Plant viruses replicating in the cytoplasm can function as both initiator and target of PTGS. Many plant viruses encode protein that can suppress PTGS as a counter-defense strategy. HC-Pro encoded by potyviruses may be able to “switch off” gene silencing in plants wherever it is expressed. The 2b proteins encoded by *Cucumber mosaic virus* (CMV) do not have any effect in tissues where PTGS is established, but are able to prevent initiation of gene silencing in newly emerging tissues (Brigneti et al. 1998; Li et al. 1999). The intracellular distribution of CMV 2b protein (Cmv2b) was investigated by fusing it with GFP to

understand the mechanism(s) of counter-defensive suppression effect of Cmv2b. This protein localized to the nuclei of tobacco suspension cells and whole plants via an arginine-rich nuclear localization signal. The nuclear targeting of 2b protein was essential for the efficient suppression of PTGS, indicating that PTGS might be blocked in the nucleus. The PTGS suppressor activity was not sufficient for virulence determination by Cmv2b protein, although it is important (Lucy et al. 2000).

The tripartite genome of *Cucumber mosaic virus* (CMV) encodes replicase function in RNA1 and RNA2, with RNA3 encoding MP and CP proteins. For local cell-to-cell movement and also for systemic movement in squash plants, both MP and CP are required (Canto et al. 1997; Kaplan et al. 1997). The systemic movement of CMV in cucumber plants was investigated by analyzing the structure that is translocated and its putative interactions with phloem components in the phloem exudates (PE) samples. The movement of CMV as intact virus particles was indicated by the rate zonal centrifugation and electron microscopy observations of PE from CMV-infected plants. The virus particles interacted with a PE protein p48 which was found to be a cucumber homolog of phloem protein 1 (PP1) from pumpkin. The PP1 from pumpkin has the PD gating property and ability to translocate in sieve tubes. Interaction between encapsidated CMV particles and p48 protein seemed to make the viral RNA more resistant to RNase. The results indicated that the interaction with p48 might modify CMV particle structure and suggested that the virus particles might interact with cucumber homolog of PP1 during translocation in sieve tubes of cucumber (Requena et al. 2006). Long-distance movement is required for the virus to become systemic. Mutations within HC-Pro coding region of *Wheat streak mosaic virus* (WSMV) were introduced by misincorporation during PCR; nonsynonymous substitutions, including that of consistent reversion to wild-type, lead to attenuation of systemic infection. Mutants bearing GUS reporter gene were evaluated for their ability to establish primary infection foci. HC-Proteinase activity was observed in mutants that could not establish foci of infection. The results indicated that a complete HC-Pro deletion mutant could infect plants systemically and that certain substitutions in this dispensable gene probably prevented systemic infection by WSMV via interference (Stenger et al. 2006).

Cucumber mosaic virus (CMV) 2b protein has dual functions as an RNA silencing suppressor protein and also inducer of disease symptoms. A hybrid virus, FRad352b-CMV (renamed as CMV-FRad2b-Pro), generated by replacement of the 2b gene of the strain Fny-CMV with that from Rad35-CMV, displayed markedly lower pathogenicity than Fny-CMV on *Nicotiana* species. However, the replacement of proline with leucine at position 55 of the 2b protein of CMV-FRad2b-Pro (protein Rad2b-Pro) created a virus (CMV-FRad2b-leu) that induced severe symptoms. Experiments on *Arabidopsis thaliana* showed that Rad2b-Pro was a weaker RNA silencing suppressor than the protein Rad2b-Leu. This was confirmed in *Nicotiana benthamiana* using agroinfiltration assays showing that, compared with either Rad2b-Leu or the Fny2b protein, Rad2b-Pro was ineffective in inhibiting local or systemic silencing of expression of a green fluorescent protein (GFP) reporter gene (*gfp*). Transgenic expression of Rad2b-Leu but not of Rad2b-Pro in *Arabidopsis* induced symptom-like phenotypes and rescued the accumulation of the 2b-deletion mutant Fny-CMV Δ 2b. Bimolecular fluorescent complementation indicated that in planta Rad2b-Leu self-interacted, but not Rad2b-Pro. Self-interaction was crucial to the ability of the 2b protein to suppress silencing and induce a symptom-like phenotype and was dependent on the properties of the residue at position 55 of the 2b protein of *Cucumber mosaic virus* (Xu et al. 2013).

8.3.3 Colonization of Plant Tissues by Viruses

Plant viruses systemically infect different kinds of plant organs such as leaf petiole, stems, roots, floral parts, and seeds. They colonize these different plant tissues which may support their replication to varying degrees and consequently exhibit different abnormalities. In some plant species, the viruses multiply to a fairly high titer without inconveniencing the host and producing any visible symptoms. These latent infections may become potential sources of virus inoculum that may be spread by the natural biological vectors. The presence of viruses in various plant tissues may be detected by employing light and electron microscopy, immunoassays, and nucleic acid-based molecular techniques.

Citrus tristeza virus (CTV) was detected by applying the in situ immunoassay (ISIA) procedure. Sections of petioles, leaf veins, and stems of CTV-infected and healthy plants were fixed with 70% ethanol and incubated with specific polyclonal antibodies (PAb) 1212 or monoclonal antibodies (MAbs) MCA13 or 17G11. The antibodies bound to plant cells were labeled with enzyme-conjugated species-specific secondary antibodies and exposed to a substrate mixture containing nitroblue tetrazolium (NBT) and 5-bromo-4-chloro-3-indolyl phosphate (BCIP). Development of a purple color, indicating the presence of CTV antigen, could be visualized by observing under the light microscope. The presence of purple color was only observed in the phloem tissues of CTV-infected plants, but not in comparable tissues of healthy plants. Locations of CTV antigens could be observed directly and accurately by in situ immunoassay (ISIA) method in both fresh tissues as well as in samples stored in plastic bags at 4°C or frozen for 4 weeks. The ISIA procedure provided a unique advantage of determining the three-dimensional distribution of CTV within the host. In addition, the ISIA test may also have applications for cross-protection and pathogen-derived resistance (PDR) investigations (Lin et al. 2000). The transcriptional responses of citrus to *Citrus tristeza virus* (CTV) were investigated. Genes (430) differentially regulated by severe CTV isolates in lime plant were identified by applying suppression subtractive hybridization (SSH) procedure. The differential expression levels of 25 expressed sequence tags (ESTs) in CTV-N21 infected lime were validated by qRT-PCR. The largest set of those genes were involved in primary metabolism (26.0%) and then in protein metabolism (15.1%). The results revealed that a large set of genes (51 ESTs) were commonly upregulated by two severe strains CTV-N21 and CTV-T305 in lime. The quantitative analysis for temporal and spatial transcriptional levels of those genes fluctuated during CTV infection and differed in different citrus leaves (Yang et al. 2013).

Tomato spotted wilt virus (TSWV) infects *Ranunculus asiaticus*, an ornamental crop grown for tuber production, potted plants, and cut flowers. Distribution of TSWV in tuber and root tissues of *R. asiaticus* was monitored by employing tissue-blot immunoassay. The cut surfaces of the desired tissues were gently blotted on nitrocellulose membranes and the tissue-blot immunoassay (TBIA) was performed using the monoclonal antibody generated against NSs of TSWV. The positive reaction was indicated by the formation of a purple precipitate. Presence and distribution of TSWV in *R. asiaticus* was monitored. TSWV was not uniformly distributed in *Ranunculus* tubers and the percentages of infected rootlets per tuber varied. The virus was detected in more than 50% of the rootlets per tuber for the majority of infected tubers assayed. When one or more roots had detectable TSWV titer, the central stem portion always tested positive. Further, TSWV could be detected in the foliage produced from the tubers in which

TSWV was detected earlier by TBIA technique. The results indicated that TSWV could be replicated in different organs of *R. asiaticus* plants, reaching sufficient titers detectable by TIBA technique (Whitefield et al. 2003). The presence of TSWV in different parts of potato tubers was monitored using enzyme-linked immunosorbent assay (ELISA). Rates of TSWV transmission from infected foliage to potato tubers and from infected tubers to progeny plants were assessed. The results indicated that cultivars of potato had a significant effect on TSWV transmission from plant to tuber and from tuber to plant. As the virus was unevenly distributed in the tubers, composite samples including different parts of potato tubers might provide reliable detection of TSWV (Bulajić et al. 2014).

Cytopathology of developing anthers and pollen mother cells from young flowers of lettuce plants infected by *Lettuce mosaic virus* (LMV) was studied. Ultrastructural investigations revealed that within infected pollen mother cells, structures reminiscent of bundles and partly formed pinwheel inclusions were discernible. Immunogold labeling showed that particles of LMV were associated with these structures. Neither large aggregates of LMV particles nor complete pinwheel inclusions were observed in pollen mother cells. The infection of the pollen mother cells was consistently correlated with infection of the adjacent tapetal cell layer. The pollen mother cells of two other LMV-infected plants were not infected, indicating that LMV infection was not successfully achieved in all pollen mother cells of LMV-infected plants. Early invasion of the floral meristem appeared to be necessary for virus infection of mature pollen grains (Hunter and Bowyer 1997). Cytopathological effects of colonization of onion tissues by *Artichoke yellow ringspot virus* were studied by electron microscopy and decoration techniques. Large cytoplasmic inclusions were observed in mesophyll cells of infected plants, but not in healthy tissues. The cytoplasmic inclusions comprised voluminous accumulations of entangled membranous elements, more or less developed and specifically arranged particle aggregates, and conspicuous globules of a supposed lipid nature. The characteristic cytopathologic structures principally consisted of complexes of two cisternae of rough endoplasmic reticulum (ER) in a parallel arrangement. A high proportion of infected cells contained AYRSV particles. Antiserum against AYRSV did not react with the onion isolate in immunosorbent electron microscopy (ISEM) and decoration tests (Maliogka et al. 2006). An antiserum specific to *Fig latent virus 1* (FLV-1) was used for visualization of the virus by ISEM procedure in seedlings of different ages and geographical origin. All seedlings irrespective of the age and origin were found to be heavily infected with FLV-1. Virus particles were readily decorated by the FLV-1-specific antiserum. The sections stained with lead citrate showed well-preserved cytological organization. Major organelles appeared to be normal, except for the chloroplasts which were swollen, misshapen, and exhibited a somewhat disarranged membrane system. Bundles of filamentous virus particles were frequently visualized in the cytoplasm of cells of parenchyma in asymptomatic seedlings, indicating the usefulness of electron microscopy to study the anatomical changes induced by FLV-1 even before the appearance of symptoms of the disease (Castellano et al. 2009).

Grapevine leafroll-associated virus 3 (GLRaV-3), a major grapevine pathogen, causes considerable production losses. A single-chain fragment variable (scFv) antibody (scFvLR3) directed against the coat protein (CP) of GLRaV-3 was expressed in *Escherichia coli* and used in immunosorbent electron microscopy (ISEM) examination for the presence of GLRaV-3 in grapevine tissue extracts. The antibody was fused to the light chain constant domain of human immunoglobulin to create the bivalent reagent C_L-LR3.

The bivalent reagent bound strongly to GLRaV-3 and the protein either captured or decorated GLRaV-3 in electron microscopy assays. The results of ISEM corroborated those of enzyme-linked immunosorbent assay (ELISA) tests (Cogotzi et al. 2009). The route of infection of cucumber by *Cucumber green mottle mosaic virus* (CGMMV) was investigated by using scanning electron microscopy (SEM). At anthesis, pollen was collected from the flowers of the infected cucumber plants and they were used to pollinate noninoculated plants. The presence of CGMMV in pollen from infected plants was detected by SEM observations. Transmission of CGMMV to the seeds and subsequently to the seedlings growing from these seeds was revealed by RT-PCR analysis (Liu et al. 2014).

The genomic viral RNA/DNA and/or the coat protein (CP) of *Carnation mottle virus*, *Carnation latent virus*, and *Carnation etched ring virus* were localized in the carnation shoot tip to determine whether any of them were capable of infecting the shoot apical meristem. The results showed that all viruses were excluded not only in single-infected but also in double-infected plants. However, these viruses showed a different infection pattern inside the shoot-tip, with different cell types being their main targets. For mixed infections, a spatial separation pattern within carnation shoot-tip meristem between the viruses in mixed infection was observed, strongly suggesting the existence of an exclusion mechanism in the shoot-tip tissue of carnation (Gonsalvez-Bernal et al. 2006).

The mechanism of seed transmission of *Pepper mild mottle virus* (PMMoV) in pepper (*Capsicum annuum*) was investigated. The virus immunolocalized in pepper seeds was visualized using fluorescence microscopy technique. Two distinct patterns of virus distribution were observed. The presence of PMMoV in the epidermis and parenchyma was seen but not in the endosperm or embryo, whereas in other seeds the virus was restricted to the surface of the epidermis and parenchyma (Genda et al. 2005). In a later study, the infection cycle of PMMoV was studied through vertical transmission of the virus. The location of PMMoV within seeds as they developed on inoculated seedlings of pepper was followed by detecting the viral coat protein using immunofluorescence microscopy procedure. Seedlings were inoculated with PMMoV when the flower buds on the first and second branching nodes were in bloom. The presence of PMMoV was inferred by the fluorescence around immature seeds and placentas in the ovaries on the fourth branching node at 20 days postanthesis (20 dpa), which corresponded to 39 days postinoculation (39 dpi). The area with fluorescence progressively expanded from the placenta into the integument and the parenchyma and finally reached the tip of immature seeds by 34 dpa. The embryo or endosperm beyond the endothelium did not fluoresce during the experiment (until 102 dpi). For visualizing the viral routes of invasion from seeds into developing seedlings, PMMoV-infected *C. annuum* seeds that were heterologous for the L³ tobamovirus-resistance were grown in soil at 30 °C. The cotyledons developed virus-induced necrosis (Genda et al. 2011).

Prunus necrotic ringspot virus (PNRSV), belonging to the genus *Ilarvirus*, infects many stone fruit trees including cherry, sour cherry, almond, peach, apricot, and plum. Infected pollen has a key role in both seed and plant-to-plant transmission of the members of *Ilarvirus* (Milne and Walter 2003). The route of infection and the pattern of distribution of PNRSV in apricot pollen were investigated. By employing dot-blot hybridization technique, PNRSV was detected inside as well as on the outside of infected apricot pollen grains. On the pollen surfaces, PNRSV was probably attached to the exine. The flower buds at different stages of development were tested to determine the route by which PNRSV invaded pollen grains. In the earliest stage in which flower buds

with anthers contained pollen mother cells (PMCs), PNRSV was detected in all flower bud tissues including sepals, petals, and anthers. Different degrees of infection of anthers were revealed by in situ hybridization assay. Viral RNA was localized only in the vascular tissue in some, whereas other anthers showed the complex invasion of PNRSV with PMCs also being infected. The virus could be detected in all tissues of flower bud, including anthers containing unicellular pollens. PNRSV infection persisted until flower maturation, when the virus was detected in the whole flower. In addition, in infected pollen grains in the early stages of maturation, PNRSV infection was uniform with cytoplasm particularly being highly invaded. PNRSV was not detected in the nucleus of any of the pollen grains examined. In the bicellular pollen grains, PNRSV was detected in the cytoplasm of the vegetative cell and the virus was sometimes localized around and inside the generative cell. The presence of viral RNA inside the generative cell was confirmed by in situ hybridization at electron microscopy level, as the gold particles corresponding to PNRSV were localized to the cytoplasm of the generative cell. In the germinated infected pollen grains, viral RNA was seen to be evenly distributed inside pollen grains as well as in the pollen tube with a higher concentration at the tip or growth zone of germinating pollen tube, but no signal was detected in comparable healthy pollen grains. The results indicated that the route of infection of PNRSV commenced from another version by first infecting the vascular system of the anther filament. The virus could then move from the vascular system to infect the anther connective tissue, using the high number of cytoplasmic connection bridges characteristic of this tissue. PNRSV invaded the tapetum cells and then pollen mother cells (PMCs). Apparently PMCs might be infected prior to the callose deposition as the callose layer might separate the PMCs from one another and also from the anther tissue. Pollen tubes, once germinated, could reach the apricot embryo sacs. Infected pollen could therefore play an important role in the vertical transmission of PNRSV in apricot (Amari et al. 2007).

In situ hybridization analyses of *Prunus necrotic ringspot virus* (PNRSV) distribution in apricot reproductive organs at different developmental stages were carried out. PNRSV was detected in the early stages in both the ovule and ovary. The virus was present in the ovules and nucellus in the megaspore stage. PNRSV was localized in the later developmental stages, in the funiculus as well as in the corresponding ovule, and the distribution of the virus was uneven in the ovary at this stage. Later, PNRSV invaded all parts of the ovule including inner and outer integuments surrounding the nucleus which enclosed the embryo sac. At this stage, two different infection patterns could be differentiated. Infection of the whole ovule occurred in some floral buds, whereas the nucellus was free of PNRSV except for the cells close to and surrounding the embryo sac. However, the presence of PNRSV was always observed in the nucellar cells located around the embryo sac, even in the more advanced developmental stage, where viral RNAs were rarely detected inside the embryo sac; when present, they were found in the fused polar cells.

Invasion of the apricot embryo by PNRSV in the early developmental stages was confirmed by dot-blot hybridization procedure. PNRSV was detected in embryos in immature seeds at globular stage. PNRSV RNA was detected in embryos in the globular developmental stage, following hand-pollination of virus-free flowers with infected pollen grains. Viral infection of seed integuments, nucellus, and testa in immature seeds could be detected using in situ hybridization assay. Infection of the testa mainly affected areas in and around its vascular tissue. Tissue-printing hybridization (TPH) from fruits obtained from pistils of hand-pollinated PNRSV-infected pollen revealed the presence of viral RNA in the periphery of fruits, whereas crosses between infected pistils and

infected pollen resulted in total invasion of entire fruits, indicating the vertical transmission of PNRSV from gametes to apricot seedlings (Amari et al. 2009).

Cocoa swollen shoot virus (CSSV), belonging to the genus *Badnavirus*, causes the devastating disease in cocoa. As cocoa is propagated largely by seeds, transmission of CSSV via seed is considered a critical factor impacting adversely cocoa production; the route of virus invasion of seed was therefore investigated. Seed embryo infection by CSSV could occur by two routes, either directly from infected gametes at fertilization or by direct invasion of immature embryo from virus-infected testa tissues (Maule and Wang 1996). All pollen grains isolated from the anthers of cocoa trees (T2 and T4) were found to contain the virus, as indicated by PCR assay/agarose electrophoresis (AE) and PCR/capillary electrophoresis (CE). Cocoa seeds from infected T2 and T4 plants and healthy plants were separated into component parts: testa, cotyledon, and embryo and tested for the presence of CSSV. The component parts of seeds of infected trees showed varying levels of CSSV infection by PCR/agarose electrophoresis, but PCR/capillary electrophoresis revealed 100% infection of seed components by CSSV. The seedlings raised from infected seeds obtained from CSSV-infected trees showed virus infection at a high frequency as revealed by PCR/CE techniques, indicating the potential danger of using seed lots without checking the levels of seed infection by CSSV (Qainoo et al. 2008). *Apple latent spherical virus* (ALSV) was detected in apple flower buds by in situ hybridization assay. ALSV was present inside almost all pollen grains and in all ovary and ovule tissue, including the embryo sac and inner integument. Although low level of seed embryo infection was detected, ALSV was not transmitted to the seedlings (Nakamura et al. 2011).

Pea enation mosaic virus (PEMV) disease is due to two obligately symbiotic viral genomes: PEMV-1, the sole member of the genus *Enamovirus* in the family Luteoviridae; and PEMV-2, a member of the genus *Umbravirus*. A satellite RNA (RNA3) is associated with PEMV-2. The PEMV-1 genomic RNA contributes to encapsidating CP gene and aphid transmissibility, while the PEMV-2 genome is responsible for mechanical transmissibility and systemic viral movement in the plant (Demler and de Zoeten 1989; de Zoeten and Skaf 2001). Accumulation and relative concentrations of PEMV-1 and PEMV-2 viral genomes in leaf and seed tissues were estimated using a quantitative real-time reverse-transcription polymerase chain reaction (qRT-PCR). The PEMV-1 and PEMV-2 genomes accumulated in all tissues, with large relative differences in mean normalized accumulation (MNA) between tissues. The PEMV genomes accumulated to high levels in stipules, whole pea, and seed coat, but to much lower levels in pea embryo tissues. On an average, PEMV-1 and PEMV-2 genome RNAs accumulated to c. 1240 and 13,000 times higher levels in stipule than in embryo, respectively. Accumulation of PEMV genomic RNA in developing seed tissues from PEMV-infected plants was investigated. PEMV-1 and PEMV-2 genomic RNAs accumulated to high amounts in all pod wall and seed coat samples. The genomic contents accumulated to similar levels in seed coats and pod walls. PEMV-1 and PEMV-2 genomes could often be detected in embryo tissues, but at much lower levels. PEMV-1 was not detected in embryo axis in three plant or pod samples or from one cotyledon and embryo axis sample. PEMV-2 was not detected in one cotyledon and two embryo axis samples. In all samples in which PEMV-1 was detected, concentrations of PEMV-1 were greater in the cotyledons than in the embryo axis. No evidence was obtained for seed transmission of PEMV, since none of the >50,000 plants grown from seeds derived from PEMV-infected source plants exhibited symptoms of pea enation mosaic disease (Timmerman-Vaughan et al. 2009).

The connection between the ability of the plant viruses to reprogram host gene expression and the pathogenicity of viruses has been investigated. The interference of viruses with cellular transport process is potentially the effective form of altering the physiology of susceptible plants. Virus multiplication and movement are necessary for the disease symptoms to develop. The rate and extent to which these processes occur may be the primary determinants of symptom development. The infective viral cycle in a susceptible host mostly begins through epidermal cells or through roots, as a result of either mechanical damage or feeding injuries caused by vectors of viruses. When the viral genome replication cycles have been completed, the progeny viruses move from infected cells and reach the vascular system to invade the distal plant parts. Movement proteins (MP) can act by forming ribonucleoprotein complexes with the viral genomes or tubular structures that hold the virions and allow them to cross plasmodesmata (Lucas 2006; Sanchez-Navarro et al. 2006). The most common way to restrict the viral invasion is through blocking its cell-to-cell movement function which may directly influence the development of disease symptoms. Studies conducted with natural or artificial mutants of the corresponding MPs or with pseudorecombinant viruses have contributed to the understanding of the role of virus movement in pathogenesis. The symptomatic variant was correlated with a mutation in MP which corresponded to the thermosensitive Ls-1 mutant of *Tobacco mosaic virus* (Nishiguchi et al. 1978). This mutant could not become systemic at high temperatures. The Ls-1 mutant had a proline-to-serine change in the MP gene (Ohno et al. 1983). An association between less symptomatic phenotypes and lesser accumulation of the MP from TMV was later established (Arie-Johnson et al. 1995).

The severity of symptoms is not always correlated with virus titer, indicating that disease development may be due to specific interaction between virus and host components. Plant virus MPs have been shown to interact with a range of host proteins to facilitate movement of the virus in the susceptible host plant. Host proteins with which the viral MPs interact may be localized in the nucleus, cytoplasm, and endoplasmic reticulum, microtubules, and plasma membrane. Most of these interactions may be essential for the intra- and intercellular movement of viruses and these interactions have significant effects on the symptom expression. TGBp2, *Potato virus X* MP, interacted with cytoplasmic protein Tip-1 which in turn interacted with β -1,3-glucanase (Fridborg et al. 2003). This enzyme is known to participate in the regulation of callose levels which have an important role in the regulation of the size exclusion limit (SEL) of the plasmodesmata (Iglesias and Meins 2000). Plants overexpressing the MP proteins have been used to shed light on the involvement of MPs in viral pathogenesis. As transgenically expressed MPs preferentially located to the plasmodesmata, the appearance of symptoms of viral infection such as abnormal accumulation of sugars, reduced photosynthesis, chlorosis, and dwarfism was attributed to overexpression of MPs in plants, causing functional interference of these proteins with cytoplasmic communication channels. Plants expressing TMV MP showed alterations in the carbohydrate distribution originating in mesophyll tissues while the primary site of action of the MPs was restricted to the phloem, as in MP17 from *Potato leafroll virus* (PLRV) which resided in the phloem tissue (Balachandran et al. 1995).

There are many determinants of viral pathogenicity. Protein P3 from potyviruses is an inducer of the responses mediated by several dominant resistance genes (Hajimorad et al. 2006; Chowda-Reddy et al. 2011). Protein P3 along with the small 6K1 peptide was bound to *Soybean mosaic virus* polyprotein and they conditioned the symptomatology

and host range of the virus (Desbiez et al. 2003; Salvador et al. 2008a). Replacement of the P1-coding sequence of *Plum pox virus* (PPV) by that of another potyvirus *Tobacco vein mottle virus* (TVMV) had no effect on the virus infectivity in plants that were hosts of both PPV and TVMV, but inhibited infection on the PPV host *Prunus persica* which was not susceptible to TVMV (Salvador et al. 2008b).

Sweet potato plants are commonly infected by *Sweet potato feathery mottle virus* (SPFMV) and *Sweet potato chlorotic stunt virus* (SPCSV), resulting in a complex called sweet potato virus disease (SPVD) complex. Aphids and white flies are involved in the transmission of SPFMV and SPCSV, respectively, and the transmission of these two viruses occurs independently in a sequential manner under natural conditions. The effect of sequential infection on symptom development and individual virus titers was assessed by inoculating the plants infected by one virus with the other virus. Symptoms were significantly more severe in plants infected with SPCSV followed by SPFMV, compared with plants infected first with SPFMV followed by SPCSV. Virus titer were not significantly different for SPCSV, but SPFMV titers in plants infected with SPCSV followed by SPFMV, were significantly higher than that of all other combinations. The sequence of infection of sweet potato plants had significant influence on disease severity and SPFMV reached higher titers in plants already infected with SPCSV (McGregor et al. 2009).

8.4 Characteristics of Viroids

Viroids are obligate plant pathogens comprising small unencapsidated, covalently closed, circular, and nonencoding single-stranded RNA molecules (246–401 nucleotides). They share some structural similarities with certain satellite RNAs. However, satellite RNAs depend on the helper viruses for their replication. Viroids do not code for any protein and therefore remain unassociated with any structural protein(s) that are present, as in the case of plant viruses. Viroids may be considered as RNA parasites that have shed off all the protein-synthesizing capacity and made efficient use of the host's synthetic machinery for their replication (Diener 1999; Tabler and Tsagris 2004; Flores et al. 2005a). Based on the structural characteristics and site of replication in the host cells, the viroids are classified into two families: Pospiviroidae and Avsunviroidae (Chapter 7). *Potato spindle tuber viroid* (PSTVd), the first viroid to be discovered and characterized, has a serial arrangement of 26 double-stranded segments interrupted by bulge loops of varying sizes. The extended secondary structure is folded into a more globular tertiary conformation, as the single-stranded loops do not interact. The viroids possess both stability and flexibility. The native rod-like structure of viroids is converted through thermal denaturation into hairpin-containing circle in a highly cooperative fashion (Diener 1979; Henco et al. 1979). The International Committee on Taxonomy of Viruses (ICTV) admitted 29 distinct viroid species and six were listed as tentative viroid species (Flores et al. 2005b).

Fruit crops are infected by several viroids. Six viroids, *Apple scar skin viroid* (ASSVd), *Apple dimple fruit viroid* (ADFVd), *Apple fruit crinkle viroid* (AFCVd), *Pear blister canker viroid* (PNCVd), *Hop stunt viroid* (HSVd), and *Peach latent mosaic viroid* (PLMVd) have been reported to infect naturally pome (apple, pear, and quince) and stone (peach, plum, and almond) fruit trees (Hadidi et al. 2003). Likewise, *Citrus* spp. are naturally infected by *Citrus exocortis viroid* (CEVd), *Hop stunt viroid* (HSVd), *Citrus viroid IV*

(CVd-IV, renamed *Citrus bark cracking viroid* (CBCVd)), *Citrus bent leaf viroid* (CBLVd), and *Citrus viroid III* (CVd-III, renamed *Citrus dwarfing viroid* (CDVd)). In addition, the incidence of two viroids – *Citrus viroid original source* (CVd-OS) and *Citrus viroid V* (CVd-V) – has also been observed (Ito et al. 2001; Serra et al. 2008). These viroids usually occur as complex mixtures coinfecting the same plant and producing overlapping symptoms. Precise, sensitive, and reliable technique(s) may be required to resolve the components of the viroid complex and to differentiate the viroids involved.

8.4.1 Biological Properties of Viroids

8.4.1.1 Types of Symptoms

Viroids cause symptoms that may be similar to those induced by viruses. However, some of the viroids such as *Potato spindle tuber viroid* (SPTVd) have a characteristic effect on tubers, which become abnormally elongated assuming a spindle or cylindrical shape with prominent eyes (Diener 1979). Likewise, symptoms caused by *Apple scar skin viroid* (ASSVd) are confined to apple fruits and symptoms on fruits may differ depending on the apple cultivar (Koganezawa et al. 2003). When graft-inoculated onto sensitive selection of Etrog citron, citrus viroids induce distinguishable symptoms; however, this required 3–9 months, good greenhouse facilities, and experienced personnel (Roistacher 1991). *Peach latent mosaic viroid* (PLMVd) causes irregularly shaped, discolored, and deformed fruits with cracked structures and enlarged pits. Some strains also induce clear-cut foliar leaf discoloration or yellowing (Malfitano et al. 2003). When the environmental conditions existing in the field were not favorable for symptom expression, the forced cutting method was followed. This procedure involved forcing cuttings taken directly from citrus orchards to sprout in a growth chamber at temperatures around 30°C. This treatment appeared to promote viroid replication. This process facilitated detection of viroids by other diagnostic methods. Forcing citrus cuttings was effective for detection of citrus strain of *Hop stunt viroid* (HSVd-cit), *Citrus exocortis viroid* (CEVd), and *Citrus viroid III* (CVd-III), even when no positive amplification by PCR was obtained from field-grown plants (Guardo et al. 2005).

8.4.1.2 Diagnostic Hosts and Host Range

The majority of the viroids cause symptoms similar to those induced by other viroids and viruses infecting the same host plant species, resulting in confusion in establishing the identity of the viroid(s) with certainty. Diagnostic or assay hosts which react by producing characteristic and distinguishable symptoms more rapidly than the natural host plant species (crops) are therefore employed. This test, known as biological indexing, usually requires a long time and a large glasshouse space. *Potato spindle tuber viroid* (PSTVd) produced necrotic local lesions in *Scopolia sinensis* following mechanical inoculation (Singh 1971). Likewise, cucumber (*Cucumis sativus*) could be inoculated to detect *Hop stunt viroid* (HSVd) in greenhouses maintained at 30°C. The cucumber bioassay was found to be useful even when the viroid was at a low concentration (1:200). The practical utility of cucumber bioassay was demonstrated by testing samples from field-grown HSVd-infected plants (Sasaki and Shikata 1977; Sasaki et al. 1981).

The use of *Gynura aurantiaca* plants as a bioindicator for effective detection and identification of *Citrus exocortis viroid* (CEVd) was demonstrated. *G. aurantiaca* plants were inoculated with total nucleic acid preparations from grapevine plants and the inoculated plants were topped to promote the production of new shoots.

The development of symptoms of CEVd infection was monitored for 30 days after inoculation. An infectious RNA isolated from *G. aurantiaca* was subjected to electrophoresis and this RNA had the same electrophoretic mobility of CEVd, establishing the identity of the viroid infecting the grapevine (Flores et al. 1985). Arizona 861-S1 Etrog citron plants were graft-inoculated with 112 citrus samples collected during a survey. The bioindexing procedure to detect and identify *Citrus exocortis viroid* (CEVd), *Hop stunt viroid* (HSVd), and *Citrus viroid III* (CV-III) was effective in 104 of 112 citrus samples tested (Malfitano et al. 2005). The distribution of CEVd and HSVd in the orchards of Central Italy was monitored by applying one-tube RT-PCR assay. Green bark and leaves from 21 varieties belonging to 9 citrus species, and 1 hybrid which showed no specific symptoms of viroid infection, were tested by one-step RT-PCR assay. All *Citrus* species except citron, limeta, and kumquat were infected by CEVd to a different extent. Sweet orange (4/4), mandarin (3/4), satsuma (2/2), clementine (2/3), and lemon (3/3) were infected by CEVd in addition to the hybrid lemon x citron. On the other hand, infection by HSVd was detected in mandarin (2/4), clementine (1/3), and kumquat. The predominance of CEVd was revealed by the one-tube RT-PCR analysis. CEVd infection in 16 citrus varieties and HSVd infection in 4 citrus varieties could be detected, although the infected plants did not exhibit any specific symptom of viroid infection (Ragozzino et al. 2005).

Citrus viroid V (CVD-V) was initially identified after transmission to *Atlantia citrioides* which was immune to CEVd, CBLVd, CDVd, HSVd, and *Citrus bark cracking viroid* (CBCVd), but allowed replication of CVD-V (Barbosa et al. 2005). CVD-V induced mild but typical symptoms and, in coinfection CVD-V, interacted synergistically with either *Citrus bent leaf viroid* (CBLVd) or *Citrus dwarfing viroid* (CDVd) producing enhanced leaf symptoms and highly severe dwarfing of infected plants (Serra et al. 2008). Grapevine viroids, *Grapevine yellow speckle viroid* 1 and 2 (GYSVd-1 and -2), *Hop stunt viroid* (HSVd), *Citrus exocortis viroid* (CEVd), and *Potato spindle tuber viroid* (PSTVd) were detected and differentiated by using cucumber (*Cucumis sativus*) cultivar Alpha, tomato (*Lycopersicon esculentum*) cultivar Castle Rock, and *Gynura aurantiaca* as bioindicators (Nasr-Eldin et al. 2012). Australian grapevine viroid (AGVd), a member of the family Pospiviroidae, was inoculated by agroinfiltration of dimer constructs of AGVd into the leaves of cucumber, tomato, squash (*Cucurbita pepo*), purple passion (*Gynura aurantiaca*), tobacco cultivar Turkish tobacco, *Nicotiana glutinosa*, and pot marigold (*Calendula officinalis*). All plant species inoculated with AGVd either showed visible symptoms or the viroid could be detected in the infected plants that were asymptomatic, with the exception of tobacco. Tobacco was not infected by AGVd, which also could not be detected by PCR assay (Zaki-Aghl et al. 2013).

Viroid infection of sweet pepper (*Capsicum annuum*) in the glasshouse-grown pepper was observed. Based on the biological and molecular properties, the pepper viroid was named as the new species *Pepper chat fruit viroid* (PCFVd) in the genus *Pospiviroid*. Seven solanaceous plant species were mechanically inoculated with PCFVd. Tomato cultivar Money-maker and potato cultivar Nicola were infected by PCFVd; leaf distortion and tuber deformation, in addition to the formation of necrotic lesions on leaves, were observed in the infected tomato and potato, respectively (Verhoeven et al. 2009). *Potato spindle tuber viroid* established appears to have the widest host range, infecting several plant species including potato. Economically important crops infected by PSTVd include tomato, avocado, pepino, and sweet potato, in addition to wild *Solanum* spp. Infection by PSTVd of ornamental species may go undetected since the infected

plants mostly remain asymptomatic; such plants may become potential sources of viroid inoculum (Lenarčič et al. 2012). *Solanum jasminoides* plants were found to be symptomless hosts of PSTVd (Anonymous 2006). Infection of *Brugmansia suaveolens*, *B. cordata*, and *B. variegata* was reported from Netherlands (Verhoeven et al. 2007). *Solanum jasminoides* and *S. rantonnetii* were found to be susceptible to PSTVd under natural conditions. The presence of PSTVd was detected by tissue-printing hybridization technique in these plant species (Di Serio 2007). The experimental host range includes a wide range of plant species from other families such as sweet potato and avocado. Infection of avocado remained latent, but when coinfecting by *Avocado sun blotch viroid* (ABVd) symptoms due to PSTVd were expressed (Querici et al. 1995).

The host range of *Chrysanthemum stunt viroid* (CSVd) and *Chrysanthemum chlorotic mottle viroid* (CChMVd) was determined. Various plant species and cultivars (51) were inoculated with circular and linear forms of CSVd purified from infected chrysanthemum plants. CSVd was pathogenic to *Gynura aurantiaca* and other plants belonging to the families Solanaceae and Asteraceae, and these plants remained symptomless. Under natural conditions, *Petunia hybrida*, *Ageratum* sp., *Dahlia* sp., *Senecio cineraria*, and *Argyranthemum frutescens* were found to be infected. The host range of CChMVd was restricted to two species of *Chrysanthemum* (Cho et al. 2013).

Viroids affecting pome and stone fruit trees have been reported to occur naturally in all countries where these crops are grown. *Apple scar skin viroid* (ASSVd) and *Apple dimple fruit viroid* (ADFVd) infect both apple and pear, while *Apple fruit crinkle viroid* (AFCVd) can infect apple, hop, and Japanese persimmon. Incidence of *Pear blister canker viroid* (PBCVd) on pear, quince (*Cydonia oblonga*), nashi (*Pyrus serotina*), and wild pear has been recorded. *Hop stunt viroid* (HSVd) has been reported to infect several herbaceous and woody plants including hops, almond, apricot, peach, pear, plum, grapevine, pomegranate, citrus, and cucumber (Cañizares et al. 1999; Lolic et al. 2007; Sano and Matsura 2004). *Tomato apical stunt viroid* (TASVd) was found to infect several plant species under natural conditions such as the ornamental species, *Brugmansia* sp., *Cestrum* sp., *Lycianthes rantonnetii*, *Solanum jasminoides*, *S. pseudocapsicum*, and *Streptosolen jamesonii*. The viroid caused serious production losses in tomatoes and possibly also in potatoes (Anonymous 2011).

8.4.1.3 Modes of Viroid Transmission

Viroids may be transmitted from infected plants via seeds, pollen, and propagules. Transmission by vectors is yet to be demonstrated conclusively. Mechanical transmission of viroids to several plant species through contaminated cutting knives and other handling equipment has also been reported.

Conventional seed testing methods, such as the growing-out test, may be adopted for estimating the extent of transmission through seeds under greenhouse conditions. Development of symptoms characteristic of the viroid infection may be observed in the seedlings growing from the specific number of seeds and the percentages of infected seeds are determined. Transmission of *Potato spindle tuber viroid* (PSTVd) was observed through true seeds and pollen of potato (Fernow et al. 1970) and through seeds of tomato (Bensen and Singh 1964). Transmission of *Grapevine yellow speckle viroid 1* (GYSVd-1) and *Hop stunt viroid* (HSVd) through seeds of eight grapevine cultivars was demonstrated by using a combination of dot-blot hybridization, Northern hybridization, and RT-PCR procedures (Wah and Symons 1997, 1999). The role of pollen in the seed transmission of *Peach latent mosaic viroid* (PLMVd) was investigated.

Pollen from nine peach trees of three cultivars infected with an Italian isolate of PLMVd as donors was used to pollinate healthy peach plants grown in insect-proof greenhouse and maintained for 6 years. PLMVd was detected in the pollen used for pollination using RT-PCR and spot-blot hybridization techniques. Five of 18 plants pollinated with pollen from infected trees were positive for PLMVd. Seeds from PLMVd-infected trees were also found to be infected. However, the seedlings from the PLMVd-positive seeds were apparently viroid-free. The results showed that PLMVd was transmitted through pollen but not through seeds of infected peach plants, indicating the possibility of pollen from peach plants being potential sources of PLMVd inoculum (Barba et al. 2007).

The route of *Hop latent viroid* (HLVd) transmission from hop plant through pollen to seed and then to seedlings was investigated during different stages of pollen and seed development. HLVd was eliminated during maturation and germination of hop pollen. HLVd degeneration in hop pollen was found to be a selective process that efficiently eliminated HLVd during pollen maturation and germination. The RT-PCR was applied to detect HLVd in pollen from infected plant. HLVd was detected by RT-PCR only in very low titer in mature pollen after anthesis and no viroid could be detected in vitro in germinating pollen. The results suggested complete degradation of circular and linear forms of HLVd. Elimination of HLVd from pollen was considered to be due to activities of pollen nuclease and specific RNases (Matoušek et al. 2008). In contrast, transmission of *Hop stunt viroid* (HSVd) through pollen and subsequently to seeds and seedlings was indicated by a later investigation. In order to verify the pollen transmission of HSVd, pollen from infected plum trees was tested by collecting pollen grains from closed flowers, using RT-PCR assay. The presence of HSVd isolate in the parental pollen donor plants, in the pollen, and in the seedling grown from seeds from plants pollinated with pollen infected by HSVd was revealed by RT-PCR assays. The dissemination of HSVd through pollen-seed-seedlings emphasized the need to check the plants, seeds, and pollen for freedom from HSVd in breeding programs (Luigi et al. 2010).

Potato spindle tuber viroid (PSTVd) can be easily transmitted by mechanical inoculation. Contaminated cutting knives used for tuber propagation led to high percentages of PSTVd transmission. Further, PSTVd transmission to healthy tubers occurred to an extent of 80–100% when tractor wheels became contaminated with infectious sap due to bruising of infected plants. Similar levels of high transmission (100%) of PSTVd were observed when cultivating and hilling equipment was used in the field where large plants were present (Bonde and Merriam 1951; Manzer and Merriam 1961). As the viroids can be readily transmitted by sap inoculation, the involvement of biological vectors appears to be less limited. The aphid species *Myzus persicae*, the most efficient vector of several plant viruses, was reported to transmit *Tomato planta macho viroid* (TPMVd) from the wild host *Physalis foetens* to tomato plants under glasshouse conditions. *Macrosiphum euphorbiae* was able to transmit *Potato spindle tuber viroid* (PSTVd), whereas *M. persicae* or *Aulacorthum solani* could not transmit PSTVd. *M. persicae* was shown to transmit PSTVd from plants doubly infected with PSTVd and *Potato leafroll virus* (PLRV) (Salazar et al. 1995). The successful transmission of PSTVd by *M. persicae* could be explained by the finding that PSTVd was heterologously encapsidated within particles of PLRV for which *M. persicae* was the natural biological vector. This phenomenon might have important implications for the epidemiology and spread of PSTVd under field conditions (Querci et al. 1997). *Tomato apical stunt viroid* (TASVd) was found to be transmitted by bumble bees in greenhouse tomato crops (Antignus et al. 2007).

8.5 Infection Process of Viroids

Viroids pathogenic to plants are classified into two families, Pospiviroidae and Avsunviroidae, with type members *Potato spindle tuber viroid* (PSTVd) and *Avocado sun blotch viroid* (ASBVd), respectively. The members of Pospiviroidae replicated in the nucleus and generally lack ribozyme activities. They have highly conserved regions in their rod-shaped secondary structure. Five broad structural domains have been identified in the secondary structures of viroids belonging to Pospiviroidae which include the left-terminal pathogenicity and central, variable, and right-terminal domains. On the other hand, members of Avsunviroidae possess highly branched secondary structures. They replicate in the chloroplasts and all have ribozyme activities (Keese and Symons 1985; Flores et al. 2005a). All viroids are readily transmitted by grafting and mechanical inoculation to healthy plants. After inoculation, development of systemic infection by viroids depends on the successful completion of the following processes: (i) import of viroid molecules into a subcellular organelle chloroplast or nucleus of the cell for Avsunviroidae or Pospiviroidae respectively; (ii) replication inside the organelle; (iii) export out of the organelle after replication; (iv) trafficking into neighboring cells; (v) entry into the phloem; (vi) long-distance trafficking within the phloem to upper leaves (away from inoculated leaf) and roots; and (vii) exit from the phloem to invade nonvascular cells and repeat the replication and trafficking cycle. As the viroids do not possess any proteins, as for viruses, the viroid RNA has to interact with host-encoded enzymes that may have the capacity to degrade RNAs (Ding 2009).

After entry into the susceptible cells that eventually become infected, viroids recruit host proteins for intracellular, cell-to-cell, and long-distance trafficking. *Potato spindle tuber viroid* (PSTVd) is the best characterized among plant-infecting viroids. PSTVd is localized in the nucleus where it is considered to replicate through the activities of the DNA-dependent RNA polymerase II via the rolling circle mechanism (Branch and Robertson 1984; Schindler and Muhlbach 1992). The tomato VirP1 protein was identified based on its property of interacting with the PSTVd replicating in the host cell nucleus (Martinez de Alba 2000). VirP1 cDNA clones were isolated from an expression library of tomato leaves by applying an RNA ligand screening procedure (Sagesser et al. 1999) using radio-labeled PSTVd RNA as a ligand. In addition to PSTVd RNA, VirP1 bound in vitro to *Hop stunt viroid* (HSVd). The amino acid sequence of VirP1 does not contain any known RNA-binding motifs; however, a bromo domain and two nuclear localization signals were identified (Martinez de Alba 2000). The partial self-complementarity that occurs along the 359 bases of PSTVd genome results in the formation of a secondary structure of an interrupted double helix with a branch at the left terminus (Gast et al. 1996).

Potato spindle tuber viroid (PSTVd) or *Hop stunt viroid* (HSVd), belonging to Pospiviroidae, have been investigated more frequently. A specific and saturable receptor mediates the cytoskeleton-independent import of PSTVd plus strands into the nucleus, where processing to the final circular forms presumably occurs. PSTVd seems to have a specific motif for transport through plasmodesmata; when injected into mesophyll cells, PSTVd moved from cell to cell through plasmodesmata (Ding et al. 1997). Two PSTVd strains were found to enter the phloem for long-distance transport but were unable to exit the phloem, suggesting regulated cell-to-cell trafficking (Zhu et al. 2002). Mutational studies on two PSTVd strains, PSTVd^{NT} and PSTVd^{NB} which differed by five nucleotides, were used to identify a bipartite motif required in young tobacco leaves for

trafficking from bundle sheath to mesophyll, but not required for trafficking in the reverse direction. This motif was not required for trafficking through the same cellular boundary in mature leaves, indicating developmental control of RNA trafficking (Qi et al. 2004). Members of the family *Avsunviroidae* might also follow the same route as members of *Pospiviroidae*. Investigations of long-distance movement of PSTVd and HSVd indicated that they were translocated through the phloem, forming complexes with phloem proteins, and this mode of trafficking might be sustained by viroid replication and governed by viroid RNA motifs and plant development. This motif was not required for trafficking in the reverse direction however, but was dependent on leaf developmental stages (Qi et al. 2004).

Potato spindle tuber viroid (PSTVd) was considered to move from the photoassimilate-source leaf into sink organs in a pattern consistent with phloem transport. This view was supported by in situ localization of PSTVd in the phloem. PSTVd failed to invade the shoot apical meristem (SAM), suggesting either inhibited trafficking into this tissue or inhibited replication once the viroid reached this tissue. However, selective transport of PSTVd RNA into sepals, but not into the other floral organs of *Nicotiana benthamiana* was observed (Zhu et al. 2001). PSTVd was transported following mechanical inoculation on the leaves of *N. benthamiana* to sepals, but not to other floral organs (petals, stamens, and ovary) of developing flowers. Although PSTVd could replicate in all floral organs, the absence of PSTVd in petals, ovary, and stamens might be attributed to restricted PSTVd movement into these organs and not to suppression of replication. The results indicated that PSTVd RNA movement within sieve tubes does not simply follow mass flow from source to sink organs, but is transported into selective sink organs. In addition, two PSTVd mutants could enter phloem to spread systemically, but could not exit the phloem in leaves of tobacco. It seems that the viroids have most likely evolved structural motifs that may mimic endogenous plant RNA motifs, so that they may be recognized by cellular factors involved in RNA trafficking (Zhu et al. 2002). Seed-transmissibility of viroids depends on the embryonic infection by the viroid concerned. In order to identify the major pattern of seed transmission of viroids, in situ hybridization was employed to histochemically analyze the distribution of *Potato spindle tuber viroid* (PSTVd) in each developmental stage of petunia from flowering to mature seed stages. PSTVd was present in the reproductive tissues of infected female $\times$ infected male and infected female $\times$ healthy male, but not of healthy female $\times$ infected male before embryogenesis. After pollination, PSTVd could be detected in the developed embryo and endosperm in all three crosses. The results indicated that PSTV was indirectly delivered to the embryo through ovule or pollen during the development of reproductive tissues before embryogenesis, but not directly through maternal tissues as cell-to-cell movement during embryogenesis (Matsushita and Tsuda 2014).

Movement of *Potato spindle tuber viroid* (PSTVd) in sections of infected tomato plants was monitored using in situ hybridization assay. Viroid signals were observed in the vascular tissues as well as in other cells in the subapical region but not in the shoot apical meristem (SAM), suggesting that the surveillance system that restricted the entry of most RNA viruses into the SAM also limited the PSTVd access to this plant compartment (Forster et al. 2002; Qi and Ding 2003). In contrast, *Peach latent mosaic viroid* (PLMVd), belonging to the family *Avsunviroidae*, was able to invade the SAM of infected peach tree (Zhu et al. 2001, 2002). Some of the PLMVd variants (PL-C40) contained an insertion of 12-13-nt folding into a hairpin capped by a U-rich loop that was responsible

for a variegated-albino phenotype known as peach calico (PC) (Malfitano et al. 2003; Rodio et al. 2006). Northern blot and in situ hybridization assays showed that PLMVd replicated in the albino leaf sectors and it could bypass the RNA surveillance system, resulting in the invasion of SAM and changes in protoplastids (Rodio et al. 2006). These results indicated a demarcating difference in the movement patterns of the two representative members, PSTVd and PLMVd, of the two viroid families. PLMVd was found to be well distributed in shoots, leaves, bark, roots, and fruits. Young developing fruits appeared to be the best source of PLMVd (Delgado et al. 2005).

Lacking the capacity to encode any protein, the genome of a viroid expresses biological functions directly. Understanding the nature of infections of a viroid requires identification of structural elements that may interact with host factors or serve as reaction substrates necessary in establishing infection. Functional genomic and proteomic analyses may provide vital inputs for determining the roles of structural motifs in the viroid genome necessary for systemic infection. A number of viroid-interacting proteins of potential functional significance have been identified. These are the chloroplast protein PARBP33 interacting with *Avocado sun blotch viroid* (ASBVd), Virp1 interacting with PSTVd, and phloem proteins interacting with several viroids (Darós and Flores 2002; Kalantidis et al. 2007). VirP1, a protein from tomato, was found to be an excellent host for PSTVd and was isolated by its capacity for its specific binding to PSTVd RNA (Maniataki et al. 2003).

Six proteins that interacted with *Peach latent mosaic viroid* (PMLVd) were identified using northwestern hybridization with peach leaf extracts partially purified by affinity column chromatography followed by mass spectrometry. These include elongation factor 1- α (eEF1A), aminomethyl transferase, putative chaperone, dynamin, 1,5-ribosomol protein and β -1,3-glucanase (JP Perreault, personal communication, see Ding 2009). The molecular mechanisms involved in the induction of effects (symptoms) characteristic of viroid infection remain unclear. Viroids may modify host gene expression interfering with normal developmental pathways. The mature RNA or its replicative intermediates are likely to be the primary pathogenic effectors interacting with host protein or RNA (Diener 2001).

Cellular changes associated with viroid disease symptoms caused by specific viroid pathogenicity determinants in both the nuclear and chloroplastic viroids have been investigated. A U257A substitution in *Potato spindle tuber viroid* (PSTVd) was recovered as a spontaneous mutation in transgenic tobacco plant expressing the viroid cDNA (Zhu et al. 2002). Incorporation of this nucleotide substitution into several PSTVd strains converted them into lethal strains that caused severe stunting and premature death of infected plants (Qi and Ding 2003). The peach calico symptoms, characterized by extreme chlorosis of infected tissues, was shown to be associated with the insertion of an extra 12-13-nt sequence which folded into a hairpin to the left terminal loop of *Peach latent mosaic viroid* (PLMVd). Such an insertion occurred sporadically de novo and could be acquired or lost during infection (Malfitano et al. 2003; Rodio et al. 2006).

It is hypothesized that simple competition for the transcription and/or subcellular, cell-to-cell, and long-distance movement of endogenous plant molecules may result in several physiological activities that contribute to the development of disease symptoms. However, the accumulation level of a viroid appears to have a minimal effect on the symptom severity. Viroid diseases may therefore be considered as a result of altered host gene expression, including gene transcription and posttranscriptional modification of gene products, caused by specific interaction between noncoding viroid RNA

and the host plant (Ding 2009). Small RNA-mediating gene silencing has been shown to be an antiviral mechanism operating in plants and animals. RNA silencing involves several classes of 21-24-nt small RNAs as key mediators. These small RNAs include microRNAs (miRNAs) and short interfering RNAs (siRNAs), produced by cleavage of structured or ds-precursor RNAs, respectively. RNase III dicer or dicer-like proteins and their associated proteins carry out the cleavage, yielding duplex miRNAs or siRNAs. One strand of the duplex is incorporated into the RNA-induced silencing complex (RISC) to guide degradation or translation inhibition of a target RNA or into an RNA-induced initiator of transcriptional silencing complex to guide DNA methylation and chromatin modifications (Jones-Rhodes et al. 2006; Chapman and Carrington 2007). The sequences of small RNAs from *Potato spindle tuber viroid* (Itaya et al. 2007; Machida et al. 2007), *Citrus exocortis viroid* (Martin et al. 2007) and *Peach latent mosaic viroid* were determined (Landry et al. 2004; St-Pierre et al. 2008).

Tomato plants infected with *Potato spindle tuber viroid* (PSTVd) showed severe leaf curling and vein clearing symptoms. The severity of disease symptoms decreased at later stages of infection however, and almost healthy-looking leaves appeared on the upper portion of tomato plants. PSTVd titers attained the peak levels in leaves with severe symptoms and declined in upper leaves recovering from severe symptoms. PSTVd-specific short interfering RNAs (siRNAs), characteristic of RNA silencing, accumulated in all leaves in which PSTVd reached a detectable level. The results suggested that recovery from a severe phase of disease was associated with RNA silencing via sequence-specific degradation of PSTVd RNA genome (Sano and Matsuura 2004). Tomato plants expressing hairpin RNA derived from PSTVd developed symptoms similar to those of PSTVd infection, suggesting that viroids may cause disease symptoms by directing RNA silencing against physiologically important host genes. The results indicated that viroid RNAs were significantly resistant to RNA silencing-mediated degradation (Wang et al. 2004). Small interfering RNAs (siRNA) resulting from the host RNA silencing, the defensive response triggered by double- or quasi-double-stranded RNAs, are considered to induce viroid disease symptoms. Viroid pathogenicity derived from viroid RNA sequences (21-24-nt) during infection may guide RNA silencing of host genes and subsequent induction of disease.

A positive correlation was observed between levels of small RNAs and symptom severity due to *Potato spindle tuber viroid* (PSTVd) and *Avocado sun blotch viroid* (ASBVd). In addition, development of symptoms was correlated with the production of small RNAs in tomato transgenic lines expressing nonreplicating hairpin PSTVd RNAs (Markarian et al. 2004; Matoušek et al. 2007; Wang et al. 2004). RNA-directed RNA polymerase 6 (RDR6) involved in the biogenesis of small RNA and many aspects of RNA silencing was required for symptom production by *Hop stunt viroid* (HSVd) in *Nicotiana benthamiana* (Chapman and Carrington 2001; Gómez et al. 2008).

Peach latent mosaic viroid (PLMVd) could induce an RNA silencing response in their hosts. By loading the second key RNase of the RNA silencing pathway, forming part of the RNA-induced silencing complex (RISC), the viroid-specific siRNAs may be able to guide the complex against their cognate genomic RNAs. Further, some of the viroid-specific siRNAs could by chance guide RISC against host messenger RNAs. This may downregulate the expression of specific host genes and eventually result in the production of disease symptoms. A link between certain macroscopic symptoms such as the albino-phenotype induced by variants of PLMVd and the underlying cytopathic and molecular alterations such as malformed protoplastids and impairment of chloroplast

formation was inferred (Flores et al. 2006). Posttranscriptional gene silencing (PTGS), considered to have an important role in antiviral defense, is triggered by the presence of ds-RNAs that are cleaved by an RNase known as Dicer. Following the cleavage, ss-RNAs (21-25-nt in length) designated small interfering RNAs (siRNAs) are formed. The siRNAs are incorporated into a multisubunit protein complex, the RNA-induced silencing complex, and act as a guide to direct this RNA degradation machinery to its target RNAs. The members of the two families of viroids have been shown to induce PTGS, based on the detection of siRNA, representing different regions of the viroid genome. Incubation of *Peach latent mosaic viroid* (PLMVd) transcripts of either plus or minus polarity with DCL enzyme(s) resulted in the detection of siRNA. Only these regions including the long p11 hairpin resulted in the formation of siRNA. The hairpin known to be implicated in the replication of PLMVd has the ability to trigger the Dicer enzyme(s). It appears unlikely that the P11 hairpin evolved specifically to be a Dicer substrate, since the viroid can evade PTGS-mediated degradation by replicating in the chloroplasts (Landry and Perreault 2005). The viroids can interact with cell factors which redirect them to replicate and traffic throughout the plant, while avoiding the RNA silencing machinery they trigger in their hosts.

Distinctly different symptoms are induced by viroid strains which are unencapsidated and lack the ability to code any protein, but have subtle difference in nucleotide sequences. A comprehensive analysis of differential gene expression patterns of tomato plants at various stages of infection by a mild and severe strain of *Potato spindle tuber viroid* (PSTVd) was carried out. Macroarrays containing 1156 clones from the subtracted cDNA library to monitor their expression patterns throughout the infection process was constructed. Alterations in the tomato gene expression following infection by PSTVd and *Tobacco mosaic virus* (TMV) were compared. The PSTVd strains altered expression of both common and unique tomato genes. The genes encode products involved in defense/stress response, cell-wall structure, chloroplast function, proven metabolism, and other diverse functions. The expression of some, but not all, of those genes altered by PSTVd was also altered by TMV infection. Viroids have the potential to trigger complex host responses, in spite of their simple structure (Itaya et al. 2007).

Coinfection of *Citrus* spp. with *Citrus tristeza virus* (CTV) and viroids occurs frequently. An assay to determine the effects of interactions between *Citrus dwarfing viroid* (CDVd) and CTV was developed. CTV encodes three RNA silencing suppressors (RSSs): p23, p20, and p25. Transgenic Mexican lines expressing each RSS were employed in this investigation. The assays were performed by comparing single and double infections of CDVd and CTV in Etrog citron (*C. medica*) (viroid bioindicator). Interactions between the pathogens were host-dependent. In the Mexican lime, but not in Etrog citron, CTV enhanced CDVd accumulation, while concomitantly CDVd limited the accumulation of CTV. The reduced CTV titer in the presence of CDVd suggested that these pathogens compete for a common biological factor. However, the higher CDVd titer in the coinfecting plants indicated that CTV might provide a beneficial effect for viroid accumulation. The potential role of RSS proteins in the accumulation of viroid RNAs (generated from ds-RNAs) in plants coinfecting with CTV and CDVd was studied. In Etrog citron CDVd-sRNAs were detected at similar concentration, regardless of whether plants were singly infected with CDVd or coinfecting with CTV and CDVd. The results indicated that, as with the accumulation of genomic CDVd, CTV did not have any effect on the accumulation of CDVd-sRNAs.

In Mexican lime, in which the accumulation of circular and linear CDVd forms was enhanced in the presence of CTV, CDVd-sRNAs were only detected in the doubly infected plants. A consistent positive correlation between the concentrations of viroid genomic RNA and sRNAs was therefore observed. Transgenic Mexican lines expressing p23 displayed an enhanced CDVd titer similar to that of nontransformed controls coinfecting with CTV. Transgenic lines expressing p20 had a viroid titer similar to that of nontransformed controls singly infected with CDVd. Transgenic lines expressing p25 had a CDVd titer slightly higher than that of singly infected nontransformed controls. Sequencing of RT-PCR amplicons from CDVd-infected plants showed that the CDVd used as inoculum remained stable in all treatments. The results showed that interaction between CDVd and CTV affected accumulation of viroid, but not symptom expression. On the other hand, CDVd infection caused a slight, but statistically significant, reduction of CTV titer (Serra et al. 2014).

Epidemiology and Management of Crop Diseases

9

Epidemiology of Seed- and Propagule-Borne Diseases

Epidemiology is one of the different aspects concerned with host–pathogen interactions, resulting in the incidence and spread of crop diseases and consequent losses in quantity and quality. The host–pathogen interactions are markedly influenced by the environment and, as a result, epidemiology also deals with the effects of biotic and abiotic environments existing in a geographic location. The term “epidemic” was originally coined for diseases affecting human beings (epi = upon; demos = people). In plant pathology, the term epidemiology refers to the production and spread of pathogen inoculum and the factors that influence both pathogen and the host plant. Interaction between a susceptible host plant species/cultivar and a virulent pathogen species/strain in a favorable environment results in the development of disease induced by the pathogen under investigation (Fry 1982). Variability in the pathogenic potential of isolates/strains of microbial pathogens and levels of resistance of host plant genotypes are important factors that determine the outcome of host–pathogen interactions, namely the incidence or absence of disease. The study of pathogen ecology helps to understand the influence of various factors that affect the buildup of pathogen populations. Disease incidence depends on the availability of susceptible host plant species or cultivar, virulent strains/isolates of pathogen, and environment favorable for the development and spread of the pathogen to wider areas. Each of these parameters are influenced by the duration (length of time) for which it is available. The term “disease triangle” applied previously has therefore been modified to “disease tetrahedron” to include the effect of duration of time of each of the three components – host, pathogen, and environment – on disease development.

A thorough understanding of epidemiology of seedborne diseases may provide a basis to evaluate the need to suppress disease development and spread and to develop effective and sustainable disease management systems. Molecular epidemiology aims to shed light on those processes that may result in a successful state of disease in a host plant, primarily to enable identification of a weak link in the biotic and molecular interactions or processes that may be capitalized upon to achieve desired level of disease reduction. When a pathogen species or its variants appear at a location, the identity of the pathogen has to be established precisely and rapidly. It is also essential to quantify the pathogen population at various stages of disease progress. Furthermore, the effects of various ecological factors on the pathogen population buildup have to be assessed. Information about the population genetics of pathogens has been useful for the advancement of epidemiological investigations (Narayanasamy 2008, 2011).

A basic need in epidemiology is the availability of a reliable diagnostic system and information on the pathogen genomics. The need to precisely and rapidly determine the pathogen population in a range of environmental settings has been emphasized for constructing models of risk of invasion by the target pathogen. Moreover, the detection of pathogens in asymptomatic plants, seeds, and propagules assumes great importance in eliminating the primary sources of infection that may be otherwise unwittingly introduced to the location(s) where the pathogen may be either absent or of minor importance. Molecular diagnostic techniques have been applied for effective assessment of host resistance/susceptibility or pathogen presence and virulence when infection is still at very low levels, providing a distinct advantage in developing effective strategies for containing the spread of the disease in the field (von Bodman et al. 2003).

9.1 Epidemiology of Fungal Diseases

Seeds and propagules infected by fungal pathogens constitute important primary sources of infection. The seedlings emerging from the infected seeds or propagules provide the inoculum for secondary spread of the disease. Seed transmission of fungal pathogens to the young seedlings or older plants may depend on the host–pathogen combinations. Rate of seed infection to seed transmission or plant infection and subsequent establishment in the field and further spread of inoculum depends on the pathogenic potential (virulence) of the fungal species/strains and levels of host plant resistance, in addition to existence of favorable environmental conditions. Seedborne pathogens have a reverse mode of transmission from infected roots, stems, and leaves to earheads/spikelets, resulting in different rates of seed infection in the earhead/seed-bearing organs of the host plant. The propagules obtained from infected mother plants may or may not exhibit symptoms of infection. Asymptomatic propagules may become potential sources of pathogen inoculum, as the plants growing from infected seeds and propagules form foci of infection from which secondary spread of the disease may occur depending on the availability of favorable environmental conditions, supporting the production of spores and other infection structures that may be spread by the wind and rain.

9.1.1 Dynamics of Host–Fungal-Pathogen Interactions

Epidemiology encompasses several subprocesses. Infection cycle, infection chain, or cycle of pathogenesis, the major subprocess, is the duration required for one dispersal unit (or infecting unit) to grow and produce the next generation of dispersal units. Some fungal pathogens, such as *Fusarium graminearum*, produce only one infection cycle during a crop season and such pathogens are known as monocyclic pathogens. On the other hand, pathogens such as *Alternaria* spp. and *Colletotrichum* spp., with many infection cycles during a single crop season, are referred to as polycyclic pathogens. The number of infection cycles produced during a crop season influences disease dynamics markedly. Another type of pathogen, infecting perennial crops, increases in population from year to year. The increase in pathogen populations and disease development therefore has to be considered over several seasons. These pathogens are called polyetic pathogens. As the susceptible plants are available for several seasons, even small increases in pathogen population in one season may result in severe epidemics.

The severity (intensity) of the disease varies with the nature of the pathogen, the virulence level (pathogenic potential) of the pathogen species, the levels of resistance/susceptibility of the crop cultivar, and environmental conditions. Further, the amount of disease is related to the pathogen population size. Often, the disease is analyzed more easily by visual observations; the scale of the disease is then quantified rather than the pathogen population, since it is easier to determine the disease severity using a standard scale than to estimate the population of the pathogen at a specified time. Yield reduction is attributed to the extent of disease occurrence in a location. The amount of diseased tissue is expressed as a proportion of total plant tissue and it is plotted over time. The shapes of disease progress curves may vary with location and time, since disease development is influenced by factors that may differ with location and time. The disease progress curve for disease induced by monocyclic pathogen usually resembles a saturation curve. On the other hand, the disease progress curve for disease induced by a polycyclic pathogen is likely to be sigmoid. The dynamics of polyetic pathogen-induced disease (represented by the proportion of infected plants over several seasons) lead to an exponential curve. Disease progress curves are useful for gathering information on disease dynamics. The influence of management strategies applied for the disease has to be assessed for forecasting disease incidence and subsequent spread.

Severe epidemics may occur, irrespective of the type of pathogen, if susceptible cultivars and favorable environmental conditions are available for long periods. Disease assessments are made to quantify the effects of diseases caused by the pathogens. Quantification of disease is often made, rather than the measurement of pathogen population, since the amount of plant tissues destroyed by the pathogen is directly related to the magnitude of crop losses. Further quantification of pathogen population requires time-consuming conventional methods or expensive modern molecular techniques and expertise. The contribution of the pathogen factors, host plant factors, and environmental factors to the buildup of epidemics of pathogen diseases are discussed in the following sections.

9.1.1.1 Pathogen Factors

Fungal pathogens exist in the form of strains, races, varieties, or biotypes that differ in their virulence (pathogenic potential), resulting in varying levels of disease severity and consequently in the degree of crop losses under a given set of environmental conditions. Using a set of differential host plant species or cultivars, formae speciales, varieties, strains, races, or biotypes have been recognized within a morphologic species of fungal pathogen. Different strains of *Fusarium graminearum*, *Ustilago tritici*, *Magnaporthe grisea* (= *Pyricularia oryzae*) and other fungal pathogens have been differentiated using different techniques. Strains of *Fusarium* spp. differ in their ability to produce the mycotoxins which cause ailments in human beings and animals following consumption of contaminated feed. These mycotoxins also function as virulence factor complementing other factors that enhance the virulence of the fungal pathogens. Mycotoxigenic species are distributed in the genera *Fusarium*, *Alternaria*, *Aspergillus*, and *Penicillium* and infect plants in the field, processed plant products after harvest, and products in storage. *Fusarium graminearum*, *F. culmorum*, *F. cerealis*, *F. avenaceum*, *F. sporotrichoides*, and *F. poae* produce deoxynivalenol, nivalenol, fusarenone, zearalenone, and moniliformin in wheat, other small grains affected by head blight or scab, and maize (corn) affected by red ear disease. Further, *F. verticillioides*, *F. proliferatum*, and *F. subglutinans*, inducing maize ear rot, produce fumonisins, beauvericin, fusaproliferin,

and moniliformin. Toxigenic *Alternaria alternata* strains, causing tomato black mold, black point of small cereals, and black mold of vegetables, produce tenuazonic acid and alternariols. *Aspergillus flavus* strains infect peanut, pea, and sesame, producing aflatoxins in seeds. Toxigenic strains of *Penicillium expansum* infecting apples and pear produce patulin in fresh and stored fruits. These mycotoxins reduce the quality of the produce significantly, rendering them unfit for consumption by humans and animals because of their carcinogenic and teratogenic properties (Logrieco et al. 2003; Narayanasamy 2005).

The coexistence of genetically divergent populations of *Fusarium graminearum*, causative agent of Fusarium head blight (FHB) disease of wheat, was observed in the upper Midwest and Gulf Coast regions of the USA. High molecular diversity was recorded within 12 individual populations of *F. graminearum* in Germany and with restricted diversity between the populations (Gale et al. 2011; Talas et al. 2011). Variations in two traits – the aggressiveness of isolates from individual field populations in terms of FHB infection and deoxynivalenol (DON) concentration in the host – within three populations of *F. graminearum* sensu stricto (s.s.) were estimated. Each population consisted of 30 single-spore isolates of a collection from four countries (Syria, Romania, Hungary, and Canada). All isolates were spray-inoculated onto a moderately resistant spring wheat cultivar at field locations over two years. The genetic proportions of phenotypic variance within population were significant for both traits. The environmental interaction was more important for mean FHB severity. Both traits were significantly ($P < 0.05$) correlated within and across populations. Within-field variation for traits of parasitic ability and selection was high. The high diversity within individual field populations as revealed by phenotypic traits and molecular markers was well reflected in the high evolutionary potential of *F. graminearum* s.s. The pathogen ability to adapt to environmental factors, including resistant cultivars, largely depended on the genetic variation within natural populations governed by the evolutionary forces mutation, recombination system, selection, genetic drift, and gene flow (Talas et al. 2011).

Although pathogenic specialization within *Fusarium graminearum* was not clearly established, difference in aggressiveness among isolates of *F. graminearum* could be recognized. High levels of variations in vegetative compatibility groups (VCGs) among *F. graminearum* isolates collected in the Midwestern USA were observed (Parry et al. 1995a; Bowden and Leslie 1996). In contrast, a low amount of genetic diversity among isolates of *F. graminearum* present in Canada was reported by Ouellet and Seifert (1993). *Fusarium avenaceum*, one of the components of Fusarium head blight (FHB) disease complex, showed wide variations in virulence of the isolates (91) on wheat. They were grouped into 15 phenotypes and 10 VCGs which formed 7 ITS rDNA phylogenetic clades and 3 EF-1 α PCR-DGEE groups. Variations in virulence within *F. avenaceum* isolates ranged from high virulence to avirulence to wheat. Virulent isolates, in general, had a wider host range and geographic distribution, while avirulent isolates exhibited greater heat tolerance, color plasticity, and growth rate compared to virulent isolates. Pathogen dynamics and outbreaks of disease might be influenced by the abundance ratio of virulent/avirulent isolates related to climate characteristics of each agroecosystem. The characterization of *F. avenaceum* sensu lato isolates obtained from western and eastern ecozones of Canada provided baseline information on the variation existing in FHB-inducing *Fusarium* species (Abdellatif et al. 2010).

Dissemination of fungal pathogens over short or long distances is one of the important factors for their survival and spread of the disease caused by them. *Fusarium graminearum* (teleomorph *Gibberella zeae*), the principal causal agent of Fusarium

head blight (FHB) disease of wheat and other cereals, is seedborne and can survive in the corn (maize) residue left in the field. Overwintered cereal debris is a potential reservoir of *Gibberella zeae* inoculum. Ascospores released from the crop debris become airborne and play a predominant role in the infection of spikes of wheat and barley at anthesis. The movement of *G. zeae* from a local source of inoculum in infested cereal debris was studied for the management of wheat FHB disease. Well-characterized clones of *G. zeae* were released and recaptured in five wheat fields in 2007 and 2008. Amplified fragment length polymorphism (AFLP) procedure was employed to track and identify unambiguously the released clones in the heterogeneous populations of the pathogen recovered from infected wheat spike collected at 0, 3, 6, and ≥ 24 m from small-area sources of infested corn residues. Isolates of *G. zeae* recovered at different distances from the center of source areas shared 65%, 19%, 13%, and 5% of the genotypes of clones respectively. The incidence of spike infection attributable to the released clones averaged 15%, 2%, 1%, and $<1\%$ at these distances. The percentages of spikes infected with the released clones varied significantly across sampling distances. The percentage of spikes infected with the released clones did not differ significantly between plots containing 3-acetyldeoxynivalenol (3-ADON) genotypes. The results suggested that FHB field experiments including a cereal debris variable have to include debris-free borders and interplot of at least 3 m (preferably 6 m) to avoid significant interplot interference from spores originating from within-field debris (Keller et al. 2010).

The relationship between *Gibberella zeae* inoculum dose and the resulting disease incidence levels in wheat was investigated under controlled condition for conidia alone and conidia and ascospores. The Fusarium head blight (FHB) disease metric (incidence or severity) was determined and this parameter increased sharply in proportion to spore contents until a maximum was reached where additional inoculum did not substantially increase the disease severity (Stack and McMullen 1985). Both kinds of pathogen propagules, conidia and ascospores, had similar pathogenic potential for infecting wheat and initiating FHB disease. The role of inoculum concentration (pathogen population) in the development of FHB disease and accumulation of deoxynivalenol (DON) was investigated to assess the effectiveness of risk advisory systems. Greenhouse-raised spring wheat plants were inoculated at flowering with suspensions that varied in *Gibberella zeae* macroconidia concentration. The spikes were covered for 72 h to enhance the infection percentage and the plants were maintained under ambient conditions for 15 days. Disease severity and DON concentrations were determined. DON concentration was assessed in grain-only and whole-spike samples for each treatment. Regression analysis was employed to evaluate the mathematical relationship between inoculum dose, disease metric (severity score), and DON contents. Both disease incidence and severity were found to increase sharply in relation to inoculum concentration until an asymptote (lack of symptom expression) was reached, where no further effects were observed with addition of inoculum. In contrast, DON accumulation in the ranges of inoculum concentration 0 to 25,000 conidia tested showed a linear function where the concentration of conidia continued to increase with additional inoculum. DON accumulation increased at a greater rate in whole-spike tissue. Functions developed from the greenhouse studies for disease severity and DON contents were not particularly effective at predicting events in the field. Disease incidence was overestimated at lower inoculum concentration, while disease severity and DON were underestimated. However, the DON accumulation in the grain was positively correlated to inoculum concentration under both greenhouse and field conditions. The combination of the models developed

in this investigation showed the potential to increase the accuracy of the existing risk advisory systems for predicting disease severity, and the risk of economically important DON concentrations (Stein et al. 2009).

Determination of sources of primary or initial inoculum for epidemics is an integral step toward understanding and managing plant diseases. Primary inoculum may be derived from dormant structures of a pathogen such as sclerotia or sexual spores or from actively growing pathogens from other plant populations. Primary inoculum may pre-exist in the field or may be introduced once or multiple times, and it may continue to arrive and cause primary infections in a plant population even after secondary cycles have commenced for polycyclic diseases. Barley net blotch caused by *Drechslera teres* became one of the most important diseases with increasing use of no-tillage agriculture and monocropping of susceptible cultivars. The pathogen is seedborne and the inoculum potential in infected seeds is a critical factor determining the extent of disease incidence and consequent yield losses. The symptomatic transmission efficiency (STE) of *D. teres* was calculated using the formula:

$$\text{STE}(\%) = \text{PS}(\%) / \text{S}(\%) \times 100$$

where PS is incidence of *D. teres* in plumules and S is incidence of *D. teres* in seeds. Seed infection of *D. teres* was determined using four replicates of 100 seeds each plated on the agar selective medium. The disease incidence in plots sown with fungicide-treated and untreated seeds was compared. The maximum *D. teres* symptomatic transmission efficiency (MSTE) registered from seed to plumule was 18.8% with mean values of 14.5%. In the absence of other sources of inoculum of *D. teres*, plumule infection after seedling emergence indicated that the infected seeds formed the primary sources of inoculum, resulting in higher levels of plumule infection in control treatment compared with fungicide treatment which reduced the seed infection percentage. The alarm threshold for net blotch disease control was established as 60% for leaf incidence. The results indicated that seedborne inoculum of *D. teres*, if unchecked, was a potential risk to barley crop (Carmona et al. 2008).

The influence of varying inoculum potential of *Fusarium verticillioides* (teleomorph *Gibberella moniliformis*), incitant of ear rot of maize, was investigated on the development of disease development in maize seedlings/plants in early stages under controlled conditions. Osmo-priming procedure was followed to obtain seeds with different levels of inoculum. The nongerminated seeds of the same seed lot exhibiting typical fructifications of *F. verticillioides* were grouped into five categories according to a grading system (0, 1–25, 26–50, 51–75, and 76–100) that was established based on the visible area of seeds covered by the pathogen propagules. The seeds of different categories were sown on soil and plants were grown under controlled conditions (25°C and 16 h light/day) for 25 days. Correlation variables, namely plant population, speed of seedling emergence, and height/weight of emerged plants were negatively correlated with increase in inoculum density of the pathogen initially present in the maize seed. The regression equations for all variables had a high correlation coefficient (>0.85), except plant height which had a lower correlation coefficient (0.77). The most drastic effect of *F. verticillioides* was noted on the root system of emerged seedlings, the adverse effect increasing with increasing inoculum density on the maize seeds planted in the soil under the greenhouse conditions. The results revealed the risk of using maize seeds

with high levels of inoculum density, which might result in drastic reduction in the quality and quantity of grain yield (Machado et al. 2013).

Fusarium verticillioides colonizes maize kernels and contaminates the grains with mycotoxins. The migration of *F. verticillioides* isolate transformed with foreign genes from inoculated to noninoculated maize ears was tracked to assess the extent of population flow of the pathogen among maize plants under field conditions. Maize ears were inoculated with *F. verticillioides* PATg strain carrying two foreign genes, one coding for hygromycin resistance (hyg^r) and the other for β -glucuronidase (GUS), through either the shuck or silk channel at one of two stages of silk development, green or brown. The average expression of hyg^r was 66% and of GUS was 96% for mycelia emerging from kernels of ears inoculated with *F. verticillioides*. Mycelia with hygromycin resistance appeared in cultures from noninoculated and water-inoculated ears at low rate (3%). However, none of the mycelia stained positive for GUS in kernels originating from noninoculated ears and only 7% of those from water-inoculated ears. The results indicated that dissemination of *F. verticillioides* PATg strain was minimal from plant to plant under field conditions during 2001–2003 in Georgia, USA. Only a few ears inoculated with water through the silk during the green silk stage of development yielded the transformed strain. The results suggested that mechanical injury during inoculation might have provided an entry site for infection by *F. verticillioides* PATg strain (Yates and Sparks 2008).

The sources of primary (or initial) inoculum required for buildup of epidemics have to be determined to develop integrated disease management systems. Primary inoculum may be derived from dormant or survival structures such as sclerotia, sexual spores of pathogens, or from actively growing pathogens from other plant populations or debris. Primary inoculum may pre-exist in the field or may be introduced once or several times during a crop season. It may continue to arrive and cause primary infections in a susceptible plant population, even after secondary cycles have begun for polycyclic pathogens. Assessment of the relative contributions of sources of primary inoculum may be of vital importance for effective management of the target disease(s). Infected seed may be a major source of primary inoculum for foliar epidemics of *Phaeosphaeria nodorum* (anamorph *Stagonospora nodorum*) as seed infection in commercial wheat seed lots is common; the mean seed infection incidence is 23% with a range of 1–71% (Shah and Bergstrom 1993). *P. nodorum* was shown to be efficiently transmitted over a broad range of soil temperatures from infected seed to aerial portions of seedlings, where the pathogen formed pycnidiospores that could be dispersed by splashing rain. In addition to revealing significant correlations between seed infection and disease severity, the genotypes of *P. nodorum* were tracked from inoculated seed to foliar epidemics and then to the next generation of wheat seed in the field. The results of these investigations provided direct evidence for the infected seed being the primary source of inoculum for *P. nodorum* (Shah et al. 1995; Shah and Bergstrom 1999). Seed infection in wheat by *P. nodorum* was observed in wheat seeds from New York, the extent of seed transmission being 70% or greater on the coleoptiles which might be exposed above soil line. Transmission also occurred to the first leaves at frequencies of 2–37% and possibly also to other leaves. The results indicated the possibility of infected wheat seeds being a primary source of inoculum of *P. nodorum* (Shah and Bergstrom 2000).

Phaeospora nodorum can infect wheat, rotational crops, and graminaceous weeds which may be potential sources of primary inoculum. In-field and out-of field wheat debris and infected wheat seeds are also important primary sources of inoculum for

P. nodorum. The relative contributions of seed-transmitted inoculum to foliar populations of *P. nodorum* in winter wheat were investigated. By infecting seed with genetically marked isolates of *P. nodorum*, releasing them by planting in the field, allowing natural seed-to-seedling transmission, and then recapturing them by sampling over the growing season, the relative contribution of seedborne isolates of the pathogen was assessed. Recapture of the released marked isolates of *P. nodorum* was performed by isolating them from leaves with necrotic lesions at spring tillering and flowering stages and mature grains from spikes showing glume blotch. The isolates from these samples were genotyped by applying amplified fragment length polymorphism (AFLPs) procedure and differentiated as released or nonreleased to infer the sources of inoculum. Both infected seed and other sources of the pathogen contributed significant primary inocula to populations recovered from leaves and harvested grains. Seed-transmitted genotypes accounted for 57% of all isolates recovered from inoculated plots with a range of 15–90% of the populations of *P. nodorum* collected over the season in individual, inoculated plots at four locations. Plants in the noninoculated control plots also yielded 95% or more of nonreleased isolates recovered from these plots. The results suggested reduction of seedborne inoculum of *P. nodorum* alone might not result in desired levels of control because of the availability of additional sources of inoculum of the pathogen. The release–recapture experimental approach provided valuable insights into the relative importance of seed-transmitted and other primary inocula in foliar epidemics of *P. nodorum* (Bennett et al. 2007).

Atmospheric motion systems are essential for the transport of many fungal pathogens. The movement of fungal pathogens in the atmosphere is characterized by the process of spore liberation, drift, and deposition on plant surfaces. The temporal patterns of deposition of viable spores of *Gibberella zeae* (anamorph *Fusarium graminearum*), causing wheat Fusarium head blight (FHB) disease, over rotational wheat fields were studied. Petri dishes containing the selective medium were placed at 30 cm above wheat canopies to collect viable, airborne spores of *G. zeae*. Over 40,000 spores were collected over a period of 73 days (06:00–20:00) or night (20:00–06:00) sampling periods in 3 years (2002, 2004, and 2005). The vast majority of spores (82–94%) was collected during night. Viable spores were deposited in all but one sampling period, spanning spike emergence in New York State. Seven major deposition events (>50 colonies/plate) occurred all at night and three of these coincided with rainfall. The results suggested that spore deposition might be separated from spore release in both time and space, and the cumulative exposure of wheat spikes to airborne spores of *G. zeae* and the deposition of these spores mainly at night are important factors to be considered while prediction models are developed (Schmalle III et al. 2006).

Chickpea Ascochyta blight disease is caused *Ascochyta rabiei* (teleomorph *Didymella rabiei*). The pathogen produces pseudothecia and pycnidia on overwintered chickpea debris. Timing of primary inoculum release from overwintered chickpea debris was investigated in the field, using potted susceptible chickpea plants as trap plants and debris heavily infested with *D. rabiei* spread over an area of 1 m² in the early fall season. Primary inoculum was trapped in spring by placing trap plants (27) adjacent to the overwintered debris for 2–3 days, followed by incubation in the greenhouse under conditions to promote infection. Disease lesions were counted 2 weeks later. Primary inoculum release began in mid-March, with the majority of lesions associated with rainfall during May in 2004 and 2005. Release continued through the beginning of June when the number of lesions on trap plants reduced dramatically,

despite the continuation of rainfall. Primary inoculum release correlated well with pseudothecial maturity and ascospore release in the laboratory. Regression analyses revealed the closest relationship of rainfall with primary inoculum release from overwintered debris, facilitating the attempts for the control of the disease to be directed to the critical period of inoculum release (Chilvers et al. 2007). *Didymella pinodes*, causing Ascochyta blight disease of pea, infects pea crop through ascospores released at the time of sowing. The relationship between the number of ascospores of *D. pinodes* at sowing and disease severity at crop maturity was investigated. Field pea stubble infested with *D. pinodes* from one site was exposed to ambient conditions at two sites, repeated in 3 years. Stubble samples were retrieved every 2 weeks, moistened and placed in the wind tunnel, and up to 2500 ascospores $\text{g}^{-1} \text{h}^{-1}$ were released. Secondary inoculum was monitored using seedling field peas as trap plants in canopies, arising from three sowing dates, and external to field pea canopies reached its peak in the early sown crops. A model was developed to calculate the effective number of ascospores using predictions from G1 blackspot manager, distance from infested stubbles, and winter rainfall. Maximum disease intensity was predicted based on the calculated number of effective ascospores, soil-borne inoculums, and spring rainfall over two seasons. Predictions were validated in the third season with data from field trials and commercial crops. A threshold amount of ascospores of *D. pinodes*, $294 \text{ g}^{-1} \text{ stubble h}^{-1}$ was determined, above which it did not increase. Below this threshold, there was a linear relationship between ascospore number and maximum disease intensity (Davidson et al. 2013).

Potato late blight disease caused by *Phytophthora infestans* is a highly destructive disease of historical importance, being primarily responsible for the infamous Irish potato famine. *P. infestans* infects potato and tomato accounting for heavy losses, especially in glasshouse crops. *P. infestans* is a polycyclic pathogen capable of producing several asexual cycles in one crop season and the asexual sporangia are well adapted for aerial dispersal. The sporangia may be disseminated over long distances (40–60 km) depending on the environmental conditions (Fry and Goodwin 1997; Aylor et al. 2001). The role of aerial dispersion of sporangia has been recognized as fundamental to the development of late blight disease since, without dispersal of infectious units, epidemics fail to progress. The temporal and spatial dynamics of disease epidemics have to be understood for development of effective strategies to restrict the incidence and spread of crop diseases. Several decision support systems (DSS) have been developed in different countries for application of fungicides at a particular time when a genuine risk was perceived to exist. These systems for predicting the risk of infection were considered to be effective strategies for management of late blight disease by making better use of fungicides than calendar-based fungicide treatments (Aylor et al. 2011).

Management of potato late blight disease caused by *Phytophthora infestans* has been found to be ineffective because of the difficulty in determining when, where, and how abundant airborne inoculum that may lead to epidemics would be present in a geographic location. It is possible that decision support system (DSS) may overestimate the risk when very little or no airborne inoculum is available. As *P. infestans* can produce multiple cycles of infection and inoculum production, the new infections may increase proportionally to both initial amount of inoculum present and amount of new inoculum produced in situ or carried by wind from external sources. The value of airborne sporangia concentration (ASC) as a monitoring tool for late blight disease inoculum has not been duly recognized. Further, information on the spatial distribution of airborne

sporangia of *P. infestans* over several seasons is also lacking. The usefulness of real-time monitoring of *P. infestans* airborne inoculum as a complement to DSS was assessed during 2010–2012 potato production seasons at two locations in New Brunswick, Canada. Airborne sporangia concentrations (ASCs) were monitored using 16 rotating-arm spore samplers placed at 3 m above ground. In both areas, the highest mean ASC in all samplers was detected between the end of July and end of August. In general, no correlation could be established between ASCs and the weather conditions such as temperature, duration of the period of high humidity, and rainfall, except for a weak significant correlation between the ASCs and a high-humidity period during 2010–2012. A gap between the magnitude of the risk estimation by DSS and the degree of ASC was discernible. The results suggested that the two DSS underestimated the late blight risk in 2010 and overestimated it in 2012. DSS estimated the potential for the disease to occur, but it could not measure the real inoculum level. The results suggested the spore sampling network devices coupled with DSS might be useful for targeting the optimal time to apply a disease control strategy (application of fungicides). The farmers in New Brunswick used the spore-sampling network as a functional strategy to control late blight epidemics. This investigation showed that area under the inoculum progress curve (AUIPC) could be used to assess disease progression and as a monitoring tool for potato late blight disease, facilitating optimization of fungicide use (Fall et al. 2015).

Severe outbreaks of late blight disease caused by *Phytophthora infestans* on potato and tomato have been observed since 2008 in the states of Andhra Pradesh, Karnataka, and Tamil Nadu in India. The phenotypic and genotypic characteristics of 63 potato isolates and 94 tomato isolates of *P. infestans* were compared with reference isolates based on the mating type, in vitro metalaxyl sensitivity, mitochondrial DNA haplotype, DNA fingerprint patterns (using the RG57 multilocus DNA probe), simple sequence repeat (SSR) markers, and aggressiveness (pathogenic potential) on potato and tomato leaves. All isolates collected from potato and tomato in different fields in South India belonged to A2 mating type, mitochondrial DNA haplotype Ia, and they were resistant to metalaxyl and highly aggressive (virulent) on both tomato and potato. This clonal lineage showed a characteristic RG57 pattern and SSR loci which matched the multilocus genotype (MLG) 13_A2 lineage present in European countries. Severe disease occurrence was observed during August–December when the average temperature ranged over 20.8–22.5°C. The results showed that the 13_A2 lineage causing severe late blight outbreaks in South Indian states replaced the US-1 and other genotypes of *P. infestans* that occurred earlier. As all isolates showed resistance to metalaxyl, alternative strategies have to be worked out for effective management of late blight disease infecting two important vegetable crops (Chowdappa et al. 2015).

Plasmopara halstedii, causal agent of sunflower downy mildew disease, is a registered quarantine pathogen on sunflower seeds in European Union. Many races (35) of *P. halstedii* have been recognized. New pathotypes are constantly emerging in different countries and can overcome resistance of sunflower cultivars available (Gulya 2007). In addition, the appearance of fungicide-resistant strains has become a great concern for growers, as the fungicide treatment was found to be less effective in reducing the disease incidence/severity. The prevalence of metalaxyl-resistant *P. halstedii* races was reported to exceed 50% of the total number of races in France (Moinard et al. 2006). This obligate pathogen resides in a quiescent state in sunflower seeds and the disease could be spread from areas of crop production by international seed trade. Hence, an

efficient optimized duplex real-time PCR technique was used to achieve the detection of fungicide-resistant strain of *P. halstedii* at the level of <1 infected seed per 1000 seeds. Such diagnostic techniques might be useful to prevent the introduction and spread of potentially new genotypes or fungicide-tolerant strains (Ioos et al. 2012).

9.1.1.2 Host Factors

The development of epidemics of fungal diseases may be dependent on host factors such as plant structure, plant age at the time of infection, genetic resistance of cultivars, host range, and susceptibility/resistance levels of rotational crops. The effect of timing on when the plant is most susceptible for successful infection of barley by *Fusarium graminearum*, causing Fusarium head blight (FHB) disease, was investigated. Wheat is highly susceptible to FHB disease during anthesis, possibly because extended anther extrusion is initially infected. Wheat is generally chasmogamous (open flowering type), whereas barley has both chasmogamous and cleistogamous (closed flowering) cultivars. The florets in cleistogamous cultivars do not open and anthers are not extruded at anthesis. The effect of infection timing on FHB disease incidence and mycotoxin accumulation in barley cultivars with two different flowering types were studied under greenhouse conditions. Cleistogamous cultivars were resistant at anthesis but susceptible at 10 days after anthesis, whereas chasmogamous cultivars were susceptible at anthesis. Regarding accumulation of mycotoxin deoxynivalenol (DON) and nivalenol (NIV) in mature grains, cleistogamous cultivars accumulated more mycotoxins (DON and NIV) when inoculated at 10 or 20 days after anthesis than at anthesis. On the other hand, chasmogamous cultivars accumulated greater concentrations of DON and NIV when inoculated at anthesis. The results showed that the most crucial time for *F. graminearum* infection and mycotoxin accumulation in barley differed with cultivar (Yoshida et al. 2007).

The relationship between incidence of Fusarium head blight (FHB) disease of wheat and number of spikelets infected on an ear (incidence of spikelet infection) was studied during three seasons and in four countries in order to derive a simple relationship for predicting disease at the spikelet level using ear infection. A robust relationship between incidence of ear infection and average number of infected spikelets per ear was obtained, assuming a fixed variance–mean relationship and a negative binomial distribution for the number of infected spikelets. A relationship between incidences of spikelet and ear infection was also obtained based on the complementary log-log or logit transformation of ear and incidence of spikelet infection. These models were found to be consistent over years and counties and it might be useful for arriving at meaningful disease management decisions involving the fungicidal applications (Xu et al. 2004).

The impact of seed infection by *Mycosphaerella pinodes*, causal agent of *Mycosphaerella* blight disease of field pea, on the development of epidemic proportions was investigated. Seed lots of susceptible and partially resistant field pea cultivars with different levels of seed infection by *M. pinodes* were produced at a single site, providing uniform handling and storage conditions. Field trials were conducted in a location where external inoculum levels were very high and another site with little external inoculum. For each cultivar, seed lots with high seed infection (26–47%), intermediate seed infection (6–15%) and low seed infection (0–2%) were planted. Seedling establishment was higher in plots planted with low seed infection than in other categories of seed infection. However, consistent differences in four of eight locations of trials were observed.

The results indicated that seed infection of field pea with *M. pinodes* did not substantially contribute to aboveground symptoms and very high levels of seed infection could reduce seedling establishment and plant stand, resulting in low yield levels (Gossen et al. 2010).

Seedborne fungal pathogens such as *Fusarium graminearum*, incitant of Fusarium head blight (FHB) of wheat and other cereals, may have a wide host range encompassing both monocotyledonous and dicotyledonous crop hosts as well as weed plant species. These sources of inoculum can contribute to development of epidemics and may supply inoculum to sustain many cycles of infection by such pathogens (Burlakoti et al. 2007). Pathogens such as *Ustilaginoidea virens*, causing rice false smut disease, have a limited host range and the availability of inoculum from other plant hosts is restricted (Lu et al. 2009). The levels of susceptibility of 20 graminaceous plant species to two sorghum ergot pathogens *Claviceps sorghi* and *C. africana* were assessed by inoculating them with a conidial suspension of 10^6 conidia mL⁻¹. Five species, namely *Sorghum arundinaceum*, *S. halepense*, *S. versicolor*, *S. virgatum*, and *Pennisetum glaucum*, were found to be susceptible to both pathogens. A marked variation in size of macroconidia of both *C. sorghi* and *C. africana* from different host plant species was observed. The results indicated that *C. sorghi* and *C. africana* had similar host ranges and the alternative hosts might be able to provide the inoculum from out-of-field locations (Muthusubramanian et al. 2005).

Host preferences of *Microdochium majus* and *M. nivale* infecting cereals have been investigated. *M. majus* occurred more frequently on the stem bases and ears of wheat compared to *M. nivale* which infected rye and turf grasses more frequently. *M. majus* had a weak/slight selective advantage over *M. nivale* in wheat, whereas *M. nivale* showed strong selective advantage over *M. majus* in oats and rye (Parry et al. 1995b; Simpson et al. 2000). Temperature-dependent differential host preference between *M. majus* and *M. nivale* was revealed under controlled environmental conditions (Simpson et al. 2004). *Fusarium graminearum* (Fg), causing Fusarium head blight (also known as scab disease), is primarily a pathogen of cereals but it could infect noncereal crops such as potato and sugar beet in the USA. Isolates (21) of *F. graminearum* collected from potato, sugar beet, and wheat inoculated on wheat earheads produced nine mycotoxins as revealed by gas chromatography and mass spectrometry. All isolates contained the *Tri5* gene coding trichodiene synthase involved in the biosynthesis of the mycotoxins. They were virulent to wheat cultivar Grandin. Isolates of *F. graminearum* differed significantly in virulence (expressed as disease severity), Fg DNA content, and mycotoxin accumulation. Potato isolates showed greater variability in producing different mycotoxins than sugar beet and wheat isolates. The results showed that *F. graminearum*, causing potato dry rot and beet decay, could be potential sources of inoculum for FHB epidemics in wheat (Burlakoti et al. 2007).

Infested spinach seed was suggested to introduce *Verticillium dahliae* into lettuce fields. Evidence for linking spinach seedborne inoculum of *V. dahliae* to wilt epidemics in lettuce was provided by experiments conducted in commercial spinach fields in four coastal CA counties in the USA. *V. isaachi* was the predominant species isolated from spinach seed, followed by *V. dahliae* and, less frequently, *V. klebahnii*, irrespective of the county. The frequency of recovery of *Verticillium* spp. was unrelated to the *Verticillium* wilt incidence in lettuce, but was related to the area under spinach production in individual counties. *Verticillium* wilt disease incidence on lettuce was determined in microplots. The disease developed on lettuce when *Verticillium*-infested spinach seeds

were planted in the same soil twice or three times. The identity of the pathogen recovered was confirmed to be *V. dahliae* using PCR assays. In addition, green fluorescent protein (GFP-) tagged mutant strain of *V. dahliae* was employed to demonstrate transmission of *V. dahliae* from infested spinach seed to lettuce roots in a greenhouse study, after two cycles incorporating infected residue into the soil. The results provided direct evidence for the transmission of *V. dahliae* from infested spinach seed to lettuce plants (Short et al. 2015).

The influence of time of infection of wheat by *Fusarium graminearum* on reduction of grain weight and mycotoxin accumulation was investigated. Earheads of Norm wheat were spray-inoculated with a macroconidial suspension of a deoxynivalenol (DON-) producing isolate of *F. graminearum* at each of six reproductive stages from flowering to hard dough. Inoculated plants were incubated in a mist chamber for 48 h and then placed in the greenhouse until maturity. Norm wheat was susceptible at all stages inoculated, but the greatest grain weight reduction and DON accumulation in grains occurred in plants inoculated from post-flowering to late milk stages. However, a high level of kernel infection and marked accumulation of DON were observed in plants inoculated at the late hard dough stage, although reduction in grain weight was not in proportion to infection levels. Commercially significant levels of DON in plump, high-yielding wheat could result from infections well after flowering stages depending on the availability of favorable environmental conditions (Del Ponte et al. 2007).

The incidence of Fusarium head blight (FHB) disease of wheat caused by *Fusarium* spp. may be influenced by the structural characteristics of spikelet organs at the time of anthesis. Wheat cultivars differ distinctly in anther extrusion. The characteristic of anther retention (anther held within the spikelets) and trapped anthers (partially extruded and trapped between the lemma and palea of wheat spikelet) was assessed. A higher proportion of anthers was weakly correlated with increased susceptibility to FHB disease (Graham and Browne 2009). In a later investigation, the relationships between the degree of anther extrusion (AE) and FHB damage were determined using double haploid lines (DHLs) derived from F1 plants from crosses between closed-flowering and opened-flowering cultivars. Various degrees of AE were seen in the DHLs, and FHB severity was the lowest in closed-flowering DHLs. The DHLs with partially extruded anthers showed significantly more severe FHB symptoms than those with closed flowering phenotypes. FHB severity was significantly correlated with Fusarium-damaged kernels (FDKs) and deoxynivalenol (DON) concentrations in the grains. Partially extruded anthers were considered to be potential sources of FHB infection (Kubo et al. 2013).

The ergot disease incidence and severity in male-sterile sorghum lines as a function of distance from pollen source and its impact on seed production and quality were determined. *Claviceps africana* causes significant losses in yield. Sorghum male-sterile lines E15A × E15B and the hybrid A155 × R8509 were planted in seed production fields with a female to male row ratio of 8:4, 0.76 m row width, and 0.1 m spacing between plants. Disease incidence, ergot severity, and seed yield were determined in female rows 1, 3, 5, and 8 and in male rows 1 and 3. Regression analyses between distance from pollen emission source and disease incidence, disease severity, and seed yield were carried out for each field. The results indicated that yield reduction, ergot incidence, and disease severity were lower in female rows of the line than in those of the hybrid seed production field. As the distance increased from pollen source to the female row, the ergot incidence increased from 42 to 67% in the furthest row (3.04 m) and from 19 to 22% for ergot

severity, and seed yield decreased from 45 to 56%. The seed quality was not markedly affected. Ergot disease affected seed physiological quality by decreasing viability, vigor, and germination. Ergot-contaminated seeds were more readily invaded by larger number of fungi than the healthy seed lot (Hernández-Martínez et al. 2006).

The plant age is an important factor that significantly influences the level of susceptibility/resistance of plants to fungal pathogens. *Alternaria sesame* causes the Alternaria leaf spot disease in sesame (gingelly) in all countries. The effects of plant age on disease severity and seed infection by *A. sesami* were determined using the sesame accession SPSSIK110 at five different stages of plant growth. Rates of increase in blighted leaf area and defoliation, and areas under the disease progress curves (AUDPCs), varied among the different plant ages. Plants inoculated at 8 and 12 weeks of age were the most susceptible to the disease. The susceptibility level of 4 week old plants was the least. In order to assess seed infection, the pathogen was isolated from seeds of plants inoculated at different ages on oatmeal agar. Seed infection by *A. sesami* was the highest in plants infected at 8 and 10 weeks of age, whereas plants inoculated at 4, 6, and 12 weeks of age had the least infection levels. The results indicated that the susceptibility of plants to infection by *A. sesami* differed but without a significant relationship with plant age (Ojiambo et al. 1999).

Cladosporium variable and *Stemphylium botryosum*, causing leaf spot diseases of spinach, were responsible for reducing the quality of fresh market crops and seed crops. Spinach “seed,” as it is commonly called, is actually a fruit with a seed enclosed by a thick, corky pericarp. The true seed consists of a seed coat, embryo, and nonliving perisperm (maternal storage tissue). The entire spinach fruit consisting of the pericarp, testa, embryo, and perisperm was used in this investigation. Both pathogens were seed-transmitted and seed assays demonstrated that *S. botryosum* and *C. variable* were internal and external in spinach seed. The presence of *S. botryosum* was detected in 5–76% of the embryos of five seed lots tested, whereas *Cladosporium variable* or *C. macrosporum* was present in only up to 1% of embryos of these seed lots. The survival of the seedborne fungal pathogens is affected by storage conditions. Pathogenic isolates of *S. botryosum* were detected by freeze-blotter seed health assay in each of the 12 seed lots stored for up to 11 years at 4.4°C and 60% relative humidity. On the other hand, *C. variable* or *C. macrocarpum* could be detected in only 2 of 11 seed lots which had been stored for 3 and 8 years. Conditions favorable for long-term storage of seed also favored the survival of seedborne pathogens (Hernández-Pérez and du Toit 2006).

9.1.1.3 Environmental Factors

9.1.1.3.1 Agricultural Practices

The influence of agricultural practices on the incidence and intensity of wheat Fusarium head blight (FHB) disease on susceptible wheat cultivar “Ritmo” and moderately susceptible cultivar “Buteo” and “Dekan” was investigated. Four *Fusarium* species – *F. graminearum* (teleomorph *Gibberella zeae*), *F. culmorum*, *F. poae*, and *F. avenaceum* – were associated with FHB disease in North and Baltic areas. Genus- and species-specific primers were employed in the PCR assays for the identification of these pathogens. Higher frequencies of *G. zeae* and *F. avenaceum* were observed in Ritmo, compared with Buteo. Average leaf wetness between May and the middle of July and at the time of anthesis was positively correlated to relative frequencies of *G. zeae*, but negatively correlated to relative detection frequencies of *F. culmorum*. Temperature, precipitation (rainfall), and relative humidity during the same periods

of time did not influence the detection frequencies observed for any of the pathogen species. Relative frequencies of PCR amplicons specific for *Fusarium* spp. were positively correlated to the deoxynivalenol (DON) content of grain ($R = 0.685$, $P < 0.0001$). Tillage and previous crop might affect the severity of FHB epidemics, but they did not change the species composition significantly. In contrast, the resistance level of wheat genotype and leaf wetness affected the spectrum of *Fusarium* spp. on wheat heads in a selective manner (Klix et al. 2008).

Bread-making wheat in Japan requires a higher protein content which could be obtained by top-dressing with nitrogen near anthesis of wheat. Such N applications might increase the incidence of Fusarium head blight (FHB) disease however, and consequently increase accumulation of deoxynivalenol (DON) and nivalenol (NIV) in the grains. The effect of N application (0, 4, and 8 g m^{-2}) at anthesis on FHB infection and mycotoxin accumulation in wheat cultivars Nishinokaori and Minaminokaori was therefore assessed under greenhouse conditions and in two fields in 2006. Plants were spray-inoculated at 3, 10, and 20 days after N application. Colonized maize kernels which produced ascospores of the pathogen served as inoculum for the field experiments. The results demonstrated that grain protein level increased due to N treatment, but no significant effect on the FHB incidence and levels of DON and NIV accumulation could be seen. It was suggested that N application at anthesis might not increase the risk of FHB and mycotoxin contamination of wheat grains (Yoshida et al. 2008).

Tillage is one of the agricultural practices that may have a decisive influence on the incidence of fungal diseases. The effects of tillage (ploughing vs minimum tillage) and application of chopped maize stalks on infection by *Fusarium graminearum* and *F. culmorum* on winter wheat cultivar Hereward were investigated. Isolation on medium and quantitative PCR assays were employed to detect the pathogens in shoot bases, stem bases, and harvested wheat grains. *F. culmorum* was more frequently detected (up to 35%) than *F. graminearum* from stem bases. A lack of rainfall probably limited the dispersal of conidia from the ground surface to the ears. Ascospores of *F. graminearum* were less dependent on rainfall for dispersal, compared to *F. culmorum*. The incidence of *F. graminearum* was increased in stem bases where maize stalks were incorporated and in grain by both the presence of maize stalks and minimum tillage. The results indicated that noninversion (minimum) tillage might increase the risk of ear infection, especially by *F. graminearum*, and the consequent mycotoxin contamination of grains. The risk imposed by a susceptible preceding crop (wheat or maize) and minimum tillage was found to be significantly high for the wheat ear infection by *F. culmorum* and *F. graminearum* (Bateman et al. 2007).

Phomopsis longicolla, a major seedborne pathogen of soybean seeds, is favored by hot, humid environments. Infection and development of *P. longicolla* in vegetative and reproductive tissues of six soybean cultivars was monitored for 3 years (2002–2004). Soybean cultivars were raised without irrigation or with irrigation applied at pre- plus post-flowering or at flowering growth stage. *P. longicolla* was recovered more frequently on seed from irrigated treatments than from the nonirrigated treatments in all three years. The percentages of *P. longicolla* isolated in 2003 were significantly greater within each irrigation treatment than in the other two years (Fig. 9.1). There was a low but significant positive correlation between recovery of *P. longicolla* from pods and recovery of *P. longicolla* from seeds in nonirrigated treatments. No correlations of *P. longicolla* from leaves and stems with that from seeds could be observed (Fig. 9.2). Likewise, no consistent correlation was noted between yield and infection of plant parts.

Figure 9.1 Influence of irrigation on development of *Phomopsis longicolla* (a) leaf, (b) stem, and (c) pod, represented by area under disease progress curve under nonirrigated (NI), post-flower irrigation (PF), and pre- plus post-flower irrigation (PPF) environments during 2003–2004. Means followed by the same letter within each irrigation environment are not significantly different ($P \leq 0.05$). Source: Mengistu et al. (2009). Reproduced with permission of the American Phytopathological Society, MN, USA.

Figure 9.2 Effects of irrigation on percentage of recovery of *Phomopsis longicolla* from (a) infected seed, (b) seed germination percentage, and (c) seed hardness in soybean crop grown in nonirrigated (NI), post-flower irrigation (PF), and pre- plus post-flower (PPF) irrigation environments. Means followed by the same letter within each irrigation environment are not significantly different ($P \leq 0.05$). Source: Mengistu et al. (2009). Reproduced with permission of the American Phytopathological Society, MN, USA.

The isolation of *P. longicolla* was negatively correlated with percent seed germination in irrigated environment. The results indicated that seed infection by *P. longicolla* was moisture- and cultivar-dependent. The levels of infection of seed of some cultivars increased with an increase in moisture availability during the growing season (Mengistu et al. 2009).

9.1.1.3.2 Weather Variables

Fusarium head blight (FHB) disease infecting wheat, barley, and other small grain crops is caused by different species of *Fusarium*, the importance of which may vary depending on the geographical location. *Fusarium graminearum* is the predominant pathogen in many countries. These pathogens attract the attention of the growers, consumers, and administrators because of the grain yield loss and the health hazards of the mycotoxins produced by these pathogens contaminating the food grains and feed stuff. Concentrations of deoxynivalenol (DON), the main mycotoxin produced by *F. graminearum*, at $<1.0\mu\text{g g}^{-1}$ of grain are permitted in wheat meant for human consumption and up to $5.0\mu\text{g g}^{-1}$ for livestock feed (Miller 1994). DON can be produced in the seeds that may not exhibit any visual symptoms of infection by *F. graminearum*. Accurate measurement of DON is therefore preferred to determine the suitability of the harvested produce for consumption, rather than the loss in grain weight. Epidemiological factors that favor incidence of FHB and accumulation of mycotoxins have to be determined to understand the effects of the disease on the economy of the crop cultivation. The epidemics of Fusarium head blight (FHB) disease is generally associated with availability of inoculum abundantly, susceptible wheat or barley cultivars, and favorable weather conditions at the time of heading. Regardless of the levels of inoculum, favorable weather conditions are critical for infection to occur in wheat heads. A small quantity of inoculum may be adequate to cause concern for high concentrations of deoxynivalenol (DON) in grains, if weather conditions are favorable for infection (Miller et al. 1998).

Important weather variables and their timing were determined for predicting concentrations of DON in mature grain at wheat heading. Weather variables such as daily rainfall, daily minimum and maximum air temperatures, and hourly relative humidity were recorded for each field from nearby weather stations and normalized to the date of 50% head emergence. DON was correlatable to weather in three critical periods around heading: 4–7 days before heading with a general increase in DON with number of days with 75 mm of rain and a decrease with the number of days of $<10^{\circ}\text{C}$; 3–6 days after heading, with an increase in DON with number of days of $>3\text{ mm}$ rain and a decrease with days exceeding 32°C ; and 7–10 days after heading, with a DON increase with number of days with $>3\text{ mm}$ rain. Relative humidity did not show any relationship with DON content in grains. Based on the data collected from 399 farm fields, concentrations of DON of $<1.0\mu\text{g g}^{-1}$ could be predicted correctly on over 89% of fields (Hooker et al. 2002).

Qualitative and quantitative effects of environmental factors on initial infection and subsequent development of Fusarium head blight (FHB) disease have to be determined for assessing the disease risks. In Europe, the FHB disease may be caused by several fungal pathogens: *Fusarium graminearum*, *F. culmorum*, *F. avenaceum*, *F. poae*, *Microdochium nivale*, and *M. majus*. These pathogens may differ in their requirements for infection and subsequent development (Rossi et al. 2001). Models developed, based on field data entirely, may lead to significant errors. Further, the models derived from

single-pathogen inoculations may also result in erroneous conclusions, because of interactions between different FHB pathogens. Experiments were therefore performed under controlled environmental conditions to investigate the relationship between environmental conditions, development of FHB, and mycotoxin production. A single isolate from each of *F. avenaceum*, *F. culmorum*, *F. graminearum*, and *F. poae* were inoculated onto wheat ears separately. In addition, combinations of two or three isolates were also inoculated onto wheat ears simultaneously. Inoculated ears were subjected to various combinations of duration of wetness (6–48 h) and temperature (10–30°C). Both incidence of FHB and mycotoxin concentration increased generally in all treatments, with increasing length of wetness period and temperature. There were significant positive correlations among disease incidence, fungal biomass (quantified as total amount of fungal DNA), and mycotoxins. Mycotoxin production was significantly increased by high temperatures ($\geq 20^\circ\text{C}$) during infection periods. No synergistic interaction seemed to occur between fungal isolates in causing visual symptoms. However, the results suggested that, in most cases, the pathogen isolates competed with each other as a large reduction in fungal biomass was observed compared to single-isolate inoculations, often >90% reduction for the weaker isolates. In contrast, the production of mycotoxins dramatically increased in coinoculations by as much as a factor of 1000, suggesting that competition among FHB pathogens resulted in greater production of trichothecene mycotoxins. *F. graminearum* isolate was the most competitive and isolates of the other three species had similar levels of competitiveness. The results revealed that FHB pathogens could compete for nutrients or infection sites on wheat ears (Xu et al. 2007).

Germination of ascospores is the initial step for successful infection of wheat spikes by *Fusarium graminearum*. The effects of age of spores (0–18 days after discharge), temperature (4–30°C), relative humidity (0–100), and pH (2.5–6.5) on the germination of ascospores of the mycotoxin-producing *Gibberella zeae* strain were investigated. Freshly discharged ascospores germinated within 4 h at 20°C and 100% RH and the rate of germination and the percentage of viable ascospores decreased over time after discharge from perithecia. The period of time needed to maintain 50% ascospore germination at 100% RH was 26.9 h at 4°C, 10.4 h at 14°C, 3.44 h at 20°C, and 3.31 h at 30°C, indicating the adverse effects of higher temperatures on the ascospore germinability. The time course of ascospore germination was affected by pH, the maximum being at pH 3.76. Dry atmosphere (0% RH) abolished the ascospore germination almost instantaneously. Ascospores kept at 53% RH lost the germinability rapidly from 93% to 6% within 10 min. The results indicated that age of spores, RH, temperature, and pH were vital factors affecting the percentage of germination of ascospores of *G. zeae* (Beyer and Verreet 2005).

Fusarium verticillioides (= *F. moniliforme*) infects maize (corn) plants at different stages of growth, inducing root rot, stalk rot, ear rot, and seedling blight symptoms. Maize seeds were inoculated with four different strains of *F. verticillioides* and planted in the field. The seed-inoculated strains of the pathogen could be recovered from crowns (65%), nodes (34–54%), cobs (10%), and kernels (8%), revealing the ability of *F. verticillioides* to be transmitted to seedlings and remaining dormant till the earheads are formed. This kind of infection is referred to as systemic or endophytic infection (Kedera et al. 1992). The effect of temperature on the first step in the systemic infection process was studied. Commercial maize hybrid seeds were inoculated with a strain of *F. verticillioides* transformed with green fluorescent protein (*gfp*) gene and planted in growth chambers. Three temperature regimes – low, average, and extreme

temperatures – occurring in Iowa, USA were maintained. At V2 growth stage, >90% of the root and mesocotyl tissues were infected by the transformed strain at all three regimes. At V6 growth stage, infection of root and mesocotyl tissues persisted and was detected in 97–100% of plants at all three temperature regimes. Plants remained asymptomatic and the percentage of such plants increased with increase in temperature. Seed transmission and systemic infection detected at different temperatures did not differ significantly among treatments (Wilke et al. 2007).

Relationships between Fusarium head blight (FHB) of spring malting barley caused by *Gibberella zeae* (anamorph *Fusarium graminearum*) and accumulation of deoxynivalenol (DON) and hourly weather conditions were investigated to develop predictive models. Three popular barley cultivars were planted throughout the US Northern Great Plains for six growing seasons. FHB disease incidence and DON concentration in grains were recorded. Nine predictor variables were calculated using hourly temperature and relative humidity during the 10 days preceding full head spike emergence. Simple logistic regression models were developed using these predictor variables based on a binary threshold for DON of 0.5 mg kg^{-1} . Four of the nine models had sensitivity greater than 80% and specificity of these models ranged over 67–84% ($n = 150$). The FHB incidence was significantly associated with DON accumulation in the grain and the weather conditions prior to full head emergence, which could be used to accurately predict the risk of economically significant DON accumulation for spring malting barley (Bondalapati et al. 2012).

Stagonospora nodorum (teleomorph *Phaseosphaeria nodorum*) causes Stagonospora nodorum blotch (SNB) disease of wheat. Rainfall was found to be vital for development of SNB disease because pycnidiospores of *S. nodorum* might be dispersed in splash droplets. Rainfall during stem elongation (facilitating vertical progress of the disease in the developing canopy) as well as rainfall during seed developmental stages (for splashing onto the spikes) may be important factors affecting the incidence of wheat seed infection by *S. nodorum* (Pietravalle et al. 2001). A simple model was developed to predict the regional distribution of the incidence of wheat seed infection by *S. nodorum* shortly after harvest, or even before, without having to wait for the results of seed assays. Mean monthly rainfalls in May and in June across western and central New York were used to predict seed infection. The distribution of the incidence was well reflected by beta-binomial probability distribution (parameters p and θ). The model was validated with independent data collected from New York. The predicted distribution of seed infection incidence was not statistically different from the actual distribution of the incidence of seed infection. This investigation provided a method of estimating the probability of a given seed infection incidence level of a particular seed lot produced in western and central New York in any year (Shah and Bergstrom 2002).

The effects of infection of linseed cultivar Antares by *Botrytis cinerea* or *Alternaria linicola* on seedling emergence at varying temperatures of 5–20°C and transmission of the pathogen from infected seeds to the seedlings were investigated. The maximum percentage of seedling emergence decreased linearly as the seed infection by *B. cinerea* increased from 0 to 83% at 18°C day/12°C night temperatures. Transmission of *B. cinerea* to seedlings, as revealed by the production of symptoms on the hypocotyls and post-emergence death, increased as temperature decreased from 20 to 5°C. On the other hand, a decrease in percentage of seedling emergence due to seed infection by *A. linicola* and transmission of the infection to seedlings by *A. linicola* increased as the temperature increased from 5 to 20°C. At 10°C, infection of seeds by *A. linicola*

decreased seedling emergence to a greater extent compared with infection of seeds by *B. cinerea*, even though the percent of seed infection by *A. linicola* was considerably smaller. Regression analyses indicated that maximum percentages of seedling emergence (logit transformed) against temperature were well correlated (Harold et al. 1997).

The mating types A1 and A2 of *Phytophthora infestans* were found to be in a 1:1 ratio in the highlands of Mexico, favoring the sexually derived genetic diversity of the potato late blight pathogen. The widespread occurrence of A1 and A2 mating types guaranteed successful infection of even resistant potato cultivars/wild species by *P. infestans*. Wild *Solanum* spp. present in this region could serve as alternative hosts to the pathogen. Knowledge of the external factors that influence the dynamics of potato late blight disease may facilitate the assessment and selection for genetically resistant potato cultivars, in addition to facilitating the prediction of late blight epidemics. Using 8 year weather datasets, six ideal situations were predicted with four to eight infection cycles of 6–12 h each. The observed effect of the area under disease progress curve (AUDPC) and its components was highly significant, with a low coefficient of variation among potato cultivars used in this investigation. LateBlight-LB2004 model was found to be useful for simulating and predicting late blight epidemics based on weather factors existing in Chapingo, Mexico, except for the magnitude of relative humidity threshold variable (RH-threshold) which required calibration for each potato cultivar (Diaz de la Cruz et al. 2014).

9.1.1.3.3 Soil Environment

The soil environment is always in a state of constant and dynamic variations and changes in physical, chemical, and biological constituents of the soil occur constantly, resulting in favorable or adverse conditions for the development of the pathogens as well as of the antagonistic microorganism and other microorganisms involved in the decomposition of soil organic matter. *Gibberella zeae* (anamorph *Fusarium graminearum*), the pathogen causing wheat Fusarium head blight (FHB) disease, produces macroconidia which are splash-dispersed by rain and are involved in the secondary infection of wheat earheads. Sexual fruiting bodies, perithecia, are formed in the spring on infected crop residue with rainfall greater than 5 mm. Ascospores formed in the perithecia are forcibly discharged and dispersed by wind, leading to initiation of primary infections. With increase in no-till or conservation tillage practices, large amounts of crop residues accumulate on the soil surface and form sources of inoculum of FHB pathogen. Macroconidia and perithecia could be produced from the residues on or above the soil surface up to 3 years (Konga and Sutton 1988). Survival of *G. zeae* in *Fusarium* damaged kernel (FDK) was investigated under field conditions. FDKs were either left on the soil surface or buried 5 or 10 cm deep and monitored for 24 months. Perithecia developed on FDKs from all locations and treatments, but ascospores developed only in perithecia on kernels located on the soil surface. The survival of the pathogen in kernels left on the soil surface or buried at 5 cm in heat-treated and nontreated soil at –10, 2, and 20°C was investigated. The fungus survived in 76–100% of kernels. When the kernels were incubated at 20°C, *G. zeae* was recovered from 83 and 76% of kernels in heat-treated and nontreated soils, respectively. Perithecia developed on kernels incubated at 2 and 20°C, but ascospores were formed only in perithecia on FDKs at 20°C on soil surface. The pathogen could survive for 24 months (Inch and Gilbert 2003).

Potato tubers infected by *Phytophthora infestans*, incitant of late blight disease, may remain in the soil after harvest. Growth, sporulation, and survival of *P. infestans* on the

volunteer tubers were investigated under temperatures representative of winter (4, 7, and 10°C) and spring (13, 16, and 19°C) soil conditions in western Washington. Inoculated tubers stored at 10°C for 8 days had a significantly higher percentage of disease symptoms ($P < 0.05$) on tuber surfaces and a higher number of lenticels and eyes showed infection with *P. infestans* and sporulation, compared with those stored at 4 or 7°C. Sporulation of the pathogen on cut tuber surfaces was observed following 3 week storage at three soil temperatures. At 12 week storage, tubers inoculated with a US-8 isolate had a significantly higher percentage (70%) of late blight symptoms on cut potato tuber surfaces than those inoculated with a US-11 isolates (50%). At temperatures simulating spring, tubers inoculated with US-8 isolate and held at 19°C had a significantly higher number of lenticels/tuber with *P. infestans* sporulation than the tubers held at 10°C or 16°C. Sporulation of *P. infestans* on tuber surfaces was detected on infected tubers buried at 5 cm depth in potting medium at all tested temperatures (winter and spring) for 3–6 day periods. Tubers with late blight infection that survive the winter in western Washington and support sporulation of *P. infestans* via lenticels and eyes may enable the transmission of *P. infestans* from infected tissues to sprouts of volunteer plants. However, as the mild winter conditions favored tuber breakdown in soil, the likelihood of infected tubers producing inoculum appeared to be limited (Gigot et al. 2009).

Verticillium dahliae, a soilborne fungal pathogen, infects spinach crops and is transmitted via seeds of spinach in the USA and Europe. The planting of infected seeds increased the soil inoculum density and might introduce exotic strains that contribute to epidemics of Verticillium wilt disease of lettuce and other crops grown in rotation with spinach. Further, other crop residues that are returned to the soil harbor pathogen inoculum for infection of lettuce or other crops. Detection and quantification of *V. dahliae* inoculum by employing sensitive techniques such as real-time quantitative polymerase chain reaction (qPCR) assay was therefore found to be an effective procedure for reducing seedborne inoculum of *V. dahliae* (Duressa et al. 2012).

Verticillium dahliae is the primary causal agent of Verticillium wilt of potato transmitted through tubers and soil. This disease is a monocyclic and polyetic disease and the primary inoculum consists of microsclerotia which are produced during plant senescence, and they may persist in soil for long periods of time. The disease thresholds in potato were estimated to range between 5 and 30 CFU cm⁻³ of soil for *V. dahliae* (Powelson and Rowe 1993). Microsclerotia production in potato was most abundant in aerial stems and colonized host plant debris. *V. dahliae* was isolated from the vascular system of 94% of plants grown in infested soils and 8% of plants grown from infected tubers in noninfested soil. Further, plants grown in infested soil contained microsclerotia on 46% of stems, while plants grown from infected tubers in noninfested soils exhibited microsclerotia formation only on 1% of stems, indicating that soilborne inoculum was more important for disease incidence (Dung and Johnson 2012).

Contribution of seed infection by *Pyricularia grisea* to the development of rice blast epidemic was assessed under field conditions. A marked strain of *P. grisea* (sulfate nonutilizing (*sul*) mutant) was used to determine if inoculum from infested rice grain could cause primary infections and sustain rice blast epidemic during the growing season (1996–1997) by inducing leaf, collar, and neck blast symptoms in susceptible cultivar M-201. Leaf blast symptoms were first detected in plots containing infested grain at 35 days after seedling emergence in both years. Leaf blast increased more rapidly in plots with 25 and 50 infested grains/0.1 m² than in plots with less inoculum pressure (0.5 and 2.5 infested grains/0.1 m²). At the end of both seasons, the mutant

strain could be recovered from over 90% of the leaf, collar, and neck blast lesions. Rice blast was not detected in the control plots until 65 days after planting. The results indicated that seed infection could play an important role in the development of rice blast epidemics (Long et al. 2001).

Tilletia indica, the incitant of Karnal bunt or partial bunt disease, infects wheat crops in several countries. The teliospores of *T. indica* are introduced into the soil during harvest time and persist in the soil for long time. Teliospores present on the soil surface germinate producing primary and secondary sporidia (basidiospores) when favorable conditions exist, and infect plants at flowering stage. *T. indica* teliospores survived for 3 years on the soil surface, but spores buried at 20 cm depth had reduced viability (2 years) (Krishna and Singh 1983). The teliospores survived for a longer period in dry soil than in wet soil. The viability of teliospores decreased with increase in the depth of soil from 5 to 20 cm (Ratan and Auja 1992; Sidharta et al. 1995).

In a later investigation, survival of teliospores of *Tilletia (Neovossia) indica* in soils differing in texture and other characteristics was studied. The teliospores were placed in 20 µm polyester bags which were sealed and placed at 2, 10, and 25 cm depths in polyvinyl chloride tubes containing the representative soils. The rates of teliospore recovery from soil samples were 90.2, 18.7, 16.1, and 13.1% at 1 day and 8, 20, and 30 months after incorporation of teliospores into the soils, respectively, and the recovery was significantly ($P < 0.01$) affected by soil source. The percentage of germination of teliospores was significantly affected by soil source and depth of burial over the 32 month period. The results showed that teliospores of *T. indica* could survive for more than 32 months and remain viable in conditions existing in Montana, USA (Babadoost et al. 2004).

9.1.2 Molecular Ecology and Epidemiology of Fungal Diseases

Models of disease foci and the patterns in which these foci expand in time and space have been developed in epidemiological investigations. In agricultural systems, the spatial patterns of host genotypic resistance manipulated through use of intercrops or mixed genotypes (multilines) within a crop species has been successfully adopted as a disease management strategy (Zhu et al. 2000; Mundt 2002). The genomics approach in epidemiological investigations may be useful to obtain a better understanding of multiple spatial and temporal scales as well as levels of details of genomic status of microbial plant pathogens. It is essential to determine the type of scale of variation required to include in the prediction of epidemics for the desired pathosystem. Microarray analyses have the potential to provide required information in optimal scales of variation in expression data that may be included in prediction models. Within a host plant, the local phenotype might be at the scale of a leaf or cell. Local gene expression may be at the point of infection as exemplified by the presence of a green island of host tissue formed around the initial infection site where necrotic or chlorotic lesions may appear, as in the case of bean anthracnose or rice blast diseases. Regional gene expression within an individual plant might be the expression in tissues adjacent to infection. In addition, competition between two pathogens may influence differentially depending on the time of infection and type of plant tissues infected (Al-Naimi et al. 2005).

Reverse-transcription (RT-) PCR assay is preferable for the assessment of cell viability by detecting mRNA to the DNA-based techniques, which do not differentiate dead and living cells. An RT-PCR method was developed to determine viable populations of *Mycosphaerella graminicola* in wheat presymptomatically and monitor disease

development during epidemic period. By employing a specific primer set E1/STSP2R, single fragment was only amplified from total RNA of *M. graminicola* and infected wheat leaves but not from those of healthy leaves. Further, no amplification was detected with total RNA of five other common fungal pathogens infecting wheat, indicating the specificity of the assay. This diagnostic test was applied successfully to monitor the disease development in inoculated and naturally infected plants, using the same primer set (E1/STSP2R) developed from a sequence of β -tubulin genes. The specificity and sensitivity (5 ng of total RNA) of this test was high enough to detect *M. graminicola* presymptomatically in inoculated plants as well as in field samples at 4 days after inoculation (dai), when no visible symptoms could be observed. After the production of symptoms, the increase in band intensity of the amplified RT-PCR products in the gel was in general agreement with the results of visual disease assessment (Guo et al. 2005).

Factors governing long-term disease dynamics could not be clearly understood because of a lack of long-term data. Generally surveys assess short-term responses to disease problems of immediate concern. PCR assay was applied to investigate long-term dynamics of *Phaeosphaeria nodorum* and *Mycosphaerella graminicola*, causing Septoria blotch diseases of wheat crops. An archive of data from a long-term Broadbalk winter experiment, run continuously at Rothamsted since autumn 1843, was utilized. Quantitative real-time PCR assays were applied to quantify the fungal pathogens and wheat DNAs present in a set of samples covering a 160 year period of wheat production. The relative abundance of DNA of these two fungal pathogens in a sample reflected the relative importance of the two wheat diseases they caused as determined in disease surveys undertaken in the UK. Unexpectedly, positive correlations between the abundance of *P. nodorum* DNA and SO₂ emissions, and negative correlations between the abundance of *M. graminicola* DNA and SO₂ emission, were observed, indicating a possible link between pathogen infection and extent of atmospheric pollution by SO₂ (Bearechell et al. 2005).

The mode of dissemination of fungal pathogens, a major epidemiological factor, may be through air, rain, water, soil and, in some cases, through insects. Free water or high relative humidity is required by the oomycetes for the production of sporangia. Splash droplets generated by raindrop compaction on plants have shown to be the dispersal agent of *Phytophthora infestans*, causal agent of late blight disease of potato and tomato. The traditional procedure involving collection of droplets carrying spores on glass is cumbersome and time-consuming. Further, adequate skill is required for the specific and precise identification of the pathogen structures. A new approach was therefore applied for the analysis of splash-dispersed *P. infestans*, involving the use of an engineered fluorescent strain transformed with the gene (*gfp*), encoding the green fluorescent protein (GFP). The use of fluorescent sporangia facilitated dependable detection and counting of exclusively viable sporangia of epidemiological significance by image processing. This investigation demonstrated the usefulness of GFP marker in plant disease epidemiology to provide clear evidence and a safe conclusion (Saint-Jean et al. 2005).

Potato late blight epidemics due to *Phytophthora infestans* devastated potato crops because of cultivation of single cultivar across large areas. Such uniformity contrasts with natural ecosystems in which host genotypes are usually both locally diverse and distributed in small areas. Natural ecosystems have been found to be less prone to the rapid development of severe epidemics. Intimate mixing of cultivars is a proven approach for introducing diversity to reduce incidence and intensity of crop diseases

(Akem et al. 2000; Zhu et al. 2000). Crop variety mixtures may reduce disease in three basic ways: (i) induction of resistance by avirulent isolate (spores), preventing or delaying infection by adjacent virulent isolate; (ii) resistant cultivars acting as barriers to pathogen spread; and (iii) dilution effect of resistant cultivar preventing continuous availability of susceptible plants. Potato varieties with contrasting levels of resistance to late blight pathogen were planted in pure or mixed stands in four experiments over 3 years. Late blight severity and progress in mixtures were compared with that in pure stands. Disease on susceptible (S) or moderately resistant (MR) varieties typical of those in commercial use was similar in mixtures and pure stand. On the other hand, mixtures

Figure 9.3 Differential disease progress curves of late blight disease in pure stands of potato (a) cultivar Sante and (b) cultivar Cara and mixtures with Sante or Cara at three planting densities. Source: Phillips et al. (2005). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

of an immune or near-immune companion with cultivars Cara (MR) or Sante (S) substantially reduced disease on the latter. The size of the plot had a distinct effect on late blight disease. Larger plots (9×7.5 m) had a greater area under the disease progress curve (AUDPC), but the average rate of disease progress was greater in smaller plots (4.5×4.5 m). This may be because most disease progress took place later, under more favorable conditions in smaller plots. Planting density did not have any effect on disease and did not interact with mixture effects. Overall, planting mixtures of potato cultivars did not offer any improvement on the average disease resistance of the components under the set of conditions of experimentation (Fig. 9.3). It was suggested that potato variety mixture should be designed to improve yield of more resistant varieties by reducing the negative effects of inter-cultivar competition and to improve the yield of more susceptible varieties by reducing disease through mixing with a resistant variety (Phillips et al. 2005).

9.2 Epidemiology of Bacterial Diseases

Phytopathogenic bacterial species may require one or more susceptible plant species and environmental conditions suitable for their proliferation to reach optimal inoculum potential in or on seeds and plant organs. Bacterial cells are surrounded by mucilage which protects them against desiccation, loss of viability, and dry weather. The bacterial cells restrict their dispersal to periods of rainfall when conditions favor splash spread and free water required for activation of bacterial cells and infection of the host. Wind-driven rain is responsible for dissemination of the majority of bacterial pathogens. Seed transmission of bacterial pathogens is a major concern for developing effective management systems to limit the introduction and spread of bacterial pathogens in different agroecosystems. Seed transmission accounts more than ever before for the movement of bacterial pathogens across long distances, natural barriers, and even political borders in the present global economy with liberal trade between countries.

9.2.1 Dynamics of Host–Bacterial–Pathogen Interactions

The number of infective propagules (pathogen population) and their pathogenic potential (virulence) constitute inoculum potential of the bacterial species pathogenic to different plant species. Disease potential depends on the level of host susceptibility which in turn is positively/negatively influenced by environment, availability of nutrition and stage of plant growth at which level of susceptibility may vary significantly. Further, host susceptibility is governed by genetic constitution. Development of epidemics is influenced by number of infective bacterial cells (propagules), virulence, host susceptibility/resistance and existence of favorable environmental conditions. Agricultural practices aimed to increase the yield of crops have been found to favor development of bacterial diseases in some crops. Incidence and spread of seed-transmitted bacterial pathogens are influenced by several factors.

9.2.1.1 Pathogen Factors

Bacterial pathogens may gain entry into the plants through different avenues, and have to reach the seed tissues and be able to tolerate the intense desiccation during seed maturation. The rate of seed infection to seed transmission or infection of seedlings

and subsequent establishment under field conditions are determined by the genetic constitution of the bacterial pathogen. Bacterial species with the ability to be transmitted through seeds at a higher rate may have greater number of foci of infection from which the disease can spread at a faster rate when favorable environmental conditions are available. In the case of some bacterial pathogens, even with a low percentage of seed infection, the disease may spread at a faster rate and cause heavy losses.

Infection of *Brassica* seeds at a rate of only 2 infected with *Xanthomonas campestris* pv. *campestris* (Xcc) per 10,000 seeds, and less than 1% of tomato seeds infected with *X. campestris* pv. *vesicatoria* (Xcv), resulted in epidemics of cabbage black rot and tomato bacterial spot diseases in the respective crops under favorable environmental conditions (Cox 1966; Schaad et al. 1978). Likewise, high levels of disease incidence occurred when bean seed lots with 0.02% infection with *Pseudomonas syringae* pv. *phaseolicola* and cowpea seeds with 1% infection by *X. campestris* pv. *vignicola* were planted (Walker and Patel 1964; Shekawat and Patel 1977). In another investigation, use of bean seed lot containing 5 infected seeds per 1000 seeds led to an epidemic of halo blight disease, while disease development was arrested when a seed lot with a single infected seed per 20,000 seeds was used, indicating the role of infected seeds in epidemics. Significant reduction in cabbage black rot caused by *X. campestris* pv. *campestris* (Xcc) was observed when the seed infection was reduced from 0.03 to 0.01% (Trigalet and Bidaud 1978; Schaad 1988).

The threshold of inoculum for seed-transmitted pathogen is influenced by several factors including inoculum concentration, inoculum location (external or internal), nature and quantum of seedborne and soilborne microflora, soil temperature, moisture, and pH, in addition to vector populations involved in the spread of some of the diseases. Information on these factors for many seed-transmitted bacterial pathogens is incomplete or these factors have not been determined. The disease transmission thresholds for *Acidovorax avenae* subsp. *citrulli* were different under field and greenhouse conditions for causing bacterial fruit blotch (BFB) disease in watermelon. The direct seeded melons in the field with a plant spacing of 1 plant/4 m² and greenhouse-grown watermelon with a spacing of 1 plant/2.54 cm² required different disease transmission thresholds. Generally, the seed infection threshold of 1/10,000 determined for cabbage black rot disease was also used for other bacterial diseases. The threshold for BFB infections in a transplant greenhouse is one plant/total populations of plants in greenhouse. If the greenhouse holds one million transplants, then the threshold is one infected plant/1,000,000 as the presence of one infected seedling might be sufficient to spread infection to all plants, resulting in rejection of all plants and a loss of 100% (Gitaitis 1993; Gitaitis and Walcott 2007).

The true inoculum density on naturally infested seed may not be correctly determined because of the nature of pathogen distribution. The efficiency of assay could be inflated if based on a naturally infested seed harboring 1×10^7 CFU of bacteria, when in reality most infested seed in the population contain only 1×10^2 CFU of bacteria. Overestimation of the sensitivity of seed health assay may result in incorrect assumptions when calculating the sample size necessary to be analyzed statistically for a predetermined infection threshold. The inoculum density on seeds is likely to affect the results of grow-out tests. For example, the mean number of *Pseudomonas syringae* pv. *pisi* (incitant of pea bacterial blight disease), CFU on the seed, and soil moisture were found to be the major factors influencing the number of diseased seedlings that emerged and the mean number of lesions/seedling (Roberts et al. 1996). The effects of

cultural conditions, pathogen strain aggressiveness, and varietal susceptibility for each disease have to be assessed to make proper assumptions for determining infection threshold on seeds for bacterial pathogens (Gitaitis and Walcott 2007).

Acidovorax citrulli, causative agent of cucurbit bacterial fruit blotch (BFB) disease, is seedborne and the infested seeds form the primary sources of inoculum for disease spread. An inoculum threshold of 1 infested seed per 10,000 seeds has been widely used in seed health testing for BFB pathogen. A later investigation showed that disease transmission to seedling occurred even with 1 infested seed containing 10^4 *A. citrulli* CFU; a zero-tolerance approach for BFB was therefore suggested for adoption for effective management of BFB disease. Seedling transmission experiments indicated that temporal spread of BFB in 128-cell seedling trays increased linearly with *A. citrulli* inoculum load ($r^2 = 0.976$; $P = 0.0037$). In addition, the frequency of spatial spread of BFB from an inoculated seedling in the center of a planting tray to adjacent healthy seedlings over 1, 2, or 3-cell distances was greater for lots with one seed infested with at least 1×10^5 CFU than for lots with one seed infested at lower inoculum loads (1×10^4 and 1×10^3 CFU/seed) (Dutta et al. 2012).

Pseudomonas syringae pv. *coriandricola* (*Psc*) causes bacterial blight disease of coriander, and epidemics of the disease resulted in significant yield reduction and consequent reduction in planting of coriander in Australia (Dennis and Wilson 1997). Coriander seeds could be inoculated by mixing them with a suspension of *Psc* wild-type strain containing methyl cellulose. Seed inoculation with *Psc* resulted in disease symptoms and the plant height was reduced significantly. The inoculum potential for seed infection and induction of disease symptoms on seedlings was $>10^5$ CFU mL⁻¹. At a concentration of 10^7 and 10^8 CFU mL⁻¹, disease developed earlier and the mortality of some plants was also observed. Disease progress was more rapid at higher concentrations, but final disease incidence was not increased at concentrations of pathogen above 10^3 CFU mL⁻¹ (Refshaug et al. 2010).

Three *Erwinia* spp., *E. carotovora* subsp. *carotovora* (*Ecc*), *E. c. atroseptica* (*Eca*), and *E. chrysanthemi*, are associated with potato tuber soft rot and black leg (stem rot). Late infection of potato tubers was found to be widespread. These bacterial species are opportunistic pathogens capable of infecting tubers when resistance was impaired. They are Gram-negative, nonsporing facultative anaerobes, characterized by the production of large quantities of extracellular pectic enzymes. They rely mainly on the production of these enzymes along with a wide range of other plant cell-wall-degrading enzymes (CWDEs) to induce disease (Collmer and Keen 1986). Soft rot *erwinias* tend to out-compete other bacteria in tuber rots, because of their ability to produce larger quantities of a wide range of cell-wall-degrading enzymes. Some pathogenicity characteristics, including motility, adhesion, siderophores, detoxifying systems, and the *hrp* gene complex, common to most bacteria including symbionts and saprophytes, have been shown to be important for infection and disease development (Pérombelon 2002).

Potato tuber-borne pathogens have the advantage of being introduced into the field at the earliest possible time, resulting in early incidence of the disease and its further spread. The effect of tuber-borne *Streptomyces* on potato common scab disease incidence in daughter tubers was investigated under microplot conditions. Visually healthy tubers, surface-sterilized healthy tubers, and tubers with 25% scab coverage were planted in pasteurized soil. Samples of soil and below-ground plant parts were obtained at 30, 57, and 93 days after planting (dap) from various zones around the mother tuber.

The total population of actinomycetes was determined by plating on a semiselective medium and colonies of pathogenic *Streptomyces* were identified using PCR assay targeting the *txtA* gene. The populations of the pathogen were below detectable levels at 30 dap. After proliferation of the pathogen, the population reached measurable levels at 93 dap in below-ground plant parts and in soil adjacent to scabby mother tubers at 10^4 – 10^5 CFU g⁻¹ of soil. Incidence of scab in progeny tubers was 89% at harvest. Progeny tubers produced by visually healthy seed tubers had an incidence of 60% scab and high populations of pathogenic *Streptomyces* were detected in the zone near the mother tuber (10^4 CFU g⁻¹ soil). On the other hand, plots planted with surface-disinfested seed tubers had a very low pathogen population in the tuber zone and yielded 100% marketable tubers. Significant correlation ($r=1.00$) between the population densities of the pathogen in the root zone and daughter tuber disease incidence was observed. After harvest, high populations of *Streptomyces* (10^6 – 10^7 CFU g⁻¹ lesion tissue) on mother tubers were observed. The results clearly showed that measurement of pathogen populations in the field could be a reliable predictor of scab disease incidence in potato (Wang and Lazarovits 2005).

Ralstonia solanacearum (*Rs*), causal agent of bacterial wilt and brown rot of potato plants and tubers, has a worldwide distribution. Based on the host range, strains of *Rs* have been classified into five races (Hayward 1991). *R. solanacearum* is considered as a heterogenous species or a species complex (Fegan and Prior 2005). Apart from races, *R. solanacearum* strains have also been grouped into biovars based on their ability to utilize and/or oxidize several hexose alcohols and disaccharides. The relationship between races and biovars could be seen only with race strains which generally correlated with biovar 2 phenotype (Hayward 1991). Diverse genes of *R. solanacearum*, such as those coding for lytic enzymes and extracellular polysaccharides (EPS), hypersensitive reaction and pathogenicity (*hrp*) genes, structural genes encoding effector proteins injected by type III secretion system (T3SS) from the pathogen into host plant cell, and genes coding for factors implicated in cell adherence are involved in colonization and symptom production (Genin and Boucher 2004). The pathogen attaches to the plant roots, infects the cortex, colonizes the xylem, and spreads to other plant organs and tubers. After the death of the plant, the pathogen returns to the soil, water, or other host plants for survival as a saprophyte or parasite. *R. solanacearum* could survive in the soil for variable periods. It survived up to 1 year in agricultural soils, even after treatment with herbicide to eliminate alternative plants. The pathogen has remarkable ability for survival in the environment in different forms such as viable, but nonculturable (VBNC) forms, starved cells, PC (physiological characteristics)-type, and biofilms (Álvarez et al. 2010).

Pantoea ananatis, incitant of onion central rot disease, was found to be seedborne in addition to its transmission via bulbs. The infected leaves of onion become bleached, followed by colonization of bulb tissues. Although *P. ananatis* cannot produce pectinolytic enzymes, secondary microbes frequently colonized infected bulbs produce these enzymes, resulting in tissue liquefaction and a foul odor. The presence of *P. ananatis* in lakes was indicated by using specific bacteriophages (Eayre et al. 1995). Further, the pathogen is capable of surviving as an epiphyte on several weed species (22) and also on Bermuda grass (*Cynodon dactylon*), cowpea, and soybean (Gitaitis et al. 2002a). *P. ananatis* was isolated from the gut of thrips (Gitaitis et al. 2002b). Sanitation by elimination of sources of inoculum of the pathogen may delay the onset of an epidemic, but may not reduce the rate. The situation becomes more difficult and challenging

when three sources of inoculums, namely seed, thrips vector, and weeds, exist as in the case of onion center rot caused by *P. ananatis* (Gitaitis et al. 2004).

Asiatic citrus canker (Acc) disease caused by *Xanthomonas axonopodis* pv. *citri* (*Xac*) (= *Xanthomonas campestris* pv. *citri* pathotype A) is widely distributed and endemic in many tropical and subtropical citrus-growing nations. International phytosanitary activities did not effectively prevent the reintroduction of infected plants or plant materials (Stall and Civerolo 1991). The inoculum density required for infection may differ depending on the mode of infection by citrus canker pathogen. For effective entry through stomata and infection, a concentration of 10^4 to 10^5 CFU mL⁻¹ was required, whereas a lower concentration of *Xac* (10^2 CFU mL⁻¹) might be sufficient for infection through wounds (Goodman 1982; Zubrzycki and de Zubrzyck 1987).

Strains of *X. axonopodis* pv. *citri* *Xac*-A, *Xac*-A^W, and *Xac*-A*, varying in pathogenic potential (virulence), were recognized (Sun et al. 2004). PCR assay was employed to detect *Xanthomonas axonopodis* pv. *citri* (*Xac*) in aqueous sonicates from 3491 mature asymptomatic fruits harvested from severely diseased Satsuma mandarin trees growing in Saga City, Japan. None of the strains of *Xac* could be recovered from the Satsuma mandarin fruits during 2005–2006, indicating that asymptomatic fruits were unlikely to harbor detectable populations of *Xac*. The survival of *Xac* on Satsuma mandarin fruits discarded in an orchard was determined in two consecutive years. Bacterial populations on the contaminated fruits declined significantly in the first 3 days after the fruits were discarded. No detectable spread of *Xac* from contaminated fruit into rainwater occurred, as shown by the results of PCR assays. The results showed that the bacterial pathogen was not transferred from the contaminated fruit to susceptible host plants, even when the fruits were placed in close proximity to plants at a receptive stage. The risk of transmission of *X. axonopodis* pv. *citri* from Satsuma mandarin fruits to plants appeared to be low (Shiotani et al. 2009).

Potato zebra chip (ZC) disease was shown to be caused by “*Candidatus Liberibacter solanacearum*” which is a putative fastidious, unculturable bacterium (Abad et al. 2009). As the pathogen is yet to be cultured in a cell-free medium, information on biology, physiology, and pathogenicity is lacking. Phylogenetic analyses of the 16S rRNA gene indicated that “*Ca. Liberibacter*” spp. belong to the α -Proteobacteria group. A new strain of “*Ca. L. solanacearum*” infected a nonsolanaceous crop carrot (Munyanza et al. 2010). Genetic diversity assessments showed that haplotypes, based on single nucleotide polymorphism (SNP) typing in the sequences of 16S rRNA, 16S/23S ISR, and 50S rplJ-rplL ribosome gene loci, were differentiated in ZC pathogen. Two haplotypes were identified in North and Central America and in New Zealand (Nelson et al. 2011). “*Ca. L. solanacearum*” has a circular chromosome which encodes a total of 1192 putative proteins coding sequence (Lin and Gudmestad 2013). The ZC pathogen is transmitted by potato psyllid *Bactericera cockerelli* (Munyanza et al. 2007).

Potato psyllid populations differed in their vector efficiency in transmitting “*Ca. L. solanacearum*” associated with ZC disease. The bacteria–vector relationship is one of the important factors influencing incidence and spread of the disease. Adult psyllids were more efficient than nymphs in transmitting “*Ca. L. solanacearum*.” Acquisition success was influenced by feeding site and was highest when psyllids had access to the whole plant. The rates of successful inoculation increased with a higher number of vectors, and plants inoculated with many psyllids had higher pathogen concentrations. The disease progress and tuber yield was independent of psyllid density. A single adult psyllid successfully transmitted the ZC pathogen (Liu and Trumble 2007; Buchman et al. 2011).

9.2.1.2 Host Factors

The ability of the bacterial pathogen to infect a few or several host plant species in addition to the primary host plant (crop species) is an important factor influencing the incidence and spread of the disease(s) caused by the pathogen under investigation. *Ralstonia solanacearum*, causing bacterial wilt and brown rot disease of potato plants and tubers, has a wide host range which appears to expand continuously. Among the host plants, crops such as banana, potato, tomato, tobacco, bean, and groundnut (peanut) and many ornamental plants are infected. Five races based on the host plant species infected have been recognized (Hayward 1991). *R. solanacearum* race 1 infects the largest number of plant species and is the most widespread. Major economic losses caused by bacterial wilt epidemics have been recorded in tomato, potato, banana, groundnut, and ginger crops (Elphinstone 2005).

The presence of alternative host plants functioning as a reservoir of inoculum and infected plant debris/residue on the soil supported survival of *R. solanacearum* in soil or water, favoring overwintering in temperate regions. Alternative host plants may be tolerant and the pathogens may invade xylem in the roots and weakly colonize at stem level (Álvarez et al. 2008). Tolerant plants did not allow further movement of *R. solanacearum* onto the stem as seen in susceptible hosts, and this might be due to the operation of defense mechanisms such as presence of inhibitory compounds, tyloses, and gums that occlude vessels whose success will depend on the rapidity of the plant response (Prior et al. 1994). Among the reservoir plants, several weed species harbored *R. solanacearum* without showing symptoms of infection. Some of them with latent infection, such as *Solanum dulcamara* (bitter sweet nightshade), *S. nigrum* (black nightshade), and *Urtica dioica* (stinging nettle), had the potential to be sources of inoculum for *R. solanacearum* (Hayward 1991; Pradhanang et al. 2000). The host range of potato zebra chip (ZC) disease pathogen "*Candidatus* Liberibacter solanacearum" included *Solanum betaceum* (tamarillo) and *Physalis peruviana* (cape gooseberry) in addition to carrot, a nonsolanaceous plant species (Liefting et al. 2008, 2009). Silver nightshade (*Solanum elaeagnifolium*), wolfberry (*Lycium barbarum*), black nightshade (*S. ptychanthum*), and jalapeno pepper (*Capsicum annuum*) were found to be hosts for ZC pathogen. The presence of "*Ca. L. solanacearum*" in these solanaceous hosts in Texas was confirmed by comparing the partial 16S rRNA gene sequences isolated from these hosts. They showed 99.8% similarity with the bacterium isolated from potato plants infected by ZC disease (Wen et al. 2009). The epidemiological significance of the perennial solanaceous plant species (wolfberry and silver leaf nightshade) has to be studied to establish their contribution to disease incidence and spread.

The incidence and intensity of Asiatic citrus canker (Acc) disease caused by *Xanthomonas axonopodis* pv. *citri* (*Xac*) were favored by wounding or mechanical damage. Feeding injuries by the larvae of the Asian citrus leaf miner (*Phyllocnistis citrella*) increased infection during the flush periods (Gottwald et al. 1997). Susceptibility of *Citrus* spp. to leaf miner is a factor influencing canker disease incidence and development. The susceptibility level may vary with the type of citrus tissues. The susceptibility of leaves and fully developed greenwood was at a similar level following wounding inoculations. Concentrations of inoculum required to cause infection were lower for younger tissues compared with mature tissues (Gottwald and Graham 1992). Citrus tissue age rating at the time of infection was found to be a good predictor of disease rating, resulting from spray inoculation on fruits and leaves and also on fruits following wound

inoculation. Mature green stems were highly susceptible after wounding, similar to leaves, but buds and leaf scars showed the lowest level of susceptibility. These variations in disease development in different tissues of citrus might have different impact on citrus canker disease incidence and severity (Vernière et al. 2003).

Clavibacter michiganensis subsp. *michiganensis* (*Cmm*) has the potential to spread in commercial greenhouses, causing epidemics of tomato bacterial canker disease. When contaminated tools were used, the disease spread only to a limited distance (<4 plants) from infected plants, but touching symptomless tomato plants bearing guttation droplets prior to touching nearby plants spread the pathogen over longer distances within rows (>22 plants). The pathogen was exuded in large numbers in the guttation fluid of infected plants. The presence of *Cmm* in the guttation fluid was not influenced by inoculation procedures, leaf age, or the volume of guttation (fluid) droplets. Population size of *Cmm* and the incidence of epiphytic bacteria on leaflets were significantly higher in plants placed in the guttation-induction chamber than those kept in a growth chamber with high humidity, suggesting that exudation through guttation contributed to the formation of epiphytic populations on leaflets. The results indicated that this simple and environmentally friendly method of avoiding contact with plants during periods when they form guttation droplets could be adopted to significantly decrease the spread of bacterial canker disease in the greenhouse-grown tomato crops (Sharabani et al. 2013).

The ability of *Clavibacter michiganensis* subsp. *sepedonicus* (*Cms*), causal agent of potato ring rot disease, to infect crops grown in rotation with potato in Europe was assessed. The crop plant species were inoculated by stem end inoculation with suspensions of *Cms*, and the presence of the pathogen in the inoculated plants was detected using immunofluorescence cell-staining (IF) method. *Cms* could be detected in maize, wheat, barley, oat, bush bean, broad bean, rape, and pea, but not in onion or five cultivars of sugar beet tested. Larger populations of *Cms* were detected in stems (10^5 – 10^6 cells g^{-1} of tissue) than in roots ($\leq 10^3$ cells g^{-1} of tissues). *Cms* was isolated only from IF-positive stem samples of maize, bush bean, broad bean, rape, and pea, but not from roots. Of the 12 solanaceous weed plant species tested, only *Solanum rostratum* was found to be susceptible to *Cms* which persisted in large numbers (10^8 cells g^{-1} of tissues) in stems and leaves which showed visible symptoms of infection. Different weed species (14) present in potato fields were tested for the presence of *Cms*, using immunofluorescence colony-staining (IFC) and AmpliDet RNA techniques. *Cms* was detected in the roots but not in stems of *Elymus repens* growing through rotten potato tubers, and in some *Viola arvensis* and *Stellaria media* plants in which the pathogen was detected both in stems and roots. AmpliDet RNA procedure was more sensitive than IFC in detecting *C. michiganensis* subsp. *sepedonicus* (van der Wolf et al. 2005).

Pierce's disease (PD) caused by *Xylella fastidiosa* (*Xf*) occurred in severe forms on grapevines in the Texas Gulf Coast region in the USA. As the disease pressure was intense in this region, it was expected that there might be alternative host plant species functioning as potential sources of inoculum of *Xf* for grapevine orchards. Native and ornamental plant species (101) representing 40 families were indexed for the presence of Pierce's disease pathogen by employing ELISA, standard PCR, and quantitative real-time PCR (RT-qPCR) procedures. The pathogen *X. fastidiosa* was detected in 17 plant species by two or more diagnostic methods used in this investigation (McGaha et al. 2007).

9.2.1.3 Environmental Factors

Disease development depends on several different variables involving host, pathogen, and environment in addition to a set of predictors and a set of potential responses, and they are often correlated with each other. The number of variables has to be limited in order to simplify data analysis and interpretation of results. Principal component analysis (PCA) is a statistical procedure that allows the exploration of data structure and can address variable reduction and dimensionality. PCR allows the transformation of a set of original variables into a new set of uncorrelated variables known as principal components, which may provide highly concise information. Canonical correlation analysis (CCA) is a multivariate approach which may identify environmental variables that highly influence disease expression or disease variables that are highly influenced by the environment (Vernière et al. 2003). The influence of agricultural practices and weather variables has to be investigated to estimate the extent of disease incidence and rate of disease spread.

9.2.1.3.1 Effect of Agricultural Practices

Various agricultural practices are followed primarily to enhance the quality and quantity of the produce. However, some of them provide favorable conditions for development of crop diseases. The effects of two cultural practices on the incidence and spread of onion center rot disease caused by *Pantoea ananatis* were assessed. Use of mulch and irrigation has been reported to influence disease incidence by repelling insect vectors and water-splashing by overhead irrigation. Overhead sprinkler irrigation or drip irrigation as main plots and black plastic film, wheat straw mulch, or bare ground as subplots were tested in split-plot design. The type of irrigation did not have any significant influence on the incidence of onion center rot disease. Final disease incidence was greater in plants grown on black plastic and less for those raised on straw mulch (Fig. 9.2). Further, the standard commercial practice of using black plastic hastened the onset of center rot by c. 5 or 16 days in 2000 and 2001, respectively. In contrast, straw mulch delayed the onset of center rot disease by 15 days when compared with black plastic. In both years, the least amount of disease levels was observed in straw mulch. Final disease levels among mulch treatments could be primarily attributed to a shift in the onset of the epidemic and not changes in infection rates. Plants developing infections by *P. ananatis* immediately before harvest showed significantly higher levels of rot during storage despite passing grade at harvest. This latent infection was found to be a major constraint for quality control in onion industry, since it has been not possible to grade onions on external bulb appearance alone. The results indicated the need to train workers to rogue out infected plants before harvest or during harvest to reduce losses due to center rot disease in storage (Gitaitis et al. 2004).

9.2.1.3.2 Weather Variables

The interactions between a set of environmental and epidemic variables associated with expression of Asiatic citrus canker (Acc) disease caused by *Xanthomonas axonopodis* pv. *citri* (*Xac*) were studied. Moisture is not a limiting factor in the tropics and is present in different forms daily. The quantity of rain and relative humidity (RH) therefore showed little effect on disease development and symptom expression. The moisture provided a very conducive environment and fulfilled the most immediate requirement of *Xac* for proliferation. In the treatment where wounding preceded inoculation, pathogen cells were in direct contact with free water due to the prevalence of high RH.

Disease incidence was adequately represented by a single integrated variable – area under disease progress curve (AUDPC) – which took into account many of the characteristics associated with the other epidemic variables that were eliminated. AUDPC as the strongest dependent variable and combinations of the environmental parameters as independent variables were used in multiple regression analyses. The AUDPC offered a quantitative measure of symptom development. The disease as represented by AUDPC could be predicted by a minimum set of environmental variables. The age of tissues at the time of infection was a good predictor for disease resulting from spray inoculation on fruits and leaves, representing natural rain-splash deposition of inoculum. Temperature, denoted $T_{\min}$ or $T_{\max}$, was also a significant factor influencing disease development reflected by AUDPC. *Xanthomonas axonopodis* pv. *citri* (*Xac*) could grow at the temperature range of 6–36°C. At the minimum temperature of 6°C the pathogen growth was minimal, just being able to establish in plant tissues. The growth of *Xac* in planta resulted in lesion formation between 15 and 36°C. The optimum temperature for lesion development was approximately 30°C. The range of $T_{\min}$ and $T_{\max}$ was 15.5–23.5°C and 19.7–31.8°C in Tahiti lime and 12.2–22°C and 19.7–30.7°C in pineapple sweet orange plots, respectively. Relative humidity did not have a significant effect on *Xac* survival on leaves and leaf infection. Estimates of the quantity and availability of inoculum in the orchard and the ratio of young and mature tissues will be useful for determining an effective strategy for Asian citrus canker disease (Vernière et al. 2003).

9.2.2 Molecular Ecology and Epidemiology of Bacterial Diseases

The structure, host specificity, and phylogenetics of microbial populations associated with plant diseases may be understood better by comparing the DNA sequences of the target pathogen(s). The identity of the pathogen up to species level may be efficiently established by determining the sequences of specific genes. The number and types of resistance genes in natural populations of plant hosts may be determined by identifying the sequences associated with resistance (R) genes. Similarly, estimates of the number and types of effector proteins in a single bacterial pathogen, such as the number of gene products transferred into plant cells by the type III secretion system (TTSS) of *Pseudomonas syringae* pv. *tomato* DC3000, could be obtained (Collmer et al. 2002; Alfano and Collmer 2004; Chang et al. 2005).

The effector proteins may function as virulence proteins and also targets of plant disease resistance proteins. Genetic and pathogenic variation of *Xylella fastidiosa* (*Xf*), the xylem-limited bacterial pathogen of almond, grapevine, and several other crops, is an important factor affecting the epidemiology of diseases caused by this pathogen. The almond leaf scorch disease (ALSD) induced by *Xf* has become a serious threat to almond production in the San Joaquin Valley, California. Pure culture-dependent DNA polymorphism-based methods such as random amplified polymorphism DNA (RAPD) and random fragment length polymorphism (RFLP) technique were employed to differentiate the strains of *X. fastidiosa*. A conserved genomic region may be used for recognition of bacterial species. On the other hand, a single nucleotide polymorphism (SNP) within the conserved region had to be used for differentiation of genotypes below the species level. Based on SNPs in the 16S rRNA gene (16S rDNA), *Xf* strains (G- and A- types) were found to coexist simultaneously in the same infected almond orchard. The assumption that one genotype of *X. fastidiosa* caused ALS in one location might be erroneous. The epidemiological investigation has to consider the concept of mixed

genotype infections and modify disease management strategy to limit the incidence and spread of multiple genotypes with differing pathogenic potential, survival ability, and other biological characteristics (Chen et al. 2005).

Xanthomonas axonopodis pv. *allii* (*Xaa*), incitant of bacterial blight of onion (BBO) disease, also infects garlic, leek, and Welsh onion. Seedborne inoculum was considered to contribute to the development of BBO epidemic. The extent of seed contamination with *Xaa* in experimental plots was assessed and the relationship between disease status of leaves and inflorescences and seed infestation was investigated by employing molecular techniques. Seedborne inoculum associated with naturally contaminated seeds was likely to be the primary source of BBO outbreaks in the tropical environment, as indicated by this investigation. The onion plants in experimental plots, established in an area where no other commercial crops were present, were inoculated with a rare bacterial haplotype that has unique AFLP fingerprint. The haplotype had not been observed earlier at the experimental site or in its vicinity, so the occurrence of exogenous inoculum in the experimental plots could be quantified by AFLP analysis. Most of the strains of *Xaa* isolated from onion leaf or floral stem lesions had fingerprints identical to that of the inoculated LMG16528 strain, as indicated by the AFLP analysis. However, a single haplotype different from the LMG16528 strain was also found during the experimental duration of 2 years. This variant CFBP6369-like haplotype was detected in two to five foci per plot, making a total of 12 foci of infection. The application of nested PCR assay revealed the seed contamination with *Xaa* which could be ascertained by using the semiselective medium NCTM1. Both tests showed similar levels of seed contamination with *Xaa*. This indicated that seedborne *Xaa* population were composed, at least in part, of live cells. Seed contamination by *Xaa* was observed at rates of 0.01 and 0.05% only from plots with high disease incidence in 2004. The systematic AFLP analysis showed the presence of a haplotype different from the inoculated haplotype in all experimental plots. The proportion of strains recovered from diseased plants that were genotyped by AFLP represented 18.4% of the total number of diseased plants in 2003 and 3.5% in 2004, due to the high levels of disease incidence in that year. This investigation demonstrated that AFLP analysis was very effective in identifying exogenous inoculum in epidemiological studies at a microgeographic scale, and stressed the need for an accurate assessment of the biological significance of the putative inoculum sources for a sustainable disease management system. The usefulness of a genotyping procedure involving application of AFLP and rep-PCR assays was demonstrated for assessing the epidemiological significance of multiple inoculum sources on a pathosystem involving plant bacterial pathogen for the first time (Humeau et al. 2006).

Isolates (42) of *Xanthomonas axonopodis* subsp. *citri* (*Xac*), causative agent of Asiatic citrus bacterial canker (CBC) disease, were collected from diverse *Citrus* spp. across 17 different citrus orchards in Argentina. Molecular, biochemical, and pathogenicity tests were performed to assess the extent of variations among the isolates. Based on the analysis of genome-specific *X. citri* markers and DNA polymorphisms repetitive elements-based PCR assay, all the 42 isolates were identified as *X. citri*. However, one isolate that shared >90% genetic similarity to the reference strain *X. citri*^{A^T} exhibited host range specificity. This strain, designated *X. citri*^{A^T} and deficient in xanthan production, induced an atypical, noncancerous chlorotic phenotype in *Citrus limon* and *C. paradisi* and weak cankerous lesions in *C. aurantifolia* and *C. clementine* leaves. Suppression of canker development in *C. limon* was concomitant with an oxidative burst.

It was suggested that bacterial factors other than xanthan might be involved in triggering the defense responses (Chiesa et al. 2013).

“*Candidatus Liberibacter asiaticus*” (CLA), the causal agent of citrus huanglongbing (HLB) disease, is a phloem-limited bacterial pathogen and its principal vector is the Asian citrus psyllid *Diaphorina citri*. In order to have a better understanding of virulence mechanisms of CLA, a procedure was developed to detect live bacterial populations of CLA in the citrus and vector tissues using a novel DNA binding dye, propidium monoazide, in conjunction with real-time PCR (PMA-qPCR). Chinese box orange (*Severinia buxifolia*), a common ornamental plant in Florida, could be a host for both CLA and *D. citri*. The changes in live CLA populations in graft- and psyllid-transmitted Valencia orange (*Citrus sinensis*, Valencia) and *S. buxifolia* plants were monitored by PMA-qPCR procedure. The results indicated that the live CLA population was significantly lower in the months of December, January, and February than in the rest of the year in both host plant and psyllid vector. Different patterns in total bacterial population growth of “*Ca. L. asiaticus*” depending on the growth of the host plant were observed (Hu et al. 2014).

9.3 Epidemiology of Virus Diseases

9.3.1 Dynamics of Host–Virus Interactions

Epidemiology is an aspect of plant diseases dealing with different dynamic factors influencing disease incidence, severity, and spread. An epidemic is the culmination of the major interacting components: the pathogen, host plant, and environment. In the case of most virus diseases, the additional component of vector(s) is also involved, making the interactions more complex. Except for a few, most viruses have one or more species of vectors which show varying vector efficiency and specificity with the virus(es) transmitted by them. The type of relationship of the virus with its vector, namely nonpersistent (styletborne), semipersistent (circulative), or persistent (propagative), is determined by the virus. Structures of virus disease epidemics show different and complex patterns which may vary with the virus characteristics, relationship with vector, geographical location, and weather.

The complex interactions between viruses, vectors, host plants, and the environment may be highlighted by appropriate epidemiological models. However, the value of the model's predictions depends on the quality of the data from which the model is constructed and the validity of the assumptions made. Models may be classified according to their main objectives as conceptual (also known as explanatory or analytical), predictive, or descriptive (Kranz and Royle 1978). Predictive models describe and forecast occurrence and severity of epidemics, identify effective control measures, and provide risk assessments (van Maanen and Xu 2003). Statistical modeling techniques for predicting epidemics involve calculations such as simple, linear regression, and multivariate analysis time series. Statistical models are empirical and describe relationships between factors by equations without theoretical foundation, and are correlative if the descriptions are based on theoretical relationships. Predictive simulation models are usually dynamic and may predict changes in an epidemic over time. Simulation models can also be termed deterministic if they make definite predictions for quantities such as virus incidence without any associated probability distribution (Miyai 1993; Bertchinger 1997).

Extensive knowledge of the factors (virus, host, vector, and environment) and the dynamics of these factors have to be incorporated into the predictive model. The development of an epidemic commences with the introduction of the virus into the field or a geographical location via various modes. In addition, the nature and disposition of the primary infection source(s), mode of spread of the virus from infected plant to healthy plant within a crop, survival of the virus in the absence of primary (crop) host plant, type of vector and its relationship with the virus, ability to survive in the soil in a free state or in plant debris/volunteer plants, and other relevant information have to be gathered. Furthermore, some of the viruses are seed- and/or pollen-borne and the propagules may carry the viruses asymptomatically. Viruses infect annuals and perennials, wild relatives and weeds, and crops grown in rotation in the same farm. Virus epidemics have been observed under varying crop-growing conditions ranging from monocultures to mixed cultivation, rainfed to irrigated, intensive high input to extensive low input, under controlled greenhouse conditions, and hydroponics. Sources of virus infection may be internal or external (brought from outside the field concerned) (Jones et al. 2010).

9.3.2 Quantitative Epidemiology

Factors influencing the spread of virus diseases from infected plants are investigated. The host plant may contract virus inoculum from germinating infected seeds which introduce the disease into the field. The host plant is static, whereas viruses carried by infected seeds and/or viruliferous vectors are dynamic. The spread of the virus may depend on the characteristics of the virus itself. Virus strains that become systemic rapidly are more easily spread by their vectors compared with the strains that spread slowly in the infected plant or that cause necrotic lesions. The spread of viruses has two dimensions – spatial and temporal – considered in quantitative epidemiological investigations.

The spatial distribution of infected plants may indicate whether the disease spread from internal sources or external sources. The appearance of infected plants in groups may indicate spread of the disease from internal sources such as plants growing from infected seeds or infected volunteer plants left in the field after harvest. In contrast, the random distribution of infected plants may suggest the possibility of disease spread from external sources by the vectors carrying the inoculum from nearby plants or plants that are far away. The wind direction and speed also influence spatial distribution of virus diseases, especially when vector movement is significantly altered by wind. The spatial distribution patterns of *Tomato mosaic virus* and its vector *Myzus persicae* were investigated. The pattern of appearance of infected plants varied with time. In the initial stages, the diseased plants were randomly distributed; with increasing time, a clustering of infected plants followed by an even distribution towards the end of crop growth was observed. On the other hand, the presence of aphids on adjacent plants was noticed, indicating that alate aphids were mostly involved in the spread of tomato mosaic disease (Zhang and Wang 2002).

The disease progress with time indicates temporal distribution of the disease(s) under investigation. When the cumulative incidence of the disease is plotted against time, the curves generally tend to be sigmoid. However, within the same overall pattern, differences due to locations, seasons, and disease onset, rate, duration, and total amount of spread may be observed. A rapid increase in diseased plants after the initial appearance

of disease may be observed followed by a decline in new infections, possibly because of unfavorable weather conditions or a reduction in the vector population or development of adult plant resistance to the viruses. Young plants are generally more susceptible to viruses and the level of susceptibility decreases as the plants become older. A differential increase in the populations of vectors, when two or more species of vectors are involved in virus spread, becomes an important factor affecting temporal distribution of diseases. Virus transport by different aphid vector species occurs to different extents, as in the case of *Soybean mosaic virus*-soybean pathosystem. Different aphid species with different flight activities transmit the viruses, increasing the complexity of the epidemiological conditions (Irwin 1999). The activity of aphid species associated with lettuce and transmission of *Lettuce mosaic virus* (LMV) was studied in Spain. Aphid flight during spring and autumn growing seasons was monitored. Populations of *Aphis spiraeicola* and *Myzus persicae* varied over different seasons and also in different areas in the country. Differences in the populations of aphid species may affect the rate of virus disease spread (Kuchne 2004).

The pattern of current season spread of *Potato virus Y* (PVY) was studied in 11 potato fields planted with six different cultivars in New Burnswick, Canada during the 2009–2010 growing season. In all, 100 plants/field were selected and the current season spread of PVY infection was monitored using ELISA and real-time RT-PCR assay. Average PVY incidence increased from 0.6% in 2009 and 2% in 2010 in leaves to 20.3% in 2009 and 21.9% in tubers at the time of harvest. In individual fields, PVY incidence in tubers reached as high as 37% in 2009 and 39% in 2010 at the time of harvest. Real-time RT-PCR assay detected PVY in greater number of leaf samples compared with ELISA test. Real-time RT-PCR also detected PVY in a larger number of samples from growing tubers than in leaf samples collected from the same plant at the same time. PVY incidence determined from the growing tubers showed a significant positive correlation with PVY incidence of tubers after harvest. The results suggested that when the PVY incidence was low the crop might be top-killed immediately to secure seed market; when the incidence of PVY was high, the tubers might be allowed to develop further for table or processing purposes (Fageria et al. 2013).

9.3.3 Molecular Ecology and Epidemiology of Virus Diseases

Over the past decades, molecular ecology including epidemiology has emerged as a fast expanding branch of biological sciences. The need for an interdisciplinary approach to unravel and obtain solutions to intricate problems in biology, ecology, epidemiology, molecular evolution, and genetics was realized. Molecular techniques have been applied to study complex patterns and the processes of biological diversity at different levels of organization from genes to organisms, populations, species, and ecosystems, with a focus on genomes of organisms. Molecular ecological principles have the potential to shed light on unresolved questions raised by earlier studies. Molecular epidemiology examines the processes that may result in a successful state of disease in host plant, facilitating identification of a weak link in the biotic and molecular interactions or process that may be useful to develop effective systems for plant disease management. Various crops are affected by different viruses and other microbial pathogens, each one requiring a specific set of conditions for population buildup to reach levels required for infection and spread in different geographical locations. A basic requirement for epidemiological investigations is the availability of efficient, sensitive, and reliable diagnostic

technique(s) that can provide results rapidly. When a virus or its variants appear at a location, it should be possible to establish its identity and also quantify the population at different stages of disease development as early as possible. Information about the viral genomics may provide a range of tools for choosing the appropriate technique. Nucleic acid-based techniques have been demonstrated to be preferable to gather precise information about the viral genomes required for identification and differentiation of target virus and its strains (Narayanasamy 2008).

9.3.3.1 Molecular Biology of Virus Infection

The DNA microarray technique allows the resolution of specific hybridization events between nucleic acid in a sample and known nucleic acid probes bound to a solid phase. Nucleic acid from the sample is extracted and labeled. The labeled nucleic acid (target) is then hybridized to the array which is scanned to resolve the presence of target nucleic acid. Potato viruses and cucurbit-infecting tobamoviruses were detected either individually or in mixed infections by array technique. The sensitivity levels of array and ELISA techniques were similar (Boonham et al. 2003; Lee et al. 2003). Further, microarrays could detect a range of virus isolates and strains and discriminate them at species level by employing synthetic oligonucleotide-based arrays. The serotypes and subgroups of *Cucumber mosaic virus* (CMV) that differed by only 8% in an amplified PCR product larger than 700bp were discriminated by employing an oligonucleotide-based assay (Deyong et al. 2005).

Investigations of the association of satellite viruses/RNAs laid the foundation for the development of molecular epidemiology. Experiments on epidemiology may commence with models within individuals, predicting infection levels based on the particular gene(s) and then expand on these to predict infection rates in plant populations based on gene expression rates in individuals. The genetic structure of populations of *Cucumber mosaic virus* (CMV) satellite RNA (sat-RNA) and its evolution were analyzed during the course of a CMV epidemic in tomatoes in eastern Spain. RNase protection assay (RPA) was employed to characterize 62 variants of CMV-sat-RNA from three epidemic episodes during 1987–1991. Sixty haplotypes were differentiated by RPA patterns. High genetic variability of CMV-sat-RNA resulted in very heterogeneous populations. The high diversity of the population was maintained through time by the continuous generation of variants by mutation, counterbalanced by negative selection. Because of this, the replacement of certain haplotypes might occur from year to year. The sequential accumulation of mutations in CMV-sat-RNA may result in fast genetic divergence, possibly reaching the upper permitted threshold level (Aranda et al. 1993). In a further study, molecular epidemiology of CMV and its sat-RNA in locations where CMV was endemic in vegetable crops was investigated. The genetic structure of CMV populations (about 300 isolates) representing 17 outbreaks (subpopulations) in different crops, regions, and years was compared. The RPA for genetic analyses of CMV isolates was performed using cRNA probes representing RNA-1, RNA-2, and two ORFs in RNA-3. The results indicated that heterologous genetic combinations were not favored. About 30% of CMV isolates were supporting sat-RNA. Molecular analyses of CMV-sat-RNA isolates revealed high genetic diversity due to the accumulation of point mutations and to recombination. Further, CMV-sat-RNA might have spread epidemiologically on the existing virus population from an original reservoir in eastern Spain (Garcia-Arenal et al. 2000).

The diversity of genetic characteristics may be due to recombination and mutation in viral nucleotide sequences. Natural variations in the strains of *Citrus tristeza virus* (CTV) have been studied. A sudden outbreak of CTV in Israel was attributed to a new form of the virus. Uneven distribution of genomic variants of CTV was observed. Individuals of *Aphis gossypii* could transmit the new variant of CTV occurring in Israel. As citrus plants were continuously exposed to aphids which might carry different variants at different periods of time, changes in CTV population might be possible. It was presumed that continuous genetic recombination might take place, resulting in divergence of nucleotide sequence of CTV with varying time and space (de Orso et al. 2000). The passage of variants through host plants may lead to the selection of variants that find suitable environment in the infected host plant species. Evolutionary analysis of genetic variation in CTV isolates after host passage revealed that genetic variability occurred in two genes (*p18* and *p20*) in two groups of CTV isolates. One group of isolates (T385, T318, T317, and T305) was derived from a Spanish source by successive host passage. On the other hand, the group of isolates (T388 and T390) was obtained using aphid vectors that transmitted these isolates from a Japanese source. Sequences derived from the severe isolates T318, T305, and T388 clustered together and differed from those of mild or moderate CTV isolates, as indicated by phylogenetic analysis, regardless of the geographic origin. Molecular variance based on hierarchical analyses indicated that up to 53% of the total genetic variability in *p18* and up to 87% variability in *p20* might be due to differences in the pathogenic potential (virulence) of the isolates and different selection forces might act differentially on isolates and their genes involved in pathogenicity and other characteristics (Sentandreu et al. 2006).

In another investigation, the structure and genetic diversity of a California CMV population were studied by using single-strand conformation polymorphism (SSCP) and nucleotide sequence analyses of genomic regions of 2b, CP, MP, and 3' nontranslated region of RNA-3. Low genetic diversity and the presence of one to three predominant haplotypes for specific genomic regions were revealed in California CMV population. Phylogenetic analysis suggested that genetic exchange by reassortment contributed to the evolution of the CMV population genetic parameters, whereas the distribution of synonymous and nonsynonymous mutations indicated that different coding regions and even different parts of coding regions were under different evolutionary constraints, including a short region of the *2b* gene (Lin et al. 2004).

9.3.3.2 Molecular Biology of Virus Transmission

The development of virus disease epidemics depends on several factors, of which transmission of the virus from infected plant to healthy plants is a vital factor. The frequency of transmission and population and efficiency of vectors involved in the transmission may influence the development of epidemics. As viruses cannot infect plants independently by themselves, they depend on plant-feeding organisms such as insects, mites, nematodes, or fungi which function as agents of transportation from plant to plant. Three steps in transmission of viruses by vectors have been recognized: acquisition, retention, and inoculation of the virus by the vector. The mechanisms of virus–vector interaction (relationship) may vary widely depending on the nature of the virus. Most of the viruses transmitted through seeds are noncirculative (mechanical or nonpersistent) viruses. In these viruses, two distinct molecular strategies regulate the

virus–vector interaction: (i) the capsid strategy in which the virus coat protein (CP) interacts directly with the vector; and (ii) the helper strategy in which at least one nonstructural viral gene product, the helper component (HC), is required for effective transmission of the virus (Foissart et al. 2002).

The characteristics of viral coat protein (CP) determine the vector transmissibility of viruses belonging to genus *Cucumovirus*, whereas the vector transmissibility of the viruses belonging to genera *Potyvirus* and *Caulimovirus* depends on the characteristics of both CP and the virus-encoded nonstructural accessory factors such as helper component (HC). The CP of *Cucumber mosaic virus* (CMV) has multiple functions such as the encapsidation of viral genomes involved in the systemic movement, host range, and determinant of vector transmission. Two domains in the CP amino acids are involved in aphid transmission of CMV (Palukaitis et al. 1992). Variations in the amino acid sequences of CP may influence the vector specificity, while vector efficiencies for CMV by one aphid species may not have any effect on transmission rates with another aphid species (Perry et al. 1998).

The ease of binding and/or release of virions in the mouthparts or foregut of the vector or instability of virus particles during the transmission of noncirculative viruses was assessed by Lopez-Moya (2002). A bridge hypothesis was proposed to explain the helper strategy adopted by the genera *Potyvirus* and *Caulimovirus*. The nonstructural HC protein molecules may be capable of engaging two types of interactions. The HC protein molecules interact with the virus CP on one side and with a putative receptor present in the mouthparts of the vector on the other side, creating a reversible “molecular bridge” allowing virus retention in the vector. The loss of vector transmissibility may possibly be due to either the mutations in the HC rendering it nonfunctional or defects in the CP abolishing of HC–CP interaction. This phenomenon was designated HC-transcomplementation involving sequential acquisition of HC and virus particles. The HC acquired by the aphid assisted in the transmission of virus particles present in the same cell, in other cells, or even other host plants probed by the vector (Foissart et al. 2002).

Crop Disease Management

Exclusion of Pathogens

Crop disease management is primarily based on three principles, namely: exclusion of pathogens, eradication of sources of inoculum of pathogens, and immunization of host plant for enhancement of resistance to pathogens. Information on pathogen biology, infection processes, and epidemiological factors may provide the basis for development of strategies for effective management of diseases transmitted through seeds and propagules. As soon as the incidence of a disease is observed, the basic step for development of disease management system is the detection and identification of the pathogen(s) involved in the disease by employing rapid, reliable, sensitive, and specific diagnostic techniques. The presence of microbial pathogens – oomycetes, fungi, bacteria, phytoplasmas, viruses, and viroids – in/on seeds and propagules has to be detected and identified precisely. Use of disease-free seed/propagules is the basic requirement for successful crop cultivation to achieve potential yield of cultivars both quantitatively and qualitatively.

10.1 Health Status of Seeds and Propagules

It is well known that seeds infected by microbial pathogens are potential sources of primary inoculum, introducing and spreading the diseases into near and distant locations efficiently. Pathogens can multiply rapidly in the plants growing from infected seeds and secondary spread may lead to the development of epidemics when optimal environmental conditions or natural biological vectors of the pathogens are available. In addition to the reduction in yield from infected seed lots, the quality of produce may be substantially affected. As a result of removal of restrictions in the import of seeds, propagules, and plants following international agreements set by the World Trade Organization, the frequency of pathogen introduction to various geographical locations has dramatically increased. The need to ensure a supply of disease-free seeds and propagules has been emphasized to prevent the introduction of new or more virulent strains of the pathogen through them. Certified seeds pass through tests at different stages prior to sowing, during crop growth, at harvest, and in storage of seeds and propagules.

The management of plant diseases through exclusion consists of three phases: sanitation, quarantine, and certification. Sanitation programs aim at recovering healthy plants from selected local cultivar(s). The recommended procedure for sanitary

programs involves the selection of mother plants/trees of local cultivars, indexing mother plants, recovery of pathogen-free plants by shoot-tip grafting (STG) *in vitro*, indexing micrografted plants, evaluation of genetic characteristics of healthy plants generated, and maintenance of healthy source plants. Quarantine programs are entrusted with the responsibility of preventing/avoiding the introduction of new pathogens through seeds and propagules. The imported plants, seeds, and propagules may be kept under observations or indexed using appropriate diagnostic methods under controlled greenhouse conditions. The certification programs are responsible for producing seeds and propagules or oversee the agencies given this responsibility. The sanitary status and trueness-to-type on the initial material is maintained during the process of commercial propagation at the nurseries. They are given the authority to control the quality of nursery plants. These programs have to enforce legal regulations for different steps of nursery operations and periodic indexing and inspection. A certification program should be established in all countries for the production of high-quality and healthy nursery plants (Navarro 1993).

10.1.1 Certification of Seeds and Propagules

The freedom of seeds and propagules from diseases, insects, and weeds has to be ensured to obtain high-quality grains and other food materials. Certain quality standards such as genetic purity, percentage of seed germination, and seedling vigor are also applied. The International Seed Testing Association (ISTA) and Official Seed Certifying Agencies (AOSCA) have suggested minimum seed certification standards. Certification procedures aim to maintain genetic purity and quality of seed production in the field and during harvest, processing, storage, and inspection of the commercial seed lots in the market. Microbial pathogens significantly reduce the quantity and quality of the seeds and propagules. Standards (tolerance limits) have therefore been fixed for adoption by seed producing agencies. The standards are based on aggressiveness and potential of the pathogen to cause epidemics, resulting in the adverse impact of the pathogen(s) on the quality and quantity of the produce.

10.1.1.1 Application of Diagnostic Techniques

Various diagnostic techniques have been applied for the detection and identification of oomycetes, fungi, bacteria, phytoplasmas, viruses, and viroids in seeds and propagules. Traditional methods, namely direct seed examination, plating, or grow-out assays, have been found to be time-consuming, require a large space, and often the results are inconsistent. Immunoassays have been shown to be more efficient and sensitive than conventional methods. However, they have some limitations such as nonavailability of antisera, and lesser sensitivity for detection of many viruses which are present in low concentrations and unevenly distributed in infected plants (which in some cases may remain asymptomatic). Nucleic acid-based techniques have higher levels of sensitivity, specificity, and reliability and can provide the results rapidly and reproducibly. However, the major drawback of the immunoassays and nucleic acid-based techniques is their inability to differentiate live and dead propagules of fungal, bacterial, and phytoplasmal pathogens. The need to obtain results rapidly and cost-effectively may determine the selection of tests(s) for detection of pathogens and subsequent selection of healthy seed and propagules (Chapters 2, 5 and 7).

Plants are exposed to numerous plant pathogens, but they are susceptible to only a few pathogens. Resistance of plants to pathogens is more common than susceptibility. The frequency of transmission of microbial pathogens from mother plants to seeds and from seeds to seedlings may vary widely depending on the cultivar–pathogen combinations. Cultivars differ in their resistance to seed transmission and the infected seeds may or may not show symptoms of infection. Diagnostic techniques should be sensitive enough to detect the pathogen in seed lots, especially in the case of viruses and viroids. Soybean plants/seeds may be infected by different pathogens causing anthracnose (*Colletotrichum lindemuthianum*), soybean bacterial blight (*Pseudomonas syringae* pv. *glycinea*), Phomopsis seed decay (*Phomopsis longicolla*), and soybean mosaic disease (*Soybean mosaic virus*). These pathogens did not induce any visible symptoms on seeds and in the plants until they became older. Field inspections may be useful in eliminating the infected plants and rejecting the seed lots from fields with high levels of seed infection (Sinclair and Backman 1989). The importance of many diseases that were previously responsible for heavy losses has been addressed by adopting efficient certification programs which restricted the incidence and spread of those diseases effectively. Certification standards have been prescribed based on several factors such as the relative role of seedborne infection in disease development, perpetuation of seedborne inoculum by other means, factors affecting seed transmission, economic loss due to the target pathogen(s), planting area of the crop, influence of seed treatment on seedborne infection, and treatments of seed during processing procedures (Agarwal and Sinclair 1996). Certification standards are essential to determine seed and plant health status for different diseases infecting different crops. Different certification standards are enforced by different countries to restrict/prevent the introduction of pathogens through seeds, plants, and planting materials, based on the perceived importance/potential risks of allowing the plant materials. The standards may be altered as and when necessary to make the certification programs more efficient and comprehensive. The certification standards for the pathogens carried in or on the seeds have been suggested for adoption in the UK (Rennie 1993).

Certification programs are usually applied to maintain genetic purity primarily for breeders' seeds through successive multiplication. Detection methods have been employed to assess the extent of seed infection by plant pathogens and to reject the seed lots with levels of infection above the prescribed standards. Seed testing for seedborne pathogens in seed certification programs was emphasized because of the substantial quantitative and qualitative losses caused by the plant pathogen concerned when uncertified seeds with greater levels of infection were used. Effective control of wheat and barley loose smut disease could be achieved through seed certification programs based on the results of diagnostic assays in India, UK, and Sweden (Agarwal 1983; Rennie 1993). Different levels of disease incidence under field conditions are fixed for certification of seeds. Other criteria included are seed production isolation, field inspection at required intervals, laboratory evaluation by the embryo count method, and seed treatment with recommended fungicide. For loose smut, the standard for field approval for wheat and barley was 1 smutted ear per 10,000 ears. In the case of susceptible cultivars of wheat and barley, the permissible level was not more than 1 smutted ear in 2000 in commercial crops and 1 in 5000 in crops raised for multiplication. Field assessment of loose smut disease incidence is unreliable, unless the crop is inspected at the appropriate time (heading stage) and adequate ears are taken for counting diseased and healthy ears. Later, the embryo count test permitting 0.2% infection

was preferred to field assessment of loose smut infection (Doling 1966; Neergaard 1977). In India, seed lots with seed infection up to 0.5% (assessed by seed embryo test) were certified without fungicide treatment; whole seed lot with infection levels of 0.51–2.0% had to be treated with fungicide for certification. Adoption of this standard resulted in significant reduction in loose smut incidence in wheat (Agarwal 1983). In Australia, seed lots of *Lupinus angustifolius* with >0.5% infection by *Cucumber mosaic virus* were not permitted for sowing (Jones and Proudlove 1991).

Benefits of strict enforcement of certification standards have also been evident in the reduced disease incidence in other crops. In bean (*Phaseolus vulgaris*), bacterial blight disease caused by *Pseudomonas syringae* pv. *phaseolicola* infection up to 0.005% was permitted under field conditions. Under laboratory conditions however, zero tolerance in seeds using the seedling infection test with leachates from 2.27 kg of seeds was applied for this bacterial disease (Copeland and Adams 1975). Dramatic reduction in losses in yield could be achieved by using *Lettuce mosaic virus*- (LMV-) free seeds in the Imperial Valley, CA, USA. Seed lots without a single LMV-infected seed were grown in insect-free greenhouses, followed by careful inspection to rogue out all infected seedlings. Seeds from the healthy plants were certified after grow-out infectivity tests. The certified seed lots were distributed to growers only when they did not have a single infected seed in 30,000 seeds. In Europe, the tolerance limit was fixed at 0.1% seed infection (Marrou et al. 1967; Grogan 1980). Seed certification was instrumental in reducing the incidence and severity of *Barley stripe mosaic virus* (BSMV) disease. Immunoassays were employed to detect the presence of BSMV in barley embryos. Foundation, registered, and certified seeds were tested rigorously to produce BSMV-free seeds by employing sodium dodecylsulfate-disk test/latex flocculation test. The certification program saved the crops from losses worth millions of dollars (Carroll 1983).

Phaseosphaeria nodorum (anamorph *Stagonospora nodorum*), causing glume blotch disease in wheat, barley, and oats, is transmitted through seeds. The extent of seed transmission of *P. nodorum* was 70% or more on the coleoptiles from germinated winter wheat seeds which might be exposed above the soil. Transmission of the pathogen from infected seed was also noted on the first leaves at frequencies of 2–37%. The infected wheat seeds were likely to be the primary sources of inoculum of *P. nodorum* (Shah and Bergstrom 2000). Barley net blotch disease caused by *Drechslera teres* was shown to be seed-transmitted. Transmission of the pathogen from infected barley seeds to plumule was up to 18.8% with mean values of 14.5% under glasshouse conditions. In the absence of other sources of inoculum of *D. teres*, plumule infection after seedling emergence indicated that the infected seeds formed the primary sources of inoculums, resulting in higher levels of plumule infection. The alarm threshold for net blotch disease control was determined to be 60% for incidence of disease on leaves (Carmona et al. 2008).

Seedborne obligate pathogen *Plasmopara halstedii*, causative agent of sunflower downy mildew disease, is difficult to isolate and to study its biological characteristics. The quantitative polymerase chain reaction (PCR) assay was found to be specific and sensitive in detecting the presence of 1 infected seed in a sample of 1000 seeds. The assay could provide consistent results and the procedure was adaptable to routine analysis of seed samples (Ioos et al. 2012). Use of disease-free seeds is the most effective strategy for the management of rice grain rot disease caused by *Burkholderia glumae*. The reliable and sensitive SYBR Green real-time quantitative diagnostic assay was therefore applied for the detection and identification of *B. glumae* in rice seeds.

This test not only detected *B. glumae* efficiently, but also differentiated *B. glumae* from 6 other species of *Burkholderia* and 18 other reference pathogenic bacterial species. The SYBR Green real-time PCR was highly sensitive and it was possible to detect the pathogen even at a concentration of 1 CFU/reaction. The diagnostic technique has the potential for detecting the pathogen present in very low concentrations, facilitating the elimination of infected seed lots to achieve disease-free seed stocks (Kim et al. 2012).

Several diagnostic tests based on biological, biochemical, immunological, and nucleic acid characteristics of the pathogen(s) have been developed for the detection of seed- and propagule-borne pathogens and have different levels of sensitivity and specificity. Further, they are only able to detect a single pathogen in seed or propagules. This may lead to longer periods to obtain results when the plant materials are infected by two or more pathogens. To save time, labor, and cost of testing, it is preferable to choose technique(s) that have the potential to detect multiple pathogens present in the seeds or propagules. Barley crops are infected by *Pyrenophora graminea* and *P. teres* which are seedborne. DNA primer sequences were designed based on the unique sequences of these pathogens and were used to detect the target pathogens. PCR was performed in a Lightcycler with real-time measurement of the product using a fluorescent dye. *P. teres* infection was quantitatively assessed and the assay provided the results within 48 h. This rapid seed health testing technique provided the results rapidly, facilitating application of disease management strategies to restrict disease incidence by seed treatment with fungicides (Thomas et al. 2000). The presence of *Pyrenophora teres* and *Rhynchosporium secalis* in barley seeds was detected by employing a PCR-based assay using species-specific primers. The PCR primers RS1-RS2 and RS8-RS9 were able to detect *R. secalis* in barley seeds and leaves, whereas the primers PTT-F/PTT-R and PTM-F/PTM-R could detect *P. teres* in barley seeds effectively (Gubis et al. 2004). *Fusarium circinatum*, incitant of pitch canker disease affecting many *Pinus* spp., was detected using a real-time PCR assay. The real-time PCR assay was found to be highly specific and more sensitive than conventional PCR format. The real-time PCR assay could detect *F. circinatum* in samples containing 1 infected seed among 1000 seeds, preventing long-distance movement of the pathogen (Ioos et al. 2009).

A multiplex PCR assay was developed using probe color in real-time PCR analysis to detect *Tilletia indica*, the quarantinable Karnal bunt pathogen which has significant impact on the international wheat trade. A single-tube five-plex fluorescent assay was employed to detect and identify five different *Tilletia* spp. This fluorescent assay could detect even one spore of *T. indica* and therefore bypass the germination step which is mandatory for testing seeds/grains for the presence of seedborne fungal pathogens. This protocol was found to be effective and economically sustainable because of the high specificity and sensitivity of the assay, requiring less labor and reagents (Tan et al. 2009). Magnetic capture hybridization (MCH) in combination with multiplex real-time PCR technique was developed for simultaneous detection of *Acidovorax avenae* subsp. *citrulli* (*Aac*), causative agent of bacterial fruit blotch (BFB) disease, and *Didymella bryoniae*, incitant of gummy blight disease in cucurbit seeds. The comparative frequencies of detection of *Aac* for direct real-time PCR assay and MCH real-time PCR formats were 25% (1 of 4 samples) and 100% (4 of 4 samples) at the same pathogen DNA concentration, respectively. However, a combination of MCH and real-time PCR procedures did not improve the sensitivity of detection of *D. bryoniae* relative to the direct real-time PCR format using seed washes from infested cucurbit seed. The MCH real-time PCR procedure could be effectively applied for the detection of pathogens present

in watermelon and melon seed samples ($n = 5000$ seeds/sample) in which 0.02% of the seeds were infested with *Aac* and also at the same level (0.02%) by *D. bryoniae* (Hay et al. 2009). Likewise, *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*) and *Pepino mosaic virus* (PepMV) could be detected in tomato seeds. The combination of MCH and multiplex real-time PCR had a detection threshold of 10^5 cells for *Cmm* and 10^4 fold dilution of total RNA extracted from infected tomato tissues. The results showed that MCH facilitated the simultaneous detection of *Cmm* and PepMV by multiplex real-time PCR format (Johnson and Walcott 2012).

The extent of seed transmission and endophytic activity of the seedborne bacterial pathogen *Pseudomonas fuscovaginae*, causal agent of rice seed rot disease, were investigated using a rifampicin-marked strain of *P. fuscovaginae* (*Pf^R*). Rice seeds with five different levels of contamination, namely 0, ≤ 25 , ≤ 50 , ≤ 75 , and ≤ 100 , with rifampicin marked strain were tested. The relative seedborne bacterial concentration increased significantly with increasing levels of seed lot infection/discoloration. The *Pf^R* strain was recovered from all growth stages of rice plants, the maximum recovery being at seedling stage. Drastic reduction in bacterial cell recovery was observed at 75 days after sowing (das) and at milk stage (100 das). Crushed discolored seeds contained a greater bacterial population than the noncrushed discolored seeds. The use of clean or healthy-looking seed is not an assurance of disease-free seed, since low levels of bacterial pathogen cells could be detected in visibly clean seeds. Application of sodium hypochlorite (5%) for seed disinfection reduced the bacterial population present externally. However, endophytic bacterial contamination persisted since the pathogen *Pf^R* strain could be recovered from rice plants up to milk stage. The disease-free nature of the rice seeds therefore has to be ensured by treatment with effective chemicals (Adorada et al. 2015).

The effectiveness of seed health testing depends on a test that can provide timely sensitive and broad-spectrum detection of all genetic variants of a pathogen or, in some cases, of several different pathogens infecting the same crop. Soybean seeds are predisposed to infection by fungal pathogen *Phomopsis* spp. because of infection of soybean plants by *Soybean mosaic virus* (SbMV). Both SbMV and *Phomopsis* spp. were found to be associated with soybean seed coat mottling. Seed infection with *Phomopsis* spp. was determined by isolation and SbMV accumulation was assessed by enzyme-linked immunosorbent assay (ELISA) and nucleic acid hybridization techniques. *Phomopsis* spp. could be isolated from four categories of seed mottling, with infection percentage increasing with increasing levels of mottling. On the other hand, SbMV was detected in both mottled and nonmottled seed coats, with generally higher levels of SbMV in mottled seed coats. However, the relationship of SbMV concentrations with seed coat mottling was inconsistent across cultivars and years (Koning and Tekrony 2003). A sensitive, reverse-transcription (RT-) PCR-based qRT-PCR was developed for broad-spectrum detection of both serotypes of *Squash mosaic virus* (SqMV) that could be incorporated into the simultaneous detection of three pathogen types in a single PCR reaction. SqMV RNA was converted into cDNA using reverse transcriptase prior to multiplexing to stabilize the viral template, which was then mixed with two other DNA templates of *Acidovorax avenae* subsp. *citrulli* (*Aac*), causative agent of bacterial fruit blotch (BFB), and *Didymella bryoniae* (DB), incitant of gummy stem blight disease. A generic plant nucleic acid extraction procedure was also developed to facilitate seed health testing for cucurbit seeds. Nucleic acids extracted from seed samples gave strong signals for each of the three target pathogens (a fungus, a bacterium, and a virus)

infecting cucurbits in a multiplex qPCR format. The ability to use a common general nucleic acid extraction procedure with subsequent PCR to detect three kinds of plant pathogens formed the foundation for a universal system for cucurbit seed health testing (Ling et al. 2011).

Stone fruits are infected by several economically important viruses belonging to different genera: *Apple mosaic virus* (ApMV), *Prunus necrotic ringspot virus* (PNRSV), *Prune dwarf virus* (PDV), and *American plum line pattern virus* (APLPV) belonging to *Ilarvirus*, *Plum pox virus* (PPV) belonging to *Potyvirus*, and *Apple chlorotic leaf spot virus* (ACLSV) belonging to *Trichovirus*. Two viruses *Apricot latent virus* (ApLV) belonging to *Feavirus* and *Plum bark necrosis stem pitting-associated virus* (PBNPaV), belonging to *Ampelovirus*, have also been reported to infect stone fruits. A sensitive and reliable one-step RT-PCR assay with an internal control was employed to detect and differentiate the abovementioned viruses affecting stone fruit trees. The primer cocktail was used to analyze samples from 38 stone fruits originating from nine countries and six fruit tree species. A large number of virus combinations and mixed infections by up to three different viruses in five samples were detected by the multiplex RT-PCR assay. The use of five different primer pairs in a cocktail resulted in a decrease in sensitivity of detection. However, comparative analyses showed that the multiplex RT-PCR containing eight virus primer pairs was even more sensitive than ELISA or molecular hybridization assays. The multiplex RT-PCR procedure could allow routine and reliable detection of eight different viruses infecting stone fruit trees (Sánchez-Navarro et al. 2005). *Apple stem pitting virus* (ASPV), *Apple chlorotic leaf spot virus* (ACLSV), and *Apple stem grooving virus* (ASGV) infect apple and pear, but these viruses remain asymptomatic in commercial pear and apple cultivars. Two multiplex RT-PCR techniques with coamplification of an internal control from a plant mRNA sequence (mitochondrial *nad5* gene) were employed to detect these viruses simultaneously. The internal control was effectively coamplified with multiple I and II RT-PCR assays to detect ACLSV, ASGV, and ASPV in Korla pear in Xinjiang, China. Detection assays, using bark chips of 1- or 2 year old pear branches, could be performed both in the growing season and in dormant trees. Purified RNA of viruses as amplification template was not required. Three virus-specific primer pairs were designed to allow two multiplex RT-PCR amplifications accompanied by one pair of primers of the mitochondrial *nad5* gene. Four amplification products specific to three viruses and the internal RNA control were employed for specific detection of the corresponding viruses. Use of internal control reduced the risk of false negatives attributable to inhibition of conventional RT-PCR due to presence of inhibitors coextracted with target viral nucleic acids (Ma et al. 2008).

Prune dwarf virus (PDV) and *Prunus necrotic ringspot virus* (PNRSV) naturally infect the majority of *Prunus* spp. and have a worldwide distribution. They have multiple modes of transmission through mechanical inoculation, grafting, pollen, and seeds. Use of healthy plant material for propagation is the primary requirement to prevent virus spread in fruit crops. Certification programs have been established in many countries with the aim of identifying healthy sources for propagation. Several molecular techniques have been developed to detect the viruses precisely even at low virus titers in plant tissues and also in asymptomatic plants. Certification programs specify standards of fewer than 5% of virus-infected plants. ELISA tests were applied for the detection of PNRSV and PDV in *Prunus* seed lots planted in Montana and Washington (Mink and Aichele 1984). The operational capacity of the duplex RT-PCR

procedure for the detection of PDV and PNRS simultaneously was established by nine European laboratories. Samples (576) from *Prunus* trees with known sanitary status (corresponding to 32 samples in two repetitions for each laboratory) were analyzed. The assay had a level of sensitivity of 98.3% for PDV and 90.4% for PNRSV, whereas the specificity levels were 87.4% for PDV and 94.3% for PNRSV. This protocol showed high potential for large-scale application to determine health status of mother plants (Massart et al. 2008).

The sanitary status of the clonal Genebank collection of stone fruit was assessed by employing ELISA, tissue-printing (TP) hybridization, and GF305 woody indexing for detecting the presence of *Plum pox virus* (PPV), *Prunus necrotic ringspot virus* (PNRSV), *Prune dwarf virus* (PDV), *Peach latent mosaic viroid* (PLMVd), and *Hop stunt viroid* (HSVd). A total of 645 trees (197 peach and nectarine, 183 sweet and sour cherries, 106 plum, 106 apricot, and 53 other cherries) were indexed. PNRSV and PDV were frequently detected in single and mixed infections by ELISA tests and PPV was not detected in any of the fruit trees tested. Tissue-printing (TP) assay detected PLMVd and HSVd after testing a total of 336 trees. The presence of PLMVd in peaches (28/116 peach and nectarine) and HSVd in apricots (2/44) was detected by TP assay. Infection of 114 (38.4%) of 297 accessions tested by at least one virus and/or viroid could be detected by the assays (Michelutti et al. 2005).

Assessment of the health status of plum planting materials was carried out to establish plum mother plantations according to the recommendations of European Plant Protection Organization (EPPO) and Certification Standards of the Republic of Serbia. Propagules from pomologically selected trees in commercial and experimental orchards were grafted onto virus-free Myrobalan rootstock. Candidate clones were maintained in a screenhouse to protect the plants from external inoculum. Fifteen plum cultivars and a prospective hybrid (14/21) were included in this investigation. The selected clones were tested on woody indicators *Prunus tomentosa*, *P. persica*, and *P. serrulata* cultivar Shirofugen. The ELISA test was applied for the detection of possible presence of *Plum pox virus*, *Prune dwarf virus*, *Prunus necrotic ringspot virus*, *Apple chlorotic leaf spot virus*, *Apple mosaic virus*, and *Myrobalan latent ringspot virus*. Immunocapture (IC-) RT-PCR procedure was also applied for greater detection sensitivity. Nested PCR format was used for the detection of the phytoplasma "*Candidatus* Phytoplasma prunorum." The ELISA tests indicated the presence of *Apple chlorotic leaf spot virus* in four plants of cultivar Jelica. Latent infection with *Plum pox virus* was detected by IC-RT-PCR assay in four candidate clones. All other selected clones were free of all other viruses and the phytoplasma infection was not found in any planting materials tested. The investigation showed that ELISA test was suitable for routine diagnosis of viruses for which antiserum was available. Detection of ACLSV in cultivar Jelica by ELISA reduced the time required by biological testing. IC-RT-PCR format effectively detected PPV in plants with low virus titer and in young plants with uneven distribution of PPV. Based on the results, four plants were eliminated to maintain a higher level of health status in the collection (Jevremović and Paunović 2010).

Grapevine is the host for several viruses and viroids. A multiplex RT-PCR assay was developed for the simultaneous detection of *Grapevine leaf roll-associated virus 1, 2, and 4* (GLRaV-1, -2 and -4), *Grapevine viruses A and B* (GVA, GVB), *Grapevine fleck virus* (GFV) and *Grapevine fan leaf virus* (GFLV). These viruses were efficiently detected up to a 10^{-3} fold or higher dilution of the original plant extract. Two viroids infecting grapevines, *Hop stunt viroid* (HSVd) and *Grapevine yellow speckle viroid* (GYSVd), were also amplified to

the same level as the viruses by employing viroid-specific primers. This protocol showed potential for providing reliable diagnosis of grapevine virus and viroid diseases (Nakaume and Nakano 2006). In another investigation, a multiplex RT-PCR (mRT-PCR) procedure involving the use of primers specific to target viruses and a plant RNA as internal control was employed. The viruses *Arabid mosaic virus* (ArMV), *Grapevine leaf roll-associated virus 1, 2, 3* (GLRaV-1, 2 and 3), *Grapevine fleck virus* (GFV), and *Grapevine fan leaf virus* (GFLV) were detected (Gambino and Gribaudo 2006).

Degenerate and species-specific primers were designed for the simultaneous detection of GFLV, ArMV, *Tobacco ringspot virus* (TRSV), *Grapevine chrome mosaic virus* (GCMV), *Grapevine deformation virus* (GDefV), *Grapevine Anatolian ringspot virus* (GARSV), *Artichoke Italian latent virus* (AILV), *Grapevine Bulgarian latent virus* (GBLV), and *Grapevine Tunisian ringspot virus* (GTRSV). Four different virus species could be detected in single grapevine samples containing mixtures of viruses of the same subgroup, using sense and antisense primers. PCR products amplified for TRSV, GFLV, ArMV, and GDefV (subgroup A) were 190, 259, 301, and 371 bp, respectively, whereas GCMV, AILV, GARSV, and GTRSV produced amplicons of 190, 278, 425, and 485 bp. This one-step RT-PCR procedure could rapidly resolve the components of mixed infections in grapevine (Digiario et al. 2007). In another investigation, simultaneous detection of GLRaV-4, -5, and -6 and isolates of GLRaV-De and -Pr was reported by Maliogka et al. (2008). These investigations indicated the need to apply multiplex assays to assess the health status of mother plants rapidly in the case of crops which are frequently infected by two or more pathogens simultaneously.

The occurrence of many viruses on strawberry crops leads to complex symptoms and heavy losses in many countries. Multiplex RT-PCR assays were therefore employed for simultaneous detection of isolates (18) of *Strawberry crinkle virus* (SCV), *Strawberry mild yellow edge virus* (SMYEV), *Strawberry mottle virus* (SMoV), and *Strawberry vein banding virus* (SVBV), which infected strawberry plants in different combinations. The upper limit of detection of the target viruses in plant tissue extracts was 1/200 (Thompson et al. 2003). In a later investigation, a multiple RT-PCR format was applied for the detection of *Raspberry ringspot virus* (RpRSV), *Strawberry latent ringspot virus* (SLRSV), and *Tomato bushy stunt virus* (ToBSV), employing virus-specific primers along with a plant internal amplification control (PIAC). Interactions between primers and coamplification of inhibitors of PCR amplification were avoided. This protocol had similar levels of specificity and sensitivity as conventional PCR applied for detection of individual viruses (Wei et al. 2008).

Total nucleic acid extracted from strawberry leaves was compared with total RNA as the template for detection of two RNA and one DNA viruses by both single and multiplex RT-PCR assays. Primer pairs D1/D3, 12/SM2, and YT1 and Y2 were employed for the amplification of expected fragments from *Strawberry mottle virus* (SMoV), *Strawberry vein banding virus* (SVBV), and *Strawberry mild yellow edge virus* (SMYEV), by multiplex RT-PCR using total nucleic acid as the template. When total RNA and total nucleic acid extracts were used as templates, detection efficiency for SMYEV and SMoV was in equivalence and the intensity of band amplified by single or duplex RT-PCR format was also similar. On the other hand, with total nucleic acid as template, detection results for SMYEV and SMoV by multiplex RT-PCR showed good correlation with those of single and duplex RT-PCR assays. The protocol developed in this investigation could be effectively used for detecting both RNA and DNA viruses simultaneously (Chang et al. 2007).

Multiple infections by viruses have been frequently observed in *Citrus* spp. In order to detect the presence of two or more viruses simultaneously, a multiplex RT-PCR (mRT-PCR) assay was employed for the detection of seven viruses, namely *Citrus leaf rugose virus* (CLRV), *Citrus psorosis virus* (CPsV), *Citrus tatter leaf virus* (CTLV), *Citrus tristeza virus* (CTV), *Citrus yellow mosaic virus* (CYMV), and *Indian citrus ringspot virus* (ICRSV). Based on the sequences of the respective viruses, degenerate primers were designed. PCR products with different sizes varying from 245 bp to 943 bp specific to each virus were amplified, facilitating the identification of individual virus. The protocol offered the advantages of reduced contamination risk and cost of testing, reduction in time and labor, and rapidity in providing results (Roy et al. 2005). The simultaneous infection of viruses is commonly seen in *Citrus* spp., leading to rapid decline and ultimate death of affected trees in India. *Citrus tristeza virus* (CTV) with an RNA genome and *Citrus mosaic badna virus* (CMBV) with a DNA genome infected sweet orange simultaneously. Primers targeting ORF 8 of CTV genome and ORF 3 of CMBV genome amplified PCR products of expected sizes, 510 and 245 bp respectively, enabling the detection and identification of CTV and CMBV in a single duplex PCR format (Ghosh et al. 2008).

Potato plants are infected by several viruses belonging to the genera *Alfavirus*, *Carlavirus*, *Luteovirus*, *Potexvirus*, *Potyvirus*, *Tobravirus*, *Tospovirus*, and *Tymovirus*. Infected progeny tubers are likely to become sources of virus inoculums, contributing to the spread of diseases induced by these viruses in new geographical locations where they are nonexistent or less important. Potato plants, generated through tissue culture technique, have to be indexed for the presence of viruses before their vegetative propagation. Multiplex assays are preferable to methods that can detect only a single virus in plant tissues, saving time, labor, and cost of testing. A multiplex nonradioactive nucleic acid spot hybridization (NASH) assay was applied for simultaneous detection of *Potato virus S* (PVS, *Carlavirus*), *Potato virus Y* (PVY, *Potyvirus*), and *Potato virus X* (PVX, *Potexvirus*) in potato tissue-cultured plantlets. The sensitivity of NASH procedure was determined by hybridization of PVS-, PVX-, and PVY-specific probes labeled with nonradioactive digoxigenin (DIG) on membranes spotted with a dilution series of extracts of tissue-cultured plantlets. The viruses could also be detected individually with specific probes. The probe which was amplified from plantlets infected with PVY^O could also detect other strains of PVY in plantlets infected with PVY^N, PVY^{NTN}, and PVY^{N:O}. In addition, the multiplex NASH assay was effective in detecting PVS, PVX, and PVY in a single hybridization assay by employing a cocktail of different probes specific to the respective viruses to be detected (Janczur et al. 2006).

The effectiveness of the 18S ribosomal RNA (rRNA) was compared with the commonly employed *nad2* mRNA as internal control for enhancing the sensitivity of detection of five potato viruses using a multiplex RT-PCR assay. The protocol simultaneously amplified cDNAs from *Potato virus A* (PVA), *Potato virus X* (PVX), *Potato virus Y* (PVY), *Potato leafroll virus* (PLRV), *Potato virus S* (PVS), and 18S rRNA as well. This multiplex RT-PCR assay could detect all five viruses in different combinations. The multiplex RT-PCR format had a 100-fold greater sensitivity than DAS-ELISA for detection of PVX, in addition to its ability to detect the viruses in ELISA-negative samples. The internal control 18S rRNA was found to be better than *nad2* mRNA as internal control in terms of detection sensitivity. Multiplex RT-PCR was more convenient and less expensive compared with several individual RT-PCR assays required for detecting individual viruses (Du et al. 2006). A multiplex RT-PCR assay

was developed for the detection of three viruses, namely *Potato yellow vein virus* (PYVV), *Tomato infectious chlorosis virus* (TICV), and *Tobacco rattle virus* (TRV), including the plant internal amplification control (PIAC). The multiplex RT-PCR assay had a detection sensitivity of the same order as the conventional RT-PCR format, revealing that the multiplex RT-PCR protocol was a simple cost-effective, sensitive, and convenient tool for the detection of multiple infection of potato by two or three viruses (Wei et al. 2009).

Garlic crops are infected by viruses belonging to different taxa, collectively designated the virus complex including *Onion yellow dwarf virus* (OYDV) and *Leek yellow stripe virus* (LYSV) (potyviruses), *Shallot latent virus* (SLV), and *Garlic common latent virus* (Gar CLV) (carlaviruses). Recognizing the need for a sensitive and rapid diagnostic technique, a duplex RT-PCR assay was standardized for the simultaneous detection of OYDV and SLV (synonym *Garlic latent virus*) in ten selections of garlic. The protocol employed was sensitive enough for the detection of OYDV and SLV in cloves and leaves of garlic. The titer of OYDV was greater both in leaves and bulbs compared with SLV. This protocol was cost-effective, sensitive, and showed potential for use in certification and quarantine programs (Majumder et al. 2008).

Ornamental plants are infected by different viruses, resulting in substantial reduction of their market values. *Cymbidium mosaic virus* (CyMV) and *Odontoglossum ringspot virus* (ORSV) are economically important viruses adversely affecting orchid industry. They induce less conspicuous foliar symptoms and cannot be detected by visual inspection. A multiplex RT-PCR assay was employed to detect CyMV and ORSV in *Phalaenopsis* orchid plants, using specific primers targeting the sequences of the coat protein (CP) of the respective viruses and one primer pair derived from the plant mitochondrial NADH dehydrogenase gene (*nad5*) as the internal control. The presence of CyMV and ORSV in *Phalaenopsis* orchids from the flower market in Taiwan was detected by multiplex RT-PCR protocol. The expected fragments of 666, 474, and 185 bp specific for CyMV, ORSV, and plant *nad5* mRNA, respectively, were amplified only in the orchid plants infected by CyMV or ORSV or by both viruses. The multiplex RT-PCR assay was shown to reduce the time, labor, and cost of testing compared with single assays, in addition to minimizing the risk of false-negative results required for routine large-scale orchid virus disease diagnosis in certification programs (Lee and Chang 2006).

Leaf yellowing of *Phalaenopsis* orchid was investigated to determine the identity of the virus(es) involved. A multiplex RT-PCR was employed for simultaneous detection of the commonly prevalent viruses, *Odontoglossum ringspot virus* (ORSV) and *Cymbidium mosaic virus* (CyMV), present in the total RNA extracts. Both commercial kits and the simple-direct tube (SDT) technique were tested, using the primers designed in this investigation. ORSV was detected in a greater number of samples (55%) compared with CyMV (34%). Severe symptoms were observed in plants coinfecting by both viruses. The SDT procedure was efficient in extracting RNA suitable for the RT-PCR assay, which was cost-effective in undertaking screening of *Phalaenopsis* plants on a commercial scale in orchid nurseries. Another virus *Orchid fleck virus* (OFV) could also be detected in Australian orchid using virus-specific primers (Yamane et al. 2008). The usefulness of a multiplex RT-PCR format for the simultaneous detection of *Dasheen mosaic virus* (DsMV), *Turnip mosaic virus* (TuMV), and *Konjac mosaic virus* (KoMV) in *Calla lily* (*Zantedeschia* spp.) was demonstrated. This multiplex RT-PCR assay detected virus infection in 72% (36/50) of *Calla lily*, and about two-thirds (23/36) of infected samples showed mixed infections (Hu et al. 2010).

10.2 Plant Quarantines for Preventing Entry of Microbial Pathogens

Regulatory methods aim to prevent the import and spread of microbial pathogens into a country, state, or province. Legislative measures are formulated to regulate the cultivation of crops and distribution of planting materials between countries or states within the country. Regulatory control is enforced by establishing quarantines, inspections of crops in field/greenhouses/warehouses and, in some cases, by voluntary or compulsory eradication of host plants of certain pathogens. The primary aim of establishing plant quarantines is to prevent/restrict the introduction and spread of diseases and pests into new areas, where they have little or no chance of spreading naturally. Quarantines therefore enable importing countries to protect agriculture and the environment from avoidable damage that may be induced by diseases introduced by humans inadvertently. The appearance of epidemics caused by introduced pathogens indicates the important role of plant quarantines in international trade and the need for international standards. After the adoption of the General Agreement on Tariffs and Trade (GATT) there has been a dramatic increase in the movement of plant products, necessitating the enforcement of sanitary and phytosanitary measures at the global level. Legislative measures have become necessary to prevent or delay the establishment of plant pathogens in locations where they are absent or unimportant. The International Plant Protection Convention (IPPC) came into existence on 4 April 1991, following the acceptance of GATT by the majority of nations. An Expert Consultation on the Harmonization of Plant Quarantine Principles was convened by the Food and Agriculture Organization (FAO) to identify the basic principles necessary for formulating standards for plant quarantine procedures in relation to international trade (FAO, 1991).

10.2.1 Principles of Plant Quarantines

The principles of establishing plant quarantines recognize the sovereignty of the importing country which has the right to implement the phytosanitary measures deemed fit by that country. Restrictive measures for a minimum impact on the international movement of plant materials are ensured by different member countries. There is freedom to effect necessary modifications as and when required, and plant quarantine regulations are transparent so that there is harmonization of phytosanitary measures with no discrimination between countries. Plant quarantine activities vary based on the hazard and risk associated in allowing the import of plant materials likely to carry pathogens. Hazard is the danger that a specified pathogen may present to the agriculture of the importing country and the possibility of becoming established at the new location. Risk is the chance that a hazardous organism will enter and become established. The levels of risk of the pathogens may be low, medium, or high depending on their aggressiveness and survival capacity in a wide range of environmental conditions. Safeguards include rules and regulations, phytosanitary certificates, inspection treatments, isolation, passage through a quarantine greenhouse (post-entry), seed health evaluation, and other measures formulated by the importing country. The importing country has the option of either permitting or denying the entry of high-risk material for commercial purposes or to issue a permit for plant material imported for scientific purposes (Kahn 1988, 1991). Plant quarantines have been established by most countries, with regulations ensuring that exporting countries adhere to the measures

prescribed by the importing country to protect their country against possible invasion by more aggressive pathogens or their strains.

10.2.2 Functions of Regional Plant Quarantine Organizations

In compliance with the International Plant Protection Convention (IPPC) in 1951, the following eight regional plant protection organizations were set up to advise and assist the member governments on the technical, administrative, and legislative measures concerned with plant protection activities: (i) Comité Interamericano de Protection Agricola (CIPA); (ii) Caribbean Plant Protection Commission (CPPC); (iii) European and Mediterranean Plant Protection Organization; (iv) Interafrican Phytosanitary Council (IAPSC); (v) Near East Plant Protection Organization (APPO); (vi) North American Plant Protection Organization (NAPPO); (vii) Organismo Internacional Regional de Sanidad Agropecuaria (ORISA); and (viii) Plant Protection Committee for the South East Asia and Pacific Region (SEAPPC). The member countries governed by the respective regional plant protection organizations disseminate information on changes in the quarantine regulations and requirements and examine the possibilities of simplification and unification of phytosanitary regulations and issue of certificates.

A pathogen or insect pest is considered to be of quarantine significance (QS) if its exclusion is perceived as important enough to the agriculture and natural vegetation of the importing country for its government to provide necessary infrastructure and personnel to prevent or delay its entry along manmade pathways (Kahn 1991). Plant pathogens/pests coming under plant quarantine regulations are selected based on the following parameters: (i) the pathogen is capable of causing serious losses in economically important crops grown in the country/region; (ii) the pathogen(s), if introduced, will not be able to spread rapidly by natural means; (iii) the pathogen(s) may survive under conditions existing in the field/glasshouses; and (iv) current trade practices may introduce the pathogen(s). The pathogens selected are grouped into three categories as follows.

- List A: dangerous quarantine organisms. This is further subdivided into two categories:
 - List A1: pathogens absent from all member countries (exotic pathogens); and
 - List A2: pathogens present only in some countries in the region.
- List B: pathogens included by individual countries under regulations; comparatively less stringent measures are enforced by the country concerned.

The necessity for inclusion of additional pathogens or deletion of pathogens from the current list is constantly reviewed and modified, if required. Various countries have enacted Acts that authorize the Plant Protection Organization of the respective country to take necessary steps for the establishment of plant quarantines in seaports and airports, and for intercepting organisms of quarantine importance. A list of quarantine pathogens are prepared and the countries from which the plants and plant products are imported are informed of the regulations and requirements to be satisfied. Each country may have certain specific acceptable entry procedures. For example, in the USA, a procedure known as “preclearance” is insisted upon. This procedure entails removal of the pathogen/pest risk at the point of origin of plants/plant products by technical personnel at the port of entry. Inspection of plants/plant products by technical personnel of the USA at the country of origin is necessary, and the cost of

such inspections/examinations have to be met by the exporting country. Deciduous fruits from South Africa, apples from New Zealand, Unshu (Satsuma) oranges from Japan, fern plants and bulbs from the Netherlands, grapes from Chile, mangoes from Haiti, and bulbs from Germany, France, Israel, Italy, and South Africa are allowed entry into the USA after adoption of preclearance procedure pertaining to the crops concerned (Rohwer 1979). Domestic quarantines operate at the boundaries between states/provinces to restrict the movement of plants and planting materials as per the specifications.

10.2.3 Impact of Introduced Pathogens

The number of plant pathogens brought along with new crops/varieties increased steadily from the nineteenth century, and many crops in different countries were ruined as the pathogens found suitable environmental conditions and available susceptible plants in large areas. The need to regulate the entry of plants/plant materials into the country was recognized. Some of the destructive diseases of economically important crops that were primarily responsible for the establishment of plant quarantines in various countries are discussed in the following sections.

10.2.3.1 Potato Late Blight Disease

Potato late blight disease caused by *Phytophthora infestans* destroys all infected plant parts and also infects the tubers which spread the inoculum to various locations. The center of origin of potato (*Solanum tuberosum*) and its wild relatives is considered to be the mountains of Mexico and Guatemala, and the pathogen *P. infestans* might also have coevolved with its host plants (Leppik 1970). The potato late blight disease is one of the earliest recorded plant diseases for which the association of a fungus *Phytophthora infestans* was established as the causative agent, and was primarily responsible for the infamous Irish famine in 1845. Potato crops were entirely devastated, leading to one of the greatest migrations of impoverished humans to other European countries and North America. The pathogen was introduced with seed potatoes from Peru to Belgium or France by about 1842 to 1844 (Agarwal and Sinclair 1996). Potato was introduced along with the pathogen into Europe and other countries. As the potato cultivars were selected for higher yield and attributes other than resistance to pathogen(s), conditions became increasingly favorable for the pathogen as the area under potato cultivation enlarged year after year. The population diversity of *P. infestans*, differing in their virulence and sensitivity to fungicides, had to be investigated since genotypes with a greater level of virulence and resistance to fungicides may be introduced through infected seed tubers. Clonal propagation and migration through seed tubers contributed to long-distance transport of *P. infestans*. Both A1 and A2 mating types of *P. infestans* were found in the same potato seed tuber production areas in Canada. This situation might increase the potential for sexual recombination within the pathogen populations, leading to the production of oospores (sexual spores) that could survive in the absence of host tissues and create new strains of *P. infestans* (Peters et al. 2014).

10.2.3.2 Citrus Canker Disease

Xanthomonas axonopodis pv. *citri* (Xac) causes citrus canker disease in all parts of the plants, including fruits, reducing the market value of the fruits of *Citrus* spp. The pathogen was considered to have been introduced into the USA from Asian countries

through infected budwood materials. The application of quarantine regulations effectively prevented the establishment of the disease. Federal quarantine laws were enforced in 1912 as soon as the first incidence of the disease was observed. State and federal regulatory personnel initiated programs to eradicate 20 million citrus trees at a cost exceeding US\$ 20 million. The infected trees and all plant materials within 125 feet (41 m) were required to be burnt as per quarantine regulations. Clothes of workers, tools, machinery, and vehicles were thoroughly cleansed (Schumann 1991). The eradication of infected plants, combined with quarantine regulation to prevent further entry of the pathogen, has made the disease management system very effective (Fry 1982). The preclearance program operated by the personnel of the USA and Japan has created a formidable barrier preventing the pathogen spreading from other countries (Rohwer 1979). However, reintroduction of the pathogen through infected fruits and plants carried by travelers remains a distinct possibility.

10.2.3.3 Panama (*Fusarium*) Wilt Disease of Banana

Panama (*Fusarium*) wilt disease of banana caused by *Fusarium oxysporum* f.sp. *cubense* is one of the most destructive diseases of banana, named after the country where the first epidemic of the disease was recorded. The disease incidence progressively increases in subsequent generations causing heavy losses if proper care is not taken to select healthy suckers (corms). In Costa Rica, banana production was drastically reduced from 11 million bunches in 1923 to 1.4 million bunches in 1941 (Schumann 1991). The pathogen primarily spreads through infected suckers and survives in the soil in new areas after introduction through infected suckers. This fungal pathogen may also be introduced into new areas by contaminated soil, footwear (or feet), and agricultural tools. Once the pathogen reaches the soil, it is very difficult to eliminate the pathogen entirely from the field. When the crop production becomes unprofitable because of the death of infected plants, infested areas have to be abandoned since the pathogen can survive in the soil for several years. Fallowing for long periods may be required. As the quarantine regulations were ineffective, the disease incidence is seen in all banana-growing countries in the world. This situation underscores the need for strict enforcement of regulatory measures by both domestic and international quarantines on the movement of planting materials from one state to another and from one country to another, to restrict the further spread of the disease.

10.2.3.4 Banana Bunchy Top Disease

The causative agent of banana bunchy top disease (BBTD), *Banana bunchy top virus* (BBTV), has been responsible for ruining banana production in Australia, Fiji, India, and several other countries in the Asia-Pacific basin and Africa. The virus spreads primarily through infected suckers which may or may not exhibit any visible symptoms of virus infection, and secondary spread occurs through the banana aphid *Pentalonia nigronervosa* in a persistent manner. However, the new infections due to aphid transmission in a growing season are far less compared to introduction of the disease by infected suckers obtained without indexing for the presence of BBTV. Successful management of BBTD was achieved in Australia (Queensland) by inspection of suckers for health status, eradication of infected plants completely in old plantations, and planting virus-free suckers in new plantations. It is an excellent model for emulation by other banana-growing countries. Use of suckers from BBTV-infected plantations was prevented by legislation and the infected plants were destroyed with the cooperation of growers.

Virus-free suckers were planted in new plantations (Magee 1936; Eastwood 1946; Colborne 1953). Because of strict enforcement of these regulations for over 50 years, bunchy top disease incidence was reduced from a mean of 6.6 plants ha⁻¹ in 1937 to 0.1 ha⁻¹ in 1967. Following the application of the set of operations required for the management of BBTD, a rather unique situation developed: it became difficult to find even a few infected banana plants required to train inspection personnel (Allen 1983). This example of banana bunchy top disease reveals the importance and effectiveness of plant quarantines in preventing the introduction and subsequent spread of destructive diseases of economically important crops.

10.2.3.5 Strawberry Anthracnose Disease

Phytosanitary legislation was considered to be the most effective means of restricting the entry of alien pathogens into the country without impacting trade. However, the limitations and weaknesses of the phytosanitary systems worldwide were revealed by the entry and establishment of *Colletotrichum acutatum* in the UK in the 1980s. Datasets of disease incidence gathered by personnel involved in plant health programs between 1984 and 2008 were analyzed to determine how and why the pathogen entered the UK in 1982 in plants originating from the USA, 1 year earlier than the first UK record of the disease was reported. At least 54 further cases of infested plant materials breached the phytosanitary procedures and entered the UK, 75% of which originated from EU countries. Further, internal trade transmission was found to be highly influential in the successful spread of the disease. The nurseries that had a track record of selling infested plant material were blacklisted, even if they were accompanied by a plant passport (certificate). The results revealed the huge responsibility of personnel concerned in the nurseries throughout the EU in limiting the spread of quarantine diseases (Calleja et al. 2013).

10.2.3.6 Potato Virus Diseases

Seed potato certification programs were first established in Europe and the concept was extended to North America in 1913. At that time, the purity of potato varieties and the use of fewer well-characterized cultivars were considered as the primary goals. State-based potato grower associations were formed prior to 1913 in many regions and these associations were responsible for setting up seed certification schemes. Each state in the USA has different regulations and certification agencies are managed by the state department of agriculture, universities, or grower groups. Later, control of necrotic strains of *Potato virus Y* (PVY) was one of the main reasons for the establishment of federal seed potato certification standards (Trank 1991). Seed potato certification in North America is based mainly on visual inspection of growing plants, since it was considered effective and the small benefit of large-scale laboratory testing for the pathogen was not worth the added cost. Varieties that did not exhibit early recognizable symptoms of important pathogens were therefore discouraged (de Souza-Dias and Betti 2003). However, the evolution of new PVY strains that elicited few symptoms, regardless of the potato genotype, made identification of infected plants difficult. This situation changed the views of potato seed certification in favor of using sensitive, specific, and reliable techniques based on immunological and nucleic acid properties of viruses.

Potato virus X and *Potato leafroll virus* (PLRV) have limited host ranges and spread by mechanical transmission and aphids. They can be effectively dealt with by eliminating seed potato lots carrying these viruses. The recent emergence of soilborne viruses

Tobacco rattle virus (TRV) and *Potato mop-top virus* (PMTV) has become a challenge for seed potato certification programs (Johnson 2008). PVY incidence in seed lots was one of the main characteristics used to determine which class a seed potato lot would fall into. The virus incidence threshold for each seed class varies by seed potato certification agency. There is a zero tolerance for every virus in tissue-culture-derived plantlets and in greenhouses and this could be ensured by visual inspection and mandatory laboratory testing for growers of certified seed potatoes. The cost of extensive laboratory testing, while providing more accurate data, is prohibitively expensive (Halterman et al. 2012).

10.2.4 Assessment of Efficiency of Quarantines

Plant quarantines should be rational and based on biological and sociological data on pathogens/pests. Restrictions have to be imposed on the entry of exotic pathogens likely to cause substantial losses if introduced into the country concerned. The efficiency of plant quarantines can be increased by a proper choice of effective strategies. The expected economic impact should be estimated so that the data constitute a basis for prioritizing quarantine activity. The plant protection organization of the country should be alert and responsive to initiation of appropriate investigations on reports of possible new introduction of pathogens. The rapid action taken by the USA may possibly serve as a model in enforcing quarantine regulations. Wheat Karnal bunt caused by *Tilletia indica* infects seeds and the pathogen presence was detected by the personnel of the US Department of Agriculture in Arizona on 8 March 1996. The presence of *T. indica* was confirmed by PCR assay and quarantine activities immediately accelerated. Within a period of less than 2 weeks, the Secretary of Agriculture announced a “Declaration of Emergency” to contain the spread of the disease. Growers and handlers were adequately compensated for losses due to quarantine action. Information on the disease was disseminated through media and the internet (Bonde et al. 1997). Such urgent and coordinated actions may be necessary to prevent the introduction and subsequent spread of the disease in other countries. Cooperation between countries and importers of plant materials would enhance the efficacy of plant quarantines. Adequate care and attention should be exercised by the exporting countries to ensure the required level of phytosanitary status of the plant materials. Travelers form a potential source of immigrant pathogens and pests. It has been reported that about 80% of all uncertified plant materials with potential pathogens/pests were carried in traveler’s baggage in Canada. It is probably worthwhile to thoroughly examine baggage in view of the potential risks involved. According to Schumann (1991), a dog was employed to sniff out citrus fruits to prevent the reintroduction of citrus canker pathogen into the USA.

The use of efficient, sensitive, and reliable diagnostic techniques for the detection of pathogens in plant materials becomes indispensable, especially when asymptomatic infection has to be detected to enhance the effectiveness of plant quarantine measures in preventing the introduction of exotic pathogens. Constant vigilance and coordinated efforts of all personnel are required because of ever-increasing travel and liberalization of trade among countries. Conventional methods involving the isolation of pathogens and their identification based on classical taxonomic characteristics require a long time to obtain results that are sometimes inconclusive. Molecular methods have been shown to be more sensitive, specific, rapid, and reliable. These methods are more useful and effective in detecting phytoplasma, virus, and viroid pathogens which have not been

isolated in cell-free media so far. The choice of technique for diagnosis of crop pathogen(s) carried in seed and propagules depends on the sensitivity, specificity, and reliability of the results obtained, in addition to the cost-effectiveness of the technique. Multiplex assays that can detect two or more pathogens simultaneously have been developed. These techniques offer the advantages of saving time, labor, and cost of testing significantly.

The arrival and subsequent establishment and spread of nonindigenous pathogens and other organisms may result in substantial economic loss of crops, either directly or through trade barriers. To be a successful invader, a pathogen must negotiate a sequence of events that include arriving, surviving, and thriving in a new environment. Limiting the survival of a pathogen after successful entry is the principal goal of regulatory activities, such as eradication and quarantine. In the USA, the exclusion, eradication, and quarantine of plant pathogens is the responsibility of the USDA Animal and Plant Health Inspection Service (APHIS). The increase in the volume of international trade and travel has increased the likelihood of immigration of nonindigenous, invasive pathogens into several countries. Identification of the pathways of introduction of nonindigenous pathogens may significantly assist efforts to curtail their entry into the country concerned.

Karnal bunt of wheat caused by *Tilletia indica* was first detected in the USA in Arizona in 1996. The seed lots of infected, spring-habit, durum wheat associated with the initial detection were traced to planted fields in California, Arizona, New Mexico, and Texas. In 1997, the bunt disease incidence was observed at several locations about 700 km away from the potentially contaminated wheat which was destroyed prior to reinfection. The pathways of introduction of *T. indica* were sought by analyzing the USDA/APHIS Port Information Network (PIN) database from 1984 to 2000. All interceptions were made on wheat transported from Mexico, with the majority (98.8%) being intercepted at land border crossings. Karnal bunt was not intercepted from any other country over the 17 year period analyzed. Most interceptions were on wheat found in automobiles, trucks, and railway cars. The interceptions peaked in 1986 and 1987, although the pathogen was intercepted during the entire 17 year period. Averaged over the years, a significantly greater number of interceptions were made during May (19.2% of interceptions) and the fewest interceptions were in July (4.0%). The relatively unaggressive nature of the disease and its reliance on rather exacting weather conditions for infection may be the possible reasons for the long period between the arrival of the pathogen and establishment at the invaded agroecosystem (Marshall et al. 2003).

A dot-blot hybridization procedure using nonradioactive digoxigenin (DIG-) labeled riboprobes and chemiluminescent detection could be employed for the diagnosis of infections by *Cucumber mosaic virus* (CMV), *Tomato spotted wilt virus* (TSWV), *Tomato yellow leafcurl virus* (TYLCV), *Alfalfa mosaic virus* (AMV), and *Tomato mosaic virus* (TMoV) in tomato seedlings. This procedure was successfully applied for phytosanitary purposes in Italy (Salderelli et al. 1996). Multiplex tissue-print immunoassay (TPIA) and dot-blot immunoassay (DBIA) were evaluated for their efficacy for the detection of *Potato leafroll virus* (PLRV), *Potato virus S* (PVS), *Potato virus X* (PVX), and *Potato virus Y* (PVY) in the extracts of green and/or tuber tissues. In TPIA, the specific precipitation patterns in infected tissues of leaf petioles or stem cross-sections observed with each virus allowed the specific virus or mixed infections to be identified in a single multiplex assay. DBIA was more sensitive (50 times) than ELISA for the detection of PVY in green tissues. TPIA and ELISA tests were suitable for rapid detection of PVY and PVS in the

extracts from tuber stem end or eyes without prior germination of tubers. PVS was evenly distributed in potato tuber tissue, whereas PVY was localized in the vascular tissue beneath the epidermis, with irregular distribution along the periphery of the potato tuber. TPIA technique was recommended for monitoring the incidence of PVS and PVY as a suitable alternative to ELISA tests for laboratories lacking the time and facilities for tests based on tuber germination (Samsatly et al. 2014).

The procedure for the detection of viral infection based on the presence of double-stranded (ds-) RNA in plants was developed. Plants infected by *Cucumber mosaic virus* (CMV) and *Potato virus X* (PVX) could be identified by detecting the ds-RNAs which show characteristic patterns. This procedure has the potential for the first screening of infection by those widely distributed viruses for plant quarantine regulations (Yamashita et al. 1996). Although molecular assays have been shown to be preferable for the rapid detection and identification of microbial pathogens, conventional (biological) assays should remain as the fundamental assay for the continued success of clean stock/certification programs because numerous uncharacterized graft-transmissible agents (GTAs) infect *Vitis* spp. and *Prunus* spp. For example, the Red Globe virus, described as *Grapevine leafroll-associated virus 2RG* (GLRaV-2RG), did not induce leafroll symptoms in the standard indicators (Cabernet France or Cabernet Sauvignon) used for viruses infecting grapevine. On the other hand, GLRaV-2 caused an acute reaction on certain grape rootstock (Uyemoto et al. 2001). GLRaV-2RG was serologically related to GLRaV-2 and both shared 74% nucleotide sequence homology. Red Globe strain passed the required assays of the California Department of Food and Agriculture (CDFA) and California Registration and Certification (CRC) program. However, when Red Globe scion materials were bench-grafted onto different rootstocks and planted in commercial orchards, all plants of acutely sensitive rootstocks died within two growing seasons. The molecular technique enabled the identification of GLRaV-2RG strain and its pathology in sensitive rootstocks was useful to study the variations in host–virus interaction (Rowhani et al. 2005).

The extent of the presence of viruses was assessed in the samples of imported propagation materials with phytosanitary certificate pertaining to the Turkish Regulation on Agriculture Quarantine. A total of 114 fruit propagation materials (rootstock and seedling varieties) were tested by DAS-ELISA and compound direct ELISA formats. Apple rootstock samples (26) and apple seedling samples (17) were tested for the presence of *Apple mosaic virus* (ApMV) and *Apple chlorotic leaf spot virus* (ACLSV), while pear rootstock samples (5) and pear seedling samples (6) were tested for the presence of ACLSV. Apple and pear rootstocks and seedling samples were found to be free of the viruses tested. *Prunus necrotic ringspot virus* (PNRSV) was detected in one plum rootstock sample. *Prune dwarf virus* (PDV) infection was detected in two cherry seedling samples and one sample each from peach rootstock and cherry rootstock and seedlings were positive for *Plum pox virus* (PPV). One cherry seedling sample showed mixed infection by PDV and PPV. Overall, 6.13% of fruit propagation materials intended to be imported were found to be infected by one or both viruses (Özdemir and Kaya 2008).

Apple chlorotic leaf spot virus (ACLSV), the type member of the genus *Trichovirus*, *Flexiviridae*, has a worldwide distribution infecting a wide range of rosaceous hosts, and is an important pathogen targeted in certification and quarantine programs. Detection of ACLSV was accomplished based on biological indexing, ELISA, and RT-PCR assays. The RT-PCR assay was evaluated for its suitability as a reliable molecular indexing tool, using a broad spectrum of virus isolates from various hosts. Oligonucleotide

primers targeting the viral CP and replicase regions of ACLSV were tested for the detection of virus isolates from natural hosts originating from domestic and imported sources of plant germplasm. The primers CLS6860 and CLS7536 amplifying a 676 bp fragment in the CP coding region were the most reliable, detecting all isolates in all tested hosts. Comparison of the RT-PCR data with ELISA and biological indexing results revealed the advantages of using a reliable molecular tool for problematic hosts (Spiegel et al. 2006). The phytosanitary status of the sources should be precisely assessed before nursery propagation or for germplasm exchange.

The phytosanitary status of *Prunus* spp. in the National Clonal Germplasm Repository (NCGR) in California was evaluated. A total of 221 trees representing 185 different cultivars of cherry, almond, peach, apricot, and plum were sampled. Conventional RT-PCR assay was employed for the detection of *Prunus necrotic ringspot virus* (PNRSV), *Prune dwarf virus* (PDV), *Plum bark necrosis stem pitting-associated virus* (PBNSPaV), *American plum line pattern virus* (APLPV), *Cherry virus A* (CVA), *Cherry leafroll virus* (CLRV), *Cherry rasp leaf virus* (CRLV), *Cherry green ring mottle virus* (CGRMV), *Cherry necrotic rusty mottle virus* (CNRMV), *Apple chlorotic spot virus* (ACLSV), *Tomato ringspot virus* (ToRSV), *Little cherry virus 1* (LChV-1), *Little cherry virus 2* (LChV-2), *Peach latent mosaic viroid* (PLMVd), and *Hop stunt viroid* (HSVd). Although the majority of the trees were asymptomatic, all tested viruses (11 of 13; ToRSV and CRLV excluded) and two viroids were detected. Two of the viruses ACLSV and LChV-2 had never been found in California previously. The incidence of PNRSV was the highest (55 trees), followed by the two viroids (PLMVd and HSVd) with 33 and 32 infected trees, respectively. The incidence of other viruses ranged over 0–19 trees. The infection rate of all tested samples ranged over 0.5–24.9%. The results revealed the need to evaluate the mother plants for their phytosanitary status periodically to restrict the spread of the virus(es) and viroid(s) through propagules (Osman et al. 2012).

Citrus spp. are infected by many viroids, in addition to different viruses. Detection of viroids through biological indexing on sensitive indicator plants followed by sequential polyacrylamide gel electrophoresis (sPAGE) was widely adopted previously, but this procedure was found to be time-consuming and the test plants had to be maintained at optimum conditions. A conditional use of RT-PCR assay was shown to be an efficient and alternative detection method for testing plant materials in the Texas virus-free citrus budwood certification program. Prior to final biological indexing, RT-PCR assay was used to detect, clone, and sequence full-length viroids of *Citrus exocortis viroid* (CEVd), *Hop stunt viroid* (HSVd) (both cachexia and non-cachexia variants), *Citrus viroid-III* (*Citrus dwarfing viroid*), and *Citrus viroid-IV* (*Citrus bark cracking viroid*) from a collection of viroid-inoculated grapefruit plants. The presence of viroids in source plants was checked earlier by biological indexing in Etrog citron plants. The results indicated that RT-PCR could be a conditional substitute for biological indexing of mother trees in the virus-free budwood program. Trees that are positive for RT-PCR may be discarded from the pool before extensive biological indexing (Kunta et al. 2007).

All known grapevine viruses are graft-transmissible and are spread over long distances through infected propagative materials (buds/cuttings) or by using rooted cuttings from infected canes. An important strategy for the management of grapevine viruses is therefore through clean stock programs. In accordance with the European Legislation and national system for production of certified vine-growing materials, 1295 samples from grapevine cultivars and rootstocks were tested for their health status during 2004–2006. Application of ELISA tests showed that 30.5% of tested grapevine cultivars

and rootstocks were infected by one (86.1%) or more viruses (13.9%). *Grapevine fleck virus* (GFKV) was the most widespread (23.3%) among grapevine viruses, followed by *Grapevine fan leaf virus* (GFLV) (5.05%) and *Grapevine leafroll-associated virus-1* and *-3* (GLRaV-1 and -3) (3.34% and 2.78%, respectively). *Grapevine Bulgarian latent virus* (GBLV) (0.37%) was detected occasionally. *Arabid mosaic virus* (ArMV), *Grapevine leafroll-associated virus-2* and *-7* (GLRaV-2 and -7), *Grapevine virus A* (GVA), or *Grapevine virus B* (GVB) were entirely absent from the locations where the diagnostic tests were carried out. Mixed infections by eight virus combinations were observed. The most widespread virus combinations were GFKV + GLRaV-1 (8.3%) and GFLV + GLRaV-3 (8.3%). The wild relatives of *Vitis vinifera* ssp. *sylvestris* were free of ArMV, GFLV, and GBLV. The results showed that ELISA tests were effective in detecting grapevine viruses in source plants (Kamenova et al. 2007).

10.3 Production of Disease-Free Seeds and Propagules

As seeds and propagules carry the microbial pathogens, they form the primary sources of inoculum for the pathogens; natural biological vectors or environmental conditions such as wind or rain may be responsible for the secondary spread of the disease(s). Use of pathogen-free seeds and propagules is therefore the basic requirement for successful and profitable crop cultivation. The role of certification and plant quarantine programs in providing pathogen-free seeds and propagules was discussed in Sections 10.1 and 10.2. These approaches aim to select the mother plants or seed lots which satisfy the limits of pathogen presence, and those that are either free of pathogens or carry the pathogens not exceeding tolerance limits are distributed to the growers. On the other hand, concerted efforts have been taken to eliminate the pathogen(s) present in and/or on the seeds and propagules. Plant viruses are known to be transmitted through true seeds of some crops such as lettuce, barley, peanut, and soybean at higher frequencies compared to other crops. In contrast, transmission of viruses occurs through propagules of all vegetatively propagated crops. Different approaches have been made to contain the virus diseases depending on the virus distribution in infected plants, susceptibility to heat, and antiviral chemicals.

10.3.1 Production of Virus-Free Plants

10.3.1.1 Meristem-Tip Culture

Microshoot-tip tissue culture is a preferred method to eliminate virus(es) and other plant pathogens from many plant species. This method provides the advantage of regenerating a single plant from a single minuscule (approximately 0.5 mm) shoot. This technique avoids the production of plants from callus which may lead to regeneration of an off-type plant. The combination of low hormone levels combined with a minimum time in culture reduces the chance of mutation and regeneration of an off-type plant. At the same time, many pathogens including viruses are eliminated by this technique. As the meristem is able to grow faster than it can be infected by viruses that may be present in the mother plants, this technique can be useful to build up virus-free stocks. The apical meristems of systemically infected plants are generally free of the virus infecting the plant species. Meristem-tip culture may be effective in obtaining virus-free plants, even when all the plants of a valuable cultivar or germplasm are

infected by the virus. The meristem piece (0.5–1.0 mm long) is planted in an appropriate medium such as Murashige-Skoog (MS) medium under aseptic conditions, and incubated at the required temperature–light conditions. The plantlets growing from the meristem are indexed for the presence of virus by various assay methods. Viruses infecting members of Araceae and strawberry could be eliminated by such procedures (Hartman 1974; Tong et al. 1994).

In China, sweet potato viruses including *Sweet potato feathery mottle virus* (SPFMV), *Sweet potato latent virus* (SPLV), and *Sweet potato caulimo-like virus* (SPCLV) were observed in all sweet potato production regions in China, which is the largest cultivator of sweet potato in the world. Shoot-tip cultures of sweet potato have been effective in eliminating sweet potato viruses. An effective propagation and delivery system of virus-free sweet potato plants was established and carried out successfully in Shandong and Jiangsu provinces. The use of virus-free sweet potato plants could restore high yield and quality, in addition to improving the resistance against other pathogens such as the fungal pathogens *Monilochaetes infusans* and *Ceratocystis fimbriata* and the nematode *Pratylenchus coffeae*. Further, the area of virus-free sweet potato production reached 70,000 ha in 1994, 90,000 ha in 1995, and 466,000 ha in 1998. The effectiveness of meristem-tip culture for the elimination of sweet potato viruses has therefore been amply demonstrated in China (Feng et al. 2000).

Cucumber mosaic virus (CMV) infection in chrysanthemum significantly reduced production. By using meristem-tip culture method, CMV was eliminated and virus-free plants were produced by planting meristem tips (0.3 mm) planted in MS medium. When indexed by RT-PCR assay, 72% of the plants generated were found to be free of CMV (Verma et al. 2004). *Onion yellow dwarf virus* (OYDV) infects onion and garlic crops severely, causing serious losses. The basic requirement to restrict the incidence and spread of OYDV is to use virus-free planting materials; propagation materials were therefore generated by meristem-tip culture to build virus-free nuclear stocks. The absence of OYDV in the tissue-culture-generated plantlets was ensured by applying RT-PCR assay. Specific primers from conserved region of RNA-dependent RNA polymerase (RdRp) gene and 3' UTR region of RNA of OYDV isolates were designed and employed in the RT-PCR assay. The primers successfully amplified virus-specific fragments (c. 1.1 kb) in naturally infected garlic bulbs. The RT-PCR protocol developed in this investigation provided rapid and reliable detection of OYDV in propagation materials generated through meristem-tip culture, facilitating production of virus-free stocks (Arya et al. 2006).

The introduction of micro- and minitubers revolutionized potato tuber production, resulting in a shortening of the field production cycle to obtain an adequate number of seed potatoes, thus guaranteeing a high level of healthiness of base materials. Minitubers are small tubers produced on in vitro plantlets or microtubers under covers. The possibility of multiplying the materials produced in vitro directly under field conditions was examined. The extent of infection by *Potato virus Y* (PVY), *Potato virus M* (PVM), and *Potato leafroll virus* (PLRV) of potato tubers derived from plants grown directly from in vitro plants, microtubers, minitubers, and traditional seed potatoes planted in the field at different times was assessed. The levels of susceptibility to the viruses using aphid vectors were determined. Infection of tubers derived from in vitro plants and microtubers was greater than that of seed potatoes and minitubers. However, the greater susceptibility was largely considered to be due to unknown causes. Multiplication of microtubers and in vitro plantlets under field conditions could be very economical if

cultivars with relatively higher level of resistance are used. Adopting a later-than-usual planting period (end of June) and applying an additional protective cover, such as non-woven agricultural fabric, in the first phase of plant growth promoted multiplication of minitubers and in vitro plantlets in the field conditions for cultivars with low level of resistance (Wróbel 2014).

Cucumber mosaic virus (CMV) and *Cymbidium mosaic virus* (CyMV) were successfully eliminated from vanilla (*Vanilla planifolia*) through meristem culture. Apical meristems (0.1–0.25 mm) were planted in Murashige-Skoog medium supplemented with nutrients and hormones. The regenerated plantlets were hardened in an insect-free glasshouse and checked for the presence of viruses by RT-PCR assay using virus-specific primers. The frequency of CMV elimination was 79.4%, whereas CyMV was eliminated in 82.4% of the regenerated plants. Simultaneous elimination of both CMV and CyMV was up to 75% (Retheesh and Bhat 2010).

Phalaenopsis, a very popular orchid plant species in the global market, is frequently coinfectd by *Odonotoglossum ringspot virus* (ORSV) and *Cymbidium mosaic virus* (CyMV) in Taiwan. A relatively simple procedure for eliminating ORSV and CyMV using shoot-tip culture was developed. Early isolation and selection of virus-free protocorm-like body (PLB) through subcultures was accomplished. The indexing of viruses in the field-grown plants, PLBs, and tissue-cultured plants was carried out by indirect ELISA and one-step multiplex RT-PCR assay. Induction of PLBs in shoot-tips was achieved on $1/2 \times$ Murashige-Skoog (MS) basal medium supplemented with 1% sucrose, 6% potato pulp, 0.5 g L^{-1} tryptone, 0.25% activated charcoal, and 0.6% Bactoagar. The regenerated plants from virus-free PLBs acclimatized easily in the greenhouse and showed 100% survival rate. All the *Phalaenopsis* plants raised through shoot-tip culture tested negative for both viruses. At least three subcultures were necessary to authenticate that the shoot-tip culture-derived plants were virus-free. The protocol developed in this investigation showed potential for reliable elimination of viruses and mass propagation of genetically uniform and virus-free *Phalaenopsis* plants (Chien et al. 2015).

Viruses infecting grapevines could be eliminated by adopting microshoot-tip culture, involving culturing of growing tips (less than 0.5 mm) excised from the grapevine shoot tip. Many viruses and the crown gall bacterium were eliminated by this procedure. *Grapevine leafroll-associated viruses*, *Grapevine fan leaf virus*, *Grapevine virus A*, *-B*, and *-D*, and *Rupestris stem pitting-associated virus* were eliminated successfully by microshoot-tip culture. In addition, *Agrobacterium vitis*, causing crown gall disease, could be effectively eliminated by adopting microshoot-tip culture technique (using growing tip of about 5–10 mm in length) (Susan et al. 2010).

A combination of thermo (heat) -therapy and meristem-tip culture has been demonstrated to be more effective than the use of meristem-tip culture alone. The effect of selective virus elimination on vigor, yield, and fruit quality of *Vitis vinifera* cultivar Chardonnay was assessed under field conditions over 6 years. The test materials were propagated from three clones infected by multiple combinations of *Grapevine leafroll-associated virus 1* (GLRaV-1), *Grapevine virus B* (GVB), *Grapevine rupestris stem pitting-associated virus* (GRSPaV), *Grapevine fleck virus* (GFkV), GVB and GRSPaV, GLRaV-2, GLRaV-3, and GRSPaV and virus-like diseases (vein mosaic and vein necrosis). Progenies were selected after virus elimination by heat therapy and in vitro apex grafting. It was not possible to eliminate all grapevine viruses in the progeny, as revealed by graft indexing and DAS-ELISA. Elimination of GLRaV-2 was achieved to the highest level and the progenies showed a marked increase in cumulative weight growth (21%),

fresh fruit yield (22%), and sugar content of fruit juice (9%). Selective elimination of GLRaV-1, GLRaV-3, and GVB also provided a beneficial impact in terms of growth and yield, but maturity index was variably affected. The results suggested that GLRaV-2 should be included in certification programs because of detrimental effects on the grapevine growth and yield (Komar et al. 2007).

In vitro thermotherapy and tissue culture technique were combined for elimination of *Grapevine leafroll-associated virus 1* (GLRaV-1) and *Grapevine rupestris stem pitting-associated virus* (GRSPaV) from *Vitis vinifera* cultivar Agiorgitiko. GRSPaV was found to be quite resistant to elimination, whereas GLRaV-1 was more easily eradicated. In vitro thermotherapy was performed in a growth chamber for 6 weeks with a 16 h photoperiod. The initial temperature of 26°C (day) and 23°C (night) was gradually increased by 3°C/week; during the final week, the temperatures maintained were 40°C (day) and 37°C (night). Regeneration rates from meristem- and shoot-tip culture were 55.7% and 80.3%, respectively. The combination of thermotherapy and tissue culture effectively eliminated both GLRaV-1 and GRSPaV-1. Both viruses were more readily eliminated when thermotherapy was followed by meristem-tip rather than shoot-tip culture procedure. The respective values were 91.2% and 73.8% for GLRaV-1 and 67.6% and 50.8% for GRSPaV-1. On the other hand, 61.8% meristem-tip and 37.7% of shoot-tip culture-derived plants were free from both viruses. Elimination of GLRaV-1 was easier than that of GRSPaV-1 with both meristem-tip and shoot-tip culture methods. The ratio of virus elimination to explants survival was higher for meristem-tip than for shoot-tip culture (1.108 and 0.469, respectively). Freedom of regenerated plantlets from GLRaV-1 and GRSPaV-1 was confirmed by employing nested RT-PCR assay (Skiada et al. 2009).

The elimination of viruses and viroids has been shown to be possible by employing micrografting technique in vitro from local citrus cultivars and/or clones in Cyprus during 2000–2005 through a special program. All mother plants were tested for viruses and viroids by biological indexing and ELISA for *Citrus tristeza virus* (CTV) and by RT-PCR assay for viroids. All mother plants were found to be free of CTV and *Citrus viroid V*, but were found to be infected by *Citrus exocortis viroid* (CEVd) and/or other viroids including *Citrus cacahexia viroid* (CaVd) and *Citrus bent leaf viroid* (CBLVd). Some mother trees were infected by *Citrus psorosis virus* (CPsV). Shoot-tip grafting technique was employed for the elimination of viroids and CPsV in the selected citrus isolates. The average micrografting success was 40–60% from the 500 micrografts. Micrografted plants were regrafted on sour orange seedlings in vivo and were established successfully and transferred to the glasshouse. They were tested at 6–9 months later for the viruses and viroids present in the meristem of donor mother plants. The micrografted plants free of CPsV and viroids were used as primary source materials for the basic citrus plantation and for further propagation for distribution through government agencies, private nurseries, and private growers. The micrografting technique was successfully employed to produce healthy planting materials of valuable traditional varieties in Cyprus, and the healthy plants were made available to citriculture (Kaparia-Isaia et al. 2007).

The sanitation procedure of shoot-tip grafting (STG) has been used extensively in citrus improvement programs to restrict *Citrus tristeza virus* (CTV) incidence and spread. Shoot tips of 0.14–0.18 mm in length, aseptically isolated from diseased citrus plants, were grafted (inverted T graft) onto young etiolated seedlings grown in vitro. About 1 month after grafting, plants were transferred in vivo and these plants

set fruits 2–3 years later. To increase explants survival, bigger shoot tips were collected from thermo-treated buds at 32–35°C. This thermotherapy treatment reduced virus replication and increased meristematic cell activity, facilitating production of clean shoot-tips for use in shoot-tip grafting (STG). The combination of thermotherapy and STG was useful to eliminate *Citrus psorosis virus* (CPsV) which was found to be difficult to eliminate by STG alone. Safe introduction of citrus germplasm could be achieved by micrografting in vivo shoot tips excised from imported budsticks in vitro cultured at 32°C. The number of successful grafts depended on *Citrus* spp. varieties and type of virus strain, in addition to the operator's skill which was considered a crucial factor for survival and sanitation rate (Navarro et al. 1975, 1991; Carvalho et al. 2002; Meziane et al. 2009).

Citrus somatic embryogenesis from stigma and style in vitro culture is another technique used for total recovery of healthy plants from most of infected *Citrus* spp., except for clementines and pomelos. Styles and stigmas were dissected from freshly collected closed flowers under laminar flow. Explants were vertically placed in petridishes with the cut surface in contact with the medium supplemented with N6-benzyl-aminopurine (BAP). A creamy-white callus appeared on the cut surface of the style base at about 2 weeks after culture initiation, whereas green somatic embryos developed at 2–7 months after several subcultures. After germination, embryos developed into plantlets which were transferred in vivo. Regenerated plants produced fruits on some branches after 3 years. All embryos formed were totally free of CTV. The regenerated plants could be used in the safe exchange of citrus germplasm with very little manipulation. The crucial point in the successful regeneration of plant by embryogenesis was the requirement of collection of flower explants before opening or storing at 4°C for 5–6 days (De Pasquale 1999).

Thermotherapy followed by the microbudding technique along with indexing by ELISA test was applied to produce and multiply *Citrus tristeza virus* (CTV-) free Musambi plants. Source plants were maintained under the greenhouse conditions for thermotherapy. The budwood of 3 and 4 mm in size was budded at two different heights (15 and 23 cm) of the plants. Source plants of sweet orange, both infected and apparently healthy were collected from orchards. The microbudded Musambi sweet orange plants were indexed for CTV by DAS-ELISA test. Maximum (50%) success of microbudding was achieved when budwood of 4 mm was microbudded at a height of 23 cm. The results showed that thermotherapy combined with microbudding and indexing by ELISA test might significantly reduce the time to obtain CTV-free Musambi plants (Abbas et al. 2006).

Indian citrus ringspot virus (ICRSV), infecting Kinnor (*Citrus nobilis* x *C. deliciosa*) plants, is widespread in India. The effect of thermotherapy coupled with shoot-tip grafting (STG) in vitro on the elimination of ICRSV from infected plants was assessed. Nodal segments from infected mother plants (indexed by ELISA test and RT-PCR assay) were treated both in water bath and moist hot air at the different temperatures of 40, 45, and 50°C for 30, 60, and 120 min, and cultured on Murashige-Skoog medium (MS). Mother plants from which the explants were taken were found to be ICRSV-positive by indirect ELISA format. Application of RT-PCR assay showed the presence of ICRSV-specific 539bp fragment of partial coat protein gene in mother plants. On the other hand, no virus-specific product was detected in some of the in vitro raised plantlets through thermotherapy coupled with STG procedure. Shoot tips were excised from nodal

Figure 10.1 Effectiveness of in vitro thermotherapy coupled with shoot-tip grafting for elimination of *Indian citrus ringspot virus* (ICRSV) from citrus plantlets. Note the absence of ICRSV-specific amplicons in treated plantlets. Lane M: DNA size standards; lanes 1 and 2: positive and negative controls, respectively; lanes 3–6: samples from treated citrus plantlets. Source: Sharma et al. (2008). Reproduced with permission of Springer Science, Heidelberg, Germany.

sprouts and grafted onto rough lemon (*C. jambhiri*) root stock under aseptic conditions. Water bath treatment was more effective compared to moist hot air treatment, as the maximum number of ICRSV-free plants (36.84%) was obtained by grafting the tips (0.7 mm) taken from the nodal segments treated at 50°C in the water bath for 120 min. With treatment of 1 year old infected plants, a maximum of 60% ICRSV-free plants could be obtained by grafting the tips (0.7 mm) from plants treated at 40°C. Plants/plantlets negative to both ELISA and RT-PCR assays were considered as virus-free (Fig. 10.1) (Sharma et al. 2008).

Thermotherapy coupled with shoot-tip grafting technique was applied for the elimination of *Apple chlorotic leaf spot virus* (ACLSV), *Apple stem pitting virus* (ASPV), *Apple stem grooving virus* (ASGV), *Apple mosaic virus* (ApMV), and *Apple scar skin virus* (ApSSV) from apple plants infected by one or more viruses. The mixed infections were detected by RT-PCR assay in 95.8% of the potted apple plants of four cultivars, and these plants were subjected to thermotherapy (37 + 1°C) followed by shoot-tip grafting. The sprouts of cultivar Dahongrong (DHR) and Qiyuetianxian (QYT) were inhibited by high-temperature treatment. However, some buds of these cultivars were able to sprout and grow slowly. The survival rate of shoot tips cut after thermotherapy was 41.2% (61/148). The survival rate of DHR (63.2%) was highest among the four cultivars tested. An average virus elimination rate of 65.6% (40/61) for new leaves and 37.7% (23/61) for dormant branches was attained. The results indicated that the virus detection and elimination was more difficult in the dormant branches than in actively growing plants (Hu et al. 2015).

Sweet potato plants are infected by many viruses; infection by *Sweet potato feathery mottle virus* (SPFMV) is more frequently observed in various countries. Apical cuttings (65, each 15 cm in length) from the cultivar Abees plants were collected and tested for the presence of SPFMV using spot-ELISA test. The cuttings were found to be infected by SPFMV and kept under controlled glasshouse conditions. Infected plants were

subjected to thermotherapy (42°C by day and 39°C by night for 3 weeks). Meristem-tip culture method was followed and regenerated plants were grown in vitro. Of the 65 nodal cuttings infected by SPFMV, 62 were found to be virus-free after thermotherapy and meristem-tip culturing. RT-PCR assay was employed to ensure freedom of rooted plantlets from SPFMV virus (Fig. 10.2). The tissue-culture-generated plants were tested for two successive years using dot-ELISA format and the plants remained virus-free under in vitro conditions (El-Far and Ashoub 2009).

A system of production of virus-free lilies involving repeated shoot meristem excision, before and during in vitro culture and thermotherapy applied to bulblets in vitro, was developed. *Lily symptomless virus* (LSV) causes no distinct symptoms, but decreases plant growth, vigor, and the quality of cut flowers. Stock bulbs of pollenless Asiatic hybrid lily (*L. x elegans*) lines (499 and 599) were used as explants. Excised shoot meristems were micropropagated. In vitro grown bulblets were subjected to thermotherapy at 35°C for 42 days and a second meristem cut was made from heat-treated material. Leaf tissues from bulblets formed prior to post-heat treatments were tested by ELISA test or RT-PCR assay. Line 499 produced LSV-free plants without heat treatments. On the other hand, heat treatment was needed to eliminate LSV from line 599. The amplified banding patterns after electrophoresis in agarose gel followed by staining with ethidium bromide revealed the absence of the virus-specific band in line 499 after first meristem isolation. The virus-free bulblets grew vigorously in vitro and acclimatized well. Thermotherapy applied to in vitro growing bulbs might effectively eliminate the virus, resulting in the production of fast-growing mother plant stocks (Nesi et al. 2009).

Standard thermotherapy employed to eliminate *Potato virus X* (PVX) from potato (*Solanum tuberosum*) microplants of the Mexican National Potato Program was modified to improve the effectiveness of thermotherapy. Microplants were cultured with or without 10^{-5} M salicylic acid (SA) for 4 weeks, then subcultured without SA and exposed to 42°C for 30 days. Survival was more consistent in SA-treated microplants. Among seven genotypes, 40–100% of SA-treated plants and 0–96% of controls survived at the end of thermotherapy. In addition, SA also improved survival of post-thermotherapy subculture. Among the surviving microplants, SA increased the yield of virus-free microplants up to 100% as against 40–65% in the controls. Further, 98% of the surviving SA-treated microplants of 30 PVX-positive genotypes became free of PVX after thermotherapy treatment, compared to 75% of virus-free control plants. Assessment of physiological activities of SA-treated microplants indicated that SA treatment induced higher hydrogen peroxide levels, while catalase activity was reduced by SA treatment (López-Delgado et al. 2004).

Auxins or antiviral chemicals have been applied to virus-infected plants to accelerate stem elongation or to inactivate the virus to obtain virus-free plants. Sweet potato plants infected by leaf spotting, internal cork, and feathery mottle viruses were treated with a combination of kinetin and indole acetic acid (IAA). The meristems of treated plants elongated at a rate faster than the virus could invade newly formed tissues, providing a longer piece of meristem free of virus (Alconero et al. 1975). Among the several antiphytoviral chemicals tested, ribavirin (also known as virazole, 4(5)-amino-1H-1,2,3-triazole-5(4)-carboximide) was found to show higher inhibitory activity against many animal and plant viruses (Matthews 1991). A combination of thermotherapy and incorporation of ribavirin as a component of growth medium in which the apical meristem was grown enhanced the effectiveness of virus elimination. This approach

Figure 10.2 Efficiency of hot water treatment (HT) in eliminating *Xanthomonas fragariae* from strawberry plants. (a) Survival of plants (percentage) after different periods of heat treatment (min) at 44°C and 48°C; (b) average number of runners in survivors after HT; and (c) average number of flower trusses formed in plants exposed to HT. was adopted for the successful elimination of *Peanut stripe virus* (PStV) and *Tomato spotted wilt virus* (TSWV) from peanut plants (Dunbar et al. 1993). A similar approach was successfully applied for the elimination of *Potato virus S* (PVS) from potatoes. However, seven subcultures were required to eliminate PVS from the potato cultivar Red Pontiac. The potato plantlets were free of PVS, as revealed by ELISA tests. The combined treatment of thermotherapy and chemotherapy demonstrated a synergistic effect on virus elimination (Park et al. 1994; Kim et al. 1996).

Carnation latent virus (CLV) remains latent in several carnation cultivars, but causes considerable loss in yield and quality. CLV induced distinct chlorotic spots and/or mosaic mottling in the carnation cultivar Scania. The infected plants were placed in the heat therapy chamber at $35 \pm 2^\circ\text{C}$ and $40 \pm 2^\circ\text{C}$ for 1, 2, 3, and 4 weeks. Axillary bud explants from the heat-treated and untreated plants were cultured on MS medium. Regenerated plants were indexed by indirect ELISA and indicator plants. The survival of plants had a negative correlation with temperature treatment. Plants exposed to $35 \pm 2^\circ\text{C}$ for 4 weeks and those treated at $40 \pm 2^\circ\text{C}$ for 3 weeks were freed from CLV. ELISA tests confirmed the virus-free nature of these carnation plants following thermotherapy (Mangal et al. 2004).

Plum pox virus (PPV) causes the sharka disease, which is considered to be one of the most devastating virus diseases of plum in many countries in the Europe. One of the preventive measures suggested for the management of PPV is the use of virus-free planting materials to establish healthy orchards. Different methods such as meristem-tip culture and thermotherapy have been applied to produce virus-free planting materials. The effectiveness of chemotherapy in vitro with ribavirin to produce PPV-free plum plants (*Prunus domestica* cultivar Cacanska Lepotica) was evaluated. The infected shoots were multiplied in MS medium amended with different concentrations of ribavirin for 6 weeks. Regenerated and rooted plants were grown under greenhouse conditions for 2 years. The plants were tested by DAS-ELISA and IC-RT-PCR assay for the presence of PPV. Chemotherapy with ribavirin at 4 and 6 mg L^{-1} was effective in producing PPV-free plants to the extent of 15.38 and 16.66%, respectively. Phytotoxicity symptoms due to higher concentrations (80 and 100 mg L^{-1}) were observed. The DAS-ELISA test was less efficient in detecting PPV in ribavirin-treated plantlets, and IC-RT-PCR assay could detect PPV in several ELISA-negative plantlets (Paunovic et al. 2007).

10.3.1.2 Chemotherapy

Potato viruses *Potato virus A* (PVA), *Potato virus M* (PVM), *Potato virus S* (PVS), *Potato virus X* (PVX), *Potato virus Y* (PVY), and *Potato leafroll virus* (PLRV) were present in potato plantlets singly or in a mixture of *Potato virus M*, PVS, and PVY. Infected plantlets were raised in the MS medium amended with different concentrations of ribavirin (0 – 200 mg L^{-1}), an antiviral chemical. Phytotoxicity due to ribavirin increased with increasing concentration of the chemical, as reflected by plant height and fresh weight of treated plantlets. At the maximal concentration (200 mg L^{-1}), the plantlets could not survive. Ribavirin was more efficient in eliminating PVA, PVM, PVS, and PVX than PVY and PLRV, as revealed by ELISA tests. Healthy plantlets could be generated with high frequency (up to 100%) by culturing the plantlets in the MS medium containing 75 – 150 mg L^{-1} ribavirin after 2–3 subcultures. On the other hand, PVY- and PLRV-free plants could be obtained by using ribavirin at 75 – 150 mg L^{-1} in the medium for growing plants after three subcultures. Reduction in virus content following ribavirin treatment

was indicated by quantitative RT-PCR (qPCR) analysis. Healthy seedlings could be generated from infected stocks at the first or end of propagation and no virus could be detected at the post-eradication stage. No genetic variation in plantlets could be discerned in ribavirin-treated plantlets. The results indicated the possibility of eliminating viruses from potatoes for the propagation of virus-free planting materials using antiviral chemicals (Yang et al. 2014).

10.3.1.3 Electrotherapy

Electrotherapy is a simple method of virus eradication without the need to use any special or expensive equipment. In this technique, an electric current is applied to plant tissues in order to disrupt or degrade viral nucleoprotein and eliminate its pathogenic potential. This technique was first comprehensively employed for the elimination of *Potato virus X* (PVX) from potato plants. Potato stems infected with PVX were treated with electrical current at 15 milliamperes (mA) for 5 min and the axillary bud tips planted in growth medium in vitro immediately. The tissue temperatures in treated stems increased from 4 to 10°C during exposure to electric current. The therapy efficiency was determined as the product of percentage of virus-free plants after a 60 day growing period in vitro. Both organogenesis and virus elimination were stimulated by electrotherapy. The treatment resulted in 40–80% regeneration of buds and 60–100% of the regenerated plantlets were free of PVX (Lozoya-Saldaña et al. 1996).

Successful elimination of several viruses such as *Potato virus X*, *Potato virus Y*, *Potato virus A*, *Potato virus S*, and *Potato leafroll virus* (Pazhouhande and Mozafari 2001), *Onion yellow dwarf virus*, and *Leek yellow stripe virus* from garlic (Hernández et al. 1997) and *Banana streak virus* from banana (Hernández et al. 2002) using electrotherapy procedure, has been reported. *Bean common mosaic virus* (BCMV) is a major seed-transmitted virus infecting common bean (*Phaseolus vulgaris*). Production of BCMV-free seeds is the basic requirement for certification of seeds.

The efficiency of electrotherapy in eliminating BCMV and producing virus-free plants of two common bean cultivars Khomein and Capsouli was evaluated. Nodal cuttings of infected plants were exposed to electric currents of 5, 10, and 15 mA for 10 min. The cuttings were cultured in test tubes containing MS5 medium. The test tubes were maintained in a growth chamber under light conditions of 16 h light and 8 h darkness at 23–25°C. One month old regenerated plants were indexed by DAS-ELISA test for the presence of BCMV. The three intensities of electric current resulted in mean virus elimination percentages of 37.2%, 45.5%, and 71.9% and mean plant regeneration of 79.5%, 68.6%, and 58.4%, respectively. The therapy efficiency index (TEI) for three electrotherapy treatments was determined to be 28.9, 29.2, and 39.1 in cultivar Khomein and 26.9, 33.3, and 44.8 in cultivar Capsouli. The results showed that the electric current of 15 mA for 10 min most effectively eliminated BCMV from both common bean cultivars tested. Regenerated plants after exposure to electrotherapy were morphologically identical to those regenerated from nontreated control explants. Electrotherapy was found to be more effective, simpler, faster, easier, and less demanding than other techniques applied for elimination of viruses from seeds (Hormozi-Nejad et al. 2010).

10.3.1.4 Cryotherapy

Cryopreservation of shoot tips is a process in which shoot tips are exposed to ultra-low temperature, stored, and regenerated for multiplication. A critical step in this process is dehydration of cells before immersing tissues into liquid nitrogen. Crystallization of

intracellular water inside cells damages them lethally, because the crystals penetrate membrane structures. In cryotherapy, lethal injury of cells during cryotreatment is utilized to kill infected tissues/cells that are located far from the apical dome (AD), as they are more likely to be infected by viruses or phytoplasmas and are more sensitive to injury than the cells that are located in the meristematic zone of AD. Cells in the AD and in the first-leaf primordia are therefore likely to survive and regenerate into pathogen-free shoots. Consequently, a larger proportion of plants regenerated following cryotherapy may become pathogen-free than what could be obtained through traditional meristem culture. The effectiveness of cryotherapy may be due to enhancement of pathogen eradication by combining with thermotherapy of shoots before excision of shoot tips. Cryotherapy provides an alternative, efficient strategy for eradication of plant pathogens in many crops. Cryopreserved shoot tips may be considered to be safer for exchange of germplasm between countries and regions within a country, since the cryogenic methods may reduce the amount of viable infected tissues (Panis et al. 2005; Wang et al. 2008b).

Banana crops are seriously affected by *Cucumber mosaic virus* (CMV) (genus *Cucumovirus*) and *Banana streak virus* (BSV) (genus *Badnavirus*), reducing the fruit yield significantly. Cryotherapy by vitrification was applied to eradicate CMV and BSV from in vitro cultures of meristematic clumps of desert banana cultivar Williams. The regenerated plantlets were free of CMV and BSV up to 30% and 90%, respectively (Helliot et al. 2002). *Plum pox virus* (PPV), causative agent of the most destructive sharka disease, infects stone fruits of *Prunus* spp., including plum, peach, almond, nectarine, sweet cherry, and sour cherry. By using cryotherapy, virus-free plants were generated from in-vitro-grown shoot tips taken from inoculated plants. A vitrification protocol was applied for elimination of PPV. Virus-free plants were obtained with high frequencies (45–60%), regardless of the size of the shoot tips used. Larger shoot tips (0.5–2.0 mm) had better regrowth (56–70%) as against the regrowth of 11% with smallest shoot tips (0.3–0.5 mm) (Brison et al. 1997).

Notable success in eradicating viruses from infected plants has been reported in grapevine and raspberry plants. *Grapevine virus A* (GVA) could be eliminated from cultivar Bruti. About 96% of plants regenerated from cryotreated shoot tips were virus-free, while only a low percentage of plants (12%) could be freed from GVA by following meristem-tip culture method (Wang et al. 2003). It was difficult to eliminate *Raspberry bushy dwarf virus* (RBDV) from infected plants by thermotherapy. By combining thermotherapy of RBDV-infected shoot cultures with by cryotherapy of shoot tips excised from heat-treated shoots, RBDV could be eliminated from plantlets up to 33–35% (Wang et al. 2008a).

Potato virus Y (PVY) (genus *Potyvirus*) and its strains and *Potato leafroll virus* (PLRV) (genus *Polerovirus*) occur in most potato-growing countries around the world, and they are important factors limiting production. Three cryogenic procedures (encapsulation-dehydration, encapsulation-vitrification, and droplet-vitrification) were employed to eliminate PVY and PLRV. Naturally doubly infected plants were treated with the cryogenic methods. Both viruses were efficiently eradicated by all three procedures resulting in 83–86% and 91–95% plants free of PLRV and PVY respectively, with no significant differences in their efficacy (Wang et al. 2006). Sweet potato feathery mottle virus (SPFMV) belonging to the genus *Potyvirus* (transmitted by aphids) infects all types of tissues of sweet potato. *Sweet potato chlorotic stunt virus* (SPCSV) belonging to the genus *Crinivirus* (transmitted by whiteflies) is restricted to the phloem tissue of

infected sweet potato plants (Wang and Valkonen 2008b). These two viruses are found to infect sweet potato plants simultaneously causing the complex sweet potato virus disease (SPVD), the most serious limiting factor for production (up to 90% losses) (Mukasa et al. 2006). As sweet potatoes are clonally propagated, the need for using virus-free planting materials was realized. Shoot tips (0.5–1.5 mm) from sweet potato plants infected by SPFMV or SPCSV singly or in combination and treated by cryotherapy were propagated in MS medium. These two viruses could be eradicated from all (100%) shoots by cryotherapy treatment. On the other hand, meristem-tip culture produced only 7–10% SPFMV-free regenerants from the coinfecting plants (Wang and Valkonen 2008b; Section 10.4.1).

10.3.2 Production of Viroid-Free Plants

Viroids are transmitted through seeds and propagules, as for plant viruses. They may coinfect plants along with viruses, causing complex symptoms. The presence of viroids in seeds and propagules may be detected by various techniques described elsewhere (Chapter 7), and the infected seeds and planting materials can be freed of the viroids to obtain viroid-free nuclear stocks by eliminating infected mother plants. The presence of *Potato spindle tuber viroid* (PSTVd) in the propagating materials may be detected by inoculating an intermediate tomato plant to amplify PSTVd to enhance the analytical sensitivity of detection based on the PAGE technique (Morris and Smith 1975). Return gel electrophoresis (RGE) was more effective in detecting PSTVd in potato true seeds and was comparable with or superior to the nucleic acid hybridization procedure (Singh et al. 1988).

Citrus spp. infected by different viroids and mixed infections by two or more viroids have been observed. Sequential polyacrylamide gel electrophoresis (sPAGE) method was effective in detecting *Citrus exocortis viroid* (CEVd), *Citrus viroid II* (CVd-II), and *Citrus viroid III* (CVd-III) in the extracts of young bark tissues. CEVd, CVd-II and CVd-III were detected during warm season (June to November), but CEVd could also be detected in other months (Tessitori et al. 1996). The sPAGE technique was successfully applied for the detection of *Hop stunt viroid* (HSVd), CEVd, and *Citrus viroid III*. Two or more viroid-like RNAs with similar electrophoretic mobility as CEVd, *Citrus bent leaf viroid* (CBLVd), HSVd, CVd-II, and/or CVd-III were also detected. The sPAGE detection results were similar to those obtained with Northern and dot-blot analyses. The techniques had the potential to eliminate infected source plants and select healthy mother plants for propagation of planting materials (Malfitano et al. 2005). Northern blot hybridization procedure was applied for the detection of *Citrus exocortis viroid* (CEVd), *Citrus bent leaf viroid* (CBLVd), *Hop stunt viroid* (HSVd), *Citrus viroid III* (CEV-III), and *Citrus viroid IV* (CVd-IV) in inoculated Etrog citron used as biological indicator (Barbosa et al. 2005). A total of 113 samples from commercial citrus orchards and nurseries were tested. Washington Navel and Naveline oranges (11 of 32) were found to be infected by CTV, whereas Clementine trees (4) were infected by *Citrus infectious variegation virus* (CIVV). All of these virus-infected trees were also coinfecting by HSVd, and 50% were also infected by *Citrus exocortis viroid* (CEVd) (Barbosa et al. 2007).

Tissue-printing hybridization (TPH) technique was effective in detecting viroids infecting stone fruit trees. Of the 352 stone fruit samples tested, 88 were found to be infected by viroids. *Peach latent mosaic viroid* (PLMVd) infection was detected in

61 peaches and apricots. The remaining 27 samples showed infection by *Hop stunt viroid* (HSVd). Mixed infection by PLMVd and HSVd were detected in two samples. The TPH assays provided a relatively clear assessment of the sanitary status of stone fruit crops in Turkey (Gümüş et al. 2007). In another investigation, tissue-printing hybridization (TPH) was demonstrated to be effective for the detection of *Apple scar skin viroid* (ASSVd) and *Pear blister canker viroid* (PBCVd) in field-grown plants. Using nonradioactive probes specific to the respective viroids, all three viroids were effectively detected by TPH as well as by dot-blot hybridization techniques in experimentally inoculated apple plants. Each probe hybridized strongly and exclusively with the complementary viroid RNA. Petioles collected from apical parts of the shoots reacted by producing the best TPH signals, suggesting that petioles of young leaves are most suitable tissue for detection of viroids and differentiation of viroids by TPH procedure (Lolic et al. 2007).

Peach latent mosaic viroid (PLMVd) and *Hop stunt viroid* (HSVd), both belonging to the family Pospiviroidae, were listed as quarantine pathogens by EPPO because of the heavy losses caused by them. An optimized RT-PCR protocol was developed for detecting PLMVd and HSVd that was suitable for a certification system in operation in the Czech Republic. The primers employed for detection of the viroids were specific and sensitive, capable of detecting nucleic acid equivalent to 10 ng of leaf tissue. PLMVd was detected in several peach cultivars of different ages (5–12 years). HSVd was also detected in leaves, petioles, and bark tissues obtained from field-grown cultivar NJC103 plants (Hassan et al. 2004). RT-PCR assay was efficient in detecting PLMVd in peach and pear trees, HSVd in pear, peach, and almond trees and *Pear blister canker viroid* (PBCVd) in pear trees. Mixed infections of pear with PBCVd + HSVd and PLMVd + HSVd were detected. This protocol had the potential for use in routine indexing of plants and planting materials in certification programs (Hassani et al. 2006).

10.3.3 Production of Bacterial and Phytoplasmal Pathogen-Free Plants

Seeds and planting materials carry a large number of bacterial pathogens. They may reduce the seed quality and germination capacity and seedling vigor. Depending on the extent of seed-to-plant transfer, they are capable of causing significant losses; infected plants growing from infected seeds/propagules may become potential infection foci for a secondary spread of the disease(s). Different heat treatments have been applied for the elimination of bacterial pathogens from seed, although the seed germination is affected to varying degrees. A combination of seed dry heat treatment and thermotherapy of seedlings followed by meristem- and shoot-tip culturing was evaluated for elimination of common and halo blight pathogens *Xanthomonas campestris* pv. *phaseolicola* (*Xcp*) and *Pseudomonas syringae* pv. *phaseolicola* (*Psp*) from bean seeds that form the primary sources of inoculum for these diseases. The bean seeds exposed to dry heat at 47–48°C for 3 days had significant reduction of germination. However, the contamination rate of explants excised from seedlings of dry-heat-treated seeds and cultured for 3 weeks in MS medium was significantly lower than that recorded in seedlings of untreated seeds. Seedlings growing from heat-treated seeds were exposed to thermotherapy for 10–14 days at 37°C. Meristem- and shoot-tips from plants that were exposed to thermotherapy treatment were cultured. The bacterial pathogens *Xcp* and *Psp* were eliminated effectively from bean seeds. Although common bean was recalcitrant in culture, the regeneration of shoots and transfer of a few plantlets for acclimatization was successfully accomplished.

Tissue cultures showed lower levels of bacterial contamination because of the dry heat treatment of seeds and thermotherapy of seedlings grown from heat-treated bean seeds, resulting in the elimination of *X. campestris* pv. *phaseoli* and its fuscous variant (Grum et al. 1998).

Citrus huanglongbing (HLB) disease occurs in more than 40 countries in Asia, Africa, and the Americas and is reported to be caused by three different bacterial species, namely "*Candidatus Liberibacter asiaticus*," "*C. L. africanus*," and "*C. L. americanus*." The HLB pathogen could be eliminated from infected in vitro plantlets by cryotherapy of shoot tips and HLB-free plants were produced at a frequency of 98%. Cryotherapy of shoot tips of sweet orange accession Luogang (*Citrus sinensis*), mandarin Ponkan (*C. reticulata*), Shatianyou Pumelo (*C. grandis*), and Beijing lemon (*C. limon*) resulted in production of almost all regenerated plants being HLB-free to the extent of 93%, 93%, 94%, and 91% respectively, indicating the effectiveness of cryotherapy in eradicating this important citrus pathogen (Ding et al. 2008).

Pecan (*Carya illionoinensis*) bacterial leaf scorch (PBLs) disease caused by *Xylella fastidiosa* (Xf) reduced the nut yield significantly when the disease became persistent for several years in the infected trees. Graft transmission through infected scion wood is one of the principal modes of Xf transmission, because pecan cultivars are clonally propagated. Submersion of pecan scion wood in 46°C for 30 min reduced transmission of Xf to a great extent following grafting. During a 2 year investigation, potted rootstock was grafted to either hot-water-treated or nontreated scion wood collected from limbs of "Cap Fear" pecan infected with Xf. The pathogen was detected in 21% of the trees that developed from nontreated scion wood and 0.7% of the trees from hot-water-treated scions. Only 1 of the 140 trees produced from hot-water-treated scions was infected with Xf. Hot water treatment (46°C for 30 min) did not affect graft success and the scion diameter did not affect graft establishment or efficiency of the hot water treatment. No increase in the number of pecan plants showing symptoms in plants grafted with hot-water-treated scion was observed during the 2 year period (2005–2006). The results indicated that hot water treatment of scion wood material was very effective in reducing transmission of PBLs disease through scion wood. Elimination of Xf infection was also successfully achieved in grapevine (Sanderlin and Melanson 2008).

Xanthomonas fragariae, incitant of strawberry angular leaf spot disease and listed as an A2 quarantine pathogen, affects nursery production seriously. This pathogen is transmitted to production fields almost exclusively through infected nursery stock. As the pathogen is absent from European countries, nurseries have to maintain specific phytosanitary standards to avoid rejection. Planting materials should be derived from mother plants certified free of *X. fragariae*. The effectiveness of heat treatment for killing or reducing the number of viable bacterial cells in the crown tissue was assessed. Plants were treated by immersing them in hot water at 44 or 48°C for 0, 60, 120, 180, and 240 min. The plants were then potted after thermotherapy treatment and rated for growth characteristics. Results showed that bacterial populations in cultures exposed to 56°C and 52°C were killed completely after 15 min and 60 min of exposure, respectively; however, both treatments killed the plants. Bacterial populations exposed to 44°C for 4 h or 48°C for 2 h were reduced by 10^5 or 10^6 CFU mL⁻¹. These treatments minimally affected vegetative growth of plants bagged dry (sealed in plastic bag which was immersed in water). Flowering in treated plants was adversely affected. These heat treatments were applied for several cultivars in field trials established in two locations in successive years. The survival rate among cultivars was similar to that observed in

Table 10.1 Effect of heat treatments on survival of strawberry plants infected by angular leaf spot disease under field conditions (Turechek and Peres 2009).

^a For each cultivar, treatments were 44°C for 4 h bagged dry, 48°C for 2 h bagged dry, or an untreated control (UTC); ^b Mean number of plants per plot (maximum = 20) surviving heat treatment; ^c Least square means (LSM) are derived from the interaction of cultivar treatment; means followed by the same letter are not significantly different from each other.

greenhouse trials. The thermotolerant cultivars might be considered for heat treatment to reduce the pathogen population to acceptable levels and consequent reduction in disease incidence (Table 10.1). However, careful attention should be paid to monitoring the disease development in the strawberry cultivar(s) selected for raising nurseries (Turechek and Peres 2009).

Phytoplasmas cause several important diseases affecting many crops, especially horticultural and floricultural plants. The infected asexually propagated plant materials are the primary sources of inoculum and carry the infection to subsequent generations if the planting materials are not properly indexed and healthy materials are not selected for planting. Budwood materials, setts, and tubers therefore have to be thoroughly indexed for the presence of phytoplasmas by employing efficient and sensitive techniques. Among the phytoplasmas infecting potatoes, phytoplasmas causing potato purple top (PPT), potato witches' broom (PWB), and potato stolbur diseases are important and occur in North and South America and eastern Europe. Eight batches of seed potatoes collected from different locations were planted under glasshouse conditions. A total of 625 plantlets were indexed as they were asymptomatic. Nested PCR assay of both single and grouped samples with general ribosomal primers without spacer region allowed detection of phytoplasmas. Phytoplasmas belonging to diverse ribosomal

groups were identified after RFLP analysis. Ribosome subgroups 16 SrII-D (related to stolbur) were identified in different percentages. The protocol used in this investigation reflected OEPP/EPPO 2004, which was found to be reliable and sensitive for the elimination of phytoplasma-infected seed tubers when the plantlets growing from them were asymptomatic which might escape visual examination. Nested PCR could be employed to screen potato seed tuber lots for high-quality seed potatoes (Paltrinieri and Bertaccini 2007).

Phytoplasma-free plants could be obtained by the stem culture technique. Mulberry stem segments of nursery plants infected by dwarf phytoplasma were cultured on MS medium for 2–3 months. The regenerated plants were grown in the greenhouse for 3 years and then indexed by employing PCR assay, DAPI staining, and visual examination for the development of disease symptoms. A high percentage of regenerated plants (70–80%) were found to be free of mulberry dwarf phytoplasma (Dai et al. 1997). Elm yellows (EY) disease occurring in North America and Europe are caused by different strains of the phytoplasma. The effectiveness of hot water treatment (HWT) on the elimination of EY phytoplasma was assessed using an experiment device at $50 \pm 0.5^\circ\text{C}$ for 45 min. The plants were forced in the climatic chamber. None of the treated plants developed any adverse effects due to treatment, and they showed earlier bud-burst and better growth characteristics. None of the plants revealed the presence of EY phytoplasma in PCR assay. Plants grown from cuttings taken from EY-infected clones soaked in hot water (50°C for 45 min) did not develop disease symptoms and tested negative for EY phytoplasma. In contrast, untreated control plants developed disease symptoms and were EY-positive in PCR assay. The results showed that HWT was effective in eliminating EY phytoplasma (Boudon-Padieu et al. 2004).

Sugarcane grassy shoot disease (SGSD) is caused by the phytoplasma which is classified as a member of the 16Sr XI-B group. The disease may become severe in ratoon crops if the planting materials (setts) are not prepared from healthy mother plants. Sugarcane setts are traditionally treated by different thermotherapy methods involving the use of hot air, hot water, or aerated steam to inactivate/reduce the pathogen inoculum. The effectiveness of apical meristem culture technique for producing phytoplasma-free planting material was assessed. Apical meristems (2, 3, and 4 mm) were aseptically excised and placed on the MS medium amended with benzylaminopurine (BAP) and kinetin. The developing shoots were subcultured at weekly interval and transferred to multiplication medium. Freedom from GSD phytoplasma was verified using PCR assay and those free of the phytoplasma were multiplied and transferred to pots in the greenhouse. The elimination frequency of the phytoplasma was 80% and 60% for plantlets derived from 2 mm and 3 mm meristems at the first multiplication stage, respectively. The results showed that GSD phytoplasma could be effectively eliminated from planting materials by employing meristem culture techniques (Tiwari et al. 2011).

Grapevine flavescente dorée (FD) phytoplasma, causing flavescente dorée (FD) disease of grapevine, is an EU listed A2 pathogen as included in Annexe II/A2 of the EU Plant Health Directive (2000/20/EC) and as an EPPO A2 Pest recommended for regulation as a quarantine pest. Two types of hot water treatment have been applied as prophylactic and quarantine measures for grapevine propagation material for all countries in the world. A short duration of hot water treatment at 52°C for 5 min was used against the external pathogens. A long-duration hot water treatment was recommended for both external and internal pathogens such as FD pathogen. Hot water treatment may result in a loss of varying quantities of treated planting materials. The planting materials

have to be placed at room temperature (for 12–24 h) both prior to and after hot water treatment at 50°C. After completion of hot water treatment, the treated planting materials should be grafted onto healthy plants. Hot water treatment against FD phytoplasma was found to be a reliable technique and was mandatory for all basic propagation materials in France and Australia (Ministère de l'Agriculture, France 2003; ICA 2007).

Another phytoplasma disease caused by the Bois Noir (BN) phytoplasma is one of the most widespread yellows diseases in grapevines in European and Middle Eastern countries. Propagation of infected plants by nurseries widely contributed to the introduction and spread of BN disease in locations that had previously been free of the disease. The strategy of producing phytoplasma-free planting materials therefore assumed greater importance for the management of BN disease. The efficiency of procedures using tissue culture techniques associated with or without heat treatment or hot water treatment was evaluated for producing phytoplasma-free vines cultivar Chardonnay. Nested PCR assay was employed to ensure the presence or absence of BN phytoplasma in the infected grapevine plants from which young shoots were taken for hot water treatment, and also in shoots derived from tissue cultures. Stem cuttings with or without thermotherapy at $38 \pm 1^\circ\text{C}$ for 4 days were used for culturing. Young shoots (0.4–0.5 mm in diameter) were excised from single-node stem cuttings and grown in MS medium. The nested PCR assays at the end of the first subculture showed sanitation rates varying over 36–100%. All tested shoots regenerated from the stem cuttings treated in hot water bath at 50°C for 15 or 30 min were phytoplasma-free, whereas the sanitary rates dropped to 76% for the shoots regenerated from stem cuttings exposed to heat treatment. In the case of shoots regenerated from shoot tips, heat treatment increased the sanitation rate from 36% to 76%. The second nested PCR assays carried out at the end of the third subculture (after 120 h of culture) revealed the absence of BN phytoplasma in the shoots that were negative in the first test. The hot water bath treatment for 15 min only was also effective in eliminating the BN phytoplasma. Despite the lower explants survival rate at the beginning, hot water treatment was considered as the most efficient sanitation technique since it yielded 100% BN-free shoots. The protocol based on tissue culture followed by micropropagation of sanitized explants appeared to be a good candidate for producing phytoplasma-free vines for certification programs (Chalak et al. 2013).

Sweet potato little leaf phytoplasma (SPLL) pathogen "*Candidatus* Phytoplasma aurantifolia" causes the devastating disease of sweet potato (*Ipomoea batatas*) in several countries. As the crop is clonally propagated, typically using shoot cuttings and also storage roots, the efficiency of cryotherapy for production of phytoplasma-free plants from sweet potato stocks infected with SPLL disease was assessed. Shoot tips (3–4-leaf primordia) were excised from in vitro grown sweet potato plants. Survival (88%) and regrowth (85%) of the shoot tips after cryotherapy was slightly less when compared to control (untreated) treatments. However, no phytoplasma was detected in any of the regenerated shoots. PCR amplification products (c. 1.8 kb) of the expected size for SPLL pathogen was not observed in these regenerated plants (Fig. 10.3). In contrast, phytoplasmal bodies were readily observed in the control untreated plants and all the shoot tips of stock cultures. The phytoplasma-free plants obtained by cryotherapy and grown in the greenhouse had a normal appearance, good growth, and large storage roots, as for the original pathogen-free clone (199004-2). Histological and ultrastructural studies with light and transmission electron microscopy (TEM) indicated that cryotherapy was lethal to all cells except those in the apical dome of the meristem and the two youngest

Figure 10.3 Detection of sweet potato little leaf phytoplasma in *in vitro* shoot cultures by PCR assay after cryotherapy. (a, b) Lane M: DNA ladder; lane P: positive control; N: negative control; lanes 1–4: presence of c. 1.8 kb product in (a) and absence of this product from (b) indicating the effective elimination of the pathogen in cryotherapy-treated shoot cultures. leaf primordia. The surviving parts of the shoot tip contained vascular tissue and sieve elements, but TEM observations did not reveal any phytoplasmal bodies in them. In contrast, abundant phytoplasmal cells could be located at the lower nonsurviving parts of shoot tip 1.5–2.5 mm from the apical dome (Fig. 10.4). In the greenhouse, the plants treated with cryotherapy had vigorous growth that was distinctly different from that of the plants from untreated shoot tips. Cryotherapy provided an alternative tool for elimination of phytoplasmas from infected planting materials. In addition, this procedure could be of use for long-term storage of sweet potato germplasm, facilitating safe international movement of germplasm as cryopreserved stocks (Wang and Valkonen 2008b; Section 10.4.1).

10.4 Appendix

10.4.1 Elimination of Sweet Potato Little Leaf Phytoplasma from Sweet Potato by Cryotherapy of Shoot Tips (Wang and Valkonen 2008b)

10.4.1.1 Preparation of Plant Materials

- i) Surface-sterilize young shoots from plants grown under greenhouse conditions with sodium hypochlorite solution (1%) for 10 min; wash three times with sterile distilled water and blot on filter paper to remove excess water.
- ii) Excise single buds (0.5 cm in length); grow in 9 cm petridishes containing solid survival medium (SM) consisting of basic medium (BM) supplemented with 2.2 μ M benzylaminopurine (BAP); the basic medium composed of Murashige-Skoog medium (MS) inorganic medium supplemented with 88 mM sucrose, 0.62 mM calcium nitrate, 1.1 mM ascorbic acid, 0.4 mM calcium pantothenate, 0.12 mM putrescine dihydrochloride, 0.57 mM L-arginine and 0.24 Gelrite (Merck), and adjust the pH to 6.0 with NaOH prior to autoclaving at 121°C for 20 min.

(a)

Figure 10.4 (a) Visualization of sweet potato little leaf phytoplasma in TEM cross-sections of shoot tips taken at different positions of leaf primordia of plantlets after cryotherapy. (b, e) Cross-sections of leaf primordia closer to the apical dome (AD) show the elimination of the phytoplasma; (c, d, f) cross-sections of leaf primordia away from AD show partial or lack of effectiveness of cryotherapy; and (c, d, f, g) phytoplasma cells are indicated by arrows. Source: Wang and Valkonen (2008a). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

- iii) Grow the developing tissue culture at $22 \pm 2^\circ\text{C}$ under a 16h photoperiod by using cool-white fluorescent tubes.
- iv) Micropropagate plantlets by growing on shoot multiplication medium (SMM) composed of BM containing $29\mu\text{M}$ gibberellic acid and subculture the stock cultures once every 3 weeks.

10.4.1.2 Cryotherapy of In-Vitro-Grown Shoot Tips

- i) Excise shoot tips (1 mm long) containing 3–4-leaf primordia (LP) from 3 week old in vitro stock cultures and freeze in liquid nitrogen for 1 h; warm the beads that form by dropping shoot tips in sodium alginate solutions into calcium chloride solution in a water bath at 40°C for 3 min and wash with liquid ammonium-free MS supplement with 1.2 M sucrose for 20 min.
- ii) Surface dry the shoot tips by blotting on cellulose tissue; post-culture the beads for survival on ammonium-free SM in the dark for 3 days; transfer to fresh SM and culture under light conditions as provided for stock cultures.
- iii) After 2 weeks of post-culture, transfer the surviving shoot tips to SMM for shoot regrowth and express the regrowth as the percentage of shoot tips regenerating to normal shoots at 2 months after post-culture.
- iv) Subculture regenerated shoots once every 3 weeks; after 4–5 subcultures on SMM, observe for the formation of whole plantlets with well-developed roots and transfer the cryotherapy-treated in vitro plantlets to soil and establish under greenhouse conditions.
- v) Test the plantlets for the presence of the phytoplasma using polymerase chain reaction (PCR) to assess the extent of elimination of the pathogen.

Crop Disease Management

Reduction of Pathogen Inoculum

Plant disease management systems include reduction of pathogen inoculum through cultural practices and physical and chemical techniques as the initial strategy for restricting disease incidence and spread. Successful and profitable cultivation of crops depends on several factors, among which use of disease-free seeds and planting materials is the basic requirement. This aspect of disease management was discussed earlier in Chapter 10, where the various methods of producing disease-free seeds and propagules that may be useful for certification and quarantine programs were described. In addition to using disease-free seeds and propagules, field sanitation is important for reducing/eradicating the pathogen population available in the geographical location.

11.1 Reduction of Pathogen Inoculum by Cultural Practices

Cultural practices have been followed with the primary purpose of increasing the yields of crops. These practices, however, have significant influence on the incidence and spread of diseases under glasshouse and field conditions. The effects of cultural practices may vary widely from region to region and may be difficult to assess, since the beneficial effects only become slowly apparent over a period of several years or seasons. The effectiveness of cultural practices in reducing pathogen inoculum with consequent reduction in disease incidence and subsequent spread and on plant growth conditions has been assessed in some of the pathosystems.

11.1.1 Elimination of Infected Plants and Debris

Proper disposal of infected plant materials is essential for preventing buildup of inoculum capable of infecting subsequent crops. Sorghum downy mildew caused by *Peronosclerospora sorghi* causes extensive leaf shredding of infected plants at the time of oospore formation. Oospores in millions are added to the soil if infected plants and debris are not properly disposed of before oospore formation. Infected plants left in the fields, volunteer (self-sown) plants growing from infected seeds, and additional hosts of the pathogen form important sources of inoculum. Removal of all infected plants and plant parts reduces the amount of inoculum, resulting in considerable reduction in disease incidence in several crops, especially in crops such as banana, stone fruits, citrus,

and sugarcane (Kommedhal and Todd 1991). Volunteer plants growing from infected potatoes left in the field after harvest may serve as sources of inoculum for bacterial and virus diseases. Roguing of infected plants in the early stages of crop growth has been suggested as a practical measure to reduce the spread of viral diseases from the internal sources of infection. In perennials crops, even when the disease spread is slow as in the case of cocoa swollen shoot disease, roguing out infected plants and replanting with virus-free plants may result in relatively greater productive stands (Matthews, 1991). Regular roguing of infected plants was effective in reducing the spread of *African cassava mosaic virus* in tropical Africa (Robertson, 1987) and *Banana bunchy top virus* in eastern Australia (Dale, 1987).

Spread of sugarcane diseases such as smut (*Ustilago scitaminea*), red rot (*Colletotrichum falcatum*), and red stripe (*Xanthomonas rubrilineans*) could be reduced by roguing infected stools or shoots (Palti, 1981). Eradication of all weed plant species present in and adjacent to the main field to reduce the sources of inoculum is recommended to reduce the incidence and subsequent spread of diseases (Narayanasamy, 2002). Fusarium head blight (FHB) disease, affecting small grain crops, has a worldwide distribution, significantly reducing the production and quality of grains. In addition, the pathogens of FHB, *Fusarium graminearum* and *F. culmorum*, produce the mycotoxins in grains which are harmful to human beings and animals consuming the contaminated grains. The residues of maize left on the soil surface and in the top 10 cm of soil in tilled and untilled (no tillage) fields were quantified and their relative influence on *Fusarium* infection and deoxynivalenol (DON) contamination was evaluated. The total amount of residues in the first layer of soil (10 cm) was correlated with DON contamination ($R^2 = 0.848$). The results indicated that the residues lying on the surface of the soil had a major role in infection by *Fusarium* spp. and DON contamination of grains ($P < 0.05$) and that the proper disposal of previous crop residues left on the soil surface should be carried out to reduce the incidence of FHB disease in the subsequent crops (Maiorano et al. 2008).

Eradication of sources of virus infection is an important strategy to reduce pathogen inoculum to restrict the incidence and spread of the virus diseases. Management of *Citrus tristeza virus* (CTV) has been shown to be effective by planting virus-free rootstocks together with eradication of CTV-infected trees by the Central California Tristeza Eradication Agency (CCTEA) (Dodds and Gumpf, 1991). The growers in the West Fresno Pest Control District and the Tulare County Pest Control District, representing 45% (44,100 ha) of the acreage in Central California, withdrew from the eradication program between 1995 and 1996 and did not remove CTV-infected trees from their orchards. In contrast, growers in the Pest Control District of Central Valley, South Tulare County, and Kern County continued to participate in the CTV eradication program. The impact of leaving infected trees on the rate of CTV spread was determined by comparing temporal incidence of CTV in plots in Strathmore, Tulare County without eradication with incidence in a plot in McFarland, Kern County with eradication. CTV incidence in the Strathmore plots ranged over 6–42% with annual spread rates of 1.6–3.6% during 1997–2003. On the other hand, CTV incidence in McFarland plot increased over 0–5% between 2001 and 2003 before infected trees were removed. Using a subplot hierarchical bulk sampling method, virus incidence over a 3 year period in a 6.5 km² area near McFarland was estimated to range over 0.09–0.69%, indicating that CTV suppression was still effective in this area even in the presence of aphid vector (*Aphis gossypii*) that could transmit CTV isolates efficiently.

The CTV levels were high in some noneradicated areas in central California. Molecular analysis using PCR assay and sequence-specific primers showed that all isolates (36) tested had a genotype identical to the T30 mild isolate from Florida (Yokomi and De Borde, 2005).

11.1.2 Effects of Tillage Practices

In order to preserve the soil status to provide optimum conditions for plant growth and to maintain long-term productivity of soils, tillage is an important operation followed in crop management systems. Different implements are employed to turn, mix, loosen, or compact the soil. Changes in water retention, aeration, and soil temperatures therefore occur to varying degrees. These changes exert significant influence on the survival and dissemination of phytopathogens in the soils and the residues of crops left in the soil after harvest. Most of the soilborne fungal and bacterial pathogens, in addition to antagonistic microorganisms, complete a part or entire life cycle in the soil or on the plant residues left on the soil. The soil conditions altered by tillage can be expected to influence both pathogens and the antagonists to a different extent (Cook and Baker, 1983). Tillage operations reduce the disease risk primarily by reducing pathogen inoculum by hastening the decomposition of infested residues, physically separating the pathogens from the host plants by burying them in deep soil layers or by changing the soil conditions (Yang, 2002). In recent years, reduced tillage and conservation tillage practices have been followed due to a reduction in cost, improvement of soil structure, and water infiltration ensuring reduction of soil erosion. However, these tillage practices lead to accumulation of plant residues in the top layer of soil, forming potential sources of inoculum of a range of pathogens ((Jirak-Peterson and Esker, 2011); Váňová et al. 2011).

Tillage in general offers the beneficial effects of destroying the weeds and volunteer plants that may serve as sources of inoculum of pathogens. Deep ploughing may bury the pathogens for inactivation by soil microflora, or the pathogens may be exposed to sunlight resulting in inactivation by solar radiation and heat as in the case of *Rhizoctonia solani* and *Verticillium dahlia*, capable of infecting several crop plant species ((Papavizas and Lewis, 1979); Butterfield in (Fry, 1982)). In the presence of the stubbles from a fallow-sown, no-till wheat cover crop, the dispersal of soil inoculum of *Phytophthora capsici*, incitant of Phytophthora blight of bell pepper, was suppressed resulting in considerable reduction in disease incidence. The final disease incidence level was significantly low (2.5–43.0%) in no-till plots, whereas the high incidence (71–72%) was recorded in pepper planted in bare field where all dispersal mechanisms of *P. capsici* operated without hindrance (Ristaino et al. 1997). The effectiveness of moldboard plough, chisel plough, and no-till in reducing Fusarium head blight incidence in wheat was assessed. The lower incidence and severity of FHB in plots ploughed with moldboard plough than in chisel plough and no-till treatments were apparent. In addition, yields of wheat were greater by 10% in moldboard-ploughed plots than in either chisel-ploughed or no-till treatments. The results suggested that the use of conservation tillage and reduced till systems might have contributed to the FHB epidemics in the Upper Midwest in the USA (Dill-Macky and Jones, 2000).

The effects of conventional and minimum tillage treatments in combination with 2 and 3 year crop rotations on the development of soil suppressiveness to potato canker and black scurf disease caused by *Rhizoctonia solani*, dry rot caused by *Fusarium* spp., and silver scurf disease induced by *Helminthosporium solani* were assessed. Analysis of root zone bacteria recovered from the rhizosphere (exoroot) and potato root tissue

(endoroot) showed that antibiosis activity inhibiting the growth of soilborne pathogens was at a maximum level in bacterial isolates recovered from the endoroot tissues of 3 year rotation crop (barley, red clover, and potato) under the minimum tillage system. The results suggested that the soil agroecosystems could be modified through rotation and conservation tillage practices to improve disease suppression by enhancing the antibiosis of endophytic and root zone bacteria (Peters et al. 2003). Various methods of tillage have been followed to loosen the soil and improve the soil aeration. In addition, pathogen propagules in the deeper soil layers may be brought to the soil surface and activated or killed due to the exposure to sunlight and higher temperature on the soil surface. The influence of tillage practices on the incidence of wheat Karnal bunt disease caused by *Tilletia indica* in the Indo-Gangetic Plains of India was investigated. Samples of wheat 365, 171, and 370 from fields adopting zero- (no-) tillage (ZT), furrow-irrigated raised bed system (FIRBS), and conventional till (CT), respectively, were collected. Incidence of Karnal bunt disease incidence index and percent-infected samples were calculated, and data were analyzed statistically. Lowest mean incidence (9%) of the disease was observed in zero-tillage fields, whereas disease incidence levels were 18.1% and 16.2% in FIRBS and CT fields, respectively. Disease incidence index also followed the same trend as disease incidence. The results suggested that zero tillage might be adopted for a few years to reduce the soil inoculum levels, resulting in the reduction of Karnal bunt disease in this region (Sharma et al. 2007).

The different long-term conventional and conservation tillage treatments were evaluated for their efficacy in reducing the incidence and diversity of *Fusarium graminearum* and other *Fusarium* spp. causing Fusarium head blight (FHB) disease. The isolation frequency of *Fusarium* spp. and the total number of colony-forming units (CFUs) were affected by sampling years (2000 and 2001) and the cultivated crop (winter wheat, mustard, or maize), and showed significant differences between tillage treatments (moldboard plough, chisel plough, or rotary tiller). Diversity levels of *Fusarium* spp. in moldboard-ploughed plots were lower compared with those under chisel plough and rotary tiller treatments. The number of total CFU g⁻¹ of soil and *Fusarium* spp. was higher in 2000 when wheat was cultivated than in 2001 when maize was grown, and showed differences between treatments. The tillage depth also seemed to influence the *Fusarium* populations. The deeper the tillage, the lower the number of *Fusarium* spp. isolated. In conservation tillage treatment, a higher diversity of *Fusarium* spp. was found than that in moldboard-ploughed plots. Further, lower populations of pathogenic *F. graminearum* and *F. culmorum* were found in plots ploughed by moldboard. The results indicated that incidence of *Fusarium* spp. in soil might be increased by conservation tillage due to changes in soil conditions in these plots (Steinkellner and Langer, 2004). Fumonisin contamination in corn was assessed in conventional till and no-tillage systems. No-till corn following oats showed the highest mean fumonisin levels and differed significantly from conventional till corn, following either oat or fallow. Fumonisin levels ranged over 0.13–19.52 µg g⁻¹ (mean 9.97 µg g⁻¹) and 3.70–7.75 µg g⁻¹ (mean 6.29 µg g⁻¹) in no-till corn following oat in two growing seasons of 2006 and 2007. Although no-till is advantageous from a soil conservation standpoint, it may enhance the risk of higher levels of fumonisin accumulation in grains (Ono et al. 2011).

The effects of various wheat cropping systems on Fusarium head blight (FHB) disease severity and contamination levels of mycotoxins (deoxynivalenol, nivalenol, and zearalenone) were investigated. Four wheat cropping systems, namely a conventional system, integrated system, a direct drilling system, and an organic system in fields with

natural pathogen infection, were included in the investigation conducted during 1999–2002. The severity of FHB disease and mycotoxin levels differed considerably between years, reflecting climatic effects. The severity of FHB differed between cropping system in all three years were considered separately. The most severe disease incidence was recorded in direct drilling and conventional cropping system treatments in 2000. The levels of grain contamination by mycotoxins depended on both climatic conditions and cropping systems. Mycotoxin levels and disease severity reached a peak in 2000. Mycotoxin levels were highest in the direct drilling system. No clear relationship could be seen between disease severity and mycotoxin contamination levels of deoxynivalenol, nivalenol, or zearalenone under the natural conditions which existed during the period of experimentation (1999–2002) (Champeil et al. 2004).

The influence of conventional and no-tillage systems on the incidence of *Fusarium* head blight (FHB) disease, in combination with other agronomic practices such as nitrogen fertilization, and the influence of the environmental conditions on different wheat cultivars for three consecutive years was assessed. Maize was the previous crop in the first year and wheat preceded the experimental wheat crop in the latter two years. Tillage treatments – conventional tillage and no-till – were the main plot treatments in the split plot design. The FHB disease was observed in all the years. Differences in symptom expression were associated with the environmental factors prevailing during the different seasons. In the first year, the only interactions for FHB incidence were between no-till and urea application in split doses. Seedling emergence, seed health, 1000-kernel weight, and deoxynivalenol (DON) concentration did not differ, suggesting that the fertilizers and genotypes did not affect the susceptibility to FHB disease. Severity of FHB in the second year was greater because of the favorable environmental conditions. Tillage and fertilization did not affect the variables analyzed. Cultivars showed significant differences and DON values were high. In the third year, no significant differences were seen due to unfavorable climatic conditions. The results indicated that weather conditions exerted greater influence than tillage practices on FHB disease incidence (Lori et al. 2009).

11.1.3 Effects of Sowing Time and Planting Density

Date of planting/sowing of crop depends on several factors such as crop duration (long or short), availability of irrigation facility/rainfall, and other requirements for good growth of crop plants to realize maximum yield potential. From the crop disease management point of view, date of sowing/planting may be determined with the primary objective of reducing the period for which the crop may be at a vulnerable stage or viable pathogen propagules are available. In the case of viruses and other vector-borne pathogens, the date of sowing has to be so adjusted that the crop is not exposed to the period when the vector population is high with active movements. The pattern of incidence of different diseases on a crop in a given location over several years has to be studied to plan a realistic proposal to avoid the disease by suitable manipulation of sowing date. Although this approach may appear to be simple, some problems imposed by crop requirements and seasons have to be overcome (Narayanasamy, 2002).

Early planting of sugar beets, when other conditions favor rapid crop development, reduced the severity of sugar beet yellows and increased the yield in Germany (Heitefuss, 1989). Early sowing of sugar beet permitted its germination and growth when temperatures were too low for infection of roots by the fungal vector *Polymyxa betae*.

On the other hand, late sowing resulted in infection soon after sowing and development of the pathogen was also rapid. Early sowing had the additional advantage of avoiding rhizomania disease caused by *Beet necrotic yellow vein virus* transmitted by *P. betae* (Blunt et al. 1992; (Rush and Heidel, 1995)). Field experiments were conducted for three years (1995, 1997, and 2001) to determine the effects of date of planting (DOP) of soybean on the incidence of *Phomopsis longicolla* (PL) under natural conditions at Stoneville, USA. There was a significant effect of DOP on the incidence of *P. longicolla* and seed germination. Early planting of maturity group IV varieties resulted in higher level of disease incidence, lower seed health rating, and seed germination (Mengistu and Heatherly, 2006).

Planting density (spacing between plants and rows) as determined by rate of sowing (seed rate) or spacing adopted has a distinct effect on the amount of foliage canopy and consequently on the microclimate around the crop. High rates of seeds sown in nurseries or seedlings planted closely favor the diseases caused by *Rhizoctonia* and *Fusarium*. Maize stalk rots caused by *Gibberella fujikuroi* was favored by close planting (Nyvall, 1979). The severity of potato silver scurf disease caused by *Helminthosporium solani* and black scurf disease induced by *Rhizoctonia solani* were increased with an increase in plant density/unit area (Firman and Allen, 1995). Seed decay caused by *Phomopsis* spp. is endemic in all soybean-growing states in the USA. *Phomopsis* seed decay reduced the yield, quality, and germination of seeds. The effects of planting date and cultivars were determined by planting the susceptible soybean cultivar Asgrow 3834 and resistant lines SS93-6012 and SS93-618 in mid-April, mid-May, and mid-June. Generally yields averaged over years (1998–2000) were significantly greater for mid-April than mid-June plantings, and yields of cultivars were similar within a planting date. The percentage of Asgrow 3834 seed infected with *Phomopsis* spp. was significantly greater than for lines SS93-6012 and SS93-6181 seed for all planting dates. The percentage of Asgrow 3834 seed infected with *Phomopsis* spp. was significantly greater for mid-April than mid-May and significantly greater for mid-May than for mid-June plantings. The germination of seed from mid-June plantings was significantly greater than seed from mid-April plantings and significantly greater for resistant lines than for Asgrow 3834 planted in mid-April and mid-May. The percentage of Asgrow 3834 seed infected with *Phomopsis* spp. was significantly greater than lines SS-93-601 and SS93-618 for 1998 and 2000 (Wrather et al. 2003).

The effects of the date of sowing of maize (corn) on the susceptibility of maize hybrids to ear rot caused by *Fusarium* spp. and mycotoxin contamination of grains were investigated under natural conditions. Three sowing dates (March, April, or May) were compared using two hybrids with different maturity classes. The ears were scored for disease incidence and severity of symptoms at harvest and the harvested kernels were analyzed for mycotoxins, namely fumonisin B1, zearalenone, deoxynivalenol (DON), aflatoxin B1, and ochratoxin A. Sowing maize in May resulted in higher levels of infestation by European corn borer (39%) (considered to predispose plants to infection by the pathogen) *Fusarium* kernel infection and ear rot severity by a factor of 4 and 3, respectively, than in plots sown in March. The sowing date did not affect the nature of mycotoxin present in the kernels which depended on the climatic conditions and on their influence on the infection and development of *Fusarium* spp. The late sowing appeared to increase the contents of fumonisin B1 and DON to levels significantly higher than in crops sown in March or April. Late sowing (after May 10) multiplied the risk of production of fumonisins and DON in grains at harvest by a factor of 11.2 and 1.9, respectively. On the other hand, production of zearalenone and aflatoxin B1 in maize grains was not altered by dates of sowing (Blandino et al. 2009a).

The influence of plant density on the susceptibility of medium and medium-late maturity maize hybrids to ear rot and to mycotoxin contamination in natural infection conditions was investigated. Plant density significantly influenced the percentage of kernels infected by *Fusarium* infection (+24%) and higher fungal ear rot severity (+43%) than plots with lower plant densities, but the type of mycotoxin produced by the pathogen in the kernels did not show variation due to planting density. However, the climatic conditions prevailing during the season influenced infection and the development of different fungal genera and species associated with maize ear rot disease. The natural occurrence of mycotoxins found in each year (2001–2004) was always significantly higher in crops with higher plant density. Cultivation of a medium-late maturity hybrid instead of a medium maturity hybrid could lead to higher contamination of mycotoxins. Growing maize crops in temperate areas with high plant populations might result in production of mycotoxins in larger amounts and consequent higher mycotoxin risk in kernels (Blandino et al. 2008a). In a later investigation, the effects of the date of sowing, planting density, and nitrogen fertilization in kernel infection by *Fusarium verticillioides* and *F. graminearum* were assessed in maize under natural conditions. The levels of contamination of maize kernels with fumonisin and deoxynivalenol were determined in different treatments. The fumonisin concentrations were less affected by plant density, hybrid maturity, and nitrogen levels. The presence of deoxynivalenol (DON) was related to late sowing, high plant density, and nitrogen fertilization (Blandino et al. 2009b).

High plant density has been reported to reduce the incidence and spread of virus diseases of annual crops transmitted by vectors. This phenomenon of reduction in the incidence of viral diseases by adopting high-density planting (closer spacing) has been used as a practical measure of disease management in narrow-leaved lupin (*Lupinus angustifolius*). Adopting a narrow spacing (17.5 cm) resulted in the reduction of *Bean yellow mosaic virus* incidence in narrow-leaved lupine (Jones, 1994). Plant density and cowpea variety had significant effect on the incidence of *Cowpea aphidborne mosaic virus*, *Cowpea mild mottle virus*, *Cowpea mosaic virus*, *Cowpea chlorotic mottle virus*, and *Cowpea golden mosaic virus*. The lowest mean disease incidence was the lowest in plot with a spacing of 25×75 cm and the disease incidence was greater in plots with a spacing of 50×75 cm. However, the cultivar IT89KD-288 at a spacing of 50×75 cm had the lowest disease incidence and highest yield compared to other combinations (Aliyu & Balogun, 2011).

11.1.4 Effects of Irrigation Practices

Among the different agricultural practices, irrigation probably has a greater influence on the development of both host plant and microbial plant pathogens. Irrigation is essential to maintain required soil moisture levels for the absorption of plant nutrients from the soil and for maintaining turgidity of plant tissues. Both high soil moisture and water stress may predispose plants to infection by different kinds of pathogens. Four kinds of irrigation systems are generally used for various crops, depending on the quantum of water available. Flooding is carried out when the quantity of water available is abundant, but this system may spread the pathogen inoculum throughout the field. However, flooding the soil (flood fallowing) was found to be effective for the eradication of *Fusarium oxysporum* f.sp. *cubense*, the causal agent of banana Panama (Fusarium) wilt disease. This strategy was successful because flooding drastically restricted the oxygen supply to the soil, rendering conditions very unfavorable for pathogen survival. The treatment was effective for 4–5 years, after which the pathogen

reappeared (Kelman and Cook, 1977). Furrow irrigation saves some water, but spreads the pathogen inoculum along the furrows. The sprinkling system restricts the amount of water used further, but causes enormous splash dissemination of inoculum while surface dissemination is limited. The trickling system conserves water to the maximum extent, but aids in the pathogen dissemination. As irrigation is an indispensable component of field crop cultivation, suitable modification/changes in the other cultural practices have to be considered for application under field conditions existing in a geographical location.

Many fungal and bacterial pathogens are carried from one part of the infested field to other parts through irrigation water. Fungal pathogens such as *Verticillium dahliae*, *Thanatephorus cucumeris*, *Phytophthora infestans*, *Fusarium oxysporum* f.sp. *cubense*, and others are known to be spread through irrigation water. Likewise, *Xanthomonas oryzae* pv. *oryzae* (Xoo) exuded from rice leaves falls into irrigation water and is carried to adjacent fields which are irrigated from one source of water. High populations of bacteria all year around were present in irrigation water in canals and in rice fields (Ou, 1972). In these cases, if water from an infested field is prevented by suitably modifying the irrigation system, the incidence of the disease(s) may be appreciably reduced. Water released into the sewage system by sugar refineries processing sugar beets was found to carry the fungal pathogen *Polymyxa betae*, which is the vector of the rhizomania disease (Sutic and Milovanovic, 1980). The effect of three irrigation methods – daily drip, 3 day drip, and alternate-row furrow irrigation – on the incidence of *Phytophthora* root rot disease caused by *Phytophthora capsici* in pepper was compared. Drip irrigation increased the yield of marketable green fruits by providing either favorable soil moisture conditions for pepper or unfavorable conditions for the pathogen development (Xie et al. 1999). *P. capsici* produces zoospores that initiate infection of roots. Conditions of wet and dry cycles in soil are primarily required for completion of different stages in its life cycle. Rainfall and periodic furrow irrigation provide the wet–dry cycle in the soil, favoring sporangia production during dry period and zoospore release during wet period. Disease percentage was higher (78.39%) in drip irrigation system than in basin (56.27%) and furrow irrigation (59.92%) methods (Sağır et al. 2005).

The effects of irrigation on the incidence of *Phomopsis longicolla* (PL), seed germination, and seed health rating (SHR), a measure of diseased seeds and germinated seedlings in the early soybean production system, were determined along with those of date of planting (DOP). A positive relationship between disease incidence and SHR was observed for 1996, 1997, and 2001. Irrigated treatments in drier years (1995 and 1997) produced a higher level of PL incidence than in nonirrigated treatments, suggesting that soil moisture could have increased relative humidity in the canopy that provided favorable conditions for pathogen development. The incidence of PL disease was associated with total rainfall and rainfall frequency for each year. Disease incidence was higher in 1996 and 2001 than in 1995 and 1997, when a conducive moist environment overrode the effects of irrigation. The results indicated that seed health rating (SHR) and seed germination percentages could be a reliable basis for evaluation of *P. longicolla* on seed quality and that the existence of conducive environmental conditions was necessary to assess the significant treatment effects (Mengistu and Heatherly, 2006).

The beneficial effect of supplemental irrigation under drought stress conditions in improving the growth and yield of potatoes has been observed, but its influence on the incidence of tuber diseases was also indicated. Surface sprinkler irrigation was applied based on tensiometer or moisture block readings deployed in field plots. The severity of

black scurf disease (*Rhizoctonia solani*), black dot (*Colletotrichum coccodes*), silver scurf (*Helminthosporium solani*), and common scab (*Streptomyces scabiei*) was quantified on potato tubers randomly sampled at harvest and kept at storage temperature of 7.2°C before visual assessment. The mean incidence of black scurf, silver scurf, and black dot disease ranged over 3–18%, 2–33%, and 4–9%, respectively, in best, unirrigated, and reduction irrigation treatments. The results suggested that irrigation might increase disease incidence. However, other cultural practices such as rotation and application of amendments might be useful to reduce the disease incidence selectively to some extent (Olanya et al. 2010). *Colletotrichum coccodes*, causal agent of black dot disease of potato tubers, is spread through infected progeny tubers. Introduced into the previously uncontaminated soil through infected tubers, the pathogen could survive in the soil for at least 8 years (Dillard and Cobb, 1998); the contaminated soil could therefore be a potential source of inoculum for *C. coccodes*, leading to infection of subsequently planted potato crops for several years. The effects of cultural practices such as use of cultivar resistance, irrigation, and crop duration were studied by performing field trials during 2004–2007. Development of black dot disease on underground plant parts was monitored in two field trials conducted in England and Scotland. First symptoms of infection on stems were seen at 90 days after planting (dap) and the disease incidence increased rapidly thereafter, reaching 99% at 132 dap in an English trial. The incidence of the disease on stems, stolons, and roots progressed at a slower pace in the Scottish trial. The differences in disease incidence on stems, stolons, and roots did not reflect the levels of resistance of potato cultivars Maris Piper (least resistant) and Sante and Saxo (more resistant). The final disease incidence did not show significant variations across the cultivars (Fig. 11.1). Irrigation coupled with application of the fungicide azoxystrobin significantly reduced black dot disease on stem and stolons compared with other treatments (cultivar resistance and crop duration). The black dot disease on stolons and roots progressed at a similar rate at English and Scottish sites with irrigation (with or without azoxystrobin) reducing stolon and root infection by the pathogen. The results suggested that development of black dot on stems, stolons, and roots could be reduced by combining irrigation and azoxystrobin application. However, azoxystrobin had little effect on disease incidence at the English site, whereas effectiveness of irrigation in reducing disease incidence could be clearly observed (Brierley et al. 2015).

11.1.5 Effects of Crop Nutrition

Several factors such as soil fertility (productivity), water availability, weather, cost/benefit ratio, and marketability of the harvested produce have to be considered while choosing a crop in a particular location. Crop nutrition exerts a decisive influence on the growth and yield of crop plants, as well as on the development of diseases caused by microbial pathogens which have to derive nutrition from the susceptible plant hosts. As the human population increases, there is no matching increase in cultivable land area which is progressively shrinking because of industrial development and the increasing demand for housing. Crop production strategies therefore have to be modified, resulting in enhancement of the application of chemical fertilizers to increase yield and synthetic chemicals to protect crops against diseases and insects. However, early success achieved in controlling crop diseases created the wrong impression that chemical control could offer a lasting solution to the disease problems confronting the growers. The development of resistance in plant pathogens to chemicals and a growing awareness

Figure 11.1 Development of potato black dot disease on stems, stolons, and roots of three potato cultivars with different levels of resistance in (a) England and (b) Scotland. Disease severity ratings measured on potato cultivar Maris Piper (■), Sante (Δ), and Saxo (X). Source: Brierley et al. (2015). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

for the protection of the environment dramatically changed the approaches for solving plant disease problems from chemical methods to alternative methods aimed at restricting or replacing the use of fertilizers and chemicals applied against plant pathogens. The availability of sufficient nutrients to the plants is essential for satisfactory plant growth and desired level of yield. Many cultural practices such as the application of organic amendments and crop sequence (rotation) have been shown to influence disease incidence, severity, and function through altered biological activity in the soil and crop environment. It is known that plant response to a particular nutrient may be different when its level moves from deficiency to sufficiency than from sufficiency to nutrient excess. It is necessary to maintain a nutritional balance for optimum crop response, since each nutrient functions as part of a delicately balanced interdependent system influenced by plant genetic constitution and environment. Interactions between specific nutrients and pathogen development have to be clearly understood to effectively modify the nutrient requirements of the chosen crop to increase crop yield and quality and restrict the development of diseases to the required levels (Huber and Haneklaus, 2007; Narayanasamy, 2013).

11.1.5.1 Use of Organic Matter

Soil fertility may be increased by the application of organic matter, rather than through provision of nutrients to the plant density. Further, many microorganisms antagonistic to plant pathogens are activated due to addition of organic matter to the soil, and this may lead to suppression of the development of diseases transmitted by soilborne pathogens that may eventually become seedborne. Organic matter incorporated into the soil is called amendment, while organic matter spread on the soil surface may be referred to as mulch. Organic amendments may promote biological destruction of pathogen inoculum through germination-lysis mechanism and intensification of microbiological activity, leading to degradation of propagules of phytopathogens. Organic amendments may exert stimulatory or inhibitory effects on the microbial plant pathogen populations and disease development. They may either prevent infection by activating the soil microflora, potentially competitive with or antagonistic to plant pathogens present in the soil, or inhibit plant pathogen development by producing toxic metabolites in the soil environment when the organic matter decomposes in the soil. Proper composting of the organic matter before incorporation into the soil is essential, since some pathogens may survive in the organic amendments and are likely to be introduced into the soil inadvertently.

A range of soil amendments have been evaluated for their efficacy in reducing the pathogen population and disease development. Incorporation of barley straw in the topsoil reduced the populations of *Verticillium dahliae* infecting potato. Reduction in disease incidence was attributed to the direct quantitative reduction in pathogen population, since there was no change in host resistance or fungal pathogenicity (Harrison, 1996). Verticillium wilt disease of potato could be effectively contained by application of Sudan grass or corn (maize) as green manures (Davis et al. 1996). Application of perennial peanut and chitosan reduced the incidence of crown and root rot of bell pepper caused by *Phytophthora capsici* and also disease severity (Kim et al. 1997). Potato common scab (PCS) disease, one of the major economically important diseases, is caused by *Streptomyces scabies*, *S. turgidiscabies*, and *S. audiscabies*. Green manures provide substantial benefits to the soil by improving soil structure and suppressing soilborne diseases. Lopsided oat cultivar (*Avena strigosa*) used as a green manure crop in Japan was evaluated for its efficacy in reducing the incidence of PCS disease and increasing the healthy marketable potato tuber yield. Lopsided oat or woolly pod vetch (*Vicia villosa*) were more effective in suppressing PCS disease severity than oat and continuous potato cultivation ($P < 0.0001$). The marketable tuber ratio was more significantly increased (65.3% and 74.0%, respectively) compared with oat and continuous potato cultivation. The relationship between *S. turgidiscabies* density and disease incidence was positively correlated. In all field experiments, densities of *S. turgidiscabies* in the lopsided oat treatments were lower than for other treatments. The lopsided oat treatments produced higher marketable tuber ratio than sugar beet treatment. In field experiments conducted during 2000–2001 lopsided oat cultivation alone, and with the application of Ferosand (to decrease soil pH) at 1.8 t ha^{-1} or a resistant potato cultivar treatment, was significantly more effective at suppressing the disease severity and incidence than sugar beet cultivation, even under high disease pressure. The results suggested that lopsided oat used as a fallow green manure crop could reduce the severity of potato common scab disease and increase marketable potato yield (Sakuma et al. 2011).

Ralstonia solanacearum race 3 biovar 2, the incitant of potato brown rot (bacterial wilt) disease, is an economically important bacterial pathogen occurring in tropical, subtropical, and temperate regions of the world. The effects of conventional and organic

management and various amendments on brown rot development in potato tubers in different soil types, namely sand or clay from Egypt desert and Dutch (Netherlands) soils, were determined. Brown rot infection was only slightly reduced in organically raised crops compared to conventionally managed potato crops in sandy soils from Egypt. However, organic management significantly increased disease incidence and pathogen survival in Dutch sandy and clay soils, which correlated with the high dissolved organic carbon (DOC) contents in the organic Dutch soils. There was no correlation between disease incidence or severity and bacterial diversity in the potato rhizosphere in differently managed soils. Cow manure amendment significantly reduced disease incidence in organic Dutch sandy soils, but did not affect the bacterial populations. However, cow manure reduced densities of *Ralstonia solanacearum* in Egyptian sandy soils. A clear shift in population, most probably by microbial competition, was detected with denaturing gradient gel electrophoresis (DGGE) in these and Dutch sandy soils after manure amendment. The amendment with compost did not have a suppressive effect in any of the soil type investigated. It is possible that the absence of disease suppressive effect of mineral and organic nutrients in these soils could be responsible. The suppressive effects of manure added to the organic sandy soils from Netherlands and Egypt could have been due to the immediate release of ammonia, which is toxic to microorganisms, or a shift in the microbial community. Amendment of soils with wood chip compost was not effective in potato brown rot suppression. Likewise, compost from tree bark or coffee residues did not suppress, but actually increased, bacterial wilt in tomato. Amendment of conventional soils with NPK provided remarkable disease suppression only in Egyptian sandy soil and a reduction in the population of *R. solanacearum* in soils and rhizosphere of potato plants in Egyptian clay soil. When Ca and K contents of soils were high potato brown rot incidence or severity was generally low, both in soils naturally high in these elements and in soils amended with manure. The results indicated that mechanisms of potato brown rot disease suppression might vary strongly depending on the soil type (Messiha et al. 2007).

11.1.5.2 Use of Inorganic Fertilizers

Intensive agriculture systems involving the use of inorganic fertilizers, high-yielding cultivars (with susceptibility to diseases), and enhanced plant density/unit area had to be followed because of the rapid increase in human populations. Adequate organic matter was not available to meet the requirements of various crops, necessitating the application of fertilizers in large quantities. Fertilizers may act on the host plants indirectly, leading to an increase or reduction in disease incidence and/or severity. They may also have some effect on the microclimate and the microorganisms that favor plant growth or act as antagonists of plant pathogens.

Nitrogen favors vegetative growth of plants, which is required in the early growth stage of crops. However, an excessive supply of nitrogen is known to increase plant susceptibility to several diseases affecting different crops. Heavy doses of nitrogen increased the susceptibility of rice plants to blast disease caused by *Pyricularia grisea*. Delaying or splitting the application of nitrogen may therefore reduce rice blast incidence (Ou, 1972). Potato tuber rot induced by *Phytophthora infestans* was significantly increased at higher levels of nitrogen (Heitefuss, 1989).

The form of nitrogen that is applied may have some influence on the development of crop diseases. Development of cabbage club root disease caused by *Plasmodiophora brassicae* could be effectively suppressed by combined application of nitrate fertilizer

and lime to increase soil pH (Smiley, 1975). The effects of nitrogen fertilization on the development of *Fusarium* head blight (FHB) disease in wheat and the resulting deoxynivalenol (DON) contamination in kernels were investigated. The FHB disease incidence was recorded in two locations under natural conditions. Five different types of nitrogen fertilizer (both organic and mineral) were applied at five input rates of 0–160 kg ha⁻¹. A significant increase in disease severity was observed with increasing N supply, regardless of the type of N applied. Depending on the type of N fertilizer applied, the percentage of diseased spikelets increased from 2.2% at zero N rate up to 6.6% at 160 kg ha⁻¹. Under in vitro greenhouse conditions, spring wheat varieties including Durum wheat were inoculated with *Fusarium graminearum* and *F. culmorum* strain, known producers of DON. Significant increases in FHB intensity and DON contamination in the grain were observed with increasing N from 0 to 80 kg ha⁻¹. At higher input, levels of FHB intensity and DON contamination were at constant levels. The application of nitrogen fertilizers may not be useful for the management of FHB disease (Lemmens et al. 2004).

Field experiments were conducted in northwest Italy to determine the effects of the type (urea and a slow-release fertilizer) and the application rate of nitrogen (N) fertilizer (0, 100, 200, 300, or 400 kg ha⁻¹) on the susceptibility of maize hybrids to ear rot caused by *Fusarium* spp. and to mycotoxin contamination under natural infection conditions. Disease incidence and severity at harvest were scored and the contents of the mycotoxins, fumonisin B1, zearalenone, deoxynivalenol, aflatoxin B1, and ochratoxin A were determined. No significant differences were observed between the two types of N fertilizer in any of the years (2000–2004) for zearalenone, fumonisin B1, or ochratoxin A. Ear rot incidence and severity were generally higher in ears from plants fertilized with insufficient N, but high N fertilizer doses (>300 kg ha⁻¹) significantly increased zearalenone content while for fumonisins the highest contaminations were related to nitrogen deficiencies (+80%). Deoxynivalenol (DON) and ochratoxin A were not detected in all treatments, but when present in detectable concentrations they did not show a clear relationship to N fertilization rate. On the other hand, a negative correlation was found between N rate and aflatoxin B1 contamination when the climatic conditions during the ripening period favored accumulation of aflatoxin B1. The results suggested that a balanced N fertilizer application (200 kg ha⁻¹) might lower mycotoxin contamination, and this practice might be adopted without compromising yield and quality (Blandino et al. 2008b). The effects of nitrogen levels on *Fusarium* spp.-induced fumonisin levels in corn were investigated. Plots treated with 0 and 22.5 kg ha⁻¹ nitrogen showed highest mean fumonisin levels, differing significantly from those plots treated with 45.0 and 90.0 kg ha⁻¹ nitrogen. Fumonisin levels correlated negatively with nitrogen fertilization rates ($P < 0.05$) (Ono et al. 2011).

Since adequate nitrogen fertilization was considered to be one of the factors for achieving high yields in wheat (*Triticum aestivum*), the influence of nitrogen supply on the development of speckled leaf spot disease caused by *Septoria tritici* was studied under field conditions during 1996 and 1997 seasons. Six cultivars were supplied with nitrogen at 0 and 100–150 kg ha⁻¹ levels in a split-plot design. Percentages of necrosis (severity) of the two upper leaves of plants in each treatment were recorded three times during the growing season. With weather conditions being conducive for disease development in 1996, areas under the disease progress curve (AUDPC) were higher in fertilized treatment. On the other hand, with insufficient rains in 1997, the disease progressed faster in plots fertilized with N in the flag leaf which was exposed to conducive environmental conditions from its appearance. The cultivar characteristics,

climatic, and agronomic conditions had a distinct influence on the effect of nitrogen application. The results indicated that the effect of nitrogen fertilization in favoring the development of *S. tritici* might be useful for developing disease management system for different wheat cultivars and for optimizing conditions for the selection of disease tolerant/resistant lines (Simón et al. 2003).

Fusarium graminearum is the major component of Fusarium head blight (FHB) disease of wheat in Serbia. The influence of nitrogen (N) fertilization on FHB intensity (disease index), spike weight (SW), grain weight/spike (GWS), disease incidence, and accumulation of deoxynivalenol (DON) and zearalenone (ZON) was investigated using two cultivars Pobeda and Renesansa under field conditions during two growing seasons of 2010–2012. Three nitrogen rates (0, 75, and 150 kg ha⁻¹) were applied. The levels of N applied did not significantly affect FHB index or mycotoxin accumulation in wheat grains in 2011. In 2012 however, higher DON and ZON levels were recorded at the highest rate of N (150 kg ha⁻¹). It is likely that in 2012 weather factors for Fusarium kernel infection were more favorable compared to the effect of N rates. Likewise, in both cultivars harvested kernels under conditions of artificial inoculation had higher disease incidence and increased DON contents which, in most cases, exceeded tolerance limits adopted in the European Union countries. This situation indicated that the cultivation of susceptible cultivar was at risk of mycotoxin A contamination which is of a serious concern in the production of quality wheat grains. Individual management strategies could reduce the incidence of FHB and the risk of mycotoxin contamination. Nevertheless, integration of two or more strategies is likely to be more effective in reducing FHB incidence and mycotoxin contamination of wheat grains (Krnjaja et al. 2015).

The need for rational use of fertilizers and other agricultural practices that do not favor lodging of cereal crops before harvest has been revealed by experiments conducted during 2002 to 2006. The effects of lodging on the level of deoxynivalenol (DON) and nivalenol (NIV) contamination in wheat, barley, and rice infected with *Fusarium graminearum* species complex were assessed. A total of 66 grain samples collected from each field in 12 Japanese prefectures was analyzed using each sample set consisting of grains from lodged and nonlodged plants. All samples of wheat and barley were contaminated with DON and NIV. On the other hand, NIV was the only contaminant of rice grains. In intervention trials to investigate the effects of lodging duration, a small area of wheat inoculated with *F. graminearum* was completely lodged by trampling. The levels of DON + NIV increased by 27–51% in wheat within 5 days of lodging compared to nonlodged control plots. In the case of rice, half of each plot area was lodged completely by trampling at 20 days prior to harvest. A significant increase in the level of NIV was observed due to lodging over the nonlodged rice at optimum and delayed harvest, indicating that lodging significantly increased the level of mycotoxin in three crops. The results showed that lodging of wheat, barley, and rice should be avoided to prevent mycotoxin contamination in grains (Nakajima et al. 2008).

The effects of agronomic practices such as nitrogen fertilizer rates, irrigation frequencies, and previous crops in rotations on the incidence of powdery scab disease of potato caused by *Spongiospora subterranea* and potato yields were assessed. Nitrogen application (400 kg ha⁻¹) increased tuber weight/plant by 38%. However, incidence and/or severity of powdery scab were increased by nitrogen applications. Measurements of *S. subterranea* DNA in soil samples taken at harvest greatly reflected the severity of powdery scab in harvested tubers. The amounts of DNA were greater after nitrogen application than without nitrogen fertilizer, less after “optimum” irrigation than “low”

irrigation, and greater after a potato/wheat rotation than after potato/pea. The field plots were used for two subsequent potato growing seasons, without the agronomic practices applied earlier, to determine whether the preplanting measurements of *Spongospora* DNA in soil could predict powdery scab in harvested potatoes. The disease generally decreased during the following two growing seasons and the effects of different agronomic treatments on powdery scab had disappeared by the second season. However, the greater amounts of pathogen DNA in soil in plots where nitrogen had been applied compared to where no fertilizer was used continued for the two following growing seasons. Relationships between amounts of preplanting *S. subterranea* DNA content in soil and powdery scab in subsequently harvested tubers were weak in the second growing season and nonexistent in the third season. The results showed that agronomic practices, especially nitrogen application, might increase severity of powdery scab in harvested tubers. In addition, preplanting measurements of pathogen DNA in the soil did not provide reliable predictions of the incidence/severity of powdery scab in harvested potatoes (Shah et al. 2014).

The application of phosphorus favors plant growth by promoting rapid root development. Enhancement of resistance to diseases in crops receiving adequate phosphoric fertilizers has also been indicated. Higher levels of phosphorus were reported to reduce the incidence and lesion morphology of potato scab disease caused by *Streptomyces scabies* (Davis et al. 1976), potato late blight induced by *Phytophthora infestans* (Heitefuss, 1989), and cowpea anthracnose disease caused by *Colletotrichum lindemuthianum* (Adebitan, 1996). Addition of phosphorus in the deficient soil restricted the development of wheat leaf blotch disease due to *Septoria nodorum* (Cunfer and Touchton, 1979) and reduced the incidence of *Cucumber mosaic virus* in spinach (Cheo et al. 1952). Phosphates are generally applied to correct deficiency in soil, but their effect on disease incidence has not been investigated adequately enough to allow valid conclusions to be drawn. Potassium has a key role in the osmoregulation in the cell and maintenance of electrical balance across the plasma membrane. The deficiency of potassium, phosphorus, magnesium, and minor nutrients leads to impairment of processes involved in the maintenance of cell structure and function. The formation of cellulose and sclerenchymatous structures is accelerated by a supply of adequate concentrations of potassium, resulting in enhancement of resistance to fungal diseases of cereal, counteracting the adverse effects of excess nitrogen which lead to lodging of plants (Heitefuss, 1989). Potassium supply in the absence of nitrogen and phosphorus increased the incidence of *Soybean mosaic virus* (SMV) disease, but plants receiving complete fertilizer (20:20:20 kg NPK ha⁻¹) showed lower incidence of the virus disease and the highest increase in the yield of soybean (Pacumbaba et al. 1997).

The stimulation of passive and active mechanisms of disease control may be possible by appropriate nutrient management tactics. Mineral nutrients are components of plants and regulate metabolic activity associated with resistance of a plant species and virulence of a pathogen capable of infecting the plant species concerned. Nutrients such as calcium may suppress the development of diseases caused by *Erwinia* spp. (bacterial soft rots of potato) and *Rhizoctonia solani* (potato black scurf) by increasing the structural integrity and resistance of the middle lamella, cell-wall components, and cell membranes to counteract the activity of extracellular macerating enzymes produced by these pathogens ((Bateman and Basham, 1976); Kelman et al. 1989). Immobilization of manganese (Mn) at infection sites of *Magnaporthe grisea* predisposed rice to blast disease. The ability to oxidize Mn from the reduced, plant-available form to the

oxidized nonavailable form was identified as a virulence mechanism of fungal pathogens. However, some isolates of *M. grisea* that could not oxidize Mn were also found to be virulent. Many cultural disease control practices may function through their effect on mineral availability. Transformation from insoluble Mn^{+3} or Mn^{+4} oxides to plant-available soluble Mn^{+2} is highly dependent on environmental conditions; many factors predisposing plants to diseases may act through their effect on Mn availability (Huber and Haneklaus, 2007). The effect of magnesium on the development of sheath blight disease caused by *Rhizoctonia solani* on rice plants of two cultivars grown in nutrient solution was assessed. Sheath blight disease progress on inoculated sheath was evaluated by measuring lesion expansion (in millimeters) at 24, 48, 72, and 96 h after inoculation. The magnesium (Mg) concentration on leaf sheath tissue was the highest at Mg rates of 0.389 and 0.40 mM for cultivars BR-IRGA409 and Labelle, respectively. A linear model revealed the relationship between area under lesion expansion progress curve (AULEPC) and the Mg rates applied. The AULEPC decreased by 48.7% and 26.2% for cultivars BR-IRGA409 and Labelle, respectively, as the Mg rates in the nutrient solution increased from 0.062 to 0.5 mM. The results indicated that the high foliar Mg concentration played a pivotal role in decreasing sheath blight lesion expansion (Schurt et al. 2014).

11.1.6 Effects of Other Crops

Land use patterns may vary in different seasons and locations, depending on the water availability, rainfall, and other environmental conditions. Many crops may be cultivated in the same farm in rotation with the primary crop or as intercrop along with the primary crop. Different crops in adjacent fields in the same farm may be raised. The incidence of diseases may be influenced by other crops, depending on their susceptibility/resistance levels to the pathogen(s) infecting the primary crop. These crops may exert either a positive or negative effects, depending on whether they are susceptible or resistant to the pathogens of primary crop.

11.1.6.1 Crop Sequence

Crop sequence or crop rotation involves the use of appropriate crops in sequence for a definite duration of time (2–3 years in most cases). The effectiveness of crop sequence in reducing disease incidence depends on several factors such as duration, environment, the nature of the pathogen(s) to be managed, and crop requirements. Use of nonhost(s) in rotation for a sufficient period may allow enough time for the decomposition of infected crop residues and/or a reduction in the viability of the pathogen survival structures and the ability of the pathogen to produce inoculum, thus eliminating the potential source(s) of the disease. Crop rotation may be effective for certain diseases under a set of conditions if the sources of inoculum are present only in the field concerned or the movement of the pathogen from adjacent or other fields is limited. Crop rotation may be effective for the diseases caused by the pathogens that are soil-borne or plant-residue-borne. The inclusion of legumes in crop rotation may provide an additional benefit in reducing disease incidence because of their ability to fix atmospheric nitrogen that can be used by the succeeding crops. Crop rotation may not be effective in the case of seedborne pathogens, pathogens that have a wide host range, or pathogens that can survive for long time (several years by producing resistant structures) in the soil. Further, crop rotation may not be an effective option for the management of pathogens that have additional mode(s) of dispersal, such as air or irrigation water.

The incidence of crown rot disease of wheat caused by *Fusarium graminearum* was reduced by chickpea-wheat rotation compared with a wheat-wheat monocropping system. The mean incidence of the disease was 12% for chickpea-wheat rotation, as against 30% infection in wheat-wheat system (Felton et al. 1998). In a later investigation, the effects of crop rotation including canola, lupine, medic, and medic-clover mixture on the incidence of wheat crown rot disease of wheat were assessed. Wheat and canola in rotation significantly increased the incidence of the disease. The disease incidence and severity were the highest in this treatment. Medic-clover mixture, as the rotation component, reduced the disease incidence to the maximum extent and enhanced the yield of wheat grains (Lamprecht et al. 2006). The effects of the previous and adjacent crops on *Fusarium* head blight (FHB) disease incidence were determined. The number of viable airborne propagules of *Fusarium graminearum* (teleomorph *Gibberella zeae*) trapped at anthesis, FHB index, percentage of seeds infected with *F. graminearum*, and deoxynivalenol (DON) accumulation in seed of winter wheat from commercial fields across southeastern Ontario were recorded. More viable airborne propagules of the pathogen were trapped in wheat fields that were planted on corn or wheat stubble than in wheat fields in which previous crops were nonhosts. Previous crop, field size, and tillage interacted affecting FHB index, DON accumulation, and the percentage of seeds infected with *F. graminearum*. Large fields where corn was planted one year previous to wheat with minimum or no tillage had the highest values. Adjacent crops (nonhost, corn, and wheat) affected the number of viable airborne propagules trapped, FHB index, and percentage of seeds infected with *F. graminearum*. The number of viable airborne propagules trapped at wheat anthesis was not predictive of FHB symptoms or DON accumulation in grain (Schaafsma et al. 2005).

The influence of different cropping systems and cropping successions (sequence) was investigated on natural *Fusarium* sp. contamination and fumonisin levels in corn. In addition, the effect of different levels of nitrogen fertilizer (0, 22.5, 45, and 90.0 kg ha⁻¹ nitrogen supplemented with potassium oxide) on fumonisin contamination was assessed. The cropping system, consisting of a conventional and no-till corn following oats, showed the highest mean fumonisin levels and differed significantly ($P < 0.005$) from all other treatments in 2006. Fumonisin levels ranged over 0.13–19.52 µg g⁻¹ (mean 6.97 µg g⁻¹) and over 3.70–7.75 µg g⁻¹ (mean 6.29 µg g⁻¹) in no-till corn following oats during the 2006 and 2007 growing seasons respectively (Ono et al. 2011). *Fusarium* head blight (FHB) disease, infecting small grain cereals, is the result of complex interactions between weather conditions and agricultural practices including crop rotation, tillage, fungicide application, and host resistance. The influence of maize-wheat rotation on the development of disease symptoms of FHB and deoxynivalenol (DON) content in winter wheat was investigated under field conditions using randomized complete block design during 2009–2010 and 2011–2012 in Belgium. The susceptibility of maize cultivar to *Fusarium* spp. and maize harvest method had only a minor effect on the FHB incidence and DON content of wheat grains during the subsequent growing season. The tillage method and resistance of wheat cultivars were more important and capable of exerting significant influence on FHB incidence and DON content. Further, the quantitative effect of these factors depended on the disease pressure. Repeated maize-wheat rotation in combination with favorable weather conditions for FHB might have resulted in accumulation of pathogen inoculums, which led to DON contents of up to 9.90 mg kg⁻¹ in 2012 (Landschoot et al. 2013).

The effect of crop rotation on the incidence of *Phytophthora* blight in pepper (*Capsicum annuum*) was determined. Rotation of pepper with peanut (groundnut) reduced the disease incidence more effectively (by 39%) than with sesame (by 11%) (Kim, 1989). Inclusion of nonhosts in the rotation and/or fallowing may reduce the selection pressure for a given soilborne pathogen and “starve” it out, preventing the large pathogen population buildup and consequently resulting in the reduction in infection of primary crop. Incidence and development of soilborne diseases affecting potato crops are significantly influenced by the frequency and composition of rotation with other crops. The potato pink rot pathogen *Phytophthora erythroseptica* may survive as oospores in the soil for many years and may be endemic in soils where potatoes are cultivated repeatedly; however, it might be possible to reduce the incidence of pink rot disease by adopting crop rotation (Lambert and Salas, 2001). The effect of 2 and 3 year crop rotations and conservation tillage (reduced or no-till) practices on the incidence of potato pink rot disease caused by *Phytophthora erythroseptica* was investigated in Prince Edward Island, Canada. Spring barley and potato cultivar Russet Burbank were included in the 2 year rotation, whereas the 3 year rotation comprised barley (undersown with red clover), red clover, and potato. the development of pink rot disease was significantly less pronounced in potatoes from 3 year rotational soils than from 2 year rotational soils. Potato plants grown in a greenhouse using soils from field plots had less disease in the 3 year rotation than in the 2 year rotation ($P=0.05$). The results suggested that potatoes grown in soils managed under a 3 year rotation appeared to be intrinsically more resistant to infection by *P. erythroseptica* than those managed under the 2 year rotation. Inclusion of red clover in the 3 year rotation might contribute to the disease-suppressive effect in the succeeding potato crop because of its ability to fix atmospheric nitrogen and consequent provision of additional nutrients (Peters et al. 2005).

The effects of the origin of seed potatoes and the cropping history on the phenotypic structure of late blight pathogen *Phytophthora infestans* populations were investigated in Germany during 2000–2002. Populations originating from fields with a history of potato cropping with only a short or no rotation (old fields) were compared with populations from new fields (not cropped to potato for at least 30 years). Seed potatoes were either obtained from breeders or produced on-farm (certified). The importance of seed potato infection in the establishment of new *P. infestans* populations was assessed. Isolates were characterized for mating type, virulence, and rep (repetitive extragenic palindromic) -PCR fingerprints. Among a total of 639 isolates examined from 31 sites, mating types A1 and A2 coexisted in all 3 years in 60–92% of the sites. Over all 3 years, 53 pathotypes were detected in a subsample of 272 isolates. The isolates originating from new fields had significantly higher frequencies of the virulences v1, v2, v6, and v7, indicating the general effects of seed introduction into a new region. Thirty-six fingerprints were detected in a subsample of 281 isolates of which 22 were unique, while 4 occurred in all 3 years and at many sites. Pathogen populations from potato fields that were grown from seed tubers of geographically different origin differed significantly based on χ^2 tests. The genetic distances were less than 0.1 among local populations. On the other hand, distances of US lineages US-1, US-6, US-7, and US-8 ranged over 0.22–0.47. Populations from old fields were more diverse and 14 of the 22 rep-PCR types occurred there among 132 isolates tested, in comparison to 6 in the new fields ($n=140$ isolates) and 2 among 6 isolates from volunteers. The results suggested that both sexual and asexual reproduction cycles play a role in pathogen establishment (Bouws and Frinckh, 2007).

Rotation crops may help conserve, maintain, or replenish soil resources and improve the physical and chemical properties of soil, whereas cover crops are primarily grown to cover and protect the soil from erosion and nutrient losses between periods of crop production. Crops used in rotation with potato, canola, millet (*Panicum milliaceum*), soybean, sweet corn, barley, and red clover and continuous potato (nonrotation) were evaluated for their ability to reduce the incidence/severity of *Rhizoctonia* canker (black scurf), silver scurf, and powdery scab diseases in potato tubers. Overall, canola, rapeseed, sweet corn, and barley/clover as rotation crops reduced the severity of *Rhizoctonia* canker relative to the control ($P=0.001$). Canola and rapeseed rotations reduced the severity to the maximum extent (15–45%) in individual years during 2000–2006 and averaging 20–23% overall during the 7 years. Canola, rapeseed, and bean rotations were also the most effective in reducing black scurf on potato tubers. These rotations had lower scurf severity than most other rotations, and reductions of 32–38% relative to the continuous potato control ($P=0.0002$) were observed (Fig. 11.2). Other rotation crops did not have a significant effect on common scab severity. Reductions in pathogens associated with the use of cover crops were generally modest (5–20%). However, the combined effects of using a cover crop in conjunction with an effective rotation crop were substantial and greater than using either strategy separately. The combination of winter rye cover crop with canola or rapeseed rotations reduced black scurf and common scab by 25–41% compared to control and 21–37% over barley/clover standard rotation. *Verticillium* wilt became a prominent disease only after four full rotation cycles. The incidence of *Verticillium* wilt was the lowest in barley rotations. Barley/clover and rapeseed rotations resulted in the highest soil bacterial populations and microbial activity. All rotations had distinct effect on soil microbial community characteristics. Addition of a cover crop increased the soil bacterial populations and microbial activity, in addition to improving tuber yield by 34%. The results suggested that a 3 year or longer rotation might be more effective, as the 2 year rotation adopted in this investigation had a limited effect on severity of the diseases of potato (Larkin et al. 2010).

Various practices adopted at pre- and postharvest stages may result in different levels of infection of maize (corn) kernels by *Aspergillus flavus* or *Fusarium* spp. Samples from 300 farmers' stores from four agroecological zones in West Africa were collected at the beginning of storage (sample A) and at six months later (sample B). *A. flavus* was predominantly present in samples A (27–47%) than in samples B (8–26%). *Fusarium* spp. were detected in 38–58% of the A kernels samples in both years, but decreased slightly to 29.5% in B samples. Aflatoxin was detected in 38.8% of 744 samples tested with an average of 105 ppb, and 60% of the aflatoxin-positive samples had contamination level of 20 ppb (the intervention levels recommended by the World Health Organization or WHO). Planting local maize varieties, intercropping with cowpea, groundnut, or cassava, use of urea as nitrogen source, damage to grains in the field, prolonged harvesting, long drying periods in the field, and winnowing were the factors associated with increased aflatoxin contamination. On the other hand, planting improved maize cultivars, mixed cropping with vegetables, use of NPK fertilizer, drying of harvested cobs for 60–90 days, drying ears without husk, and the removal of poor-quality ears contributed to a reduction in aflatoxin accumulation in maize kernels (Hell et al. 2003). Aflaroot disease of groundnut (peanut) caused by *Aspergillus flavus* affects peanut production quantitatively and qualitatively, since the mycotoxin aflatoxin produced in kernels poses potential danger to the health of human beings and animals. The efficacy of crop rotation to reduce *A. flavus* populations was assessed, in addition

Figure 11.2 Effects of different rotation crops during 2000–2006 on incidence of *Rhizoctonia* canker, black scurf, and common scab diseases in potato. (a) *Rhizoctonia* canker; (b) black scurf; and (c) common scab. Two-year rotational crops include barley (BA), canola (CN), millet/rapeseed (RP), green bean (GB), sweet corn (SC), soybean (SY), and potato (PP, control without rotation). Bars with the same letter are not significantly different as per Fischer's protected least significant difference test ($P < 0.05$). Source: Larkin et al. (2010). Reproduced with permission of the American Phytopathological Society, MN, USA.

to the identification of microorganisms that could reduce population levels of aflatoxin-producing fungi in soil. Peanut crop sequences, continuous peanut, four years of continuous bahia grass followed by peanut, and peanut-corn-cotton were evaluated for their efficacy in reducing the disease incidence and pathogen populations. Enumeration of soil microorganisms indicated that using bahia grass in rotation with peanut reduced

A. flavus population levels, compared with other cropping sequences. As the minimum population density of 2.6×10^6 CFU g⁻¹ soil was required for detection of *A. flavus* in the soil, molecular techniques such as ribosomal intergenic spacer analysis (RISA) had to be employed to determine microbial community structure with emphasis on aflatoxin-producing fungi (Sudini et al. 2011).

The possibility of using crop rotation to reduce the incidence of lettuce drop disease caused by *Sclerotinia minor* was examined. The efficacy of broccoli as a rotation crop was assessed. When lettuce was grown continuously, there was no increase in the incidence of lettuce drop disease for at least two years although soilborne sclerotia were more numerous. Rotation with broccoli reduced disease incidence to some extent only in the first year. The sclerotial density was the lowest in plots with lettuce followed by a fallow period (LFL) and highest in plots with continuous lettuce (LLL). At another location, the reduction of disease was significant in plots with broccoli in rotation. The number of broccoli crops rather than the sequence of lettuce rotations with broccoli was critical for reducing the numbers of sclerotia, possibly because of volatiles formed during the breakdown of glucosinolates present in broccoli. The results indicated that broccoli could be a desirable candidate to effectively reduce the incidence of lettuce drop disease, because it is a nonhost for *S. minor* and contains glucosinolates in the tissues inhibitory to the pathogen (Hao et al. 2003). The effectiveness of the use of *Brassica* crops as green manure or cover crop in reducing the incidence of potato stem rot disease caused by *Sclerotinia sclerotiorum* was investigated. *Brassica napus*, *B. juncea*, and *B. campestris* were grown in three naturally infested potato fields during three cropping seasons over 2008–2010. Disease incidence and mean percentage of dead plants were significantly reduced by all three *Brassica* spp. Growing *B. juncea* was the most effective practice, reducing the disease incidence by 55.6% (average over all years and sites). On the other hand, the average disease reduction percentage by *B. napus* and *B. campestris* were 31.6% and 45.8%, respectively. Cultivation of *Brassica* crops showed potential for inclusion in crop rotation with potato to contain potato stem rot disease (Ojaghian et al. 2012).

Canola (*Brassica napus* and *B. rapa*), a major oilseed crop grown worldwide, is severely infected by blackleg disease caused by *Leptosphaeria maculans* (anamorph *Phoma lingam*). The effects of a 4 year crop rotation and two tillage systems on blackleg disease incidence were investigated during 1999–2002 in Canada. Wheat (W) and flax (F) as rotation crops with canola (C) and conventional tillage (T) or zero-till (Z) were included in the study. Tillage and rotation had significant effects in reducing disease in 2001. Growing canola in rotation with wheat significantly reduced stem infection by 18% in zero-till plots and by 8% in tilled plots, compared with continuous canola. The disease incidence and severity were the least in tilled plots when canola was rotated with wheat. Zero-till plots showed greater levels of disease incidence and severity, compared with tilled plots with or without rotation. Tillage reduced stem infection and severity in all rotation plots, except in the canola-wheat-flax-canola rotation ($P < 0.05$). Tillage could play an important role in reducing the pathogen inoculum since *L. maculans* might survive in stubbles of previous canola crop and ploughing might accelerate the decomposition of canola residues, resulting in the elimination/reduction of pathogen inoculum and consequent lower level of blackleg disease (Guo et al. 2005). Canola was traditionally grown as a rotation crop once in 4 years but market opportunities led to canola being intensively cultivated, resulting in increased incidence of blackleg disease caused by *Leptosphaeria maculans*. A field experiment with split-plot

design was conducted, including blackleg-resistant cultivars in combination with pea, wheat, and flax and fungicide application. Blackleg incidence and severity was increased in rotations comprising more than one canola crop every year, regardless of cultivar, although the blackleg-resistant cultivar was much less affected than the susceptible cultivar. The yield of the resistant canola cultivar was similar among rotations that included canola every 2, 3, and 4 years. Fungicide application was of limited value to maintain canola yield. The results suggested that cultivar resistant to blackleg disease might be preferable for growing canola more intensively than once every 4 years with limited yield reduction. Intensification of canola rotations might increase the risk of inoculum carryover, resistance breakdown, and consequent yield loss. It would therefore be desirable to adhere to less intensive inclusion of canola rotations (once every 4 years) as an effective blackleg disease management strategy (Kutcher et al. 2013).

11.1.6.2 Monoculture

Continuous monoculture of annual crops may provide conditions for rapid multiplication of pathogens such as *Verticillium dahlia*, with a high level of saprophytic survival in the soil. In contrast, some pathogens have a low level of saprophytic survival in the soil and, after reaching certain levels, disease incidence begins to decline. In the case of potato scab pathogen *Streptomyces scabies*, the disease incidence showed a reversible pattern in that there was a rise in disease incidence up to some years after which the soils became more and more suppressive to the pathogen, resulting in a progressive reduction in disease incidence. Such soil that does not support development of the pathogen in subsequent years is designated suppressive soils (Shipton, 1977). Use of varietal mixtures has been demonstrated as an effective method of disease suppression in some pathosystems. Infection by wheat leaf blotch pathogen *Septoria nodorum* was significantly reduced when a mixture of wheat cultivars was grown (Jeger et al. 1981). Rice cultivar mixtures were tested for their effectiveness in controlling brown spot disease caused by *Helminthosporium oryzae* and rice blast disease caused by *Magnaporthe grisea*. The spread of brown spot disease was significantly reduced by planting in alternate rows of two rice cultivars with different levels of resistance to different strains of *H. oryzae* (Grummer and Roy, 1966). A mixture consisting of three upland rice cultivars was tested along with pure stands of individual cultivars in the Philippines. Leaf blast severity was less in the rice mixture than in the pure stand of the most susceptible component, whereas no difference in the blast disease severity on the other cultivars, either in the mixed or pure stands, could be observed (IRRI 1984).

11.1.6.3 Multiple Cropping

The system of growing two or more crops as intercrop, mixed crop, or barrier crops has been followed traditionally in several countries. Two or more crops may be planted simultaneously or in a staggered manner so that the growth periods of the two crops overlap. Crops that are not hosts for the same pathogen(s) are selected for a mixed cropping system. Crops which are planted as intercrop or mixed crop may (i) modify the microclimate of another crop; (ii) intercept or filter out the spores of the pathogen; (iii) restrict the movements of vectors of the viruses or pathogens; and (iv) reduce the infectivity of nonpersistent (stylet-borne) viruses which are lost by their vectors when they feed on nonhosts of the viruses. Intercropping or mixed cropping has been reported to be effective in reducing the incidence of some diseases.

Planting sesame (*Sesamum indicum*) or peanut as intercrops significantly reduced the Phytophthora blight of pepper caused by *Phytophthora capsici* in Korea (Kim, 1989). Extracts of soils on which peanut or sesame was grown and the root exudates of these intercrops inhibited the mycelial growth, sporangium formation, and release of zoospores by the pathogen. In soils amended with the extracts, incidence of Phytophthora blight disease was considerably reduced (Lee et al. 1990, 1991). The influence of intercropping in three consecutive cropping seasons on the incidence of barley diseases was assessed by including dual-grain legume (pea, faba bean, and lupine) -barley intercropping (IC), as compared to the respective sole crops (SC). Reduction in disease incidence was achieved in all IC systems compared to the corresponding sole crops with a general reduction in the range of 20–40%. Barley net blotch disease caused by *Pyrenophora teres* was the most serious disease during the three years of experimentation (Hauggaard-Nielsen et al. 2008). The reduction of disease caused by bacterial pathogen could be achieved by intercropping practice. The effect of intercropping cowpea (*Vigna unguiculata*) with cassava or maize was investigated in five cropping systems, namely cowpea monoculture at high density and at low density, cowpea-maize within row, and cowpea-maize in alternate rows, on the incidence of *Xanthomonas axonopodis* pv. *vignicola*, causal agent of bacterial blight disease. Cowpea monoculture at high density showed a higher level of disease incidence than cowpea-cassava in alternate rows in 1996 and cowpea-maize in alternate rows in 1997. The disease severity index was reduced by 50% in cowpea-cassava in alternate rows in 1997, but not in 1996. The yield loss of cowpea could be compensated by the additional yield of intercrops (Sikirou and Wydra, 2008).

Plant diversification in any form such as mixed cropping, cover crops, border plants, intercrops, and trap crops known as barrier cropping may be useful for protecting the primary crop plants against vector-transmitted virus diseases. The incidence of *Watermelon mosaic virus* could be effectively reduced by growing oats as barrier crop (Chalfont et al. 1977). Likewise, cultivation of different crops as inter-, mixed-, or barrier crops was shown to be effective in reducing the incidence of some virus diseases. *Potato virus Y* (PVY) infection of pepper (*Capsicum* spp.) was reduced by more than 50% when sunflower was grown as a border crop to protect pepper plants (Simmons, 1957) and in potato with borders of sorghum, soybean, or wheat (Di Fonzo et al. 1996). The incidence of PVY and *Cucumber mosaic virus* (CMV) in pepper was significantly reduced by planting maize or sunflower as barrier crops. It was suggested that reduced infection by viruses might be due to a decrease in infectivity of vectors that landed on maize or sunflower which are nonhosts of the virus, before reaching the susceptible pepper plants (Avilla et al. 1996). In a later study, sorghum, corn, or vetch as border crops were evaluated for their effectiveness in protecting pepper crops against infection by PVY and CMV. Sorghum and vetch borders were effective only in two of four experiments conducted. The level of reduction in virus disease incidence was less than 15% (Feres, 2000).

The effectiveness of intercropping with grain sorghum, peanut, soybean, or corn to reduce the incidence of *Watermelon mosaic virus* (WMV) and *Papaya ringspot virus-W* in pumpkin was determined in five field experiments conducted over a 3 year period. Disease incidence was reduced by 43–96% ($P < 0.05$) in plots with grain sorghum as intercrop. On the other hand, no significant reduction in disease incidence could be observed in pumpkin in plots with borders of peanut, soybean, or corn. Borders of grain sorghum were able to reduce the virus disease incidence to a lower

level compared to grain sorghum as intercrop. Intercropping soybean and peanut with pumpkin reduced disease incidence to a lesser extent than intercropping with grain sorghum (Damiconi et al. 2007).

The effectiveness of the intercropping models such as cassava-pepper, plantain-pepper, and maize-pepper was assessed for the extent of protection provided by them to pepper against *Pepper vein mottle virus* during 2004–2006. The effectiveness of the intercrops was assessed based on the extent of reduction in the number of plants infected, enhancement of plant vigor, and yield and quality of pepper fruits. Based on the averages of disease incidence for three years, virus disease incidence and severity were significantly reduced by all three intercrops tested. The incidence of virus disease in sole crop of pepper was relatively higher (42%). Plantain-pepper combination showed the maximum level of disease incidence of 58.3%. The yield was increased to the maximum extent (5.98 t ha^{-1}) in plots with maize intercropped with pepper as against pepper as sole crop yield (1.54 t ha^{-1}) which was far low (Fajinmi and Fajinmi, 2010). Barrier crops may have different mechanisms for reducing the incidence of virus diseases transmitted by aphid vectors in a nonpersistent manner. During the process of feeding, the aphids may probe the nonhosts as they cannot differentiate the hosts from nonhosts. Virus particles present in the stylets/mouth parts may be lost, reducing the virus charge in the probing aphids. The aphids may therefore become either noninfective or carry fewer virions that may not be able to initiate infection in the primary host (crop plant). Barrier plants may therefore function as a virus-sink for nonpersistent viruses. Alternatively, barrier plants may act as physical barriers, resulting in a reduction in the number of aphids having access to the primary crop host and consequent reduction in virus infection. Another possibility is the ability of the barrier crops to protect the primary crop by camouflaging them from vector insects. In yet another way, the protector plants may attract the aphids and function as a “decoy.” Although the barrier crop may provide protection to the primary crop, the competition for nutrients and space should not be a limiting factor for its use as protector crop (Hooks et al. 2007).

11.2 Reduction of Pathogen Inoculum by Physical Techniques

Crop diseases can be effectively managed by dovetailing physical and chemical techniques with conventional cultural practices to reduce the size of the initial pathogen population present in and/or on the seed and propagules, and to reduce the pathogenic potential (virulence) of the pathogen(s). Physical and chemical methods may be applied to whole plants, planting materials, and field soils to restrict the disease incidence.

11.2.1 Treatment of Seeds and Propagules

Seeds and propagules such as tubers, setts, corms, and bulbs may be exposed to different physical and chemical agents to reduce the pathogen inoculum by inactivation. As an initial step, infected seeds that are small in size, malformed or mixed with fungal structures such as ergot, smut sori, or sclerotia may be separated by winnowing or sieving because of the differences in seed size or weight. Alternatively, the seeds may be immersed in 20% sodium chloride (common salt) solution. The lighter, infected seed and fungal structures will float on the surface of saline solution and can be easily

removed. The seeds are then dried and stored after treatment with recommended plant protection chemicals until they are sown. Various physical techniques based on heat, radiation, and microwaves have been applied to eliminate the pathogens present in the seeds and propagules with different degrees of effectiveness.

11.2.1.1 Heat Treatments

The effectiveness of heat as a disinfectant was first demonstrated to eliminate the potato late blight disease caused by *Phytophthora infestans* from seed tubers by exposing them to a current of hot air at 40°C for four hours. Later, hot water was used for control of smuts of barley and oats (Jensen, 1888). Application of heat for the elimination of *Ustilago tritici* and *U. nuda*, causal agents of loose smut of wheat and barley respectively, was found to be effective. The seeds were immersed in water at 20–30°C to stimulate the dormant mycelium of the pathogens present in them, and the pathogens were killed when the seeds were immersed in hot water at 50–52°C (Martin and Woodcock, 1983). A useful modification of this procedure that could be adopted in tropical countries was developed by Luthra (1953) in the Punjab state in India. The wheat seeds are soaked in cold water for about four hours and then spread as a thin layer under the sun (temperatures around 50°C) for another four hours. The seeds are stored under dry conditions. This method was cumbersome but simple, and adopted widely by growers for the control of loose smut disease of wheat. The bacterial pathogen *Xanthomonas campestris* pv *vignicola* could be eliminated by solar treatment. The cowpea seeds were soaked in tap water for four hours (38°C), then for four hours under bright sun (08:00–12:00 noon) and dried for 5 hours under sunlight. This method was effective in areas where day temperatures reached 45°C or more (Jindal et al. 1989). A similar approach was found to be effective for the control of pineapple heart rot disease caused by *Phytophthora cinnamomi* by exposing pineapple crown buds, lateral buds, suckering buds, and rhizomes to sunlight for 4–8 h at a temperature of 33°C (Yang and Chang, 1998). The efficacy of treatment of winter wheat seeds with electron treatment was compared with hot water treatment (52°C for 10 min) for the control of bunt disease caused by *Tilletia caries*. There was no adverse effect on seed germination due to electron treatment, whereas hot water treatment reduced seed germination (Winter et al. 1998).

The effects of heating seeds at 60°C or 70°C for up to 14 days on loads of *Fusarium graminearum* (Fg) and seed viability of two samples each of barley (*Hordeum vulgare* B1, B2), Canadian western red spring wheat (*Triticum aestivum*, RS1 and RS2), and Canadian western amber durum wheat (AD1, AD2) were assessed. The samples RS2 and B2 with an incidence of 23 and 84% of Fg respectively were also heated at 60°C for 24 days and at 80°C for 10 days. Pathogen populations and seed viability were assessed by plating seed onto potato dextrose agar (PDA) and filter paper, respectively. Fg was eliminated from RS2 after 15 days at 60°C, 5 days at 70°C, or 2 days at 80°C. In B2, Fg was eliminated after 21 days at 60°C, 9 days at 70°C, or 5 days at 80°C. After heating at 50°C or 70°C, the frequency of *Cochliobolus sativus* in B1 declined slightly but significantly over time, whereas it substantially increased in B2. A significant reduction in the incidence of *C. sativus* was observed in B2 after heating at 80°C. Germination rates of seeds in most samples were not affected by the treatment times and temperatures that were sufficient to eradicate *F. graminearum*, but significant decline in viability was noted for AD2 and B1 heated at 70°C. The seed germination of B2 increased when heated at 70°C, but declined when heated at 80°C. The results showed that thermotherapy

might be useful for restricting national and international movements of *F. graminearum* and other heat-sensitive pathogens in germplasms used for research and breeding purposes (Patrick et al. 2002).

In a later investigation during 2001–2002, seed samples of spring wheat infested with *F. graminearum* or uninfested seeds were heat treated at 30, 50, 70, or 90°C or kept at room temperature (20–25°C) for 5 days. Seed germination (%) and field assessments including seedling emergence, plant height and grain yield, 1000-grain weight, and test weight were recorded. Treatments at 30°C and 50°C were ineffective and treatment at 90°C killed both the seed and the pathogen. At 70°C, recovery of *F. graminearum* was less than 1%. Emergence from seed infested with *F. graminearum* was significantly lower than emergence from seed free from pathogen in each year. Based on the results, heat treatment at 70°C for 5 days was recommended as a means of essentially eradicating *F. graminearum* from wheat seed prior to sowing and preventing the movement of *F. graminearum* to other areas that were free of the pathogen (Gilbert et al. 2005).

Application of hot air at 85°C for five days to pepper (chilli) seeds effectively reduced seedborne infection by fruit rot pathogen *Colletotrichum capsici*. The hot air treatment reduced seed germination to some extent (Kobayashi, 1990). Drying tomato seeds with discoloration in an air oven at 29.5–37.5°C for 6 h resulted in elimination of *Phytophthora infestans*, incitant of late blight disease (Vartanian and Endo, 1985). Similar dry heat treatment of tomato seeds at 78°C for 2 days resulted in the eradication of *Tomato mosaic virus*. Heat treatment did not show any adverse effect on seed germination and was found to be more effective when compared to soaking the seeds in trisodium phosphate recommended for seed disinfection (Green et al. 1987). Soaking onion seeds in hot water at 50°C for 20 min was found to be more efficient in reducing seedborne infection by *Alternaria porri* and *Stemphylium vesicarium*. However, seed germination and seedling emergence were affected (Aveling et al. 1993).

Aerated steam treatment was found to be effective in eliminating the seedborne pathogens. *Alternaria carthami* in sunflower seeds and *Fusarium moniliforme* in corn seeds were eliminated by treating the seeds at 54°C and 62°C for 30 min, respectively, but seed viability was affected slightly (Navaratnam and Shuttleworth, 1983). Eradication of *Septoria apiicola* completely from celery was achieved after treatment of seeds with aerated steam at 64°C for 30 min. Likewise, the bacterial pathogens *Clavibacter michiganensis* subsp. *michiganensis* in tomato seeds and *Xanthomonas campestris* pv. *campestris* in cabbage seeds were eliminated after treatment at 56°C for 30 min and 54°C for 30 min, respectively (Navaratnam et al. 1980). Hot water treatment of rice seeds at 60°C for 10 min effectively suppressed colonization of seeds by *Drechslera oryzae*, causal agent of brown spot disease, which is internally seedborne (Krishnamurthy et al. 2001).

A high-precision method involving the use of warm air in moisture equilibrium with the wheat seeds to be treated was employed for the elimination of seedborne fungal pathogens *Tilletia caries* and *Microdochium nivale*. The warm air treatment of wheat seeds was as effective as chemical seed treatment. In addition, seed germination and plant development were not impaired due to warm air treatment. This method may be useful for large-scale applications for pathogen elimination at a low cost (Forsberg, 2001). Canadian western red spring wheat and barley seeds with high levels of infection (84% and 23%) by *Fusarium graminearum*, causing Fusarium head blight (FHB) disease, were subjected to different dry heat treatments at 60°C for 15 days, at 70°C for 5 days, or at 80°C for 2 days. These treatments effectively eradicated the pathogen from wheat seeds. A similar approach for successful elimination of the pathogen from barley seeds

by treatment at 60°C for 21 days, 70°C for 9 days, or at 80°C for 5 days. Seed germination in most of the samples was not significantly affected (Clear et al. 2003).

The effectiveness of the application of dry heat treatment for the eradication of the bacterial pathogen *Acidovorax axonopoides* subsp. *citrulli* (*Aac*) causing bacterial fruit blotch (BFB) disease in melon, watermelon, and wax gourd from the seeds was evaluated since the Japanese Government legally restricted entry of this pathogen into Japan. The seeds of melon, cucumber, squash, wax gourd, and bottle gourd infested with *Aac* were treated at different temperatures and were sown in the soil. Complete disinfection of seeds of melon and cucumber and small-seeded squash was achieved by dry treatment at 85°C for 3–5 days. The large-seeded squash, wax gourd, and bottle gourd were sensitive to dry heat, indicating that disinfection of seeds for elimination of BFB pathogen seeds by dry heat treatment may not be feasible in crops with large seeds (Kubota et al. 2012).

Thermotherapy has been shown to be effective in eliminating some plant viruses from seeds and propagules. However, heat treatment of seeds carrying a virus internally has not been effective in eradicating the virus in a high percentage of treated seeds, and heat treatments generally impair seed viability. The effectiveness of heat treatments for the eradication of *Lettuce mosaic virus* (Walkey and Dance, 1979), *Cowpea mosaic virus* (Verma, 1971), and *Capsicum mosaic virus* (Stijger and Rast, 1988) from seeds has been reported. Dry heat treatment of tomato seeds at 70°C for 3 days or at 80°C for 1 day was effective in eliminating *Tomato mosaic virus* (TMoV) in less deeply seated seeds extracted freshly (Broadbent, 1976). Heat treatment of tomato seeds at 85°C for 24 h eliminated TMoV without impairing seed germination (Noor-Hassan et al. 1988). *Cucumber green mottle mosaic virus*, a member of the genus *Tobamovirus*, is easily transmitted through sap inoculation and is also seed-transmitted. The CGMMV could be eliminated by heat treatment of seeds. In order to determine the effect of heat treatment on CGMMV, virus-contaminated oriental melon (*Cucumis melo*) seeds from field-grown plants were gradually dried at 35°C and 50°C for 24 h each and then incubated at the different temperatures of 72, 75, 79, or 82°C for 72 h. Heat treatment at 75°C for 72 h completely inactivated CGMMV on contaminated seeds, as indicated by bioassay of the heat-treated seeds on *Nicotiana benthamiana*. Heat treatment reduced the amount of coat protein (CP) of CGMMV in the preparations purified from heat-treated seeds. However, there was no clear relationship with temperature. Electron microscope observations of virus particles purified from heat-treated seeds showed increased breakdown of virions into a range of fragments as the temperatures increased. Results of RT-PCR confirmed the heat inactivation of virus in melon seeds using primers for a heat-sensitive region. The results indicated that elimination of CGMMV from melon seeds could be due to inactivation of virions present on seed surface (Kim et al. 2003).

Thermotherapy through use of hot water has been shown to be effective in eliminating pathogens from propagules. *Sugarcane mosaic virus* and its strains (A, B, D, H, and I) were eliminated from sugarcane setts by serial hot water treatment on four successive days at 54.8, 57.3, 57.3, and 57.3°C for 7 min on each day (Benda, 1972; Benda and Ricaud, 1978). For the control of sugarcane grassy shoot disease caused by phytoplasma, treatment of sugarcane setts in aerated steam was demonstrated to be effective in eliminating the pathogen (Edison and Ramakrishnan, 1972). The ratoon stunt disease caused by *Clavibacter xyli* subsp. *xyli* was efficiently eliminated by treating the setts in hot water at 50°C for 2–3 h (Steindl, 1961). Hot air (Steindl, 1961) and moist-hot air treatment (Shukla et al. 1974) were also reported to be effective against sugarcane

ratoon stunt disease. The adverse effects of hot water/hot air/aerated steam treatment on germination of setts are considered a limiting factor. However, large-scale use of heat therapy as a disease control measure is advocated in several sugarcane-growing countries.

Agrobacterium (tumefaciens biovar 3) vitis, causal agent of crown gall disease of grapevine, destroys infected plants in due course causing serious production losses. Hot water treatment of dormant cuttings of grapevine cultivar Thompson seedless and rootstock NAZ3 (*Vitis vinifera* x *V. rupestris*) at 50°C for 30 min effectively eradicated or reduced the pathogen population below detection level. *A. vitis* strains differed in their sensitivity to heat, but they showed greater levels of sensitivity to heat compared with strains of *A. tumefaciens* biovar 1 and 2. Treatment for 30 min killed a population of about 10^3 CFU mL⁻¹ in broth culture. Nontumorigenic biovar 1 strains could be recovered from hot-water-treated cuttings. The effects of hot water treatment of dormant cuttings were assessed in a field nursery for a period of 9 months. The viability and growth of different cultivars/rootstocks were affected by hot water treatment to different levels. The number and length of canes, root dry weight and length of canes, dry weight of roots, and length and diameter of trunks increased in most cultivars/rootstocks following hot water treatment. Treatment time generally affected the bud survival and, in most cases, increased the level of callus formation at the base of the cuttings. Hot water treatment of dormant grapevine cuttings provided a simple, effective, economical, and environmentally safe means of eradicating *A. vitis* (Mahmoodzadeh et al. 2003).

The effectiveness of hot water treatment (HWT) for the elimination of elm yellows phytoplasma from dormant cuttings and branches of elm plants was assessed. The selected planting materials were treated in hot water at $50 \pm 0.5^\circ\text{C}$ for 45 min. The cuttings were then processed for rooting and the rooted plants were grown in the greenhouse for two years. The plants were closely checked for the development of disease symptoms and also indexed by nested PCR assay. None of the 105 plants growing from HWT-treated cuttings showed disease symptoms, and they were also PCR negative. Plants from untreated cuttings developed symptoms and the presence of EY phytoplasma was also detected by PCR assay (Boudon-Padieu et al. 2004). The efficacy of hot water treatment alone or in combination with the application of tetracycline hydrochloride at a concentration of 500 ppm was assessed for the elimination of sugarcane white leaf phytoplasma. Soaking cane stalks in hot water at 50°C for 2 h, followed by soaking the stalks in tetracycline HCl for 2 h, reduced the phytoplasma incidence up to 28.57% more than using hot water treatment alone. Further, the phytoplasma population was reduced by the combined treatment to the maximum extent as revealed by PCR assay, in addition to enhanced germination of setts (Kaewmanec and Hanboonsong, 2011).

Verticillium sp. and *Fusarium* sp. are involved in the internal discoloration of horseradish roots. Horseradish propagative rootstocks (sets) 0.5–3.0 cm in diameter and 20–25 cm long were treated by immersing them in water at 44–50°C at 1°C interval for 30 min. Treated and untreated sets were cultured on acidified potato dextrose agar to detect the presence of the fungal pathogens in the sets. Treated and untreated control sets were planted in the greenhouse and fields to determine the effects of hot water treatment on germination of sets and vigor of the plants. Treatments at 46°C and below were ineffective at eradicating the sett-borne inoculum. The most effective hot water treatment was 47°C for 20 min, which did not affect set germination or plant vigor but eliminated pathogens to the maximum extent. Temperatures of 48–50°C either delayed or reduced set germination as well as plant vigor (Eranthodi et al. 2010).

Azalea web blight caused by binucleate *Rhizoctonia* species seriously affects the production of Rhododendron cultivar Gumpo White. The effectiveness of submerging terminal leafy cuttings in water at 50°C for 21 min for the elimination of the pathogen was assessed. In addition, the rooting response and tissue sensitivity of evergreen azalea cultivars (12) to submersion of leafy cuttings in water at 50°C for 20, 40, 60, and 80 min were determined. The cuttings showed difference in their thermosensitivity when exposed to 50°C for 60–80 min, resulting in differing responses in root development and final leaf count. Incremental increase in temperature of water resulted in increased leaf damage. However, submerging azalea cuttings of all 12 cultivars in hot water at 50°C eliminated *Rhizoctonia* spp. from stem and leaf tissue with only a low likelihood of sustaining detrimental damage to cuttings (Copes and Blythe, 2011).

11.2.1.2 Forced-Air Treatment

The effect of fan-forced wind on the incidence of rice blast disease caused by *Magnaporthe grisea* was assessed under field conditions in two successive seasons in Japan. Electric fans (5 kW, 110 cm blade diameter) set on the ridge of paddy fields at a height of 5 m above ground level were used to artificially generate wind. The fan operated twice daily for 30 min periods at 23:00 h and 04:00 h from June 15 to September 1, and the wind speed ranged over 2.0–7.3 m s⁻¹. In season 1, the incidence of both rice leaf blast and panicle blast was significantly lower in zones receiving wind at speeds of 2.6–7.2 m s⁻¹. However, the zone receiving a wind velocity of >7.3 m s⁻¹ was severely affected by leaf and panicle blast. The zone that received a wind speed of 2.6 m s⁻¹ or lower showed inefficient reduction of leaf and panicle blast disease, but it was better than the central zones. In season 2, a fan-forced wind was applied from June 16 to September 9 with the velocity adjusted to 3.0–6.0 m s⁻¹. The incidence and severity of leaf and panicle blasts (chaff, rachis-branch, and neck blast) were efficiently reduced in wind-treated fields. The fan-forced wind was more effective in reducing the rice blast disease severity than conventional fungicides. The results indicated the potential of fan-forced wind for managing rice blast disease effectively (Taguchi et al. 2014).

11.2.1.3 Radiation and Microwave Treatments

Ionizing radiation, particularly gamma rays, has been used extensively for the preservation of food products and also for extending the shelf life of fruits and vegetables. Gamma irradiation was shown to be effective in eliminating fungi associated with maize (corn) seeds without affecting seed germination (Cuero et al. 1986). Elimination of the endophytic fungus *Acremonium coenophialum* from tall red fescue seeds by applying gamma radiation at noninjurious doses was achievable (Bagegni et al. 1990). Following dry treatment of barley seeds with gamma irradiation up to 10,000 roentgens, the incidence of *Barley stripe mosaic virus* (BSMV) in plants growing from treated seeds was significantly reduced. However, BSMV was not eliminated when seeds pre-imbibed in water were irradiated in a similar manner (Halliwell and Langston, 1965).

Seed transmission of *Prunus necrotic ringspot virus* (PNRSV) and *Prune dwarf virus* (PDV) was reduced by exposing *Prunus* seeds to irradiation treatment (Megahed and Moore, 1969). Effectiveness of laser treatment for the elimination of four seedborne pathogens *Ustilago segetum*, *Pyrenophora graminea*, *Cochliobolus sativus*, and *Fusarium* spp. was evaluated. Barley seeds exposed to laser beams were sown in the field. Seed transmission of the fungal pathogens to developing seedlings was reduced significantly (Bel'skii and Mazulenko, 1984). *Erwinia carotovora* subsp. *carotovora* (Ecc) could be

eliminated from artificially contaminated tobacco seeds which were subjected to microwave treatment at 625 W for 20 min. Seed germination was not impaired by the microwave treatment. In contrast, microwave treatment of larger seeds of cabbage and bean reduced seed germination, possibly because of their inability to radiate the heat away from the seed during the treatment (Hankin and Sands, 1977).

The efficacy of infrared irradiation as a sterilant of seeds was evaluated for eliminating bacteria from wheat seeds. Bacterial population was significantly reduced from 5.7×10^4 CFU to 0.73×10^3 CFU by exposing the seeds to 2.0 kW range for 60 sec. Intermittent irradiation was more effective in maintaining the internal quality of wheat. A negative correlation between irradiation doses and extent or reduction of bacterial population on the seeds was observed (Hamanaka et al. 2000). Different doses of ultraviolet-C (UV-C) were applied to cabbage seeds to assess its effect on the development of black rot disease caused by *Xanthomonas campestris* pv. *campestris* (Xcc). A dose of 3.6 kJ m^{-2} was optimum and effective in reducing black rot disease incidence and the pathogen population density in infected cabbage leaves. Seeds exposed to UV-C at 3.6 kJ m^{-2} produced plants with the most desirable color, highest weight, largest head diameter, and delayed maturity. Seeds treated with a low hermetic UV-dose of 3.6 kJ m^{-2} showed 90%, 40%, 60%, and 6% reduction in black rot in plants when stored at room temperature for 2 days, 1, 5, and 8 months respectively. Eight-week-storage at room temperature for two days after UV-C treatment was the most effective (Brown et al. 2001).

The effects of microwave treatments applied for 0, 15, 30, and 45 s on fungal pathogens present in and on winter wheat seed were determined. Agar plate isolation and DNA analysis were carried out to assess the pathogen populations and seed germination and seedling emergence and seed viability were determined by tetraolium tests. For all durations tested, microwave treatment significantly reduced levels of seed contamination; it was especially effective in controlling *Fusarium* spp. and *Microdochium nivale* in wheat. Conventional seed survived microwave treatment better than organic seed. Seed moisture content was inherently linked to losses in vigor upon exposure to microwaves. The death of fungal pathogens was attributed to heat and desiccation rather than denaturation of pathogen DNA, since fungal DNA concentration in seeds did not decrease with the observed loss of culturable fungal propagules. The results indicated that microwave treatment of wheat seed could be applied to reduce fungal populations significantly on both conventional and organic wheat seed (Knox et al. 2013).

11.2.1.4 Use of Inorganic Mulches

Plastic foils have been used as inorganic mulch for effective management of some pathogens which are transmitted via seeds/plant propagules and become soilborne in the absence of the primary host (crop) plants. Soil solarization involves the use of thin clear polyethylene sheets to cover the soil after irrigation during summer or seasons with high temperatures. The solar energy is trapped by plastic sheets which prevent loss of heat by evaporation and convection currents. Solarization results in a layer of pasteurized or disinfested soil, but not sterilized soil. The effect of solarization is similar to that obtained by application of aerated steam. It is important that high soil moisture levels are maintained during solarization. The main benefit of soil solarization appears to be its long-term benefits, as it is a physical treatment which does not have a phytotoxic effect or leave any harmful residue as in the chemical treatments. Further, solarization selectively eliminates pathogens while maintaining high biological activity. Another (probably the most important) advantage of employing solarization for elimination of

pathogens is that the method is simple and safe, with none of the hazards associated with chemical treatments. Despite its several advantages, use of solarization is limited to areas where hot conditions exist and to crops which have a high economic value (Narayanasamy, 2002).

The effectiveness of soil solarization using plastic foil mulch for the control of several soilborne pathogens has been reported. Effective elimination of *Verticillium dahliae* and *Rhizoctonia solani* was achieved by covering the soil with polyethylene sheets (Pullman et al. 1981). Soil solarization using photoselective low-density polyethylene sheet for a period of 32–49 days prior to planting tomatoes significantly reduced the population of *Burkholderia solanacearum* up to a depth of 15 cm. The increase in temperature in solarized soils was 5.7, 7.1, and 5.0°C over nonsolarized soil at depths of 5, 15, and 25 cm, respectively. The sensitivity of the pathogen to higher temperatures developed in the soil covered with plastic foil might have a bearing on the effectiveness of soil solarization in the elimination of the pathogen present at different soil depths (Chellemi et al. 1994).

Soil solarization using transparent polyethylene sheets was carried out in commercial tomato production in plastic houses for the control of tomato bacterial canker disease caused by *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*). Soil mulching with polyethylene film was done for about six weeks in plastic houses. Symptoms induced by *Cmm* were drastically reduced throughout the tomato growing season. In contrast, the bacteria belonging to the genera *Pseudomonas*, *Bacillus*, and *Streptomyces*, present in the tomato rhizosphere, were able to survive the enhanced temperatures attained following solarization. The fluorescent pseudomonads isolated from the rhizosphere soil of tomato plants raised in solarized soil induced resistance to the bacterial canker disease when applied to tomato seeds. The beneficial effects of soil solarization were expected to convince the growers in favor of adopting the soil solarization practice using polyethylene sheets to reduce incidence of tomato bacterial canker disease (Antoniou et al. 1995).

The environmental conditions in the soil and above are significantly altered when the soil is covered by polyethylene mulch. The magnitude of effects depends on the characteristics of the polyethylene sheet used and how the covering of the soil is fixed (attached to the soil or not). Different kinds of polyethylene mulches, including a water-permeable agricultural textile treated with copper hydroxide, were evaluated for their efficacy in suppressing or preventing the development of potato tuber blight disease caused by *Phytophthora infestans* under field conditions. Black polyethylene film and copper hydroxide-coated agricultural textile reduced the incidence of tuber blight relative to the appropriate controls, while other mulches did not have any effect on the disease development. Black polyethylene film might block water, resulting in the prevention of infiltration of inoculum through potato hill and alteration of the soil environment within the hill. This might markedly restrict the movement of inoculum and infection capacity of *P. infestans*. The disease suppression by agricultural textile was attributed to the copper hydroxide coating (6 g m^{-2}) which could kill the sporangia and zoospores of *P. infestans* in the soil. The protection offered to tubers by the mulches was only partial, so their use may not be acceptable to potato growers (Glass et al. 2001).

In a later investigation, the effectiveness of covering the soil with polyethylene before planting, with or without application of fungicides commonly applied when growing organic tomato crop to suppress the development of late blight disease of tomato caused by *Phytophthora infestans*, was evaluated. Polyethylene mulch provided consistent,

Figure 11.3 Effectiveness of mulching with bicolor aluminized polyethylene before planting and application of chemicals provide additive effects by reducing disease severity. Unfilled bars: with chemical (Kocide 2000 + Neemguard) application and filled bars: without chemical application. Source: Shtienberg et al. (2010). Reproduced with permission of the American Phytopathological Society, MN, USA.

effective, and highly significant suppression of the late blight disease, the control efficacy being $83.6 \pm 5.5\%$. However, the fungicides were less effective with a control efficacy of $34.5 \pm 14.3\%$. The combination of mulch and fungicides demonstrated an additive effect, reducing the disease severity by 96% (Fig. 11.3). All kinds of polyethylene mulches, namely bicolor aluminized, clear, or black, were effective in suppressing tomato late blight disease development. Other benefits of using mulches could be reduction in weed infestations and saving of irrigation water requirement by 30% (Shtienberg et al. 2010).

The possibility of reducing the incidence of viral diseases by using reflective plastic mulches has been investigated. These mulches reflect short-wave light which confuses the incoming alate aphids, resulting in a reduction of the number of aphids alighting on plants. Consequently, the incidence of viruses transmitted by them is reduced. Plastic foils of different colors have been tested for their effect on the vectors of viruses (attraction/repellence) and consequently on the incidence of virus diseases. Significant reduction in the incidence of *Cucumber mosaic virus* (CMV) and *Potato virus Y* (PVY) was achieved by placing a yellow polyethylene sheet spread with a sticky substance to trap the aphids, which were attracted by the yellow color (Loebenstein and Raccach, 1980). The repellent action of the reflective surfaces was shown as the principal reason for their use in the control of aphid-borne nonpersistent viruses. Infection of bell pepper by CMV and PVY was significantly reduced by using gray plastic mulch, and the winged aphids trapped in the mulched plots were only 6–12% of that in the unmulched plots (Loebenstein et al. 1975).

Use of silver spray mulch and silver plastic mulch reduced the incidence of *Watermelon mosaic virus*, *Zucchini yellow mosaic virus*, and *Cucumber mosaic virus* on zucchini. In the crop raised in fall 100% of plants grown in unmulched plots with and without insecticide application were infected at first harvest, whereas only 10% of plants grown over silver mulch exhibited infection. Silver-pigmented mulches were more effective in repelling aphids and delaying disease incidence than white-pigmented mulches. Yields of marketable fruits increased by 75% and 80% due to silver polyester film and silver spray mulches, respectively ((Loebenstein and Raccach, 1980); Summers et al. 1995).

Symptom development in squash following infection by ZYMV, *Watermelon mosaic virus 2*, and CMV was delayed due to the use of aluminum foil mulch. The number of marketable fruits increased significantly in mulched plots. Infectivity by these viruses on courgette was reduced by reflective mulches (Ansanelli et al. 1997).

Aphid-transmitted viruses, namely *Cucumber mosaic virus* (CMV), *Watermelon mosaic virus* (WMV), and *Zucchini yellow mosaic virus* (ZYMV), severely infect cantaloupes, resulting in heavy losses. Reflective, metalized plastic mulch with a thin coat of aluminum ions reduced the incidence of the diseases caused by these viruses. The number of winged aphids/leaf was significantly higher on plants grown over bare soil (control) than those grown over plastic mulch. The lower aphid counts on plants grown over plastic mulch resulted in lower virus disease incidence. The virus disease incidence in plots covered with plastic mulch was below 10% through mid-September 2002. The incidence of virus diseases was related to the number of winged aphids/leaf, with the highest percentage of infected plants present in the control plots (Summers et al. 2005). The effect of integration of UV-reflective plastic mulch and commercially available resistance-inducing compound BioYieldTM on the incidence of *Watermelon mosaic virus* (WMV) infecting summer squash (*Cucurbita pepo* var *melo*) was assessed. Incidence of WMV was significantly reduced in plants grown on silver-on-black (UV-reflective) mulch compared with plants grown on black mulch (control). In the fall trial, highly UV-reflective silver mulch was also included for testing. Incidence of WMV and ELISA detection data showed that WMV infection was significantly lower in squash plants in the silver mulch treatment compared to silver-on-black and black mulch treatments. However, yields of squash plants in the silver-on-black mulch treatment were higher than those from plants in the silver or black mulch treatments. The treatments with BioYieldTM neither reduced WMV incidence nor increased the squash fruit yields in both spring and fall trials (Murphy et al. 2008).

11.3 Reduction of Pathogen Inoculum by Chemical Techniques

11.3.1 Treatment of Seeds

11.3.1.1 Chemical Application

Treatment of seeds with certain chemicals facilitates the application of fungicides and the seed surface may be more uniformly covered by the seed-treating chemicals. For example, cotton seeds are routinely treated with concentrated sulfuric acid (added at the rate of 1 kg/10 kg of seeds) to delint them. The seeds are then washed with water to remove the acid and shade-dried before the application of fungicides or antibiotics to protect them against seedborne and soilborne pathogens. Immersion of seeds in hot liquid carbon tetrachloride solution was found to be less damaging than hot water. Seeds of flax were exposed to carbon tetrachloride at a range of temperatures for the control of two seedborne pathogens, *Mycosphaerella linicola* and *Aureobasidium lini*. Treatment of seeds at 70°C for 15 min or at 65°C for 20 min significantly reduced the seedborne inoculum of the pathogens. Heat transference through carbon tetrachloride did not reduce seed germination, but affected the seedborne pathogens (Cruickshank, 1954). Treatment of larger seeds such as peas with carbon tetrachloride at 70°C for 2 h reduced infection by the internally seedborne pathogen

Mycosphaerella pinodes, but failed to eradicate the pathogen without causing phytotoxicity (Maude, 1960). The use of hot refined soybean oil as heat transference medium was evaluated for controlling the internal infections of *Phomopsis* spp. in soybean seeds. Immersion of soybean seeds at 70°C for 5 min or at 140°C for 10 s was effective in eliminating the fungal pathogen from seeds (Zinnen and Sinclair, 1982).

11.3.1.2 Fermentation

Fermentation of seeds in water or hot juice has been shown to be effective in reducing seed transmission of some pathogens. Transmission of *Tobacco mosaic virus* through seed of tomato was reduced by seed fermentation. The bacterial fruit blotch (BFB) of watermelon caused by *Acidovorax avenae* subsp. *citrulli* could be reduced by fermentation of seeds in watermelon juice or debris prior to washing and drying. Seed transmission of the bacterial pathogen was reduced from 61% to less than 1%. Fermentation of seeds was as effective as treatment with hydrochloric acid (1%) (Hopkins et al. 1996).

11.3.2 Treatment of Soils

Application of elemental sulfur lowers soil pH, making the conditions unsuitable for the development of soilborne pathogens. Some of the bacterial diseases may be managed by incorporation of sulfur in the soil. Infection of potatoes by *Burkholderia* (*Pseudomonas*) *solanacearum* could be reduced by treating the soil with sulfur to lower the soil pH to 3.8 in June, and the pH was maintained below 4.0 until November. Excess acidity was neutralized by the addition of limestone and the pH was increased to 5 or more. Bacterial pathogen population was significantly reduced under such conditions in Florida, USA (Stevens and Stevens, 1952). Potato scab caused by *Streptomyces scabies* was also contained by similar soil treatment with sulfur followed by liming the soil (Smiley, 1975; Fry, 1982). Soil treatment with lime to raise the soil pH was reported to be effective in reducing the club root disease of crucifers. This disease caused by *Plasmodiophora brassicae* affects cabbage, cauliflower, and broccoli, reducing the production significantly. The addition of lime to raise the soil pH to 7.2 arrested the development of the club root formation in the affected plants. The higher pH reduced spore germination, restricting the ability of the pathogen to induce the disease (Walker, 1957). The extent of disease suppression due to lime application was found to be proportional to how thoroughly the lime was mixed with soil (Dobson et al. 1983). Acid soils are generally favorable to many fusarial wilts which may be suppressed by liming the soil to raise the pH to 7.0 (Cook and Baker, 1983).

Crop Disease Management

Enhancement of Genetic Resistance of Crop Plants

The management of crop diseases has been attempted by adopting various methods either singly or in combination, resulting in varying levels of reduction in disease incidence and/or severity. These methods are directed toward the host and/or pathogen(s). Host management has primarily nongenetic and genetic components. The nongenetic component consists of cultural methods and physical and chemical techniques, and their effectiveness and feasibility of adoption have already been described (Chapter 11). The genetic component involving identification of sources of resistance to disease(s), and the utilization of selected sources of resistance in breeding programs to develop cultivars with resistance to seed- and propagule-transmitted diseases of various crops caused by microbial pathogens, is discussed in this chapter. Host management by incorporating genes for disease resistance is less expensive and environmentally safe. The farmers can grow the resistant cultivars without any need for additional cost and expertise, since the usual agronomic practices already followed would be enough in most cases. Since the buildup of the pathogen population is reduced by host resistance, management of crop diseases using resistant cultivars may be expected to be more effective and economical when considered from the benefits that may accumulate over a period of time and the area in which resistant cultivars are grown. In general, cultivation of resistant varieties is compatible with other methods of crop disease management (Narayanasamy 2002, 2008).

12.1 Types of Disease Resistance

A crop plant species has several varieties or genotypes, varying in several characteristics such as size, height, duration, yield potential, and levels of resistance to different biotic and abiotic stresses. Crop cultivars vary in their levels of resistance to a disease, one among several types of biotic stresses. Likewise, plant pathogens causing diseases exist in the form of several *formae speciales*, varieties, races, or biotypes with variations in their pathogenic potential (virulence/aggressiveness) inducing mild or severe symptoms on host plant species. Two broad kinds of resistance have been distinguished: vertical resistance and horizontal resistance, as proposed by Vanderplank (1963).

12.1.1 Vertical and Horizontal Resistances

A pathodeme may be defined as a host population consisting of individuals with a recognizable character of resistance in common. Likewise, a pathotype may be defined as a pathogen population consisting of individuals with a recognizable character of virulence in common (Robinson 1969). Two kinds of disease resistance may be differentiated using Potato-*Phytophthora infestans* pathosystem. One potato variety has the R1 gene conferring resistance to one of the races (pathotypes) of *P. infestans*, causing late blight disease of potato. This potato cultivar is resistant to pathogen race (0) that does not have a matching virulence gene, but it is susceptible to any other race of the pathogen with matching virulence gene. The unmatched resistance gene (R1) triggers the resistance mechanism in this potato cultivar. Similarly, the potato cultivar with resistance gene R2 shows resistance to infection by the race that does not possess matching virulence gene. Potato genotype with R2 shows resistance to infection by the race that does not possess matching virulence gene 2, and shows susceptible reaction to races with virulence gene 2. As the differences in the level of resistance to different races of the pathogen are parallel to the vertical axis when plotted in a graph, this kind of resistance was designated vertical resistance (Vanderplank 1963). *P. infestans* was able to overcome the effects of resistance conferred by the newly identified resistance genes, hand in hand, by producing new pathotypes (races) capable of colonizing plants incorporated with new genes for vertical resistance. It appeared that the pathogen was very highly adaptable and capable of forming new populations armed with virulence gene(s) to match the R gene(s) of the host, making the attempts to employ R genes to protect potatoes unsuccessful. The pathogen produced new races at a faster rate than the plant pathologists and breeders could produce cultivars with unmatchable resistance gene(s). However, in areas where late blight was severe, the R gene cultivars showed practical use.

The value of vertical resistance for breeding for disease resistance has been considered doubtful in the case of pathogens such as *Pyricularia oryzae*, causing rice blast disease. In the Philippines, 262 races of *P. oryzae* were identified using 12 Philippine differentials. It would be very difficult to develop cultivars with durable vertical resistance as the pathogen is pathogenically highly variable and adjustable. An international cooperative test was conducted at 60 test locations in 30 countries for identification of a rice cultivar with a broad spectrum of vertical resistance, but none of the test entries was found to be resistant or susceptible at all locations. The cultivar Tetep showed resistant reaction in the maximum percentage of tests (98%). Only a few races could infect Tetep, which showed the highest level of vertical resistance (Ou 1979).

Horizontal resistance may be exemplified by considering two cultivars of potato (A, B) which may not show distinct variations in the level of resistance to races of *Phytophthora infestans*, but a moderate level of resistance may be shown to all races of the pathogen. Between cultivars, one cultivar (A) may be more resistant than the other cultivar to all races of *P. infestans*. Differences in this kind of resistance between cultivars will be parallel to the horizontal axis of the graph. This type of resistance is therefore named horizontal resistance (Vanderplank 1963). Horizontal resistance is not due to the presence of an unmatched gene R in the host, as in the case of vertical resistance. Horizontal resistance is independent of the virulence gene of the pathogen. Horizontal resistance may be recognized by exposing the cultivars to infection by all available races of the pathogen under field conditions. The resistant plants that remain after elimination of plants with vertical resistance possess horizontal resistance. Horizontal resistance is

essentially due to polygenic action and quantitative inheritance. The grades of resistance are not distinctly defined and vary continuously. Horizontal resistance has been variously referred to as nonspecific, field, general, or polygenic resistance. Horizontal resistance may be due to a combination of many mechanisms, resulting in reduction in rates of infection, invasion of the host, and/or reproduction of the pathogen. The severity of both epidemics and endemics may be significantly reduced by growing cultivars with horizontal resistance. The level of horizontal resistance is proportional to the concentration (frequency) of polygenes in the test cultivar, since horizontal resistance is governed by polygenes. The complete set of polygenes required for the expression of horizontal resistance may be located in the different individual plants in a genetically mixed population. It may be very difficult to achieve a high level of horizontal resistance since the traditional genetic transfer techniques cannot be employed to incorporate them in a single cultivar, as in the case of vertical resistance which is governed by single gene. A number of parents with low levels of resistance to the target pathogen may be crossed in all combinations. The genes for resistance may be gradually accumulated by repeatedly crossing selected progenies over a number of generations. This diallele selective mating system was proposed by Jensen (1970).

12.1.2 Durable Resistance

The rapid loss of protection provided by single resistance genes necessitated the use of a combination of effective resistance genes; these could offer protection to the cultivars for longer periods since the pathogen would have to make multiple changes simultaneously to become compatible with the combination of resistance genes. Johnson (1981, 1983) introduced the concept of durable resistance that remains effective in a cultivar, when used over a wide area for a considerable period of time, in an environment that is favorable to the development of disease. Systems of disease management aimed at prolonging the useful life of resistance gene(s) require knowledge of the genetics of host resistance, population genetics, evolutionary biology of the pathogen, and the interaction of crop management practices with host resistance. Durability of vertical resistance may be markedly affected by the composition of pathogen population and environmental factors.

Resistance conferred by major genes in the rice-*Pyricularia* (= *Magnaporthe*) *grisea* pathosystem was rapidly broken down since the pathogen was highly adaptable to the introduced resistance genes. However, the rice cultivar IR 36 showed durable resistance which was associated with quantitative/partial resistance based on minor genes (Parlevliet 1988). This type of resistance could be recognized because of the reduction in size and number of lesions formed on leaves of IR 36 cultivar. This partial resistance was inherited through a number of minor genes (Yeh and Bonman 1986; Wang et al. 1989). The partial resistance exhibited by a rice cultivar may be durable under an irrigated tropical production system, but it may not be effective in more blast-conducive temperate environments. This differential effectiveness was observed when the Japanese rice cultivar Reimei was introduced in Korea. This cultivar exhibited an adequate level of partial resistance in northern China, but was susceptible in Korea where environmental conditions were more conducive for blast development (Lee et al. 1989). Another example to indicate the usefulness of durable resistance for tackling the crop disease problem is that of the rice bacterial leaf blight (BLB) disease caused by *Xanthomonas oryzae* pv. *oryzae*. The Chinese rice cultivar Nongken 58 showing durable resistance to the pathogen was grown on four million hectares in the Yangtze River Valley and Shandong

Province for over 20 years. The resistance gene *Xa-3* (from *japonica* rice) and *Xa-4* (from *indica* rice) provided effective protection for at least 15 years (Lee et al. 1989). Rice cultivars with *Xa-4* gene could be grown for avoiding bacterial blight epidemics successfully for 20 years in the Philippines (Bonman et al. 1992). Likewise, potato cultivar with quantitative resistance to one of the viruses (*Potato leafroll virus A*, *virus X*, and *virus Y*) showed susceptible reaction to other viruses infecting potato (Joosten 1988).

12.2 Identification of Sources of Resistance to Crop Diseases

Crop cultivars may be affected adversely to different degrees depending on their levels of resistance/susceptibility to the target pathogen(s) when the environmental conditions are favorable for disease development. Development of an efficient and reliable screening procedure to identify the source(s) of resistance to diseases in the cultivars or wild relatives is therefore the basic requirement for any breeding program aimed at developing cultivars resistant to the disease(s) concerned. All available cultivars and genotypes and wild relatives have to be screened under greenhouse and field conditions to select donors of resistance for transfer of resistance gene(s) to susceptible cultivars. Various methods have been applied to assess the levels of resistance/susceptibility, depending on the host–pathogen combinations. Visual assessment of pathogen infection and disease severity is the most common method of screening of the cultivars and genotypes to score intensity of symptoms and to categorize the entries into different groups based on the level of resistance on a standard scale (0–9) representing increase in intensity of symptoms. Although the visual assessment is simple and easy to perform, it lacks accuracy and specificity and is subject to variation due to assessors' skill and experience. In addition, it may not be possible to assess resistance to individual pathogens involved in a disease complex. Dependence on visual assessment alone may result in unreliable conclusions on the resistance of genotypes when symptoms are not distinct, nonspecific, and likely to be confused with abiotic stress-related symptoms, as in the case of wheat leaf blotch disease complex caused by *Septoria tritici* and *Stagonospora nodorum*. The coalescing lesions and pale pycnidia associated with infection by *S. nodorum* may be difficult to differentiate from natural senescence of leaves. Diagnostic techniques such as immunoassays and nucleic acid-based techniques, which are not dependent on symptom development, may be employed to detect, differentiate, and quantify the pathogen population in various plant tissues infected by microbial pathogens. These techniques are useful especially in detecting pathogen infection in plants remaining asymptomatic (Narayanasamy 2001, 2011).

12.2.1 Screening for Disease Resistance

12.2.1.1 Assessment of Resistance by Visual Examination

Screening of germplasm collections and cultivars to assess their levels of resistance/susceptibility to disease(s) caused by microbial pathogens has been performed under in vitro, greenhouse, and field conditions. An in vitro detached-leaf assay involving inoculation of detached leaves with *Microdochium nivale*, a component of Fusarium head blight (FHB) complex affecting wheat, was employed and compared with whole-plant resistance ratings to FHB of 22 commercial cultivars and 21 wheat genotypes identified

as potential sources of FHB resistance. An incubation temperature of 10°C and isolates of *M. nivale* var. *majus* of intermediate pathogenicity were found to be the most suitable for differential expression of several components of partial disease resistance (PDR), namely incubation period, latent period, and lesion length in wheat genotypes used in the detached-leaf assay. Significant differences were recorded between each component of PDR within commercial cultivars and the genotypes tested. Commercial cultivars except cultivar Tanker, identified with high resistances across all three PDR components in detached-leaf assay also had high whole-plant FHB resistance ratings. Agreement between resistances found in the detached-leaf assay and resistance to FHB suggested that resistances detected in detached leaves were under the same genetic control as much of the resistance expressed in the wheat head of the commercial cultivars tested. In contrast, the genotypes E2 and E12 together with Summai #3 known to have high levels of whole-plant FHB resistance showed less resistance in each PDR component in the detached-leaf assay. Such whole-plant resistances, which were highly effective and not detected by detached-leaf assay, did not appear to be present in Irish and UK commercial cultivars (Browne and Cooke 2004).

The relative resistances of 15 winter barley, 3 winter wheat, and 3 winter oat cultivars and two spring wheat cultivars were evaluated using *Microdochium nivale* in detached-leaf assays. Barley cultivars showed incubation periods comparable to and latent periods longer than the most FHB-resistant Irish and UK wheat cultivars evaluated. Incubation periods were longer for oats compared to barley or wheat cultivars. Oat cultivars differed from both wheat and barley in that mycelial growth was observed before obvious tissue damage was detected under macroscopic examination, indicating tolerance of infection rather than inhibition of pathogen development. The results suggested that longer periods of incubation in barley and oat cultivars than in wheat might play a role in overall FHB resistance, if under the same genetic control as PDR components expressed in the head (Browne and Cook 2005b).

Partial disease resistance (PDR) to Fusarium head blight (FHB) has been identified in diverse germplasm sources that differ with respect to the chromosomal regions governing partial disease resistance (Liu and Anderson 2003; Paillard et al. 2004). Partial resistance or quantitative resistance is characterized by a reduced rate of epidemic development in a host population and may be attributed to various components, including lower infection frequency and longer latent (incubation) period. Resistance determined in vitro using a seed-germination assay correlated with whole-plant assay FHB ratings among European wheat cultivars was hypothesized to relate to resistance expressed in the developing grain. Resistance in the seed-germination assay was not correlated with PDR components detected in the detached-leaf assay, suggesting that it was a genetically distinct PDR component from those detected using the detached-leaf assay (Browne and Cooke 2005a).

The in vivo evaluation of PDR components against the potential of the detached-leaf and seed-germination assays might be useful to distinguish between specific sources/mechanisms of FHB resistance when combined with data on whole-plant FHB reaction and pedigree information. Components of PDR to FHB detected in seed-germination assay were compared with whole-plant FHB resistance of 30 USA soft red winter wheat entries in the 2002 Uniform Southern FHB Nursery. Highly significant differences ($P < 0.001$) observed between cultivars in the in vitro seed-germination assay inoculated with *Microdochium majus* were correlated to FHB disease incidence, severity, FHB index, Fusarium-damaged kernels (FDK), deoxynivalenol (DON) concentration in grain,

and incidence/severity/kernel damage index (ISK) caused by *Fusarium graminearum*. Multiple regression analysis explained a greater percentage of variation in FHB resistance as explanatory factors using the seed-germination assay and the detached-leaf assay (reported earlier) PDR components. Shorter lesion lengths in detached-leaf assay and higher germination rates in the seed-germination assay were related to greater FHB resistance across all disease variables, collectively explaining 62% variation for incidence, 49% for severity, 56% for FDK, 39% of DON, and 59% for ISK index. The incubation period was most strongly related to disease incidence and early stages of infection, while resistance detected in the seed-germination assay and latent period were related to a greater decline in the level of FDK and a smaller reduction in DON concentration. Resistance detected in the seed-germination assay interacted with the relationship between FHB and DON accumulation. Higher resistance detected in the seed-germination assay was associated with greater reduction in FDK than FHB symptom (Browne 2007).

The vast majority of isolates of *Fusarium graminearum*, the principal cause of Fusarium head blight (FHB) disease in North America, produced 3- or 15-acetyldeoxynivalenol (3-ADON/15-ADON) in addition to deoxynivalenol (DON). In order to understand clearly the effect of population shift from 15-ADON to 3-ADON producers on relative aggressiveness of isolates and mycotoxin accumulation, a total of 58 isolates for spring wheat cultivars Robin (susceptible) and 5602 HR (moderately resistant) was tested. In the first experiment three isolates, each of which produced either 15-ADON or 3-ADON, were tested using spray inoculation. In the second experiment, 20 isolates which produced 15-ADON and 20 isolates producing 3-ADON were tested using point inoculation. No significant difference in aggressiveness among isolates could be detected, based either on geographic origin or mycotoxin type. Analysis of seeds from inoculated heads by gas chromatography/mass spectrometry indicated that 3-ADON-producing isolates had significantly higher DON levels than the 15-ADON isolates in cultivar Robin after both spray and point inoculation and in cultivar 5602 HR after point inoculation. DON levels following point inoculation by 15-ADON isolates were similar in both cultivars. The 15-ADON isolates from Alberta produced less DON than 15-ADON isolates from Manitoba and Saskatchewan consistently. More ADON was produced by 15-ADON isolates than by 3-ADON isolates (Gilbert et al. 2010).

Resistance to Fusarium head blight (FHB) in wheat was categorized into two types: resistance to initial infection (later referred to as type I resistance); and resistance to spread of blight symptoms within a spike (later referred to as type II resistance) by Schroeder and Christensen (1963). Five types of active resistance to FHB in wheat were defined by Mesterházy (1995) as follows: resistance to initial infection (type I); resistance to spread of the pathogen within a spike (type II); resistance to kernel infection (type III); tolerance (ability to produce marketable grain in the presence of FHB (type IV); and resistance to mycotoxin accumulation in grain (type V). Type I and II have been widely differentiated and adopted in other investigations, whereas type III, IV, and V do not appear to be well defined and are often used differently by researchers. Resistance to spread of FHB pathogen(s) within a spike has been studied intensively in wheat. The Chinese cultivar Sumai 3 was more frequently used as a source of this type of FHB resistance in most countries (Dubin et al. 1997). Type II resistance may be determined by inoculating a single floret near the middle of the spike and counting the spikelets blighted due to disease during 8–21 days after inoculation (dai) (Bushnell et al. 2003). Resistance to spread of the disease in a spike (type II) was found to be easier to quantify

than resistance to infection (type I). The single floret inoculation technique employed for evaluating type II resistance was shown to be more reliable and accurate and less sensitive to environmental factors, and has been applied as a standard greenhouse screening procedure in many investigations (Bai et al. 2003b; Bushnell et al. 2003; Engle et al. 2003). Using this procedure, the type II resistance from Sumai 3 and other lines was transferred to spring wheat cultivars that were grown commercially (Mergoum et al. 2008).

Analysis of the relationship between components of partial disease resistance (PDR) detected using in vitro detached-leaf assay and seed-germination assays inoculated with *Microdochium majus* and FHB resistance to *Fusarium graminearum* was performed. FHB resistance was assessed using point inoculation of individual spikelet (Type II) and by inoculation of wheat spike uniformly (Type I resistance). Shorter incubation periods, longer latent periods, shorter lesion lengths in detached-leaf assay, and higher germination rates in seed-germination assay were related to greater FHB resistance measured by single point inoculation (Type II), collectively explaining 54% of the variations. Overall, the relationships observed for Type II FHB resistance were similar to Type I resistance. However, the relative magnitude of effects of the individual PDR components determined in vitro varied between FHB disease resistance parameters. Resistance in seed germination and latent period in the detached-leaf assay were more strongly related to resistance assessed by point inoculation (Type II) and severity. Type I, as opposed to incubation period, was most strongly related to disease incidence. The results revealed that individual components of partial disease resistance differentially affected the aspect of FHB disease progression in wheat spike (Browne 2009).

The in vitro detached-leaf assay was employed to evaluate barley genotypes with known field reactions to Fusarium head blight (FHB) disease for partial disease resistance (PDR) components. The detached leaves were inoculated with *Fusarium graminearum* or *F. culmorum* and incubated at room temperature ($21 \pm 2^\circ\text{C}$) or low temperature ($10 \pm 1^\circ\text{C}$). Both pathogens had a short incubation and produced larger lesions at room temperature. *F. culmorum* produced less well-defined necrotic lesions, compared with those from inoculation using *F. graminearum* at both temperatures tested. The PDR components for *F. graminearum*, including latent period, lesion size, and macroconidial production, were correlated significantly. A negative correlation between incubation period and field ratings in one of three tests, latent period and field ratings in two of three tests, and a positive correlation between lesion size and field disease severity ratings for FHB in only one of three tests were noted. On the other hand, few PDR components of *F. culmorum* showed any correlation with each other. Overall, the most distinct differentiation between resistant and susceptible barley genotypes resulted from inoculation with *F. graminearum* at room temperature, including significant correlation between incubation and latent periods with field ratings. The results indicated that measurement of PDR components may not be a dependable basis for routine use to complement field-based disease scores, although the duration of latent period might be useful for differentiating highly susceptible and resistant genotypes (Kumar et al. 2008).

Artificial inoculation of different sets of wheat genotypes under field conditions was carried out by spraying suspensions of isolates of *Fusarium graminearum*, *F. culmorum*, *F. avenaceum*, *F. sporotrichoides*, *F. poae*, *F. verticillioides*, *F. sambucinum*, and *Microdochium nivale* during 1998–2002. The severity of Fusarium head blight (FHB) disease, *Fusarium*-damaged kernels (FDK), reduction in yield, and deoxynivalenol (DON) contamination were also measured to determine the nature of resistance.

The severity ratings of FHB in wheat genotypes inoculated with different *Fusarium* spp. and *M. nivale* were similar. This trend was observed for all other parameters measured. The extent of DON contamination of wheat grains by DON producers of *F. graminearum* and *F. culmorum* was determined. Highly significant correlations were observed between FHB, FDK, yield loss, and DON contamination. Resistance components such as resistance to kernel infection, resistance to DON contamination, and tolerance were identified in more susceptible genotypes. The Western European genotypes produced up to 700 mg DON/kg seed, whereas the Hungarian genotypes produced only 100 mg DON/kg seed at a similar FDK level. The results indicated that the resistance of genotypes was related not only to any particular isolate of *F. graminearum*, but also to isolates of other *Fusarium* spp. Further, measuring both FDK and DON contamination levels was also shown to be an important factor to be included in programs for the selection of resistant germplasm and cultivars (Mesterházy et al. 2005).

Fusarium head blight (FHB) disease of wheat is caused by different species of *Fusarium*, *F. graminearum*, *F. culmorum*, *F. avenaceum*, and *F. poae* (mycotoxin producers) and also by *Microdochium majus* and *M. nivale* (nonmycotoxigenic pathogens). Resistance of wheat to FHB appeared to be horizontal and nonspecies-specific. Two components of host resistance to FHB have been widely recognized as resistance to infection (type I) and resistance to spread within the spike (type II). Single spikelet (point) inoculation assessed type II resistance only, while spraying conidial suspension on spike assessed the combined effect of type I and type II resistances (Miedaner et al. 2003). Type I resistance may be inferred following assessment by both point (type II) and spray (type I plus II) inoculation. The genetic basis of resistance to FHB for identifying and mapping type II resistance was investigated more frequently because of the relative simplicity of assessing this type of resistance. Evaluating type I resistance was more challenging and usually carried out in field trials using spray or natural inoculation, and estimating disease as the percentage of infected spikes in plots or as disease incidence (Steiner et al. 2004). Using *Tri5* gene disrupted transformants of *F. graminearum*, DON was shown to be not essential to facilitate the spread of disease from the point of infection (Proctor et al. 1995; Bai et al. 2002). The relationship between parameters of resistance to FBH and the in vitro tolerance to DON of the winter wheat cultivar WEK 0609, along with susceptible cultivar Hobbit, was investigated using double haploid progeny lines (DHLs) developed from a cross between these cultivars. Analysis indicated that WEK 0609 resistance significantly reduced symptom development, yield loss, and the fungal pathogen DNA (FDNA) and DON content of grain relative to Hobbit. Although both DON and FDNA contents were greater in susceptible than in resistant progeny lines, the ratio of DON to FDNA decreased with increasing susceptibility. The resistance of WEK 0609 appeared to have a greater effect on colonization of the grain by the pathogen than on the accumulation of DON within the grain. In vitro tolerance of WEK 0609 to DON did not seem to be related to FHB resistance in this cultivar, so the in vitro assessment of tolerance to DON was not considered to be a reliable basis for selecting the progenies for FHB resistance derived from this cultivar (Gosman et al. 2005).

The usefulness of species or isolates that produce little or no toxin and infect wheat, but cannot spread within spike, as tools to identify type I resistance was investigated. Following spray inoculation, the average disease severity caused by *Fusarium culmorum* (52.44%) was significantly higher ($P < 0.001$) than that caused by *Microdochium majus* (14.17%). Disease following point inoculation differed dramatically between

pathogens, while *F. culmorum* caused necrosis and bleaching symptoms both above and below point of inoculation. On the other hand, *M. majus* was unable to spread beyond the spikelet into which it was inoculated. Following point inoculation with *F. culmorum*, the number of damaged spikelets per spike ranged from 12.17 (in cultivar Goodwood) to 1.25 (in cultivar Dekan), with an average of 5.98. In contrast, *M. majus* was unable to spread beyond the inoculated spikelet, infecting an average of 0.97 and 0.36 spikelets in two trials. The isolates of *F. graminearum* producing deoxynivalenol (DON) and nivale-nol (NIV) induced similar disease levels in the wheat cultivar Mercia at 12 and 18 days postinoculation after spray inoculation. In contrast, following point inoculation disease levels were significantly different for the DON- and NIV-producing isolates of *F. graminearum* at all three scoring dates (Fig. 12.1). The results indicated that spray inoculation with *Microdochium* spp. might be used to assess type I resistance directly in the absence of any confounding effects caused by differing levels of type II resistance. The cultivar Spark (UK winter wheat) exhibited the highest level of overall resistance and appeared to possess both type I and type II resistance to FHB disease. On the other hand, cultivars Grief, Nirvana, Dekan, and Renan had highly contrasting responses to point inoculation with *F. culmorum* and spray inoculation with *M. majus* with relatively high levels of resistance against *M. majus*, indicating that they possessed predominantly type I resistance with very little type II resistance. The results indicated that the use of appropriate non-DON-producing FHB pathogen species or isolates in spray inoculation experiments, combined with point inoculation using DON-producing isolates, may be useful for identifying and characterizing FHB resistance in wheat (Gosman et al. 2010).

Floral structural characteristics have been reported to influence the level of resistance of wheat cultivars to Fusarium head blight (FHB) disease caused by *Fusarium graminearum*. The closed-flowering (no anther extrusion) characteristic was found to be effective for increasing resistance to FHB infection. The relationship between the degree of anther extrusion (AE) and FHB damage was investigated using double haploid lines (DHLs) derived from F1 plants from crosses between closed-flowering and open-flowering cultivars. These DHLs exhibited various degrees of AE significantly different among DHLs regardless of the year and environment (pot- or field-grown). FHB severity was the lowest in closed-flowering DHLs, and DHLs with partially extruded anthers showed significantly more severe FHB symptoms than those with closed-flowering phenotypes. In general, DHLs with partially extruded anthers also had relatively severe FHB symptoms compared with those exhibiting full anther extrusion. FHB severity was significantly correlated with Fusarium-damaged kernels (FDKs) and deoxynivalenol (DON) concentration. The results showed that partially extruded anthers were sources of infection, whereas the closed-flowering phenotype had improved resistance to FHB infection. The phenotypes with rapid anther extrusion and ejection could also contribute to the avoidance of FHB infection (Kubo et al. 2013).

The influence of inoculum sources (conidial suspension, infested barley, and corn kernels) and inoculation frequency on the development of Fusarium head blight (FHB) and the deoxynivalenol (DON) content was investigated. Three spring wheat genotypes were used in a disease nursery in Ottawa, Canada. Development of FHB was monitored by visually estimating disease severity on a scale of 0–9, six times during each growing season. The severity of FHB over time was represented as the area under the disease progress curve (AUDPC). The intensity of symptoms was rated at a critical development stage (soft dough), as initial-time disease severity (DS), percentage of infected spikelets (IS), and FHB index. Inoculated plants showed greater DS compared with

Figure 12.1 Effects of low- and high-titer of *Fusarium graminearum* conidia in combination with (a) point- and (b) spray-inoculation with the pathogen on (c–d) means of spikes and ears infected by DON- and NIV-producing isolates in spring wheat cultivar Mercia. (e–f) High-titer inoculum produced greater disease severity; DON-producing isolates spread rapidly, while NIV-producing isolate was restricted to inoculated spikelets within the spike. Source: Gosman et al. (2010). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

uninoculated control plants. Regardless of inoculum source, two inoculations produced as much FHB, FDK, and DON as three inoculations. The conidial suspension or infested kernels as a source of inoculum yielded significantly greater AUDPC, DS, FHB index, IS, and DON contents than infested debris. Conidial suspension was a more effective inoculum source than the infested kernels or infested debris which showed similar levels of infections. The results indicated that conidial suspension and infested kernels could be used as inoculants for assessing FHB in nurseries (Xue et al. 2006).

Fusarium head blight (FHB) pathogen causes yield losses and unacceptable quality of grains because of accumulation of mycotoxins. In addition, the end-use quality such as alteration of baking characteristics was seriously affected by the disease. The ability of kernels to prevent penetration of the pathogen and mycotoxin accumulation has been investigated to select the wheat genotypes with resistance not only to FHB incidence but also to restrict accumulation of mycotoxins in grains. Eight modern Swiss spring wheat cultivars were grown in small irrigated field plots (3×1.5 m) inoculated at anthesis with a mixture of *F. culmorum* isolates. Disease ratings from 7 to 28 days postinoculation were compared with postharvest analyses for the accumulation of the mycotoxin deoxynivalenol (DON) and different baking quality parameters. Results indicated that the accumulation of DON in the kernels was correlated with visible symptoms on the ear before harvest. In terms of baking quality parameters, water absorption, dough softening, and dough resistance were impaired in susceptible varieties after FBH infection, while these parameters were not affected in resistant cultivars. Further, based on the results obtained, kernel resistance to FHB was defined by low DON accumulation in kernels and by the stability of several baking quality parameters under conditions of high FHB infection pressure (Gärtner et al. 2008).

The use of wheat cultivars resistant to Fusarium head blight (FHB) disease was considered to be the most effective option for the management of the disease. Deoxynivalenol (DON) accumulation might occur at unacceptable levels in kernels in the cultivars which have improved levels of resistance to infection and spread of *Fusarium graminearum*. The role of genetic variation for resistance to kernel infection (RKI) and resistance to toxin accumulation (RTA) in providing protection against DON was investigated. Spikes with different levels of visual symptoms from each of 32 genotypes and at four environments were collected, and DON content and fungal biomass (FB) from each sample were estimated. Significant genetic effects were recorded for RKI and RTA. The difference among genotypes was more striking for RTA than for RKI, and might have a greater impact on controlling DON levels in the grain. The average r^2 values for RTA regression were 0.39 as against 0.24 for RKI. Some genotypes consistently had low FB in the kernels, despite increasing visual symptoms suggesting a higher RTA in those genotypes. Although RKI and RTA were significantly correlated ($r = 0.58$; $P = 0.05$), RTA was predictive of DON accumulation because it modeled 32–44% of the genotype sum of square for DON among genotypes with acceptable levels of resistance to pathogen infection and spread. The results suggested that RKI and RTA in grains were independent of type I and II resistance in the wheat population and all mechanisms could be combined to produce low DON levels (Sneller et al. 2012).

Fusarium verticillioides (= *F. moniliforme*) and *F. proliferatum*, causing Fusarium ear and kernel rot of corn (maize), produces a group of homologous mycotoxins known as fumonisin which is implicated as a contributing factor in outbreaks of oesophageal cancer and neural tube birth defects in humans. Cleaned and dry milled corn meant for human consumption should not contain more than $2\text{--}4\text{ }\mu\text{g}$ of fumonisin g^{-1} of kernels,

Figure 12.2 Evaluation of corn hybrids under inoculated conditions for resistance to Fusarium ear kernel rot disease. Assessment of disease severity by visual rating based on percentage (0–100%) of ears with symptoms in different corn hybrids. Source: Clements et al. (2004). Reproduced with permission of the American Phytopathological Society, MN, USA.

as per the US Food and Drug Administration (CFR 2001). Local infection of kernels was found to be the most important pathway of infection, although systemic movement of *F. verticillioides* from infected seed and stalks to developing kernels was also indicated (Munkvold et al. 1997). Corn inbreds with high levels of resistance to fumonisin production and accumulation in grains were identified. A genetically diverse collection of inbreds were evaluated to identify potential sources of resistance to fumonisin production and accumulation in grain and Fusarium ear and kernel rot. The F1 hybrids with the inbred FR1064 and 1589 and 1030 inbreds were evaluated in inoculated and naturally infected trials, respectively, in 2000. Inoculum was prepared by blending an equal number of cultures of six isolates of *F. verticillioides* and spray inoculated using backpack sprayers. Primary ears from all plants were harvested and dried with forced air at 32°C to reduce the grain moisture to 14%, and visually rated for severity of Fusarium ear and kernel rot as a percentage (0–100%) of ear with symptoms. The severity of corn ear and kernel rot was affected by trials, hybrids, and trial-hybrid interactions ($P < 0.0001$). Treatment means for ear rot severity ranged from 0 to 59% in Illinois and from 0 to 33% in North Carolina (Fig. 12.2) (Clements et al. 2004).

Wheat lines which were adapted to the southern USA, possessing diverse sources of FHB resistance, were evaluated under greenhouse and growth chamber conditions. Wheat lines with resistance to DON chemotype isolates were even more resistant to NIV chemotype isolates. The chemotypes had similar abilities to initiate infections across the diverse resistance sources used in this investigation. The DON chemotype isolates caused more disease than NIV chemotype isolates. Differences between the DON and NIV chemotypes were most pronounced for the percentage of spikes with premature apical death. Averaged across all wheat lines and both isolates within a chemotype, isolates of the DON and NIV chemotypes caused premature apical death on 25.1 and 7.0%, respectively. DON chemotypes of *F. graminearum* were more aggressive than NIV chemotype. Selecting lines for resistance to the DON chemotype could also select for resistance to NIV chemotype. Florets at the tip of spikes that were affected by premature apical death rather than direct fungal infection were not included in the

count of florets blighted by the pathogen. Significant levels of resistance to both initial infection and spread within a spike were found among lines. Quantifying resistance to initial infection was improved by standardization of the inoculum and environmental conditions. Additional information related to resistance to spread within a spike was obtained by calculating the area under the disease progress curve (AUDPC) from 7 to 21 days after inoculation. The number of initial infection for 15 resistant lines was reduced by 58–91% compared with susceptible check, while the number of blighted florets within a spike following single-floret inoculation was reduced by 48–86% and 50–87% for 15 resistant lines compared with the number of blighted florets on Cocker 9835 for DON and NIV chemotype isolates, respectively, indicating significant effect on FHB severity and mycotoxin accumulation (Horevay et al. 2011).

Fusarium head blight (FHB) of wheat in the USA is primarily caused by the deoxynivalenol (DON-) producing chemotype *Fusarium graminearum*. The nivalenol (NIV) chemotype of *F. graminearum* was also involved in FHB disease in Louisiana and Arkansas states however, necessitating the need to develop wheat cultivars with resistance to both DON-producing and NIV-producing chemotypes. Isolates of *F. graminearum* and *F. culmorum* with DON chemotype appeared to be more phytotoxic or aggressive than isolates with NIV chemotype. Wheat cultivars (8) and rye cultivars (12) were inoculated in the field at three locations using spray inoculation with one DON chemotype isolate and one NIV chemotype isolate of *F. culmorum*, predominantly causing FHB in Europe. Based on disease severity, yield, and toxin content in grain, all tested wheat cultivars and rye lines were found to be more resistant to the NIV chemotype than to DON chemotype of *F. culmorum* (Miedaner and Reinbrecht 2001).

As genetically inherited resistance was considered the most effective option for the management of Fusarium head blight (FHB) disease of barley, a total of 266 barley cultivars and breeding lines originating from China were evaluated for FHB resistance and concentration of DON in grain. Barley plants were inoculated with isolates of *Fusarium graminearum* under field conditions by injecting conidial suspension into a single spikelet of each spike. FHB symptoms were determined by visual examination and DON content was analyzed by high-performance liquid-chromatography (HPLC) technique. Significant differences in FHB ratings and DON levels were observed among cultivars. Visual symptoms of FHB varied over 4.88–71.75% of spikelets at 21 days after inoculation and over 7.86–113.33 units of area under disease progress curve (AUDPC). Twenty-seven lines were more resistant to FHB, with fewer than 12% infected spikelets than the control resistant cultivar Zhedar 2. Twenty-one of the lines mentioned above originated from the area in the middle–low valley of the Yangtze River where FHB epidemics occurred frequently. DON levels in grains ranged over 0.05–24.39 mg kg⁻¹ among tested barley lines. Correlation coefficients were significant between FHB symptom ratings and DON levels. However, no significant correlation was observed between symptom severity and plant height or between symptom severity and heading date (Ma et al. 2009).

The occurrence of epidemics of Fusarium head blight (FHB) disease of barley caused by *Fusarium graminearum* (teleomorph *Gibberella zeae*) in the USA strongly indicated the need to develop commercial barley varieties with resistance to FHB and the ability to allow low levels of DON accumulation. FHB incidence, FHB index, and DON levels of Virginia hulled and hulless barley genotypes were evaluated for over 5 years (2006–2010) in FHB nurseries in Virginia. Barley genotypes were sprayed at 50% anthesis with aqueous suspensions of macroconidia (50,000 conidia mL⁻¹) to create sufficient

disease pressure under field conditions. Susceptibility of barley genotypes to FHB was similar at cell stages of grain development. The mean DON concentration was the lowest in 2008, whereas FHB incidence and index were highest in the same year. Significant differences in FHB and DON resistance were observed among genotypes that were selected to evaluate resistance stability across years. FHB incidence was positively correlated with DON accumulation. Early spike emergence resulted in high FHB incidence and index in 2007, 2008, and 2010. The genotypes (hulless) and Thoroughbred (hulled) ranked among the most FHB-resistant genotypes (Khalibi et al. 2012).

The wheat “Frontana”/“Remus” double haploid population ($n = 210$ lines) were investigated to map and validate the “Frontana” resistance quantitative trait loci (QTL) focusing on *Fusarium*-damaged kernels (FDK). The plant materials were evaluated for FHB resistance under six epidemic conditions created by artificially inoculating plants with either *F. graminearum* or *F. culmorum*. The genetic regulation of FHB resistance was found to be more complex than earlier suggested. FHB resistance QTLs were identified on chromosomes 3A, 4A, and 6B. Markers showed association with FDK resistance on chromosome 3D and at the marker *Xs12m15_4*. QTL on 2B, 4B, 5A, and 7B chromosomes were responsible for both FHB and FDK resistance and, in this case, the same QTL influenced both tracks and also possibly other tracts during pathogenesis. These QTLs were considered to be important because of their association with *Fusarium* resistance. Heading late QTL were detected on chromosomes 1A, 2D, and 7B overlapping with neither FHB nor FDK resistance QTL. The QTL identified in the Frontana/Remus population were in good agreement with results of early investigations (Szabio-Hevér et al. 2012). The mycotoxin DON produced by FHB pathogen *Fusarium graminearum* rendered barley grain unmarketable, if concentration of DON exceeded threshold values set for end-use markets. Elite hulled and hulless genotypes developed by the Virginia Tech winter barley breeding program were therefore screened in inoculated, mist-irrigated FHB nurseries over 2 years at two locations in Virginia to validate resistance levels over years and locations. The results showed that barley genotypes varied significantly for resistance to FHB incidence and DON accumulation in grain. The hulled “Nomini,” hulless “Eve,” and hulless line VA06H-48 were consistently resistant across locations to both FHB incidence and DON accumulation in grain. Screening the genotypes with molecular markers on chromosomes 2H and 6H for FHB and DON indicated quantitative loci regions (QTL) which might confer resistance in the Virginia Tech germplasm (Berger et al. 2014).

Maize (corn) inbred lines were evaluated in two agroecological regions in Nigeria to identify inbred lines resistant to *Fusarium* ear rot caused by *Fusarium verticillioides* and fumonisin accumulation in grain across two agroecological regions. *Fusarium* ear severity in 103 inbred lines ranged from 1.0 to 6.0 with a mean of 1.8 in a 1–7 scale in 2003. The mean severity of 52 selected inbred lines was 2.1 in 2004, as disease severity was higher in 2004 than in 2003. The disease severity of six inbred lines was consistently low in both years and at both locations. Total fumonisin and disease severity were positively correlated across years, when the disease was initiated from natural infection. However, a number of inbred lines with low ear rot severity had high levels of fumonisin concentration in grains, underpinning the need to select for resistance to both fumonisin in grain and ear rot severity in maize breeding programs. At both locations, no significant inbred $\times$ year interaction was observed for fumonisin concentration. Five inbred lines – 02C14585, 02C14603, 02C14606, 02C14624, and 02C14683 – consistently contained the lowest fumonisin concentration in both trials. Two of these inbred lines

02C14624 and 02C14585 had fumonisin levels of $<5.0 \mu\text{g g}^{-1}$ across trials where disease was initiated from both natural infection and artificial inoculation. These two inbred lines showed consistently low disease severity. These two inbred lines possessed potential for deployment of hybrids with good levels of resistance to *Fusarium* ear rot as sources of resistance to both disease development and fumonisin accumulation in kernels. Since the inbred lines were derived from different crosses, they might represent different resistance genes that could be useful in breeding maize for resistance to *Fusarium* ear rot disease (Afolabi et al. 2007).

The role of fumonisins in seedling colonization and induction of seedling blight symptoms by *Fusarium moniliforme* (teleomorph *Gibberella moniliformis*) was investigated using the complementary genetic analysis of host and pathogen. Only one of two fumonisins B1 (FB1)-insensitive maize backcross lines was more resistant than FB1-insensitive parent to seedling blight, indicating that the increase in FB1-insensitivity was not associated with an increase in resistance. FB1-producing and nonproducing isogenic fungal strains did not differ in their ability to cause seedling blight, but the FB1-producing strain was more effective in systemic colonization of seedlings in reciprocal strain challenge tests. The results indicated that the role of fumonisins depended on complex environmental and genetic factors in the maize-*F. moniliforme* pathosystem (Desjardins et al. 2007). New inbred lines with potential resistance to *Fusarium* ear rot and fumonisin accumulation caused by *Fusarium verticillioides* were identified from well-adapted breeding material used in the temperate conditions prevailing in South Africa. Genetically diverse maize inbred lines (24) were assessed for their levels of resistance to ear rot and fumonisin accumulation in field trials at two locations. After artificial silk channel inoculation with *F. verticillioides*, *Fusarium* ear rot development was determined at harvest and fumonisins B1, B2, and B3 were quantified. A significant effect on inbred line by location was observed for *Fusarium* ear rot severity ($P < 0.001$), although some lines proved to be consistently resistant across both locations. The individual inbred lines also differed considerably in fumonisin accumulation between two locations. None of the inbred lines was completely resistant to *F. verticillioides* or fumonisin accumulation. A significant correlation between *Fusarium* ear rot rating and fumonisin concentration in the grain was observed in the field trials. A greenhouse trial using artificial inoculation was carried out on a subset of potentially resistant and highly susceptible lines. A good correlation was observed between the results from the artificially inoculated greenhouse trial with those of field trials, suggesting that greenhouse trials could be used to accelerate progress in the selection of resistant germplasm. The inbred lines CML 390, CML 444, CML 182, VO619Y-2, and RO 549W consistently showed a low *Fusarium* ear rot ($\leq 5\%$) incidence at both locations as well as in the greenhouse assessment. Of these five inbred lines, CML 390 and CML 444 accumulated fumonisin levels of $<5 \text{ mg kg}^{-1}$. These two inbred lines could be dependable sources for breeding maize cultivars with resistance to *F. verticillioides* and the mycotoxins produced by the pathogen in maize kernels (Small et al. 2012).

Aspergillus flavus infecting corn kernels produces aflatoxin harmful to humans and animals following consumption of contaminated grains. Different techniques were used to assess the levels of resistance of corn hybrids to *A. flavus* and aflatoxin accumulation in kernels. The standard inoculation techniques (the side-needle and spray method) were compared with a dry carrier technique. Both techniques were comparable in their effectiveness in differentiating the resistant and susceptible hybrids in the first year of experimentation. However, only hybrids inoculated with the side-needle technique

showed statistically different levels of aflatoxin and *A. flavus* infection in the second year. A modified pinbar technique with inoculations near the tip or base of the ear was compared with side-needle method. When developing ears were inoculated near the base with the modified pinbar, adequate levels of aflatoxin were induced in both years to distinguish the resistant and susceptible corn hybrids. The modified pinbar technique showed potential for evaluation of corn germplasm for aflatoxin resistance (Windham and Williams 2007).

Sorghum crops are commonly infected by different fungal pathogens, some of which are carried by the seeds. Long smut of sorghum, caused by *Sporisorium ehrenbergii*, was found to be a limiting factor in increasing the yield levels in some countries. Sorghum accessions (51) including 31 commercial hybrids and 20 cultivars from the USA were evaluated for their resistance/susceptibility to long smut disease. The highest disease incidence of 44.33% and 16.47% was recorded in 2004 and 2005, respectively, on the hybrid A425, while the hybrids 3552 and A571 were entirely free of infection by *S. ehrenbergii* in two locations in Senegal, West Africa. Five hybrids showed low levels of infection. Among the cultivars and parental lines B. 9612 and R. 9645 consistently recorded low levels of disease incidence (Prom et al. 2007). Sorghum accessions were evaluated for resistance to grain mold and anthracnose diseases in Uganda. Accessions PI34117, PI34144, PI576337, PI297199, PI533833, and PI297210 and SC 748-5 were highly resistant to anthracnose during 2 years of observations. Accessions PI534117, PI297134, and PI297156 exhibited low levels of severity of grain mold disease. Grain mold fungi recorded were *Curvularia lunata*, *Fusarium thapsium*, *Alternaria* spp., and *Fusarium semitectum*. Significant negative correlation was observed between grain mold and seed-germination percentages and high temperatures during 2005–2006 (Prom et al. 2011).

Rice genotypes were evaluated for their resistance to false smut disease caused by *Ustilaginoidea virens*. A screening method was developed involving cultivation of the main culm of rice plants in the greenhouse and rapid preparation of conidial suspension for injection into the leaf sheath of 18 rice varieties/lines were tested by this method. Field trials were also conducted during 2007 and 2008 to compare with the results of greenhouse evaluation. The results indicated that the greenhouse method was more reproducible than field assessment of disease resistance. Commercial varieties were mostly resistant and all the forage varieties were highly susceptible. Rice blast resistant varieties were mostly resistant to false smut disease also. This screening procedure was useful for determining the level of resistance of rice genotypes to false smut disease and utilizing the resistance sources for breeding resistant cultivars (Ashizawa et al. 2011). As the rice sheath blight caused by *Rhizoctonia solani* is one of the major diseases in most rice-growing countries, the identification and subsequent development of resistant cultivars is a critical factor for increasing yield levels. Six moderately resistant cultivars (Teqing, Jasmine 85, Tetep, Peco, Azucdena, and Taducan), one susceptible cultivar MR219 and two advanced breeding lines (UKMRC2 and UKMRC9) were screened using micro-chamber and mist-chamber methods. The fungal isolate used for inoculation was confirmed as *R. solani* using ITS-rDNA sequencing. Tetep followed by Teqing showed a high level of resistance. A significant correlation of plant height and disease was observed with relative lesion height (RLH) indices. Significant correlations were also recorded among diseased plant affected area (DPAA), VRT (visual rating), and RLH, with VRT being the most dependable parameter. Tetep and Teqing were identified as suitable donors based on disease reactions to improve the

resistance of the susceptible cultivars UKMRC2 and UKMRC9. Mist-chamber screening procedure was found to be more reliable to evaluate the rice genotypes for sheath blight resistance under greenhouse conditions than the micro-chamber method (Hossain et al. 2014).

The resistance of rice to bacterial leaf blight (BLB) pathogen *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) increased as the plants of some rice cultivars became older, and this resistance was similar to the adult-plant resistance observed in other crops against virus diseases. Some rice cultivars exhibited resistance to four races of *Xoo*, whereas some others were resistant to one or two races only. Disease severity progressively reduced from seedling to flag leaf stage. The cultivar Wase Aikoku 3 showed adult-plant resistance to these races, but seedling resistance to another race. Adult-plant resistance to BLB in rice appeared to be race-specific (Qi and Mew 1985). Populations of *X. oryzae* pv. *oryzae* (*Xoo*) have been shown to vary greatly in most locations in the rice-growing countries. The *Xoo* isolates (78) collected from 13 different states of northwest and east India were grouped into 6 races based on disease symptoms on 12 near-isogenic lines (NIL). Race 4 and 6 were predominantly present in the northwest part of India, whereas race 1 and race 2 were in more abundance in the northeast hill and plains. Race 1 and race 2 were less virulent than other races, mixed infections by both were less virulent, and virulent races occurred in all locations. Rice cultivars with *R* genes *Xa1* and *Xa2* were susceptible to all races tested, whereas *Xa4*, *Xa11*, *Xa13*, and *Xa41* genes provided stable to moderate resistance to bacterial leaf blight (BLB) disease. *Xoo* secreted type III effectors (T3Es) directly into the rice cells to induce disease symptoms (Mondal et al. 2014).

Verticillium dahliae affects spinach seed production because the plants remain asymptomatic until bolting is initiated (conversion from vegetative to reproductive phase). The USDA spinach germplasm accessions were evaluated for their resistance to *Verticillium* wilt and to determine the range in the incidence of natural seed infection/infestation. A total of 120 *Spinacia* spp. accessions and 10 commercial *S. oleracea* hybrids were screened for resistance to *V. dahliae* in three trials during 2006–2008 under greenhouse conditions. Each accession was grown in either *V. dahliae*-infested or noninfested potting mix and rated weekly on a 7-step scale from 1 week before bolting to 4 weeks after bolting. Most of the accessions were highly susceptible. There was no evidence for qualitative resistance, but some showed greater levels of quantitative resistance than others. Plants grown in infested soil senesced faster and had significantly reduced biomass compared with plants in noninfested soil of the same accession. In the second and third year (2007 and 2008) trials, seed samples were infected to the extent of 34% and 16%. The presence of *V. dahliae*, *V. tricorpus*, and *Gibellulopsis nigrescens* (*V. nigrescens*) in the seed samples was also detected. The results may be useful for characterizing potential variability within spinach germplasm for resistance to *V. dahliae* (Villarreal-Zebello et al. 2012).

Barley covered smut caused by *Ustilago hordei* is a seedborne disease and Canadian cultivars were affected severely by this disease, resulting in appreciable yield reduction. Canadian barley cultivars, parents of six barley mapping populations and four differentials, namely Hannchen (*Ruh1*), Excelsior (*Ruh2*), Plush (*Ruh6*), and Odessa (universal susceptible), were evaluated to identify and map disease resistance genes. Six mated combinations of *U. hordei* sporidial lines harboring known alleles of virulence (*avr*) and avirulence (*Avr*) genes were used in the evaluation procedure. Most of the cvs of barley carried the *Ruh1* resistance gene, but some had *Ruh2* or *Ruh6* also. Many cultivars

showed resistance to a *U. hordei* sporidial mating of genotype (*avr1/avr1*, *avr2/avr2*, *avr6/avr6*) virulent on Hannchen, Excelsior, and Plush. The resistance indicated the presence of novel avirulence gene(s), corresponding to postulated resistance gene(s) in these cultivars. Double haploid lines (56) from mapping the population of Harrington/TR306 were inoculated with a sporidial mating of genotype SM1 (*Avr1/Avr1*, *avr2/avr2*, *avr6/avr6*), avirulent on Hannchen (*Ruh1*) but virulent on Excelsior (*Ruh2*) and Plush (*Ruh6*). Harrington (*ruh1*) was susceptible to this pathogen genotype possessing *Avr1* and TR306 (*Ruh1*) was resistant. Barley lines segregated into 27 resistant to 29 susceptible which were not significantly different from a 1:1 ratio ($\chi^2 = 0.07$, $P = 0.79$). The presence of a single major resistance gene *Ruh1* in TR306 was identified and *Ruh1* mapped to the short arm of chromosome I (7H) between markers iPgd1A and BCD129 on Harrington/TR306 map (Grewal et al. 2008).

Grain mold and head smut pathogens infecting sorghum cause considerable losses in the quantity and quality of grains. Pigments in plants were considered to protect grains against panicle diseases. Near isogenic tan or purple plant color genotypes with white grain were grown under field conditions. Harvested grain was plated into semiselective media to detect the presence of *Alternaria*, *Fusarium*, and *Curvularia* and colonization of grains. *Fusarium* and *Curvularia* spp. were present predominantly. However, there was no indication that grains of purple plants were more resistant to these pathogens. Most fungi were identified as *Alternaria alternata*, *Fusarium thapsinum*, and *F. proliferatum* using molecular techniques. In the case of *Sporisorium reilianum*, incitant of head smut disease, purple plants were more susceptible to the disease than tan plants producing white grains (Funnel-Harris et al. 2013).

The influence of plant age on the level of resistance/susceptibility to diseases caused by microbial pathogens has been studied in some pathosystems. The impact of plant age on resistance of Kabuli cultivars to Ascochyta blight of chickpea caused by *Ascochyta rabiei* was assessed by inoculating cultivars UC27 (susceptible), Sanford, and B90 (partially resistant) and desi cultivar Myles (partially resistant) with two isolates of *A. rabiei*. Seeds were sown at regular intervals to have plants at different growth stages, namely seedling, vegetative, flowering, and podding, which were inoculated at the same time under controlled and field conditions. Cultivar UC27 was highly susceptible at all stages of plant development, but plant age had a significant effect on resistant cultivars. In growth chamber experiments, blight severity was low in seedlings of the resistant cultivars (4–20% infection) and highest at podding stage (41–82%) at 2 weeks after inoculation. Under field conditions, severity at 2 weeks after inoculation showed a similar pattern, with mean severity among resistant cultivars ranging over 1–2% in seedlings and 3–28% in podding plants. The severity of blight disease at 8 weeks after inoculation on resistant cultivars inoculated as seedlings was low (6–14% and 10–23%) in 2 years of experimentation relative to those inoculated at podding stage (65–91% and 54.83%) under field conditions. The results indicated that resistance decreased with plant age in partially resistant chickpea cultivars adapted to western Canada, and it may not be desirable to depend on the varietal resistance alone as an effective approach for the management of Ascochyta blight disease of chickpea (Chongo and Gossen 2001).

Potato cultivars were tested under laboratory, greenhouse, and field conditions for their resistance to wart disease caused by *Synchytrium endobioticum* which was found to exist as two pathotypes 1 (D1) and 6 (O1). Susceptible cultivars produced large warts (>16 mm diameter) and had low levels of field resistance (1–6). Field-resistant cultivars (levels 7–9) produced small warts or no warts in all laboratory tests. In pot tests, at low

inoculum levels (1 sporangium per 25 g of soil) susceptible cultivars contracted infection and developed warts, whereas field-resistant cultivars did not develop any warts below 25 sporangia g⁻¹ of soil. All plants showed infection above 35 sporangia g⁻¹ of soil, whereas field-resistant cultivars had only minimal wart development. As the field-resistant cultivars did not support inoculum buildup in the soil, they did not create a risk of secondary infection (Baayen et al. 2005).

Several *R* genes conferring resistance to *Phytophthora infestans*, causal agent of potato late blight disease, have been identified in *Solanum demissum* (Malcolmson and Black 1966). The pathogen could produce new races capable of matching *R* genes at a faster rate than the researchers were able to produce new potato varieties with unmatched resistance genes. A shift in the objective of breeding therefore became necessary, and breeding for potato cultivars with polygenic or nonspecific resistance (field resistance) was considered as an effective alternative. Molecular techniques have been employed for characterization of different stages of interaction between host plant species and microbial pathogens. In potato, a high-resolution genetic map at the *R3* locus conferring high resistance to avirulent isolates of *P. infestans* was constructed. The *R3* locus consists of two genes *R3a* and *R3b* with distinct specificities. These genes from *S. demissum* were incorporated into potato. One accession of *S. demissum* had a natural recombination between *R3a* and *R3b* (Huang et al. 2004). A new late blight resistance (*R*) locus in *Solanum bulbocastanum* was identified. The late blight resistance genes *Rpi-blb3*, *Rpi-abpt2*, *R2*, and *R2*-like genes were identified in the same *R* gene cluster on chromosome 4 (Park et al. 2004).

An in vitro inoculation procedure was developed using potato plantlets for monitoring major *R* genes in potato and their corresponding *Avr* genes in *Phytophthora infestans*. A population of 93 clones was phenotyped for segregation of two closely linked and functionally distinct genes – *R3a* and *R3b* – in the *R3* locus. Phenotyping of the population was fully consistent with genotyping obtained from analysis of molecular markers that flank each gene. The in vitro assay was shown to be a reliable alternative to detached-leaf assay to phenotype a large population segregating in the *R3* locus. The significant correlation between the results obtained from the two assays indicated that the in vitro inoculation method may be preferred because of its rapidity (faster by 2 months), space-effectiveness, and accuracy (Huang et al. 2005).

The resistance characteristics of Phureja potatoes (*Solanum phureja*) cultivated in restricted areas of the Bolivian Andes were determined under natural conditions. Five Phureja cultivars along with Waych'a Paceña as susceptible control were inoculated by spraying sporangial suspension (8×10^5 mL⁻¹). Disease severity was assessed based on the area under disease progress curve (AUDPC). The potato varieties Chojllu Phureja, Phureja Amarilla, and Polo Phureja might possibly have larger copy numbers of the minor resistance gene against *P. infestans* than another two cultivars (Coca-Morante and Tolín-Tordoya 2013).

Investigations on the mapping and subsequent cloning of an avirulence gene from *Leptosphaeria maculans*, causal agent of blackleg disease of *Brassica* spp., were carried out. The gene *AvrLmJ1* conferred avirulence towards all three *B. juncea* cultivars tested. Analysis of RNA sequence data showed that *AvrLmJ1* was housed in a region of the pathogen genome that contained only one gene that was highly expressed in planta. The closest genes were 57 and 37 kb away. As for other avirulence genes of *L. maculans*, *AvrLmJ1* was located within the AT-rich, gene-poor region of the genome. The encoded protein with 141 amino acids had a predicted signal peptide and was cysteine-rich.

Two virulent isolates possessed a stop codon in *AvrLmJ1*. Complementation of an isolate that induced cotyledonary lesions on *B. juncea* with the wild-type allele of *AvrLmJ1* conferred avirulence towards all three *B. juncea* cultivar tests, suggesting that this gene might confer species-specific avirulence activity (Van de Wouw et al. 2014).

The infection of pepper (chilli) (*Capsicum* spp.) by anthracnose disease caused by *Colletotrichum capsici* was found to be the most common disease at pre- and postharvest stages. *Capsicum* genotypes (41) were initially screened for resistance to anthracnose under natural field conditions. The genotypes showing resistance reaction were tested by artificially inoculating them under in vitro conditions. Recording the results on disease incidence at 9 days after inoculation was the appropriate stage. Of the 41 genotypes tested, four genotypes remained symptomless and 11 genotypes were highly resistant to the pathogen. Based on data from field and in vitro assessments 9 lines, BS-35, BS-20, BS-28, Punjab Lal, Bhut Jolokia, Taiwan-2, IC-383072, Pant C-1, and Lankamura collection, were considered as resistant. The pepper fruits of 16 genotypes were inoculated with two isolates of *C. capsici* to determine their response to the pathogen isolates. The two isolates of *C. capsici* were found to be of different pathotypes. The resistant genotypes had the potential for use as sources of resistance to the anthracnose disease affecting pepper (Garg et al. 2013).

Phytophthora blight disease, which causes *Phytophthora capsici*, causes significant losses in pepper (*Capsicum annuum*). Genetic diversity and plant characteristics of 21 pepper accessions previously identified as resistant to the disease were evaluated using 22 simple sequence repeat (SSR) loci. Accessions resistant to *P. capsici* were identified. Accessions PI 201237 and PI 640532 appeared to have high levels of resistance to Phytophthora blight disease (McGregor et al. 2011). A novel inhibitor gene of resistance to *P. capsici* (*lpcr*) was identified in chilli pepper (*C. annuum*) in cultivar New Mexico Capsicum Accession 10399 (NMCA10399). The gene *lpcr* inhibited resistance to *P. capsici*, but not to other species of *Phytophthora*. In a cross between the highly resistant variety and NMCA10399, the resultant F1 populations screened for resistance were completely susceptible to *P. capsici* for root rot and foliar blight symptoms, despite the dominance inheritance of *P. capsici* resistance in chilli pepper. The F2 population displayed a 3:13 resistant-to-susceptible (R:S) ratio and a backcross population to MNCA10399 displayed complete susceptibility. The results demonstrated the presence of a single dominant inhibitor affecting *P. capsici* resistance in chilli pepper. Furthermore, when lines carrying the *lpcr* gene were challenged against six *Phytophthora* spp. the nonhost resistance was not overcome. The *lpcr* gene therefore appeared to interfere with the host-specific resistance but not the pathogen- or microbe-associated molecular pattern of nonhost responses (Reeves et al. 2013).

Phytophthora capsici infects squash and pumpkins (*Cucurbita* spp.) causing seedling mortality, crown and root rot, foliar blight, and fruit rot at different stages of plant growth. Accessions of *C. moschata* (119) from 39 geographic locations throughout the world, and a highly susceptible butternut squash cultivar, Butterbush, were inoculated with a suspension of three highly virulent *P. capsici* from Florida to identify resistance to crown rot. Mean disease rating (DR) of the *C. moschata* accessions ranged from 1.4 to 5.0 (0–5 scale). A set of 18 PIs from original screen were rescreened for crown rot resistance. The accessions PI176531, PI458740, PI442266, PI442262, and PI634693 with lowest disease severity of crown rot (<1.0) were identified. These accessions showed promise as donors of resistance to crown rot disease in cucurbits (Chavez et al. 2011). *P. capsici* was found to be a serious threat to the production of many vegetable crops. Crown rot disease resistance of *Cucurbita melo* (honeydew and muskmelon)

was investigated by inoculating seedlings under greenhouse conditions. USPIs (308) and two commercial cultivars (Athena and Diners) were grown in the greenhouse and seedlings at 2–4-leaf stage were inoculated with a 5-isolate zoospore suspension (1×10^4 zoospores/seedling) at the crown and monitored for 6 weeks for symptom development. All susceptible control plants of cultivar Athena were killed within 7 days postinoculation. The majority of the PIs (281 of 308) was highly susceptible to crown rot and succumbed to the disease rapidly; less than 20% of the inoculated plants survived. After first screening and reevaluation, more than 80% of the inoculated plants survived in only six PIs. Disease development was significantly slower on these PIs compared to the susceptible control plants. Based on higher levels of resistance, three accessions (PI420180, PI176936, and PI176940) were selected for exploiting their potential as sources of resistance to crown rot caused by *Phytophthora capsici* (Donahoo et al. 2013).

Managing black rot disease of cabbage caused by *Xanthomonas campestris* pv. *campestris* (Xcc) was found to be very difficult and uneconomical if the susceptible cabbage cultivar was grown in Tanzania. Local and introduced cabbage cultivars (31) were therefore screened for resistance to black rot disease under field conditions. Differences in resistance for both foliar and internal stem/head symptoms were observed. Open pollinated varieties were highly susceptible to black rot. Of the 31 varieties tested, 14 varieties showed partial resistance and some of these varieties possessed some undesirable characteristics (head splitting, poor taste, loose or flat heads). In another experiment, the reactions of five selected varieties were determined following artificial inoculation with four strains of the pathogen through roots or foliage. No significant difference in the cabbage varieties inoculated through roots or foliage could be observed (Massomo et al. 2004).

Bacterial fruit blotch (BFB) disease of watermelon and melon caused by *Acidovorax avenae* subsp. *citrulli* (Aac) was considered as a serious threat to the industry. None of the available commercial cultivars showed resistance to BFB disease. The levels of tolerance/resistance of the commercial varieties and breeding and wild lines to BFB disease were therefore assessed using seed-transmission assays and seedling inoculation procedures. Some of the varieties were tested in the greenhouse using mature plants. All cultivars/lines were found to be susceptible to the pathogen and most of them showed different responses to BFB disease. However, some varieties showed consistent reactions. The cultivar ADIR 339 was relatively tolerant in all tested assays and cultivar 6407 and wild lines BCB-B and EAD-B were relatively tolerant in seed-transmission assays. Evidence supporting a strong correlation between level of susceptibility of a cultivar/line and the ability of Aac to adhere to or penetrate the seed was revealed by this investigation (Bahar et al. 2009). In a later investigation, *Cucumis* spp. PIs (332) were screened for resistance to *Acidovorax avenae* subsp. *citrullii* using a newly developed seed vacuum-infusion assay. Significant difference in the reaction of the PI to bacterial fruit blotch (BFB) was observed. The majority of lines were found to be extremely susceptible to the disease. Some of the PIs had lower levels of resistance. Variability in the reaction of plants within each PI was also observed. Of the 332 PIs tested, 16 were selected for additional evaluation using a standard spraying inoculation test. The PIs 353814, PI381171, PI536573, and PI504558 (*C. ficifolius*) were found to have significantly greater levels of resistance than susceptible control cultivars or other PIs in two independent spray inoculation tests. Germplasm lines identified in this investigation might be useful as sources of resistance to BFB in *Cucumis* spp. breeding programs (Wechter et al. 2011).

Levels of resistance to common scab disease caused by *Streptomyces turgidiscabies* within potato (*Solanum tuberosum*) cultivar Russet Burbank clonal lines and other selected processing cultivars were determined. Significant variability in the resistance levels was observed. Across two-thirds, cultivars Russet Nugget and Shepody and Russet Burbank clone British Columbia were consistently grouped within the cluster of least disease incidence, whereas cultivars Russet Norkotah and Vancouver unit four grouped within the cluster showing greatest disease incidence. Russet Nugget and British Columbia were also consistently grouped within the cluster showing least disease severity, whereas Shepody and Russet Burbank clone Starks were grouped within the cluster with greatest severity scores. For some clones, consistency of rating across trials was not always apparent (Wilson 2001). Comparative resistance levels of seven potato varieties to common scab pathogen *Streptomyces turgidiscabies* were assessed in the field with a paper pot method developed in this investigation. Seedlings raised in soil in paper pots containing inocula at 1×10^3 to 10^7 CFU g⁻¹ soil were transplanted into a scab-free field and grown for 3 months. The disease severity differed across trials and years, even though their levels of resistance were approximately similar. With the paper pot method, the potato cultivar showed different resistance levels which were almost completely consistent with the results of the field trials, at more than 1×10^5 CFU g⁻¹ soil. Significant differences in disease severity between resistant and susceptible varieties could be recognized ($P=0.05$) for 2 years (Kobayashi et al. 2005).

Huanglongbing (HLB, formerly known as greening) disease of citrus caused by "*Candidatus Liberibacter asiaticus*" (CLAs) had become a serious threat to the citrus industry in Florida's Indian River region. The incidence and severity of the HLB disease was assessed in the commercial groves where HLB incidence was high. In each grove, 20 trees of each cultivar were scored for incidence and severity of HLB disease based on visual symptoms. Leaves were collected for quantitative polymerase chain reaction (qPCR) quantification of "*Ca. Liberibacter asiaticus*" (CLAs). A strong correlation between HLB rating and CLAs titer was observed as represented by Ct values. The Ct values were $r^2=0.37$ and 0.40 for whole tree and leaf sample, respectively, ($P<0.0001$) across all cultivars and groves. Although the incidence and severity of HLB differed considerably among the groves, scion-specific differences were apparent even when analyses excluded potentially confounding grove effects. The cultivar "Temple" tangor showed the least incidence and CLAs titer. In contrast, "Murcott" tangor and "Minneola" were infected heavily and CLAs titer was the highest. Levels of resistance based on the disease incidence and severity and pathogen DNA titer might be useful to identify the sources of resistance to HLB disease in *Citrus* spp. (Stover and McCollum 2011).

Some citrus accessions such as rough lemon were reported to be tolerant to huanglongbing (HLB) disease caused by "*Candidatus Liberibacter asiaticus*." In order to understand the HLB tolerance/susceptibility mechanism(s) operating in citrus, comparative anatomical analysis of tolerant rough lemon and sensitive sweet orange seedlings in response to HLB-associated bacterial pathogen were carried out. Anatomical alterations in leaf, stem, and root tissues in healthy and infected plants were determined by light and electron microscopic observations. Phloem collapse, plugged sieve elements, and accumulation of starch were observed in leaf petioles of symptomatic leaves from both HLB-disease-infected rough lemon and sweet orange, while mock-inoculated plants did not exhibit such variations. In symptomless leaves significant anatomical changes as in symptomatic leaves were only observed in diseased sweet orange, but not in rough lemon plants. Further, starch depletion, phloem cell collapse,

and the absence of phloem fibres were observed only in secondary roots of diseased sweet orange. In young green stems starch deposition occurred only in the sweet orange plants. At the whole-plant level, HLB infection induced fewer disruptive anatomical changes in rough lemon than in sweet orange; the absence of changes in rough lemon root system was considered to be critical for sustaining plant growth after infection and might contribute greatly to its HLB tolerance (Fan et al. 2013).

The resistance conferred by a gene of cultivars against viral infection is called cultivar resistance. The plant species to which the cultivar belongs is susceptible as a whole. Cultivar resistance may become ineffective when a virulent strain is formed by mutation or selection from a mixture of strains. The term tolerance is applied for an interaction between the host and virus which is not observed in the interaction between fungal or bacterial pathogens with their respective host plant species. Tolerance is resistance to symptom development rather than to the virus replication. Latent infection by a virus does not induce any recognizable symptom. When the virus becomes systemic and produces observable symptoms on other plant parts, the response is designated susceptibility (Matthews 1991). Acquired resistance is another unique phenomenon commonly associated with virus infection. When inoculated with a virus, the susceptible plant becomes resistant to subsequent infection by the same virus or its strains. Such cross-protection against related viruses or its strains has been advocated as a virus disease management strategy, especially against viruses infecting perennial crops such as citrus. Another aspect of resistance to virus diseases is the requirement of resistance to vectors which are involved in the transmission of most plant viruses from infected plants to healthy plants under natural conditions. A virus-coded function and the product of the host resistance gene may be involved in the recognition of the presence of the viral pathogen, leading to susceptibility or resistance. If the product of resistance gene is directly involved in the recognition event, it may be an inhibitor of virus infection and resistance would be constitutive in nature. Alternatively, the resistance gene product produced on meeting the virus factor may signal the induction of a host defense mechanism, leading to the production of a compound(s) inhibitory to virus replication and movement. Plants exhibit different grades of resistance to a virus which may operate at different steps of virus replication such as uncoating, synthesis of replicase, translation of virus-coded information, and production of movement protein (Narayanasamy 2011).

Resistance to viruses may be expressed by hypersensitive reaction (HR), involving necrosis of cells or tissues restricting the spread of virus in the inoculated plants. The gene for hypersensitivity in *Nicotiana glutinosa* to Tobacco mosaic virus (TMV) was incorporated into some commercial lines of tobacco (*Nicotiana tabacum*). This type of resistance is also known as field resistance. Resistance to viruses may be due to simple genetic control involving only a single locus. The resistance may be completely dominant or recessive, conditioned by a single gene or polygenes. Resistance to several viruses (69 of 87) was inherited as a monogenic dominant, incompletely dominant, or apparently recessive factor (Fraser 1990). If resistance is measured only on the basis of symptom severity, it may be considered to be dominant or recessive; if virus multiplication is the basis for assessment of resistance however, then incomplete dominance (gene-dosage dependence) of resistance may be observed. Such a situation was seen in the case of resistance due to the *Tm-1* gene to TMV in tomato (Fraser and Loughlin 1980) and resistance due to the *bc-1* gene to Bean common mosaic virus (BCMV) in *Phaseolus vulgaris* (French bean) (Day 1984). Virus multiplication as a basis of resistance

to virus may be important because symptom severity may not be always related to virus titer (concentration) in infected plants. Incomplete dominance (gene-dosage dependent) of resistance was found to be strongly associated with partial localization of the virus. The virus may be localized in the inoculated leaf itself or, if the virus is allowed to become systemic, virus multiplication was significantly reduced. Tomato cultivar with *Tm-1* gene showed systemic infection, but multiplication of TMV was inhibited (Fraser and Loughlin 1980; Watanabe et al. 1987).

A small number of recessive genes may offer complete resistance (immunity) in certain host–virus combinations. Immunity of Arlington cowpea to *Cowpea mosaic virus* was due to the constitutive expression of a single dominant gene. A protease inhibitor that specifically inhibited processing of the polyproteins of *Cowpea mosaic virus* was shown to be involved in the resistance (Bruening et al. 1987; Ponz et al. 1988b). Resistance to *Potato virus Y* in pepper plants homozygous for the recessive resistance allele y^a (Pr2') was found to be due to impaired cell-to-cell movement of the virus, rather than to interference with virus multiplication (Arroyo et al. 1996). Virus strains capable of adopting the introduced genes for resistance have rapidly restricted the usefulness of virus-resistant genotypes and made the genes ineffective in the same host–virus pathosystem. Resistance to *Cucumber mosaic virus* (CMV) was found to be “weak” and short-lived since the virus exists in the form of many strains with varying levels of virulence (Matthews 1991). The quality of the produce obtained from resistant cultivar may be poor, although the resistance gene may offer effective protection as in *Tobacco mosaic virus* (TMV-) resistant tobacco cultivar (Johnson 1983).

However, there are some virus diseases for which durable resistance was observed. The resistance genes *Tm-2²* in tomato against TMV, “Ry” in potato against *Potato virus Y*, and “N” in tobacco against TMV were found to be highly durable (Fraser 1990). Many viruses are known to be transmitted through true seeds of infected plants. Considerable difficulty was observed in eliminating the viruses from seeds. Investigations were therefore carried out to identify resistance to seed transmission of viruses with a view to reducing initial inoculum of viruses introduced through infected seeds. Resistance to seed transmission of *Barley stripe mosaic virus* (BSMV) in barley was controlled by a single recessive gene (Carroll et al. 1979). The barley cultivar Mobet had the resistance gene introduced from an Ethiopian barley cultivar Modjo Mobet barley which had high resistance to seed transmission of BSMV and desirable agronomic attributes (Carroll et al. 1983). Lines possessing resistance to seed transmission of *Lettuce mosaic virus* (LMV) in lettuce (Matthews 1991) have been identified.

Resistance to virus diseases has a unique aspect of differentiating the resistance to virus replication and resistance to symptom development. Resistance to virus ultimately results in resistance to the disease. However, necrosis as part of resistance response may prove to be lethal, as in the case of “I” gene resistance to *Bean common mosaic virus* infecting bean (*Phaseolus vulgaris*) (Collmer et al. 2000). The virus is able to become systemic in the plants of some genotypes, showing resistance to symptom expression in a manner that is distinguishable from the susceptible plants, but disease symptoms are not visible. Such plants are considered as tolerant and this trait is heritable. Tolerance to *Cucumber mosaic virus* (CMV) has been exploited as a disease management strategy in cucumber production (Hull 2002). Acquired resistance, also known as cross-protection against related strains or viruses, has been the principal management strategy adopted in the case of certain viruses infecting fruit trees such as *Citrus tristeza virus* (CTV) (Narayanasamy 2006). *Bean common mosaic virus* (BCMV) and *Bean common mosaic*

necrosis virus (BCMNV) are seed-transmitted at a high frequency, making most disease management tactics ineffective. Use of resistant cultivars therefore appeared to be the desirable approach for containing these diseases effectively. Use of molecular markers was useful to accelerate the progress in breeding programs. The *bc-1²* allele conferred resistance to BCMV strains within pathogroups I, II, and V and pathogroups III strains of BCMNV (Drijfhout 1978). The usefulness of sequence-characterized amplified regions (SCAR) markers which were tightly linked with *bc-1²* were developed (Miklas et al. 2000; Vandemark and Miklas 2002). The SCAR markers linked to *1* allele which conditioned resistance to all strains of BCMV and BCNMV was developed. For simultaneous genotyping of bean plants for the *1* and *bc-1²* alleles which condition resistance in bean to BCMV and BCNMV, a multiplex real-time PCR assay was found to be effective. The segregating bean populations could be used for assigning genotypes for both the *bc-1²* and *1* alleles. The number of F3 family progeny tests was substantially reduced. In addition, the desired genotypes could be identified at the seedling stage, resulting in acceleration of progress in germplasm enhancement and cultivar development (Melotto et al. 1996; Vandemark and Miklas 2005).

Two principal types of resistance – hypersensitive and extreme – to *Potato virus Y* (PVY) in potato have been recognized. The HR to PVY is strain-specific causing a range of necrotic reactions in both locally and systemically infected leaves (Valkonen et al. 1998). The *Ny* genes involved in *R* were identified in several potato cultivars (de Galarreta et al. 1998), but in some cultivars HR may not restrict spread of virus in plants. The *Ry* genes for extreme resistance (ER) to PVY conferred an extremely high level of protection against all PVY strains (Vidal et al. 2002). The potato chromosome contains the HR gene *Ny_{1br}* (Celebi-Toprak et al. 2002). The *Ry_{adg}* (*Solanum tuberosum* ssp. *andigena*) and *Ry_{sto}* (*S. stoloniferum*) were mapped to chromosome XI, whereas *RY_{chc}* (*S. chavense*) was located in chromosome IX (Brigneti et al. 1997; Hämäläinen et al. 1997; Hosaka et al. 2001).

Marker-assisted selection (MAS) was found to be one of the most useful applications of DNA-based markers in potato breeding programs for disease resistance. A novel locus for ER to PVY, *Ry_{fsto}*, was identified on potato chromosome XII. Bulk segregate analysis (BSA) was applied to identify an intersimple sequence repeat (ISSR) marker UC857 linked to *Ry_{fsto}*. This marker mapped to the 980 linkage group XII of a reference potato RFLP map. The RFLP markers were converted into PCR-based sequence-tagged site (STS) and cleaved amplified polymorphic sequence (CAPS) markers. The CAPS marker GP122₇₁₈ was tightly linked to the resistance gene that was reliably identified in Polish and German cultivars expressing ER to PVY. The results indicated that the CAPS marker GP122₇₁₈ has the potential for use as a diagnostic tool to monitor the distribution of specific resistance gene in a wide gene pool (Flis et al. 2005).

The incidence of *Potato virus Y* (PVY) is widespread, and as a result the yield and quality of pepper fruits are significantly reduced in the Republic of South Africa. Commercially grown pepper lines were evaluated for their resistance to PVY infection. Six commercial F1 pepper lines were challenged with PVY isolates JYW-186 by mechanical inoculation. Levels of resistance of pepper lines were assessed by visual screening for disease severity and the virus titer was determined by quantitative triple-antibody sandwich ELISA format. The pepper lines were further characterized using tetra-primer amplification refractory mutation system (ARMS-) PCR to identify and differentiate homozygous/heterozygous resistance alleles at the *pvr2* locus that conferred resistance to PVY. Two resistant lines (Double UP and Cecelia)

were identified and other lines showed susceptibility to different grades when challenged with PVY. The *pvr2* + allele was identified in all the susceptible pepper lines which confirmed the presence of this allele, dominant for PVY susceptibility (Moodley et al. 2015).

The successful deployment of the desired gene(s) into crop plant species depends more upon the identification of a positive phenotype and dissection of the phenotype, resulting in the identification of genetic markers for marker-assisted selective (MAS) breeding, and on an understanding of how the novel resistance will perform in different genetic background and under pathogen pressure in the field. The molecular markers facilitate the adoption of disease resistance strategies such as gene deployment. Pyramiding of resistance may be easily achieved using molecular markers. While breeding for resistance to one disease, the possibility of introducing susceptibility to another disease could be avoided if molecular markers are used. Pyramiding of resistance genes effective against all known pathotypes of the pathogen may be achieved using molecular markers. Manipulation of disease resistance genes through molecular approaches has opened up several opportunities to combine resistance genes of diverse origin, something which is not possible by conventional methods. However, molecular marker technology is presently very expensive and it may not be possible to use this method for routine analysis of a large number of breeding lines. Marker-assisted selection (MAS) programs may be used increasingly when the markers for a greater number of resistance genes become available at an affordable cost (Narayanasamy 2011).

12.2.1.2 Assessment of Resistance by Quantification of Pathogen Biomass

It is possible to quantify the pathogen biomass in the infected plant tissues and relate it to the level of resistance of the test plant to the pathogen concerned. A negative relationship between the pathogen biomass and resistance of plant to the pathogen has been observed in several pathosystems. Immunoassays and nucleic acid-based techniques have been demonstrated to be effective for assessing levels of host resistance to microbial pathogens causing crop diseases. The levels of resistance of wheat and triticale cultivars to leaf blotch disease caused by *Septoria tritici* and leaf and glume blotch caused by *Stagonospora nodorum* were assessed by applying a specific and quantitative biotin/avidin (BA-) enzyme-linked immunosorbent assay (ELISA) under field conditions. The antigen contents representing the target pathogens were determined in the flag leaf (F) and first leaf below the flag leaf (F-1) at a predetermined growth stage of 5 triticale and 11 wheat cultivars. *S. nodorum* was present predominantly in triticale cultivars, whereas both pathogens could be more frequently detected in wheat cultivars by BA-ELISA tests. The absorbance values correlated well with susceptibility rating in the cultivars list recommended by the German Federal Office of Plant Variety (Bundesortenamt) based on visual assessment. The diagnostic assay could be employed for detecting the pathogens before visible symptoms appeared and also when the disease pressure was low, that is, below the recognition level by visual assessment. In addition, BA-ELISA could be effectively applied to differentiate the effect of the two pathogens and provide an accurate assessment of disease severities caused by them individually. As the quantitative differences in the pathogen biomass could be ascertained by using BA-ELISA tests, the levels of resistance of cultivars and genotypes might be effectively graded (Tian et al. 2005). The BA-ELISA format has the potential for use in the assessment of levels of resistance of crop cultivars and genotypes in breeding programs.

It is well known that the responses of cultivars and genotypes differ considerably depending on the race, strain, or biotype of the pathogen. Precise identification of the isolates is therefore essential to assess the levels of susceptibility/resistance of genotypes and cultivars. The molecular identity of strains of the potato late blight pathogen *Phytophthora infestans*, present in the Toluca Valley of Mexico, was investigated. The isolates of *P. infestans* obtained from five potato varieties with differing levels of resistance were compared based on the mating type (MT), isozyme genotype for glucose-6-phosphatase isomerase (Gpi) and peptidase (Pep), and sensitivity to metal-axyl. Further, a detached-leaf assay in the laboratory and attached-leaf assay in the greenhouse was used for three potato varieties to assess the host resistance components and specificity of host-pathogen interaction. The genetically derived host factors such as efficiency of infection, number and size of lesions, latent period or time required for sporulation after infection, and sporulation capacity were considered as host resistance components. The isolate from cultivar Alpha (susceptible) did not infect cultivar Norteña (resistant) in the laboratory and greenhouse tests, indicating the existence of gene-for-gene interaction between *P. infestans* and potato cultivars. The cultivar Norteña had major or veritcal resistance genes for corresponding virulence genes of the pathogen. As the cultivar Alpha did not contain matching *R* genes, it could be infected by wild-type, virulent, and avirulent pathogen genotypes alike. The field resistance shown by cultivars Rosita and Norteña was lost when the plants of these cultivars were artificially inoculated under greenhouse conditions. However, these potato cultivars remained resistant under the natural conditions of Toluca Valley (Grünwald et al. 2002).

A real-time PCR procedure was applied for the detection and quantification of *Phytophthora capsici*, causing Phytophthora root rot disease in pepper (chilli) plants. By using the real-time PCR assay with SYBR Green Supermix (BioRad) and specific primers for *P. capsici*, the pathogen DNA could be detected as early as 8 h postinoculation. The increase in pathogen DNA was more rapid in susceptible cultivars and slower in resistant genotypes (PI1201234 and SCM331). The amount of pathogen DNA quantified in each pepper genotype was correlated with the levels of susceptibility (positive)/resistance (negative). The relationship between virulence (aggressiveness) of the pathogen and extent of plant tissue colonization was also revealed. The results demonstrated that real-time PCR with SYBR Green was sensitive and robust enough to assess both pathogen development and the levels of resistance of pepper cultivars and genotypes to *P. capsici*. The resistant genotypes selected based on the molecular technique might be used as sources of resistance to *P. capsici* in programs for development of pepper cultivars resistant to Phytophthora blight/root rot disease (Silvar et al. 2005).

Chinese wheat cultivar var. Sumai 3 and its derivatives such as Ning 7840 were used extensively as sources of resistance to Fusarium head blight (FHB) disease caused by *Fusarium graminearum*. The FHB disease resistance genes from these genotypes were characterized through molecular mapping (Bai et al. 2003a). Wangshuibai, a Chinese landrace, possessed a high level of resistance to pathogen spread within a spike and the resistance was more stable than that of Sumai 3. The recombinant inbred lines (RIL) derived from the cross between susceptible cultivars Alondra and Wangshuibai were assessed. Fifteen AFLP markers associated with three quantitative trait loci (QTL) for FHB resistance were located in two chromosomes. One QTL was mapped on 1B and two others were mapped on 3B. One QTL on 3BS had a

minor effect. The marker-assisted selection (MAS) for FHB resistance genotypes could be made using closely linked markers such as single-sequence repeat (SSR) markers. It was possible to eliminate undesirable associations between FHB resistance and other agronomic traits (Zhang et al. 2004). By making crosses between wheat and rye, common cultivars and breeding lines with FHB resistance were developed (Lu et al. 2000).

Molecular techniques have been applied for characterization of genes involved in conferring resistance to bacterial diseases affecting crop plants. Many major genes involved in resistance to rice bacterial leaf blight (BLB) disease caused by *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) have been identified and designated in a series from *Xa1* to *Xa28*. The resistance genes (>10) were mapped on various chromosomes, especially 4 and 11 (Kinoshita 1995; Lee et al. 2003; Yang et al. 2003). The wild relative *Oryza longistaminata* is highly resistant to *Xoo*. The *Xa21* locus conferring resistance to all races of *Xoo* in India and Philippines was transgressed from *O. longistaminata* to rice cultivar IR24. The *Xa21* gene coding for a receptor kinase-like protein was inherited as a single gene in transgenic plants (Song et al. 1995; Wang et al. 1996). These plants were resistant to 29 of 32 isolates of *Xoo* from India and other SE Asian countries. The presence of a single member of multigenic family *Xa21* appeared to be sufficient to confer resistance to different isolates of *Xoo* (Wang et al. 1996; Ronald 1997). The development of *Xylella fastidiosa* (*Xf*), causing grapevine Pierce's disease (PD) in resistant and susceptible genotypes and representing a diverse selection of *Vitis* spp., was monitored by measuring pathogen movement and accumulation. The pathogen was inoculated onto the selected grapevine genotypes under greenhouse conditions. DAS-ELISA format was optimized for quantification of *Xf* populations and was employed to estimate the *Xf* population quantitatively in stem, internode, petiole, and leaf blade samples from different genotypes at 12 weeks after inoculation. Differences in *Xf* populations between stems and leaves of resistant genotypes suggested that a localized mechanism might operate within xylem, one which is not fully functional or possibly absent from xylem of petioles and leaf blades. The quantitative ELISA estimates of *Xf* in the greenhouse-grown grapevines might be an effective pointer of the level of resistance to Pierce's disease under field conditions (Krivanek and Walker 2005).

Managing the loose smut of wheat caused by *Ustilago tritici* utilizing the genetic resistance has been attempted around the world as the disease reduces the grain yield roughly in proportion to the disease incidence. DNA markers of genetic resistance have been shown to greatly reduce the time and labor resources required for screening of genotypes by employing traditional inoculation methods. In order to identify DNA markers associated with resistance to loose smut disease, double haploid progeny from the four crosses Glenlea/AC Taber, SC8021V2/AC Karma, Dimant/TD12A, and 9340-CP/AC Vista were evaluated with individual races of the pathogen and simple sequence repeat markers. Simple interval mapping was performed using MQTL software and single point analysis. With complete and broad resistance to all known races of *U. tritici* in Canada, Glenlea contributed a QTL for resistance to races T2, T10, T15, T19, and T39 at *Xwmc* 160 on chromosome 5B. Glenlea also contributed QTL for resistance to races T2, T9, and T15 at *Xgwm*302 on chromosome 7B and to races T9, T19, and T39 on chromosome 3A at marker *Xwcm* 559. The chromosome 5B QTL from Glenlea coincided with a race T39 resistance locus from AC Karma. The chromosome 5B locus in combination with either the 7A or 7B genetic loci might provide resistance to predominant races of *U. tritici* present in Canada (Knox et al. 2014).

12.2.1.3 Molecular Basis of Resistance to Fungal Diseases

Two principal kinds of defense mechanisms operate in plants to prevent/restrict the infection and invasion of microbial pathogens. Passive or pre-existing defense mechanisms involving structural barriers, such as waxy cuticle or reservoirs of antimicrobial compounds that are strategically positioned to act on the invading pathogen(s), are known to operate in some pathosystems. The role of preformed pericarp phenylpropanoids in the development of resistance in maize kernels of 11 maize genotypes was investigated. Kernel rot disease severity and fumonisin accumulation were determined after inoculation with *Fusarium verticillioides* and related to contents of pericarp phenylpropanoids in samples obtained from field trials conducted for 2 years. Grain fumonisin concentrations were highly dependent on disease severity of the genotypes ($r = 0.88$). Analysis of pericarp phenylpropanoids indicated the presence of trans-ferulic acid (tFA), cis-ferulic acid (cFA), p-coumaric acid (pCA), and five diferulates (DFAtz). The most predominant diferulates were 8.5'-diferulic acid bensofuran (8.5'-DFAtz) followed by 8.5'-DFA. Except for cFA, the most resistant genotypes exhibited high levels of phenylpropanoids which were related to low levels of disease severity and grain fumonisin accumulation. A stepwise regression analysis revealed that total diferulates contents were more related to variability of disease severity ($r^2 = 0.71$) than any other parameters considered. Grain fumonisin concentration was reflected by the contents of total diferulates, 8.5'-DFAbz and pCA ($r^2 = 0.82$). The results suggested that high levels of phenylpropanoids in the kernel pericarp is a trait associated with less disease severity and lower level of accumulation of fumonisin elaborated by *F. verticillioides* (Sampietro and Fauguel 2013).

Active defense mechanisms are induced following initiation of the infection process when structural barriers are breached by pathogens, leading to prevention of further colonization of plant tissues. Active defense responses induced by fungal, bacterial, or viral pathogens may be of three types: primary responses, secondary responses, and systemically acquired responses. Primary responses are restricted to the infected cells or to cells in close proximity to the pathogen, and the specific signal molecules produced by the pathogens have to be recognized by host cells. The outcome of this interaction may rapidly result in the phenomenon known as programmed cell death (PCD) which may be defined as a self-destructive process triggered by external or internal factors. PCD is mediated through an active genetic program which is considered to have a crucial role in the development and survival of diverse organisms (Pontier et al. 2004). The secondary responses are observed in the adjacent cells surrounding the initially infected cells in response to diffusible signal molecules (elicitors) released by pathogens. Systemically acquired response is due to the action of defense-related compounds that can be translocated throughout the plant, leading to systemic acquired resistance (SAR) (Hutcheson 1998). The gene-for-gene concept of Flor (1946) proposed for the classical flax-rust (*Melampsora lini*) could be explained based on the specific genetic interaction between the host plant resistance *R* and the pathogen avirulence (*Avr*) genes. The *R* genes of the host plant encode specific receptor site(s) for direct or indirect products of the corresponding *Avr* genes. The interaction between the gene products has been demonstrated using yeast two-hybrid system (Dodds et al. 2006).

Fusarium head blight (FHB) disease caused by *Fusarium graminearum* is responsible for both quantitative and qualitative losses. The spikes responded to infection by *F. graminearum* by activating a set of defense response genes in infected spikelets. In order to determine whether defense response genes were expressed systemically

within *F. graminearum*-inoculated spikes, the transcript accumulation of four defense response genes – peroxidase and pathogenesis-related (PR) proteins PR-1, PR-3, and PR-5 – was determined in colonized and uncolonized portions of wheat spikes of resistant and susceptible genotypes. Whether the sampled regions of point-inoculated wheat spikes were colonized or not was determined using *Fusarium* spp.-specific plate assay and a *F. graminearum* isolate expressing β -glucuronidase (GUS). The GUS-expressing *F. graminearum* isolate proved particularly useful for visualizing and following the spread of the fungus and for measuring the amount of fungus biomass in spike tissues. The results showed that transcripts of the four defense response genes accumulated in both colonized and uncolonized regions of the spikes of resistant and susceptible genotypes at 48 h after inoculation. Direct contact with the pathogen was not required for induction of defense response genes, and these genes were activated in both susceptible and resistant genotypes (Pritsch et al. 2001).

Development of Fusarium head blight (FHB) caused by *Fusarium culmorum* was investigated in seven winter wheat cultivars and one spring wheat cultivar in an outdoor pot experiment. The spring wheat cultivar Frontana alone exhibited resistance against initial infection by the pathogen. Free phenolic compounds accumulated in significantly higher amounts in the glumes, lemmas, and paleas of Frontana prior to and at all sampling times after inoculation in comparison to the winter cultivar Agent. In addition, the amount of p-coumaric acid increased significantly in the glumes, lemmas, and paleas of Frontana at 2 days after inoculation (dai) compared with that in uninoculated spike tissues. However, the amount of ferulic acid between inoculated and healthy plant tissues did not differ. Ultrastructural studies indicated more pronounced structural defense responses, such as cell-wall appositions in the infected lemma tissue of Frontana comparing with cultivar Agent (susceptible) at 3 dai. Immunogold labeling of lignin revealed no differences in the density of gold particles on the cell walls of healthy lemma tissue in the two cultivars. However, the density of particles increased in the infected lemma tissue of the resistant cultivar Frontana on cell walls adjacent to the fungal cells at 3 dai. The cultivar Agent did not show any response to the infection. The results suggested that phenolic compounds might play a role in the resistance of cultivar Frontana to *F. culmorum* (Siranidou et al. 2002).

The subcellular localization of thionins and hydroxyproline-rich glycoproteins (HRGPs) or extensins in *Fusarium culmorum*-infected wheat spikes was investigated by employing the immunogold labeling technique. A rabbit polyclonal antiserum produced against cell-wall-bound thionins from barley leaf and a mouse monoclonal antibody against HRGP from maize was used for detection of the defense-related proteins in infected tissues. The proteins were localized in the cell walls of different tissues, including the lemma, ovary, and rachis, while the cytoplasm and organelles in these tissues showed almost no labeling. However, accumulation of thionins and HRGP in infected spikes of resistant wheat cultivars differed distinctly from those of susceptible cultivars. Labeling intensities for two types of proteins in cell walls of the infected lemma, ovary, and rachis increased slightly in the susceptible cultivar Agent, compared with healthy tissues of resistant cultivar Arina in which labeling densities of thionins and HRGP increased markedly. The results indicated that accumulations of thionins and HRGP in cell walls of infected resistant wheat spikes might be involved in defense responses to infection and in spreading of *F. culmorum* (Kang and Buchenauer 2003).

The metabolic profiles of spikelets of wheat cultivars Roblin (susceptible) and Sumai 3 (resistant) were analyzed using gas chromatography/mass spectrometry (GC/MS) to

develop a procedure to discriminate resistance to *Fusarium* head blight (FHB) disease. More than 700 peaks were detected and a total of 55 compounds were tentatively identified, of which 49 were induced (upregulated following pathogen inoculation), including 23 in Roblin and 26 in Sumai 3. However, only five metabolites were significantly different both between cultivars and inoculations. Although detected in all four treatments, metahydroxy-cinnamic acid exhibited a six-fold increase in abundance in Sumai 3 following pathogen inoculation with no corresponding change in Roblin. The abundance of myo-inositol in Sumai 3 was higher than that in Roblin, and in both cultivars the abundance increased following pathogen inoculation. The compounds common to all treatments were subjected to factor analysis to identify groups of compounds based on significant factor-loadings associated with the highest scores for the first and second factors that could be used for discriminating resistance against FHB disease. The first factor was associated with the higher abundances of several fatty acids and aromatic compounds, while the second factor was associated with metabolites such as p- and m-coumaric acids, myo-inositol, and other sugars and malonic acid. The treatments involving pathogen inoculation had higher factor scores for the third factor than the water-inoculated cultivar Roblin, and might be useful in indicating the susceptible reaction. The third factor had a positive correlation with metabolites from different groups, mostly amino acids, fatty acids, and aromatics. The large number of compounds detected in susceptible and resistant wheat cultivars following infection by FHB pathogen indicated the complexity of host–pathogen interaction (Hamzehzarghani et al. 2005).

A metabolomics approach was applied for the discrimination of resistance to *Fusarium* head blight (FHB) disease in wheat cultivars. Spikelets of six wheat cultivars/lines with varying degrees of resistance were inoculated with *Fusarium graminearum* or water for control treatment. The disease severity of infected spikelets was scored and the metabolic profiles were recorded using GC/MS technique. A total of 214 metabolites were detected in spikelets and rachis, including 79 with acceptable treatment effects. Univariable analysis of variance identified 41 resistance-related (RR) metabolites, whereas multivariate analysis identified 45 resistance function-associated metabolites including 28 RR metabolites. Highly resistant cultivar Wangshuibai and line AW488 contained the maximum number of constitutive (22) and induced (14) RR metabolites. The moderately resistant line BRS 177 had 12 induced RR metabolites. The RR metabolites identified in this investigation were considered to be potential candidate biomarkers for high-throughput screening of wheat breeding lines against FHB disease of wheat (Hamzehzarghani et al. 2008).

In another investigation, the responses of wheat cultivars to trichothecene mycotoxin deoxynivalenol (DON) produced by *Fusarium* spp. during pathogenesis were determined. Infusion of wheat leaves with DON induced hydrogen peroxide (H₂O₂) production within 6 h followed by cell death within 24 h accompanied by DNA laddering, the hallmark of programmed cell death. In addition, real-time PCR analysis revealed that DON treatment rapidly induced transcription of a number of defense genes in a concentration-dependent manner. Co-treatment with DON and the antioxidant ascorbic acid reduced these responses, suggesting their induction might be at least partially mediated by reactive oxygen species (ROS) which are known to be signal molecules in plants. Wheat defense genes were more highly expressed in wheat stems inoculated with a DON-producing fungal strain than those inoculated with a DON-nonproducing mutant, but only at a late stage of infection. The results were consistent with a model in

which DON production during infection of wheat induces ROS which, on the one hand, might stimulate programmed cell death (PCD) in the host plant, assisting necrotrophic fungal growth. On the other hand, the ROS might contribute to the induction of antimicrobial host defenses (Desmond et al. 2008).

The molecular mechanisms involved in the resistance in barley to *Fusarium* head blight (FHB) pathogen *Fusarium graminearum* were studied to identify proteins that were differentially expressed in FHB susceptible and resistant barley accessions. Mature seed from six barley accessions and five pairs of barley sister lines differing in FHB resistance were subject to proteome analysis by two-dimensional gel electrophoresis (2DE). Coomassie Brilliant Blue staining was employed to visualize about 100 seed protein spots of pI 4–7 on 2DE gels. Proteins were identified by liquid chromatography and tandem mass spectrometry (LC-MS/MS) sequencing after in-gel digestion by trypsin. The 2DE seed protein profiles of two FHB susceptible cultivars AC Lacombe and Stander were compared with four partially FHB-resistant barley accessions CI4196, Chevron, Penco/Chevron, and I92130. A total of 171 protein spots differed in abundance between resistant and susceptible FHB barley genotypes, and 97 protein spots differed in abundance between resistant and susceptible sister lines. Overall, 11 proteins associated with disease or stress resistance were identified. Proteins identified at a higher abundance in barley lines resistant to FHB included α -amylase inhibitor (BDAI-1), aldehyde dehydrogenase (BIS1), aconitate hydratase, and NADP-dependent malic enzyme (Zantinge et al. 2010).

The metabolomics approach was applied in another investigation to identify the metabolites in barley that were related to resistance against FHB caused by *Fusarium graminearum* (teleomorph *Gibberella zeae*). Barley genotypes Chevron and Stander were inoculated with mock or pathogen during anthesis stage. The disease severity was determined as the proportion of spikelets diseased. The genotype Chevron (0.33) showed higher level of quantitative resistance compared with Stander (0.88). Spikelet samples were harvested at 4 h postinoculation and metabolites were extracted and analyzed using an LC-ESI-LTQ-Orbitrap (Thermo Fisher, MA, USA). Of the 1826 peaks retained, a t-test identified 496 metabolites with significant treatment effects. Among these, 194 were resistance-related (RR) constitutive metabolites whose abundance was higher in resistant mock-inoculated than in susceptible mock-inoculated genotypes. The RR metabolites mainly belonged to phenylpropanoid, flavonoid, fatty acid, and terpenoid metabolic pathways. Selected RR metabolites were assayed in vitro for anti-fungal activity on the basis of fungal biomass production. Some of the RR metabolites showed potential for use as biomarkers for screening for resistance of barley genotypes against FHB pathosystem (Bollina et al. 2010).

The host responses of susceptible and resistant maize plants to *Fusarium verticillioides*, causative agent of ear rot disease of corn, were investigated. The susceptible and resistant maize kernels were sampled in the area neighboring the point of inoculation in the early stages of infection. The pathogen growth assayed by quantitative (q) RT-PCR quantification of the *tub2* gene was eight times lower on an average in resistant kernels than that detected in susceptible line over the time course of 96 h. During the very early stages of infection (12–24 h after inoculation) a small portion of the host transcripts was induced. The number of differentially regulated genes reached 147 at 48 h after infection and decreased to 140 and 98 at 72 h and 96 h postinoculation, respectively. About 1% of the genes assayed were differentially expressed and 7.1% of them were assigned to the category cell rescue, defense, and virulence. Pathogenesis-related protein (PR)-5,

endo-1,3-1,4-beta-D-glucanase PRm6, chitinase, PRm3, and MYB-like DNA binding protein had a higher level of expression in the resistant line compared to the susceptible line. The results indicated that the resistant line might activate a battery of defense genes before the invasion by *F. verticillioides* in nondamaged tissues or in adjacent tissues. In the resistant kernels, a basal defense system might be activated and the expression of defense genes might be controlled by both the host genotype and pathogen virulence (Lanubile et al. 2012).

Fusarium graminearum, incitant of wheat Fusarium head blight (FHB) disease, produces a potent mycotoxin deoxynivalenol (DON) which is a virulence factor involved in pathogenesis. The expression of the core DON biosynthetic gene *Tri5* during wheat head infection of susceptible and resistant cultivars was investigated. DON was quantified to correlate expression with toxin accumulation. The highest *Tri5* expression relative to housekeeping genes occurred at the infection front. As infection progressed the earliest infected kernels showed diminished relative *Tri5* expression, but *Tri5* expression was observed throughout the period of experimentation (21 days). The *Tri5* transcripts remained detectable but reduced in the infected tissue of the susceptible cultivar Wheaten, after the plant tissue had completely senesced. In the resistant cultivar Alsen, initial fungal invasion was arrested and the pathogen appeared to retreat by the later stages of sampling. The resistant cultivar showed minimal spread of the fungus, with no fungus detected at 21 days after inoculation. In Wheaten, DON levels were negligible at 8 days postinoculation (dpi) with detectable DON at later-sampling time points. *Tri5* expression was detected in fully senesced kernels at 21 dpi. The presence of *Tri5* transcripts in the susceptible cultivar could be detected over a much longer period than previously reported (Hallen-Adams et al. 2011).

The ability of two mutants of *Fusarium graminearum* (*tr6Δ* and *noxABA*) to prime immune responses in wheat cultivar Roblin was determined against challenge with pathogenic *F. graminearum*. Priming treatments generated FHB-resistant wheat phenotypes and reduced accumulation of mycotoxins produced by the pathogen in infected tissues. Microarray analysis detected 260 transcripts that were differentially expressed during the priming period. Expression changes were observed in genes associated with immune surveillance systems, signaling cascades, antimicrobial compound production, oxidative burst, secondary metabolism, detoxification, and transport. Genes related to jasmonate, gibberellins, and ethylene biosynthesis exhibited differential expression during priming. In addition, induction of the phenylpropanoid pathways that lead to flavonoid, coumarin, and hydroxycinnamic acid amide accumulation was also observed. The results indicated the usefulness of employing nonpathogenic mutants to elicit and delineate stages of defense responses in wheat (Ravensdale et al. 2014).

Stagonospora nodorum blotch (SNB), caused by *Stagonospora nodorum* (teleomorph *Phaeosphaeria nodorum*), is responsible for significant yield losses in wheat. Development of wheat cultivars with resistance to SNB disease was considered as an effective option for the management of the disease, in addition to adoption of cultural practices to eliminate infected plant debris. Wheat cultivars (29) with varying levels of resistance to SNB representing 10 eastern US breeding programs were infiltrated with culture filtrates from *S. nodorum* isolates in randomized complete block design. *S. nodorum* produced several necrotic effectors (NEs, also known as host-selective toxins) and the host sensitivity (Snn) corresponding to the NEs was determined. Three single-NE *Pichia pastoris* controls, two *S. nodorum* isolate controls, and six Snn-differentiated wheat controls were used. Cultivar-isolate interactions were visually

determined for sensitivity at 7 days after infiltration. Of the 39 isolates, 17 produced NEs different from those previously characterized in the Upper Great Plains region. Only 3, 0, and 23% of the 39 isolates produced SnToxA, SnTox1, and SnTox3, respectively, by the culture filtrate test. A Southern dot-blot test showed that 15, 74, and 39% of the isolates carried the genes for those NEs, respectively. Only two wheat cultivars appeared to contain known *Snn* genes, although half of the cultivars displayed sensitivity to culture filtrates containing unknown NEs. Effector sensitivity was more frequent in SNB-susceptible cultivars than in moderately resistant (MR) cultivars ($P = 0.008$), although some susceptible cultivars did not exhibit sensitivity to NEs of multiple isolates. The results suggested that sensitivities to NEs could influence, but might not be the only determinant of, wheat cultivar resistance to *S. nodorum* (Crook et al. 2012). In order to understand the mechanisms regulating the expression of maize resistance genes against *Aspergillus flavus*, the potent roles of six WRKY transcription factors and the expression of these pathway indicator genes in response to inoculation of *A. flavus* in B73 (susceptible) and TZAR101 (resistant) genotypes were investigated. The genes *ZmWRKY19*, *ZmWRKY53*, and *ZmWRKY67* showed elevated expression in resistant TZAR101 plants. *ZmNPR1* expression was induced by inoculation in TZAR101 without concurrent induction of *ZmERF1*. The results indicated that WRKY transcription factors were involved in resistance and salicylic acid (SA) ethylene signaling might coordinate defense responses (Fountain et al. 2015).

Sorghum grain molds reduce the yield quantitatively as well as qualitatively. Protein that could effectively reduce the growth of the fungi-causing grain molds in vitro were identified in the sorghum seeds. The ability of antifungal proteins (AFPs) present during grain development to restrict the development of fungal pathogens was assessed. Sureño (resistant) RT x 430 (susceptible) and their F1 hybrids were planted at two moisture levels. Caryopsis were collected from each genotype at 7 days interval after anthesis (daa) during development and maturity of the grain. Levels of four AFPs, namely sormatin, chitinases, β -1,3-glucanases, and ribosomal-inhibiting proteins (RIPs), were determined using immunoblotting technique. During grain development (7–35 daa), Sureño and the F1 hybrid showed higher levels of sormatin and chitinase than RT x 430. The levels of RIPs in Sureño and in the F1 hybrid were higher than those of RT x 430 after the grain reached physiological maturity. The results indicated that AFPs might be associated with grain mold resistance, since Sureño and the F1 hybrid induced and/or retained higher AFPs levels under grain mold infection pressure than RT x 430 (Rodriguez-Herrera et al. 2006).

The interaction between an avirulent isolate of the rice blast pathogen *Magnaporthe grisea* and the resistant rice plant was investigated. Several AVR genes were identified in *M. grisea* through classical genetic experiments. The AVR genes from *M. grisea* designated Avirulence Conferring Enzyme 1 (ACE1) was identified in a cross between Guy11, hermaphrodite isolate from South America, and ML25, a male isolate from Africa (Silué et al. 1992; Notteghem et al. 1994). The rice resistance gene *Pi33* was used to recognize the *M. grisea* isolates carrying *ACE1* gene (Berruyer et al. 2003). *ACE1* encoded a putative polyketide synthase (PKS) and a nonribosomal peptide synthase (NRPS). The expression of *ACE1* during infection was examined by fusing the green fluorescent protein (GFP) reporter gene to *ACE1* promoter and terminator sequences. GFP fluorescence was first observed in mature appressoria at 15 h after inoculation (hai) of barley or rice leaves and strongest fluorescence was detected during penetration of the leaf surface at c. 24 hai. GFP fluorescence disappeared rapidly when the secondary infection hyphae began to

spread within the leaf tissues. *ACE1* was strongly expressed during penetration of leaves, the stage at which plant defense reactions were triggered. The fungal transformants with the vector pACE1:GFP, expressing strong GFP fluorescence in appressoria, were avirulent towards rice cultivars Bala and C101Lac carrying *Pi33* but were fully virulent towards susceptible cultivar Martelli. The results indicated that the ACE-GFP fusion protein was functional, since it confirmed avirulence when introduced in a virulent strain of *M. grisea*. The fungal signal recognized by the resistant rice plant seemed to be the secondary metabolite whose synthesis is governed by *Ace1* (Böhnert et al. 2004).

Expression of defense-related genes in plants susceptible and resistant to rice blast pathogen *Magnaporthe grisea* during pathogenesis was investigated. The defense-related genes were induced within 1 h after inoculation with *M. grisea* in rice plants on which the conidia had just germinated on the leaves. Treatment of rice cells with water soluble and heat-sensitive molecule(s) released from the conidia induced rapid defense gene expression but not cytoplasmic pH decrease, which was reported to be induced by elicitors originating from the pathogen mycelium. The results suggested that, prior to penetration into plant cells, a rapid defensive response to the presence of blast pathogen was triggered by conidia-originating elicitor(s) in both resistant and susceptible rice genotypes (Kuroda et al. 2006).

The defense responses of susceptible and resistant rice cultivars against two fungal pathogens of agricultural importance, *Magnaporthe grisea* and *Cochliobolus miyabeanus* (anamorph *Helminthosporium oryzae*), incitant of rice brown spot disease, were compared. Early infection processes of these pathogens share common characteristics such as conidial attachment to host surface, appressorium formation, and direct penetration of host cuticle, using the infection hyphae differentiated from the appressorium. In cultivar Tetep, resistant to both pathogens, inoculation with them rapidly triggered the hypersensitive reaction (HR), resulting in macroscopic cell death. In rice cultivar Nakaong, susceptible to both pathogens, *M. grisea* did not induce HR whereas *C. miyabeanus* caused rapid cell death similar to that associated with HR and the reaction observed in cultivar Tetep. However, the necrotic response failed to block fungal ramification in cultivar Nakdong. Treatment with conidial germination fluid (CGF) from *C. miyabeanus* induced rapid cell death in both cultivars, suggesting the presence of phytotoxins in CGF. Pretreatment of cultivar Nakdong with CGF significantly increased resistance to *M. grisea*, while the same treatment did not enhance resistance to *C. miyabeanus*. Spray application of CGF from *C. miyabeanus* strain HIH-1 caused HR-like lesions on leaves of both cultivars Nakdong and Tetep within 12 h of application only at a concentration of CGF of ≥ 100 ppm. CGF treatment significantly increased the level of PR-1 transcripts in cultivars Tetep and Nakdong within 1 day of treatment. No expanding invasive mycelial growth of *M. grisea* (strain KJ401) was observed in the CGF-treated leaves. CGF treatment modified the expression patterns of four marker genes in cultivar Nakdong infected with KJ401 strain as in plants treated with benzothiadiazole (BTH), a known inducer of resistance against several pathogens. The modified expression patterns resembled those in cultivar Tetep infected with KJ401. Transcripts from all four genes in CGF-treated cultivar Nakdong peaked at 1 day postinoculation, whereas the transcripts of these genes in untreated Nakdong noticeably increased only at 2–3 dpi. The results indicated that distinctly different mechanisms of resistance in rice against *M. grisea* and *C. miyabeanus* might operate. The HR-associated host cell death was effective against *M. grisea*, but not against *C. miyabeanus* which produced phytotoxin during pathogenesis as a major virulence factor (Ahn et al. 2005).

Mechanisms underlying resistance in rice to *Ustilaginoidea virens*, incitant of false smut disease, were investigated. The RNA sequence analysis was performed to study the transcriptional modulation varieties resistant and susceptible rice to *U. virens*. Differentially expressed genes (DEGs) in resistant IR28 and susceptible HXZ cultivars were determined to be 1405 and 1066, respectively. Gene ontology (GO) enrichment analysis revealed a set of GO to be differentially enriched in the two rice varieties. Functional analysis of DEGs showed that a large number of genes encoding secondary metabolites flavin-containing monooxygenases and peroxidases were differentially regulated. Classification analysis of DEGs showed that brassinosteroids may have more important roles than salicylic acid (SA) and ethylene in response to *U. virens* infection. Recognition of patterns, cellular metabolic changes, and hormone signaling constitute a comprehensive network to manipulate the responses of host rice plant to *U. virens* infection (Yang et al. 2014).

Active penetration of a plant cell by producing appressoria and penetration pegs is the characteristic feature observed during the infection process of *Colletotrichum* spp. Deposition of a melanin layer in the appressoria is essential for the development of high internal turgor pressure within the appressorium. Three nonpathogenic strains of *C. lindemuthianum*, causal agent of bean anthracnose disease, with defects in each of the appressorial development stages, were generated. The strain H1 was blocked at the differentiation stage (with no appressorium production), H191 was blocked at appressorium maturation stage (appressoria defective in pigmentation), and H290 was impaired in the appressorium function (failure to penetrate the cell wall). Inoculation of bean with wild-type strain UPS9 and mutant strain H290 elicited strong accumulation of PAL3, CHS, and PvPR2 transcripts. The early induction of these genes might be linked to the perception by the plant of fungal conidia upon inoculation and/or conidial adhesion and growth of germ tubes on leaves. The mutant strains and the wild-type strain could be discriminated based on defense responses induced by them in bean plants. Appressorium maturation (but not its function) attained in the wild-type UPS69 and H290 strains was both necessary and sufficient for triggering most defense responses such as early plant defense genes and accumulation of major PR-proteins. However, appressorium function (entry into the first host cell) was required for avirulence-mediated recognition of the pathogen by the bean plant (Veneault-Fourrey et al. 2005).

Transcription of specific genes is activated early in the plant defense response against pathogens. The upregulation of genes in the early resistance reaction of bean (*Phaseolus vulgaris*) against *Colletotrichum lindemuthianum* was investigated. The effect of the light-dark transition, ultraviolet (A-Po) light, and temperature stress on these genes was also assessed. A calcium-binding protein and previously identified SUMO genes were overexpressed in the plant reaction to pathogen under environmental stress. These genes appeared to act as integrative signals and convergence points in early plant responses to pathogens and several forms of environmental stress. The calcium-binding protein gene was present in both plant and fungal genomes (Alvarado-Gutiérrez et al. 2008). The race-specific and ulvan-induced defense responses to *C. lindemuthianum* race T3 in resistant and susceptible bean cultivars were monitored and compared. When sprayed under greenhouse conditions, ulvan (a water-soluble algal polysaccharide) reduced anthracnose disease severity locally and systemically in susceptible plants by 60% and 40%, respectively. Neither race-specific resistance nor ulvan treatment affected conidial germination or appressorial formation of *C. lindemuthianum* on leaves. Race 73-specific resistance was associated with a rapid recognition of the

pathogen, expressed by a more frequent hypersensitive response (HR) in bean epidermal cells. Ulvan increased peroxidase activity in resistant but not in susceptible plants, and increased glucanase activity in both resistant and susceptible plants inoculated with the pathogen. The results indicated that ulvan application might protect bean plants against anthracnose without affecting HR (De Freitas and Stadnik 2012).

Verticillium wilt disease of potato is caused by *Verticillium dahliae* which infects a large number of crops worldwide. A differential potato-*V. dahliae* pathosystem consisting of two potato cultivars, susceptible (S) and moderately resistant (MR) *V. dahliae* isolates (weakly (WA) and highly aggressive (HA)), was used to evaluate the expression of five defense-related genes PAL-1, PAL-2, PR-1, PR-2, and PR-5 which are generally associated with the salicylic acid (SA) defense-signaling pathway. Expression levels of these genes were assessed in potato roots and leaves at 0, 4, and 21 h postinoculation (hpi) and 3, 7, and 14 days postinoculation (dpi). In the roots, the expression of PAL-1, PR-1, and PR-2 in the MR cultivar was higher than in S cultivar in response to inoculation with either one of the tested *V. dahliae* isolates. PAL2 gene expression increased gradually starting at 21 hpi in the MR cultivar, as opposed to the susceptible cultivar. Higher expression of PR-1 was detected at 7 dpi in roots. In the leaves, both *PAL1* and *PAL2* genes showed higher expression in the MR cultivar relative to the S cultivar. Combined data analyses revealed the differential transcriptional levels in response to infection by *V. dahliae*. The results indicated that SA pathway was also involved in potato defense against *V. dahliae* and added to the data gathered to elucidate the signaling mechanisms in potato-*V. dahliae* pathosystem (Derksen et al. 2013).

Fusarium oxysporum f.sp. *cubense* tropical race 4 (TR4) of Panama (*Fusarium*) wilt pathogen has a major negative impact on banana production in all countries. In order to understand the molecular interactions underlying banana defense responses, a proteomic approach was adopted. The responses of a susceptible cultivar Williams and a resistant cultivar GCTCV-119 to inoculation with race TR4 were investigated using molecular techniques. Sixteen protein spots were subjected to MALI-TOF-MS procedure. All of the proteins identified were related to metabolism, energy, immunity and defense, and unknown functions. In the resistant variety, eight spots were in higher concentrations and six spots were less concentrated compared to control. Of these, a total of five protein spots showed significant changes at at least two time points. In the susceptible variety, five spots were more abundant and three spots were at a lower concentration compared to the control. Of these, six spots changed significantly after challenge inoculation with TR4 strain. Chitinase and β -1,3-glucanase and superoxide dismutase were estimated quantitatively by employing qRT-PCR assay to determine whether the observed proteome changes were associated with changes in the mRNA levels or were due to posttranscriptional regulation. β -1,3-glucanase and chitinase were present only in pathogen-challenged plants of the resistant variety, compared with control plants at 6, 12, 24, 48, and 72h postinoculation, but β -1,3-glucanase and chitinase were expressed both in resistant and susceptible varieties in the roots of TR4-infected banana plants (Lu et al. 2013).

The defense responses of pepper (*Capsicum annuum*) infected with incompatible and compatible strains of *Phytophthora capsici*, causative agent of Phytophthora blight disease, were studied. The activities of β -1,3-glucanase and peroxidase (involved in defense mechanisms) increased substantially in the incompatible interaction. The expression patterns of four defense-related genes, *CABPR1*, *CABGLU*, *CAP01*, and *CaRGA1* in the leaves and roots of pepper inoculated with different strains of *P. capsici*

were determined. All gene expression levels were higher in the leaves than in the roots. Markedly different expression patterns were observed between incompatible and compatible host–pathogen interactions. In the incompatible interactions, the expression levels of three genes showed an increase by a factor of 13.2–20.5, but *CaRGA1* gene expression level was to a lesser degree (by a factor of 6). In contrast, the expression levels of the four defense-related genes in compatible interactions increased by the lower factor of 2.0–11.2 compared to the controls. The expression levels of the four genes were much lower in the roots than in the leaves. The highest levels of mRNA were those of *CABPR1* gene, which increased by a factor of 5.1 at 24 h in the incompatible and by 3.2 at 48 h in the compatible interactions. The results revealed the involvement of defense-related genes in the defense responses of pepper to *P. capsici* infection (Wang et al. 2013).

The role of key biochemical defense mechanisms operating in seedlings of winter oilseed rape cultivars differing in tolerance to infection with *Leptosphaeria maculans*, incitant of blackleg disease, was investigated. In the resistant cultivar, a significant increase in the activity of chitinase and β -1,3-glucanase was observed and this could be considered an indication of a systemic defense reaction. Furthermore, the resistant cultivar had a more efficient antioxidant system, as revealed by the higher activity of specific SOD isoforms and the higher level of low molecular antioxidants. Only the resistant cultivar had three Fe-SOD sub-isoforms. A correlation between the content of cell-wall-bound phenolics and hydrogen peroxide in the resistant cultivar might indicate that an important method of H_2O_2 neutralization was its participation in the process of phenolics incorporation into the cell wall. Higher concentrations of cell-wall-bound phenolics significantly enhanced the cell-wall integrity which became a more effective firewall against *L. maculans*. In addition, high utilization of soluble sugars during synthesis of the phenolic compounds in the pathogenesis was demonstrated in the resistant cultivar. The key factors contributing to a greater tolerance to *L. maculans* were shown to be an effective antioxidant system and higher activity of PR proteins such as chitinase and β -1,3-glucanase (Hura et al. 2014).

To understand disease resistance mechanisms in plants, the identification of defense response genes in the plants with different levels of resistance/susceptibility is considered to be one of the most essential steps. A suppression subtractive hybridization (SSH) library was constructed to identify the genes involved in response to infection by *Fusarium oxysporum* f.sp. *cubense*. The cDNAs from tolerant genotype *Musa acuminata* spp. *burmannicoides* “Calcutta-4” infected by wilt pathogen were used as a tester and cDNAs from uninfected “Calcutta-4” as a driver population. After hybridization and cloning, the EST library of 83 nonredundant clones was assigned to different functional categories. The expression pattern of selected eight defense-related genes, namely peroxidase, glutaredoxin, polyphenol oxidase, glutamate synthase, S-adenosyl methionine synthetase, 14-3-3, heat shock protein, and mannose-binding lectin, were analyzed through real-time PCR in contrasting genotypes. The expression of these genes during initial progression of disease was higher in tolerant “Calcutta-4” genotype, compared with the susceptible “Kadali” genotype (Swarupa et al. 2013).

12.2.1.4 Molecular Basis of Resistance to Bacterial Diseases

During pathogenesis, the plant bacterial pathogens have to successfully breach the protection offered by exterior surfaces of plants and preformed antimicrobial compounds, followed by cell walls forming an effective second barrier to invaders that are able to

gain entry into interior spaces. In addition, the pathogens have to overcome the formidable plant immunity responses. Plant immunity comprises two components operating at different time scales. The base defense system operates early in the interaction between the host and pathogen, whereas the resistant *R* gene-mediated defense operates on the time scale of hours. The pathogen-associated molecular patterns (PAMPs) that mediate early basal responses include lipopolysaccharide, peptidoglycans, bacterial flagellin, and yeast mannans (Nurenberger et al. 2004; Pemberton et al. 2005). The innate response may also be induced by the bacterial elongation factor EFTu (Kunze et al. 2004). The receptors located in the plasma membrane recognize PAMPs, activating a phosphorylation cascade upon binding, leading to the induction of early basal resistance. This basal resistance may be responsible for preventing colonization of nonpathogenic bacteria (Gómez-Gómez and Boller 2002).

The well-characterized example of plant host sensing and responding to PAMP at the cell surface is exemplified by the rice *Xa21* receptor kinase. Recognition of bacterial strains of *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) expressing AvrXa21 activity was due to *Xa21* receptor kinase. The rice plants lacking *Xa21* gene were susceptible to *Xoo* (Gómez-Gómez and Boller 2002). Rice has been considered as a model cereal crop to understand the functioning of the defense machinery. A large-scale analysis of rice gene expression in response to bacterial leaf blight (BLB) disease incited by *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) and rice blast caused by *Magnaporthe grisea* was performed during the early stages of compatible and incompatible interactions. Using a gene chip containing 10,254 rice cDNAs representing 9240 unique genes, 794 and 612 genes differentially expressed in the incompatible and compatible interactions, respectively, were detected with 274 genes coregulated during both interactions. In the rice-*Xoo* pathosystem, 454 and 498 differentially expressed genes were identified in the incompatible and compatible interactions, respectively, including 237 coregulated genes in both interactions. By clustering differentially regulated genes from all these interactions, 29 coregulated genes from all these interactions were identified in all four interactions and 86 and 74 coregulated genes in the two incompatible and two compatible interactions, respectively. These differentially expressed genes could be classified into three categories, including *M. grisea*- and *Xoo*-regulated, *M. grisea*-specific, and *Xoo*-specific genes. The expression patterns of representative defense-related genes were further confirmed by RT-PCR assay. The results of microarray analysis indicated the existence of distinctive as well as shared defense pathways between the rice-*M. grisea* and rice-*Xoo* interactions (Li et al. 2006).

Lipopolysaccharides (LPS) covering the cell surface of Gram-negative bacterial species represent typical pathogen-associated molecular patterns (PAMP) capable of inducing defense-related responses including suppression of HR, the expression of defense genes, and systemic resistance in plants. Various LPS molecules from *Pseudomonas syringae* pv. *syringae* (*Pss*), *Erwinia chrysanthemi*, *Xanthomonas oryzae* pv. *oryzae* (*Xoo*), and *Ralstonia solanacearum* and nonpathogens were shown to induce defense responses such as ROS generation and defense gene expression in rice cells. Furthermore, global analysis of gene expression induced by LPS and chitin oligosaccharide (PAMPs) also showed a correlation between the gene responses induced by them. It is possible that there could be a convergence of signaling cascades downstream of their corresponding receptors. The defense responses induced by LPS in the rice cells were demonstrated to be associated with programmed cell death (PCD) (Desaki et al. 2006).

Infection before the pathogen becomes established may be restricted by the PAMP-triggered immunity, as indicated by the evidence obtained from investigations on PAMP flagellin. The connection between inhibition of pathogen development and the recognition of the PAMP flagellin by the receptor FLS2 was demonstrated by Zipfel et al. (2004). Flagellin is the major protein of flagella and also a well-characterized PAMP which is recognized by the Leu-rich repeat receptor kinase FLS2 in the model plant *Arabidopsis*. FLS2 is located in the plasma membrane and is considered to be involved in the early bacteria–plant interaction by recognizing and binding flagellin (Dangl and McDowell 2006). Treatment of plants with flg22, a peptide representing the elicitor-active epitope of flagellin, induced the expression of several defense-related genes and triggered resistance to phytopathogen *Pseudomonas syringae* pv. *tomato* DC3000 (*Pst* DC3000) in wild-type plants, but not in plants carrying mutations in the flagellin receptor gene *FLS2*. This induced resistance seemed to be independent of salicylic acid (SA) and jasmonic acid (JA). Wild-type and *fls2* mutant expressed enhanced resistance when treated with crude bacterial extracts even devoid of elicitor-active flagellin, indicating the existence of functional perception systems of PAMPs other than flagellin. The results indicated that flagellin perception could restrict bacterial invasion, possibly at an early step, thus contributing to disease resistance in plants (Zipfel et al. 2004).

Phospholipid signaling has been suggested to have an important role in plants, including responses to biotic and abiotic stresses. In rice plants challenged by an avirulent strain of *Xanthomonas oryzae* pv. *oryzae* (*Xoo*), the incitant of bacterial leaf blight (BLB) disease, expression of phospholipase C (PLC) and phospholipase D (PLD) genes were induced. PLD was localized in the plasma membrane, especially at the part adjacent to *Xoo* in incompatible interaction (Young et al. 1996). The effects of N-acetyl chito-oligosaccharide elicitor in rice cells were assessed. Biphasic generation of reactive oxygen species (ROS) induced by the elicitor in rice cells was associated with activation of PLC and PLD. The synthetic diacetylglycerol (DG) and phosphatidic acid (PA) also were able to induce the expression of elicitor-responsive genes in the absence of elicitor. They themselves induced the biosynthesis of phytoalexins. However, they significantly increased the elicitor-induced phytoalexin accumulation. The results revealed the active involvement of phospholipid signaling in eliciting defense responses in treated plants (Yamaguchi et al. 2005).

The AvrXa21 activity of *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) was governed by four genes, namely *raxA*, *raxB*, *raxC*, and *raxST*, which encoded components of type I secretion system and sulfation system (da Silva et al. 2004). Two additional genes encoding a two-component regulatory system that were also required for AvrXa21 activity (*raxR* and *raxH*) were also identified (Burdman et al. 2004). Sequence analysis of three naturally occurring *Xoo* strains no longer recognized by *Xa21* showed alterations in the *raxST* and *rax* genes. The results indicated that bacterial type I secretion was essential for *Xa21*-mediated recognition and immunity. Further, type I secretion and modification of pathogen-associated molecules might play a significant role in triggering the immunity response in rice. Characterization of the *rax* genes indicated that type I secretion (*raxA*, *raxB*, and *raxC*) and sulfation (*raxST*, *raxP*, and *raxQ*) were found to be essential for *Xa21*-mediated recognition of *Xoo* (Shen et al. 2002; da Silva et al. 2004). The rice *NPR1* homologous genes were isolated and transgenic rice over-expressing these genes were generated. The rice homologous gene *NH1* was shown to be the rice *NPR1* ortholog (also termed as *OsNPR1*). Overexpression of *OsNPR1* conferred high levels of resistance to rice bacterial leaf blight (BLB) caused by *Xoo*.

In contrast, *OsNPR1* knockout/knockdown plants were highly susceptible. The wild-type *OsNPR1* protein (in GFP fusion) was located in the cytoplasm and was able to move into the nucleus after redox change. Different subcellular localization of *OsNPR1* antagonistically regulated salicylic acid (SA-) and jasmonic acid (JA-) responsive genes, but not SA and JA levels. The results suggested that SAR-like disease resistance might be activated against rice BLB disease through SA signaling which might be less dependent on the elevation of SA levels in rice cells. This investigation indicated the possibility of engineering rice with broad spectrum resistance to *Xoo* using site-mutated *OsNPR1* gene (Yuan et al. 2007).

Expression of pathogenesis-related (PR-) proteins in the interactions between rice plants with bacterial blight resistance gene *Xa21* and *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) was studied. Three PR genes – *OsPR1a*, *OsPR1b*, and *OsPR10a* – were cloned and fusion proteins were expressed in *Escherichia coli* to generate polyclonal antibodies (PABs). The proteins isolated at 0, 12, 24, 36, 48, 60, 72, and 144 h postinoculation (hpi) from rice leaves inoculated with incompatible *Xoo* strains were analyzed using Western blotting. All three PR proteins were significantly induced in the late stages after inoculation. Expression of PR proteins among four different modalities, namely incompatible interactions (R), compatible interaction in the absence of R gene (SR-), compatible interactions in the absence of avirulence factor in *Xoo* (SAvr-), and mock-inoculated control treatments (M), were compared. Results showed that three PR proteins were enhanced in the R, SR- and Avr- interactions more than in the control treatments. Induction of PR proteins reached the peak in the R interaction, suggesting the involvement of PR proteins in the defense mechanism in the interactions between rice plants and BLB pathogen (Wu et al. 2011).

The rice near-isogenic line (NIL) CBB23, derived from a cross between a wild rice *Oryza rufipogon* accession (RBB 16) and a susceptible *indica* rice variety (Jingang 30) was highly resistant to all field strains of *Xoo* tested. Although the bacterial leaf blight (BLB) resistance of CBB23 has been widely used in rice breeding programs, the mechanisms of its extremely broad spectrum resistance remained unclear. Molecular cloning of an avirulence gene *avrXa23* from *Xoo* strains PX099A was performed to understand the resistance mechanism against *Xoo* in rice. *AvrXa23*, a novel transcription activator-like effector, specifically triggered the broad-spectrum BLB resistance in CBB23. The presence of *avrXa23* in all *Xoo* strains tested may indicate the basis for the broad-spectrum resistance of CBB23 to *Xoo* strains. The results may provide leads, facilitating the molecular cloning of the corresponding resistance (*R*) gene in the host, leading to a better understanding of the molecular mechanism for broad-spectrum disease resistance in plants (Wang et al. 2014).

Plant bacterial pathogens produce several kinds of type III effectors which are designated avirulence (Avr) factors involved in elicitation of resistance to the pathogen species/strains concerned. In the presence of disease resistance *R* genes in specific plant genotypes, Avr factors trigger potent gene-for-gene resistance and HR-localized programmed cell death (PCD) (Dangl and Jones 2001). The functions of Avr effectors may be related to either triggering resistance or enhancing pathogen virulence (Shan et al. 2000). The *avrPto* and *avrPtoB* were the only avirulence genes in *Pseudomonas syringae* pv. *tomato* (*Pst*) DC3000 (causal agent of tomato bacterial speck disease) that elicited Pto-mediated defense responses in tomato. The *avrPtoB* deletion mutant of *Pst* DC3000 retained PtoB-specific avirulence on tomato. The double mutant DC3000 Delta *avrPtoDelta avrPtoB* caused less severe disease symptoms than single mutants and grew

slower than single mutants on susceptible leaves (Lin and Martin 2005). *P. syringae* pv. *tomato* (*Pst*) has unrelated effector proteins AvrPto and AvrPtoB that can trigger disease resistance in tomato cultivars containing the *Pto* gene. The Pto, a protein kinase, interacts directly with each effector through overlapping surface areas (Pedley and Martin 2002; Wu et al. 2004). In *P. syringae* pv. *tomato* DC3000 (*Pst* DC3000), the AvrPtoB type III effector elicited immunity-associated programmed cell death (PCD) when expressed in tomato plants carrying the Pto resistance protein. In contrast, in the absence of Pto the same AvrPtoB functioned as suppressor of PCD and immunity in tomato. The PCD eliciting and cell death suppressor (CDS) activities of AvrPtoB were mapped to distinct regions of the protein. The deletion of as few as 44 amino acids from the C-terminus resulted in the loss of CDS activity (Abramovitch and Martin 2005).

In response to pathogenic infection or abiotic elicitors, a group of low-molecular-weight compounds known as phytoalexins accumulate in treated plants (Kuč 1995). In cotton, cadinene-type sesquiterpenes including cadalene derivatives (7-hydroxylated cadinanes) are produced mostly as phytoalexins in response to stress (Bell 1986). Cotton leaves infected by incompatible races of *Xanthomonas campestris* pv. *malvacearum*, causal agent of bacterial blight, induced the cadalene derivatives as the major phytoalexins as part of HR which formed an important component of resistance to bacterial blight disease (Pierce et al. 1996). The enzyme (+)- δ -cadinene synthase (CDNS) catalyzes the first step in the biosynthesis of cadinene-type sesquiterpenes, such as gossypol, which provide constitutive and inducible protection against diseases. Infection by *X. campestris* pv. *malvacearum* induced CDNS expression in cotton. Constructs for the constitutive or seed-specific antisense suppression of *cdn-1-C4* were introduced into cotton by *Agrobacterium*-mediated transformation. The induction of CDNS mRNA and protein in response to bacterial blight infection of cotyledons was completely blocked in the constitutive antisense plants. The results suggested that *cdn1-C4* expression might be specifically induced in response to bacterial blight infection of cotton plants (Townsend et al. 2000). The gene-for-gene interaction was indicated between cotton (*Gossypium hirsutum*) cultivars and races of *Xanthomonas campestris* pv. *malvacearum* (*Xcm*). The interaction between cotton cultivar Reba B50 and race 18 of *Xcm* resulted in hypersensitive response (HR). However, this cultivar was susceptible to race 20, leading to the ultimate death of infected plants. The HR was correlated with the activity of 9S-lipoxygenase (LOX) responsible for lipid peroxidation. A LOX gene (*GhLOX1*) whose activity was involved in cell death during HR was characterized. The role of LOX in the development of resistance to bacterial blight disease was investigated using different cotton cultivars and *Xcm* race combinations. Various combinations of *R-avr* genes were selected to determine whether *GhLOX1* gene transcription and LOX activity could be correlated with the resistance phenotype. Cotton genotypes with the *B2B3*, *B2b6*, or *B12* genes or cotton near-isogenic lines containing single *B* genes (*B2*, *B6*) were infected by races 1, 18, or 10 of *Xcm*. Cotton phenotypes were analyzed for all interactions tested. For incompatible interactions, the LOX response appeared to be concomitantly triggered during cotton resistance, and this reaction might be a key event of hypersensitive cell death (Sayegh-Alhamdia et al. 2008).

Different species of *Erwinia*, namely *E. carotovora* subsp. *atroseptica* (*Eca*), *E. c.* subsp. *carotovora* (*Ecc*), and *E. chrysanthemi* (*Ech*), are involved in potato tuber soft rot disease. Potato-tuber slices and small tubers of 12 potato cultivars were inoculated with isolates of *Eca*, *Ecc*, and *Ech*. Cultivar resistance was expressed as the mean diameter of the rotted tissue area. Grouping of cultivars into classes of relatively high, intermediate, or low

resistance was different after incubation in air in comparison to incubation under anaerobic conditions, and depended on the bacteria (subspecies) used for inoculation. Grouping of the cultivars was not significantly affected by the isolates of the same subspecies of the pathogen. The results of experiments with either field-grown seed tubers or glasshouse-grown small tubers from 2 years were reproducible, except when tuber tissue was inoculated with *Ech* and incubated aerobically. In the latter case, the cultivar only showed relatively small differences for resistance. Correlation coefficients between slice and small tuber screenings were 0.71 and 0.64 for *Eca* and *Ecc*, respectively. The results showed that soft rot resistance of clones to different soft rot pathogens could be determined effectively, if standardized oxygen concentration during incubation was used (Allefs et al. 1995). *Erwinia carotovora* subsp. *atroseptica* (*Eca*) (renamed *Pectobacterium atrosepticum*) causes soft rots on tubers and blackleg on stems of potato, reducing the yield levels significantly. Partial resistance in some cultivars was recognized. The mechanistic basis of this type of resistance was investigated using a proteomic approach to identify pathways specifically activated during the interaction between potato tubers and *Eca*. Protein profiles on silver-stained gels in the 5–8 pH range were obtained from healthy and infected tubers from two cultivars differing for resistance level, analyzed by a 2DE and nano-LC-MS/MS procedure. Thirteen proteins were differentially upregulated in the partially resistant cultivar Keerpondy. In contrast, no significant difference in protein profiles of inoculated and control tuber could be observed in the susceptible cultivar Bintje. Mass spectrometry and database search showed that these proteins were involved in energetic metabolism (glyceraldehydes-3-phosphate dehydrogenase, 2-phosphoglycerate dehydratase or enolase, fructose biphosphate, aldolase, and ATPase α -subunit), cytoskeleton structure (actin), protein catabolism (cysteine protease inhibitor), and patatins or patatin precursors. A proteomic approach appeared to be efficient, providing an insight into the mechanisms and pathways leading to resistance in potatoes against *E. c. atroseptica* (Barzic and Com 2012).

12.2.1.5 Molecular Basis of Resistance to Virus Diseases

Resistance to virus diseases may be expressed at different stages of virus replication and movement to other plant organs, restricting the spread of the virus followed by development of visible symptoms, when infection becomes systemic. Cellular level resistance may be characterized as a state where virus replication is not likely to occur or occurs at an undetectable level in inoculated cells. This type of resistance was observed in cowpea cultivar Arlington challenged with *Cowpea mosaic virus* (CpMV). The involvement of a protease inhibitor in preventing CpMV polyprotein processing was suggested for the inhibition of virus replication (Ponz et al. 1988a). Another type of mechanism occurring at cellular level involves an active resistance to virus infection that limits virus replication rapidly before cell-to-cell movement is initiated. No symptoms or extremely limited necrosis may be observable in such plants. Resistance offered by *Tm-1* gene against *Tobacco mosaic virus* (TMV) in tomato (Watanabe et al. 1987), by *Nx* and *Rx* genes against *Potato virus X* (PVX), and *Ry* gene against *Potato virus Y* (PVY) in potato (Solomon-Blackburn and Barker 2001) and *Rsv1* gene against *Soybean mosaic virus* in soybean (Hajimorad and Hill 2001), has been reported. The host response of this type of extreme resistance (ER) in potato was revealed by the absence of any visible symptoms when challenged with PVY. By applying RNA hybridization and ELISA, accumulation of PVY could not be detected in the inoculated leaves of potato carrying *Ry* gene. In addition, the protoplasts isolated from these plants did not support replication of PVY.

As no HR could be seen, it was hypothesized that inhibitors of virus accumulation might be encoded by the resistance genes (Solomon-Blackburn and Barker 2001).

Pepper mild mottle virus (PMMoV) was unable to replicate in tomato plants because *tm-1* protein inhibited RNA replication. Resistance of tomato to PMMoV was durable both in the field and in vitro conditions. Several PMMoV mutants were constructed and their abilities to replicate in tomato protoplasts and plants were determined. The mutants PMMoV-899R, F976Y, PMMoV-899R, F976Y, and D1098N were able to replicate in tomato protoplasts, but only the latter mutant could multiply in tomato plants. The D1098N mutation of the replication proteins weakened the inhibitory effect of the *tm-1* protein and enhanced the replication efficiency of PMMoV-988R, F9764, and D1098N. The infectivity of the viruses decreased in the order wild-type PMMoV > PMMoV-899R, F976Y > PMMoV-899R, F976Y, and D1098N in original host plants pepper and tobacco plants. In contrary, the single mutation in D1098N abolished PMMoV replication in tobacco protoplasts. The results suggested that the deleterious side-effects of mutations in replication proteins might prevent the emergence of PMMoV mutants capable of overcoming *tm-1*-mediated resistance (Mizumoto et al. 2014).

Resistance to the movement of viruses within and between cells may occur, resulting in the failure of development of disease symptoms. In some pathosystems, the virus may be able to establish infection in or on a few cells, but the virus fails to move to other cells because of a lack of interactions between plant and viral factors required for cell-to-cell movement or due to active host defense responses that may rapidly restrict virus spread. In the case of DNA viruses, crossing the nuclear membrane is a formidable barrier for virus movement into and out of the cell nucleus (Whittaker and Helenius 1998). The viral protein required for import of virus into the nucleus and export of progeny genomes back to the cytoplasm for translation and virion assembly have been identified for some viruses. Systemic infection represents the susceptibility response of the host plant. The rate of systemic movement of virus may markedly reduce in some pathosystems as an expression of resistance. Resistance to *Potato leafroll virus* (PLRV) was associated with an exclusion of virus from external phloem bundles (Derrick and Barker 1997), whereas disrupted movement of *Cucumber mosaic virus* (CMV) in phloem tissue and confinement of CMV in the lower portions of stems of resistant pepper plants were considered to contribute to the resistance against the virus (Dufour et al. 1989). In the case of *Potato virus A*, the vascular movement of the virus was completely blocked in potato with a homozygous recessive *ra* allele (Hämäläinen et al. 2000). The genes involved in the protection of plants against viruses are yet to be identified in most pathosystems. Plasmodesmata are elaborate and highly regulated structures with which viruses can interact for both cell-to-cell and long distance movement, establishing symplastic connectivity between the epidermal/mesophyll cells and cells with the vascular elements, including sieve elements (SE) (Santa Cruz 1999). For the virus entry into the companion cell the virus may have direct access to the sieve tube, the conducting element of the phloem through which nutrients and viruses have to move. Only a few host factors that may affect the long-distance movement of viruses have been identified. Long-distance movement of *Tobacco mosaic virus* (TMV) was impaired due to down-regulation of pectin methylesterase (PME), resulting in the blocking of virion exit from phloem (Chen and Citovsky 2003).

Avirulence genes have been recognized by their requirement for disease resistance in plants possessing corresponding *R* genes. Large numbers of genomes of a single virus may be present in a single host plant cell across many cells per host. Avirulence

determinants are conventionally identified by producing chimeric clones derived from viral genotypes with different virulence levels followed by assessment of their infectivity on suitable host plant species. Avirulence factors with respect to *R* genes have been shown to be virtually any fragment of the viral genome, conferring resistance against the target virus. The viral RNA polymerase subunits, movement of protein, and CP of different viruses may function as virulence determinants. The HC-Pro and P3 proteins of *Soybean mosaic virus* function as virulence determinants for *Rsv1* in soybean (Eggenburger and Hill 1997). Evaluation of virus resistance using molecular markers was shown to be successful in several crops. Biochemical markers associated with disease resistance may be useful for accelerating the selection of resistant plants or sources of resistance to viruses affecting perennial horticultural crops. Apricot cultivars showing resistance to *Plum pox virus* (PPV) had enhanced levels of activities of catalase, ascorbate peroxidase (APX), and dehydroascorbate reductases (DHAR) compared to susceptible cultivars, suggesting the possibility of using the activities of these enzymes as biochemical markers for selecting genotypes resistant to PPV (Hernández et al. 2006).

Investigations to determine defense responses of potato cultivar Désirée to infection by *Potato virus X* were carried out. Salicylic acid (SA) biosynthesis and expression of several defense genes, including PR-1 and glutathione-S-transferase (GST) involved in ET- and ROS-dependent signaling, were highly upregulated in upper inoculated leaves of PVX-infected potato plants compared to mock-inoculated control plants. Further, the β -phenylethylamine alkaloids such as tyramine, octopamine, and norepinephrine were found to be highly induced upon PVX infection. These alkaloids may be involved in the elicitation of plant defense responses by forming hydroxycinnamic acid amides (HCAA), considered to enhance cell-wall stability by extracellular peroxidative polymerization. Infection by PVX substantially enhanced the expression of tyramine-hydroxycinnamoyl transferase (THT) and apoplastic peroxidase (POD) in systemically infected leaves. The metabolic and transcriptional changes observed in PVX-infected potato plants might represent the systemically acquired resistance (SAR) response against subsequent pathogen infection (Niehl et al. 2006).

RNA silencing is an important mechanism involved in gene regulation in several organisms, including plants. Posttranscriptional gene silencing is an RNA silencing-based approach employed to reduce the level of expression of a (viral) gene of interest. RNA silencing may be of two types: RNA-mediated transcriptional gene silencing (TGS); and posttranscriptional gene silencing (PTGS). The PTGS mechanism may be mediated through a host-encoded RNA-dependent RNA polymerase (RdRp) and RNA helices (Dalmay et al. 2001). The PTGS in plants inactivates some aberrant or highly expressed RNAs in a sequence-specific manner in the host cell cytoplasm and it is an innate and viral defense strategy of plants (Soosaar et al. 2005). Many RNA and DNA viruses stimulate PTGS shortly after infection, because of the formation of double-stranded structures (transient replication intermediates). Plants transformed with constructs that produce RNAs capable of duplex formation induce virus immunity with almost 100% efficiency when targeted against viruses (Smith et al. 2000; Wang et al. 2000; Kalantidis et al. 2002). Regardless of the origin, the occurrence of ds-RNAs in the cytoplasm induced PTGS. The RdRp was also shown to be involved in PTGS (Dalmay et al. 2000). PTGS could generate mobile silencing signals with sequence-specific information that spread from cell to cell through plasmodesmata and systemically through vascular system to different plant organs (Mlotshwa et al. 2002; Himber et al. 2003).

The potential of ds-RNA-mediated interference in plant virus infections has been assessed to exploit this phenomenon for the management of crop virus diseases. Three viruses, *Pepper mild mosaic virus* (PMMoV), *Tobacco etch virus* (TEV), and *Alfalfa mosaic virus* (AMV), belonging to the genera *Tobamovirus*, *Potyvirus*, and *Alfalfamovirus*, respectively, were investigated. The primary principle of RNAi technology is the ability to deliver ds-RNA as potent activator of RNA silencing into an organism or cell with the aim of triggering sequence-specific degradation of homologous target RNAs. Triggering RNA-interference (RNAi) could be successfully demonstrated by mechanically inoculating the host plants with in vitro transcribed ds-RNA to leaf cells together with the target virus (Tenllado and Díaz-Ruiz 2002). Homologous ds-RNA was able to interfere with virus infection in a systemic host infection. The ability of ds-RNA to specifically interfere with virus infection appeared to require a minimum length of ds-RNA. When a mixture containing infectious viral genomic RNA transcripts was used to inoculate test plants, none of the inoculated plants developed symptoms of infection. Further, AMV-RNAs 1, 2, and 3 could not be detected in the test plants (Tenllado et al. 2004). The genome of *Grapevine virus A* (GVA) was screened for the presence of a gene potentially capable of suppressing RNA silencing. Four of the five proteins encoded by GVA genome were screened using green fluorescent protein (GFP-) based transient expression assay. The expression product of ORF5 (protein p10) had the property of suppressing silencing induced by a transiently expressed ss-sense RNA. GVA P10 was found to be a suppressor belonging to a new family. This protein reduced the levels of siRNAs markedly and the recombinant protein bound ss- and ds-forms of siRNAs and microRNAs, suggesting the existence of a potential mechanism of suppression based on RNA sequestering (Zhou et al. 2006).

Satellites associated with some viruses and viroids have been shown to have small, noncoding, and highly structured RNA genomes. As in the case of viruses, the ability of viroids and viral satellites to induce RNA silencing has been observed. Tomato plants inoculated with *Potato spindle tuber viroid* (PSTVd) were analyzed for the presence of small RNAs with sequence specificity to PSTVd. Both mild and RG1 strain of PSTVd induced the production of small RNAs in infected tomato plants, but mock-inoculated tomato plants did not have the small RNAs. The siRNAs showed sequence specificity to PSTVd, indicating the operation of PSTVd-induced RNA silencing (VdIRS). However, the variations in symptoms caused by the mild and severe strains (RG1) of PSTVd did not seem to be related to development of RNA silencing (Itaya et al. 2001). The siRNAs induced following infection of tomato by PSTVd were 22- and 23-nt, representing different domains of the viroid genome. Production of the siRNAs in PSTVd infected plants indicated that nuclear replication of PSTVd RNA was able to induce PTGS. The siRNAs were slightly more abundant at 30 days postinoculation (dpi) than at late stages. No apparent relationship was noticed between the concentrations of PSTVd-specific siRNAs and the titers of viroid strain attained in infected plants (Papaefthimiou et al. 2001). Tomato plants expressing harpin (protein coded by *hrp* genes) RNA derived from *Potato spindle tuber viroid* (PSTVd) developed symptoms similar to those of PSTVd infection. Further, if RNA silencing in tobacco was prevented using a silencing suppressor, symptoms induced by *Cucumber mosaic virus* (CMV) satellite Y were markedly reduced. The results suggested that viroids and satellites appeared to cause disease symptoms by directing RNA silencing against physiologically important host genes. Viroid and satellite RNAs exhibit remarkable resistance to RNA silencing-mediated degradation that is effective against viruses. Most viroids, including PSTVd, replicate in

the nucleus and this subcellular localization possibly protect them from RNA-induced silencing complex (RISC) believed to be functioning in the cytoplasm. Nevertheless, viroids need to traverse the cytoplasm during cell-to-cell movement, during which time they are likely to be exposed to the RISC-degradation. Probably the extensive intramolecular base pairing may protect them from the degradation by the RISC complex (Wang et al. 2004).

Early evidence that PTGS occurred during viroid replication was reported by Wassenegger et al. (1994), whereas overexpression of viroid RNAs resulted in methylation of *Potato spindle tuber viroid* (PSTVd) genes incorporated into the tobacco genome. Accumulation of short RNA fragments of 21-24-nt representing different regions of PSTVd genome occurred both in pospiviroid- and avsunviroid-infected plants (Dierman et al. 2010; Owen et al. 2012). These fragments are characteristic of PTGS or RNA silencing which provides a multilayer defense system and protects plants from invasion by RNA replicons, including viruses and viroids. RNA-dependent RNA polymerase 6 (RDR6), which catalyzes the amplification producing double-stranded precursors of secondary-silencing RNAs (siRNAs), plays a role in the restriction of PSTVd spread to floral and vegetative meristems (Di Serio et al. 2010). Evidence suggests that most of these short fragments may originate from restricted regions of the viroid molecule, including the pathogenicity and the potential binding sites to host genes (Machida et al. 2007; Wang et al. 2011).

An alternative mechanism suggested is that viroid genomic RNAs or the replication process could be the effectors of pathogenesis and may impair the normal function of the RNA silencing machinery in the host. The presence of small viroid-specific RNAs in the cytoplasm of viroid-infected plants indicates that viroids can trigger RNA silencing in a host and may also be substrates for dicer-like cleavage to produce short interfering RNAs (siRNAs) (Itaya et al. 2001). However, mature monomeric, partially double-stranded, highly structured viroid molecules can overcome this RNA interference (RNAi-) mediated machinery (Gómez and Pallás et al. 2007; Schwind et al. 2009). There may be many reasons for the failure of the RNA-induced silencing complex (RISC) to target viroid RNAs (Kovalskaya and Hammond 2014).

12.3 Improvement of Disease Resistance Through Biotechnological Approaches

The use of genetically resistant cultivars for management of crop diseases is known to be the most economical option for profitable cultivation of various crops. However, the lack of durability of resistance for longer periods has been found to be the major obstacle because of selection pressure exerted on the microbial pathogens, which may sooner or later, to adapt themselves to the newly introduced resistance genes by producing new strains. In addition, the unavailability of dependable sources of resistance to several economically important diseases has necessitated the development of alternative methods of containing the diseases caused by the microbial pathogens. Rapid developments in molecular biology and genetic engineering during the past few decades have indicated the possibilities of obtaining crop cultivars resistant to diseases that have evaded the crop protection umbrella in the near future. Plants possess natural protective systems provided by a variety of constitutive barriers already present in the plant before

infection by a microbial pathogen and this type of resistance, known as constitutive resistance, is usually observed in wild relatives of the cultivated plant species. On the other hand, protective defense system(s) may be activated in response to treatment/infection by a pathogen or abiotic agent; such resistance is designated induced or acquired resistance. Investigations of the molecular biology of disease resistance have clearly elucidated various aspects of plant–microbe interactions, resulting in the expression of compatible or incompatible interactions between crop cultivars and pathogen strains or races with varying levels of resistance/virulence. Genetic engineering procedures have been shown to be effective for isolation of disease resistance gene(s) and expressing them in the desired crops. Resistance genes from diverse sources have been incorporated into cultivars to provide effective protection against pathogens that could not be contained by other techniques. Various biotechnological approaches that can be employed to improve resistance levels and restrict the incidence and spread of diseases transmitted via seeds and propagules are discussed.

12.3.1 Tissue and Cell Culture Techniques

Tissue and cell culture procedures have been employed primarily for producing disease-free seeds and mother plants which form the nuclear stock. This aspect was discussed in Chapter 10. Another important aspect is the identification of clones from the same culture which show greater levels of tolerance/resistance to target pathogen(s).

12.3.1.1 Somaclonal Variation

Variations in several characteristics including disease resistance have been observed in plants regenerated from organ cultures, calli, and protoplasts. The variability expressed by regenerated calli was named somaclonal variation by Larkin and Scowcroft (1981). Regenerants from callus cultures resistant to *Sugarcane Fuji virus* were selected (Krishnamurthi and Thaskal 1974). Later, somaclones regenerated from potato cultivar Russet Burbank protoplasts were found to be resistant to the late blight pathogen *Phytophthora infestans* and also to the early blight disease caused by *Alternaria solani* (Shepherd 1981; Doke and Furnichi 1982). Somaclones generated from individual cells or organs may exhibit resistance to pathogens or their metabolites. Sugarcane somaclonal variants displaying resistance to smut disease caused by *Ustilago scitaminea* were investigated to identify genes that are activated and associated with resistance in sugarcane, following inoculation with *U. scitaminea*. Differentially expressed transcription-derived fragments (TDFs) that were induced following challenge inoculation of resistant and susceptible somaclones were isolated using a cDNA-AFLP technique. Of these 62 differentially regulated genes, 10 were downregulated while 52 were induced; these differentially induced TDFs were isolated and sequenced. Of these TDFs, 11 were isolated from the smut-resistant somaclones. The differential expression of 19 TDFs was confirmed by Northern blots, and the mRNA levels of genes that were homologous to 7 of those TDFs were highly induced in resistant somaclones inoculated with *U. scitaminea*; only low or no expression could be detected in the susceptible parental lines, however. Only one of the 52 differentially expressed TDFs was highly induced in *U. scitaminea* and also *Bipolaris sacchari* (another important sugarcane pathogen causing eye spot disease) interactions with sugarcane somaclones. The TDF was derived from a gene encoding a putative serine-threonine kinase and might contribute to disease resistance in sugarcane (Borrás-Hidalgo et al. 2005).

Fusarium (Panama) wilt pathogen, *Fusarium oxysporum* f.sp. *cubense* (*Foc*), exists in the form of four races (1, 2, 3, and 4). The race 4 attacked Cavendish cultivar Taiwan and had a host range different from the other three races. The Cavendish plantlets from tissue culture were screened for their resistance to *Fusarium* wilt disease by planting them in a pathogen-infested field. To increase the inoculum level, diseased tissues were ploughed into the soil at 300–1000 propagules per gram of soil. Plantlets (20,000) were grown for 2 months. Suckers from each of the 18 surviving clones were selected after 1 year. Rhizomes were shaved with a knife to remove any infected tissues, revealed by the presence of reddish or brown streaks. Symptomless suckers were planted in the disease nursery again. All of the first-generation plants from suckers of six surviving clones remained healthy after 1 year. The unaffected plants in the second and third generations were tested in a similar manner. These suckers were highly resistant to *Foc* race 4, in comparison to the parent plantlets. Large numbers of plants from six clones were tested in banana farms where they were highly resistant to the wilt disease. The resistant plants were also tested with high inoculum levels in the greenhouse. Among the variants, only one (GCTCV-2/8) possessed better horticultural parameters in addition to resistance to *Fusarium* wilt disease, and the fruits were well received by consumers in Taiwan and Japan (Hwang and Ko 2004).

Powdery scab disease of potato caused by *Spongospora subterranea* is an economically important disease occurring in several countries. Variations in the resistance of somaclones to *S. subterranea* were determined by inoculating the somaclonal variants. Most of the variants consistently showed increased resistance to powdery scab disease, both under glasshouse and field conditions, when compared to parental cultivar Russet Burbank. The best variant showed reduced powdery scab incidence by 51% and disease severity (based on tuber surface coverage) by 64%. However, no improvement was observed in the severity of root infection and root galling caused by *S. subterranea*. The results suggested that mechanisms of defense responses to the root and tuber infections might be different. Correlation analyses of disease indices among the selected variants did not show any association either between root infection and gall scores, or between root infection and tuber disease severity. However, a weak positive association was indicated between root gall score and tuber disease and a strong correlation between tuber disease incidence and severity scores. The results indicated positive correlations between the levels of resistance to powdery scab and common scab (caused by *Streptomyces scabies*) expressed and incidence and severity of diseases within variants, suggesting a common defense mechanism against both diseases (Tegg et al. 2013).

12.3.1.2 In Vitro Selection for Disease Resistance

Microbial plant pathogens produce different kinds of toxic metabolites and/or resistance-inducing compounds that may play a role in host–pathogen interactions, leading to disease development or induction of resistance depending on the nature of the compounds involved. It was considered that plant cell/organ cultures showing resistance to pathogen-derived toxic compounds might give rise to plants with resistance to infection by the same pathogen-producing toxic compounds. The defense responses of calli and seeds of two rubber cultivars showing resistance (BPM-24) and susceptible reaction (PRIM600) were determined by treating them with zoospores and elicitor purified from *Phytophthora palmivora*. Both zoospores and elicitor induced the biosynthesis of phytoalexin scopoletin (Scp) in *Hevea* calli at concentrations ranging from 5×10^5 to 4.5×10^6 zoospores mL⁻¹ and 0.5–2 µg elicitor per gram fresh weight of calli.

The rate of Scp production was fastest at the highest concentration of zoospores and elicitor tested. Decline in the Scp level at the highest zoospore/elicitor concentration was correlated to the amount of cell death. The Scp and peroxide (POD) accumulations were approximately 2–3 times higher in resistant cultivar compared to susceptible cultivar. The responses of the calli to elicitor were faster than those to zoospores. The patterns of Scp and POD activities monitored in elicitor-treated *Hevea* seeds was similar to that of *Hevea* calli after treatment with zoospores or elicitor. The results showed that callus culture could be used as a tool to determine the defense mechanisms operating in rubber plants against *P. palmivora* (Chirapongsatunkul et al. 2008).

The pathogenic strains of *Streptomyces scabiei*, the primary pathogen of potato common scab disease, produce the phytotoxin thaxtomin A, whereas nonpathogenic strains do not produce the phytotoxin. This phytotoxin could induce common scab symptoms when applied on developing tubers in the absence of the pathogen. It was suggested that resistance to thaxtomin A in potato seedlings might be correlated with decreased scab disease lesions on tubers (Hiltunen et al. 2006). The effectiveness of using thaxtomin A as a positive selection agent for somatic cell selection of potato with enhanced resistance to common scab disease was assessed. A somatic cell selection procedure was developed to use thaxtomin A as a positive selection agent and 113 potato cell clones of cultivar Iowa were recovered. From these cell colonies, 39 plants were regenerated within a single subculture period. Regenerated variants (13) were selected after artificial inoculation, based on mean tuber coverage with lesions and the proportion of disease-free tubers. The best variant had an average reduction of 85–86% in disease score over that of disease severity in particular cultivar. Two (65A and 65B) of the 13 variants produced more tubers than parent cultivars in two of three trials conducted. Although not immune to infection, these two variants did not exceed an estimated 1.3% lesion tuber surface coverage and showed less tuber surface score (85–86%) than the unselected parent cultivar (Fig. 12.3). The disease-resistant variants differed in their response to

Figure 12.3 Disease severity induced by *Streptomyces scabiei* in resistant clone 65A and susceptible parent Iwa. Source: Wilson et al. (2009). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

thaxtomin A in detached leaflet and tuber slice bioassays. The results suggested that the cell selection procedure and thaxtomin A screening had limited success in selecting for toxin tolerance, and that thaxtomin A tolerance was not necessarily the critical factor for induction of disease resistance observed. Variations in the relative necrosis scores between the leaflet and tuber assays for individual variants possibly suggested differential expression of thaxtomin A tolerance in different tissues. Yield estimates from the glasshouse-grown potatoes showed that the majority of disease-resistant variants produced yields equivalent to the unselected parent cultivar, indicating the commercial viability of growing the resistant variants of potato (Wilson et al. 2009).

12.3.1.3 Induction of Mutation Using Chemicals

With the development of in vitro culturing of plant cells/organs, in vitro mutagenesis has been shown to be useful for genetic improvement in many characteristics including disease resistance/tolerance. Banana cultivars with wilt (*Fusarium*) resistance have been derived from in-vitro-induced mutants (somaclonal variants) such as cultivars Tai Chiao No.1 and Formosana (Hwang and Ko 2004). Ethyl methanesulfonate (EMS) was used for mutagenesis of banana plant and apical tissues to produce mutants (Yang and Lee 1981; Omar et al. 1989). Micro-cross-section derived from banana leaf bases were used for callus and shoot bud induction with subsequent regeneration of healthy plants (Okole and Schulz 1996). This procedure of regenerating banana plants was employed for inducing mutation in vitro using EMS and for screening for *Fusarium* wilt-resistant lines of Brazil banana (*Musa* spp.). The results indicated that the optimum EMS concentration and duration of treatment of micro-cross-sections obtained from the pseudostem of tissue-cultured plantlet were 300 mM and 60 min, respectively. One hundred generated plantlets were used for screening for *Fusarium* wilt-resistant lines by inoculating *F. oxysporum* f.sp. *cubense* race 4 (5×10^6 spores mL⁻¹). The initial disease symptom of yellowing in lower leaves of susceptible plants appeared at 2 weeks after inoculation. After 2 months, only six plants survived the preliminary field test. The early screening technique eliminated 94% of the plantlets regenerated from micro-cross-sections with mutation induction by EMS. The selected plants showed marked reduction in wilt disease incidence. The results showed that EMS-induced mutation of banana through the micro-cross-section cultural system might be useful for improvement of resistance of banana to *Fusarium* wilt disease (Chen et al. 2013).

12.3.2 Transgenic Resistance to Crop Diseases

Genetic engineering has provided numerous options for selecting the desired gene(s) from a wide range of sources, including the pathogens themselves, which could not be accessed by other methods. The disease resistance genes available in various sources, especially wild relatives of crop plant species, have been located at specific sites by the action of restriction endonucleases. The DNA fragment(s) carrying the desired gene(s) are identified and used as molecular markers. Random amplified polymorphic DNA (RAPD) technique in conjunction with PCR assay has been employed to identify resistance genes rapidly. The PCR assay has been demonstrated to be very useful to amplify the desired sequences in the DNA. Transgenic plants constitutively expressing defense-related genes from desired sources may be generated. The exogenous DNA fragment introduced artificially via genetic engineering techniques has to pass through the germ line of the plant to be transformed, following incorporation of the foreign DNA into the plant's nuclear material. Crop varieties with resistance to diseases caused by microbial

pathogens were developed within a short period by employing biotechnological methods; classical breeding procedures require several years, in addition to being hampered by obstacles posed by interspecific sterility and linkage with undesirable genes. Incorporation of genes from bacteria, fungi, viruses, or various species of plants has been accomplished by employing the Ti (tumor-inducing) plasmid containing TDNA of phytopathogenic bacterial species *Agrobacterium tumefaciens* (At). Ti DNA can be disarmed, rendering the plasmid nononcogenic but still retaining its ability to integrate with host plant genome. Depending on the nature of pathogens and their pathogenic potential (virulence), various techniques have been used for the generation of cultivars with higher levels of resistance to target pathogen(s).

12.3.2.1 Transgenic Resistance to Virus Diseases

12.3.2.1.1 Pathogen-Derived Resistance

Transgenic expression of pathogen sequences has been utilized to provide protection against respective pathogens themselves by interfering with pathogen development or multiplication. Pathogen-derived resistance (PDR) is the principal approach by which transgenic protection is offered against many viruses infecting various crop plants. Incorporation of coat protein (CP) gene of *Tobacco mosaic virus* (TMV) in tobacco was demonstrated to result in enhanced protection against TMV for the first time by Abel et al. (1986). The transgenic tobacco plants only showed resistance against intact TMV but not against viral RNA, since inoculation of transgenic plants with viral RNA resulted in the development of symptoms of TMV infection in as many plants as in nontransformed control plants (Nelson et al. 1997). As the functions encoded by different viral genes have been determined, it has been possible to transform plants with different viral genes encoding structural and nonstructural proteins with varying degrees of success.

Transgenic plants expressing the CP gene of *Potato leafroll virus* (PLRV) exhibited resistance to PLRV when inoculated by viruliferous aphids (Kawachuk et al. 1990). The CP gene of some of the plant viruses was reported to have the ability to function as an elicitor of resistance. The L^2 gene in *Capsicum* is known to confer resistance to all known tobamoviruses except *Pepper mild mottle virus* (PMMoV). A hybrid virus consisting of the CP gene of *Paprika mild mottle virus* (PsMMV), which could induce a hypersensitive reaction (HR), and the PMMoV-S sequences was able to elicit HR in *Capsicum frutescens* (L^2L^2) plants, suggesting that the CP gene had the sequences that might affect induction of HR-mediated L^2 resistance in pepper. The CP but not the RNA appeared to be the elicitor of HR in pepper (de la Cruz et al. 1997). The CPs of U2 strain of *Tobacco mosaic virus* (TMV) and *Odontoglossum ringspot virus* (ORSV) also were able to elicit HR whereas the CP gene of *Cucumber mosaic virus* (CMV) could not elicit HR in eggplant, indicating that elicitation of HR may be associated with CPs of specific tobamoviruses (Dardick and Culver 1997). The potato cultivar Igor was seriously affected by NTN isolates of *Potato virus Y* (PVY^{NTN}), causing potato necrotic ringspot disease (PNRD). This cultivar was transformed with the CP gene of PVY^{NTN} and several transgenic lines were highly resistant, showing no visible symptoms when they were graft-inoculated. The virus could not be detected by either ELISA or infectivity tests. Among the 34 transgenic lines, two showed resistance to PVY^{NTN} and PVY^O and one line was resistant to PVY^O (Racman et al. 2001). Transgenic potato plants expressing CP gene of *Potato virus X* (PVX) were found to be resistant to both intact virion and viral RNA. It was hypothesized that PVX CP might either interact with the

origin of assembly and restrict replication or interfere with translation of the replicase gene (Hemmenway et al. 1988; Spillane et al. 1997).

The T-36 strain of *Citrus tristeza virus* (CTV) expressing green fluorescent protein gene (CTV-GFP) was used to detect replication of CTV in wild-type (WT) “Hamlin” sweet orange plants, and transformed with the use of *Agrobacterium tumefaciens* (At) strain harboring binary vector with a coat protein gene from either T-36 or T-30 isolate of CTV. Soil-adapted WT and transgenic plants were challenged with CTV by grafting shoots from CTV-GFP infected plants. None of the transgenic plants appeared to be able to inhibit CTV replication, as CTV-associated GFP fluorescence was detected in all of them by fluorescent microscopy. CTV multiplication in transgenic plants was also examined by ELISA tests. GFP-labeled CTV represented a useful aid for estimating the susceptibility of citrus cultivars or transgenic lines to CTV infection. The method using CTV-GFP was found to be simpler, more economical, and less time-consuming than ELISA tests (Orbović et al. 2011).

The possible role of PTGS in the development of coat-protein-mediated resistance (CP-MR) against PVX infection was investigated. Transgenic tobacco plants expressing PVX CP were challenged with PVX under conditions in which PTGS was suppressed by low temperatures or by using PVY that encoded HC-Pro, a known suppressor of PTGS. The transgenic plants expressing PVX CP were maintained at 15 and 24°C for 10 days. The transgenic plants were resistant, producing very few small sites of infection as against production of a high number of sites of infection in nontransformed control plants. The results showed that PVX CP-MR was not temperature-dependent, indicating that resistance was not dependent on PTGS (Bazzini et al. 2006).

Plum pox virus (PPV), causing sharka disease of huge economic importance, infects all commercial stone fruit crops (*Prunus* spp.). *Agrobacterium tumefaciens* (At-) mediated transformation procedure was applied to obtain transgenic clones of *Prunus domestica* from plum hypocotyles with PPV CP gene (Scorza et al. 1994). One of the clones, C5, showed high level of resistance to PPV under glasshouse conditions (Ravelonandro et al. 1997). In another investigation, six transgenic clones (C2, C3, C4, C5, C6, and PT-6) expressing CP gene of PPV and PT-23 transformed with marker genes only and a nontransformed line were evaluated for their resistance to PPV in Poland and Spain under field conditions where disease pressure was high for 7 years. A high level of resistance to PPV was noted only in one clone C5 and none of the C5 trees showed infection by PPV under high disease pressure conditions. In contrast, all other plum trees (100%) exhibited disease symptoms and were positive for PPV by ELISA and RT-PCR assays. The C5 trees, showing distinct posttranscriptional gene silencing (PTGS), were found to be uninfected by PPV during the entire period of experimentation (7 years), representing a significant part of the productive life of plum orchards (Malinowski et al. 2006).

The posttranscriptional gene silencing (PTGS) process may be negatively impacted by some biotic and abiotic conditions, which represents potential concern for production of stable engineered virus resistance traits. The *Plum pox virus* (PPV-) *Nicotiana benthamiana* pathosystem was used to evaluate the stability of intron-harpin (ihp-) mediated virus resistance under conditions known to adversely affect PTGS. The ihp plants grown at low or high temperatures were fully resistant to multiple PPV challenges, different PPV inoculum concentrations, and even to a PPV isolate differing from the ihp construct by more than 28% at the nucleotide level. In addition, infections of ihp plants with viruses belonging to *Cucumovirus*, *Potyvirus*, or *Tombusvirus*, all known to

affect PTGS at different steps, were unable to defeat PPV resistance in transformed plants. Low temperatures did not affect the accumulation of transgenic small interfering RNAs (siRNAs), whereas a clear increase in the amount of siRNAs was observed during infections sustained by *Cucumber mosaic virus* (CMV) and *Potato virus Y* (PVY). The results indicated that stress factors tested did not appear to be important factors influencing transgenic resistance in plant species with robust virus resistance traits (Di Nicola et al. 2014).

Global climate changes may have potential influence on the distribution and profile of crop pathogens. The mechanisms of virus suppression by small RNAs (sRNAs) have been investigated. High-throughput silencing (HTS) can generate large sets of sRNA sequences which can be analyzed to recognize the abundant sRNAs that result from transcript degradation and to identify the regulatory microRNAs (miRNAs) involved in gene regulation and small inhibitory RNAs (siRNAs) that confer resistance to plant viruses. Transgenic potato plants (*Solanum tuberosum*) that were glasshouse or field grown, and that expressed the *Potato virus Y* (PVY) coat protein (CP) inverted hairpin RNA (ihRNA) from the 409S promoter with GBS S5 intron as a spacer, exhibited resistance to PVY. Southern blots of genomic DNA indicated high levels of siRNA production from the transgenic hairpin constructs. Up to 47% of the top 200 most frequent sRNA reads were attributable to the PVY CP transgenic construct in Ranger Russet line #5. This combination of transgenic and transcription strength is functional for constructing efficient resistance cassettes for crop production. Up to 95 of the top 200 sRNA sequences were 21-nt in length with as many as 19 sequences corresponding to known miRNA transcripts. Additional endogenous sRNAs with homology to resistance gene analogs may be indicative if additional or complementary resistance mechanisms are produced in concert with PVY siRNAs arising from PVY-CP RNA (McCue et al. 2012).

Grapevine fan leaf virus (GFLV) belonging to the genus *Nepovirus* enclosing the nematode-transmitted viruses contains three types of particles, namely T (top), M (middle), and B (bottom) which remain at the sequential positions in a purified virus suspension. The top (T) component contains empty virus capsids (coat protein), whereas the M and B components contain viral RNA2 and RNA1 + RNA2, respectively. RNA2 encodes viral CP and also determines vector specific transmission by the nematode *Xiphinema index*. Grapevine (*Vitis vinifera*) cultivar Russalka plants were transformed by transferring the CP gene including nontranslatable and truncated forms via At-mediated transformation. The transgenic sequences were detected by PCR in all lines. Southern blot analyses also revealed the number of inserted T-DNA copies varying from 1 to 6. Accumulation of GFLV-CP could not be detected by ELISA tests in any one of the 36 transgenic lines analyzed. Application of RT-PCR analysis revealed the presence of GFLV CP mRNA, expressed at variable levels. The levels of resistance to GFLV in grapevine transgenic lines were not assessed using the nematode vector to determine the potential value of this approach for development of GFLV-resistant grapevine cultivar (Maghuly et al. 2006).

Potyvirus form a major group of plant viruses with genome in the form of a single large ORF encoding a large primary polyprotein. The virus-encoded proteins are produced by self-proteolysis due to the action of products of three viral cistrons. The nuclear inclusion body is composed of two virus-encoded proteins, namely NIa and NIB. Transgenic peas, containing a copy of the *Pea seedborne mosaic virus* (PSbMV) isolate DPD1 NIB sequence, developed a “recovery” phenotype when challenged with either the homologous DPD1 or a heterologous (NY) PSbMV isolate. However, the

specificity of the subsequent resistance differed with respect to the initiation by and targeting of different virus isolates. Analysis of tissue in which recovery had been induced by either of the isolates revealed the presence of low molecular RNA molecules (siRNA) derived from degradation of the NIB transgene mRNA. When nontransgenic scions were grafted onto transgenic stocks in which recovery had been induced all the scions were infected, indicating that the virus might be exported from the recovered tissue. In the reciprocal grafting experiments, recovered scions were grafted onto nontransgenic stocks. The recovery phenotype could be maintained in the apparent absence of a source of virus. However, many side shoots developing on the nontransgenic stocks became infected. The results indicated that the recovered pea tissues contained extremely low levels of infectious virus with potential directly or indirectly to confer the resistance specificity. Indirectly the viral genome could act as a source of specific siRNA molecules which are present in infected tissues but were below the level of detection in recovered tissues. This could act in conjunction with siRNAs derived from the transgene mRNA to maintain a level of posttranslational gene silencing (PTGS) activity which is effective in preventing further accumulation of heterologous or related viruses (Van den Boogaardt et al. 2004).

The concept of using an RNA interference construct to silence the *Cowpea severe mosaic virus* (CPSMV) proteinase cofactor gene and the *Cowpea aphid-borne mosaic virus* (CABMV) coat protein gene was test-verified to generate resistant transgenic cowpea plants. Ten cowpea transgenic lines were produced, presenting a normal phenotype and transferring the transgene to the next generation. Plants were tested for resistance to both CABMV and CPSMV by mechanical coinoculation. Seven lines exhibited milder symptoms when compared to the control, and three lines showed enhanced resistance to both viruses. Northern analyses were performed to detect the transgene-derived small interfering RNA (siRNA) in leaves and revealed no correlation between siRNA levels and virus resistance. In addition, in the symptomless resistant lines the resistance was homozygous-dependent. Homozygous plants only remained uninfected, while hemizygous plants showed milder symptoms (Cruz and Aragão 2014).

12.3.2.1.2 Protection by Expression of Antiviral Proteins

Crop plants may be protected by transformation with genes encoding antiviral compounds. The ribozymes construct, based on the nucleotide sequence of a viral gene, may cleave the target sequence efficiently in vitro. By integrating the ribozymes sequence into the host plant genome, the invading virus may be inactivated. The construct targeting *Plum pox virus* (PPV) that contained a hammerhead ribozymes provided significantly higher level of protection compared with the antisense RNA construct (Liu et al. 2000). The presence of antiviral proteins has been shown in several nonhost plant species. A ribosome-inhibiting protein (RIP) present in the cell wall of pokeweed (*Phytolacca* spp.) was reported to have antiviral properties. A cDNA clone for the pokeweed antiviral protein (PAP) was isolated and introduced into tobacco or potato plants by transformation with *Agrobacterium tumefaciens* (At). Transgenic potato or tobacco plants that expressed PAP or double mutant derivative of PAP exhibited resistance to infection by a broad spectrum of plant viruses such as *Potato virus X* (PVX), *Potato virus Y* (PVY), and *Cucumber mosaic virus* (CMV). Resistance to the viruses was effective when transgenic plants were either inoculated by sap or aphid inoculation. PAP protected the plants by inhibition of early events in the infection process (Lodge et al. 1993). Plants expressing a low level of a C-terminal

deletion mutant of PAP showed resistance to PVX (Tumer et al. 1997). Another RIP from pokeweed PAP-II was found to be less toxic than PAP. The plants expressing PAP-II were resistant to *Tobacco mosaic virus* (TMV) and PVX (Wang et al. 1988). Another antiviral protein PAP-2 from *Phytolacca insularis* exhibited antiviral activity against TMV (Song et al. 2000).

In a later investigation, the effectiveness of pokeweed antiviral protein (PAP) in protecting *Petunia hybrida*, an important ornamental plant species, against CMV was assessed. Mutant PAP efficiently inhibited viral gene expression at both translational and transcriptional levels without causing host cell toxicity. The noncytotoxic mutant PAP gene was transferred into petunia cell via *At* transformation technique. Forty-two putative transgenic regenerated lines were obtained from selected explants. Forty-six plants immune to CMV infection were recovered from nine transgenic lines. Another 51 plants tolerant to CMV infection were obtained from 10 transgenic regenerated lines. Successful integration of the mutant PAP gene into the genome of transgenic petunia was confirmed by PCR and Southern blot analysis. Expression of the PAP gene was further confirmed by RT-PCR and Western blot analysis. These results were consistent with the assay of resistance to CMV (Li et al. 2013).

12.3.2.1.3 Protection by Engineered Mild Strains of Viruses

Cross-protection of crop plants using the naturally occurring mild strains has been successfully applied as a virus disease management strategy, as in the case of *Citrus tristeza virus* (CTV). *Papaya ringspot virus* (PRSV-) W strains can infect cucurbitaceous plants, but not papaya (infected by P strain only). Chimeric mild strains were constructed from HA5-1, a mild strain of PRSV (artificially produced from a severe Hawaii PRSV type P strain using nitrous acid) to carry a heterologous CP coding region and/or a 3' UTR (untranslated region of HA5-1 Wep 3U) of a type W strain that originated from Taiwan (PRSV W-CI). The chimeric mild virus HA5-1 Wep 3U provided a much higher level of cross-protection against the type W virus (W-CI strain) than the mutant HA5-1, while still providing a high degree of cross-protection against the type P virus P-HA in cucurbits. The results indicated that broad spectrum protection against two strains (that are differentiated by the ability or inability to infect papaya) could be accomplished by employing a mild potyvirus strain carrying a heterologous 3' genomic region, since the 3' UTR of the potyvirus was involved in the replication of positive-strand viral RNA. Sequence-homology-dependent PTGS is considered an antiviral defense mechanism in virus-infected plants, playing an important role in cross-protection against the same virus or related strains (Voinnet 2001).

12.3.2.2 Transgenic Resistance to Fungal Diseases

Fungal pathogens have more complexity in structure than bacterial and viral pathogens. Fungal pathogens possess the capacity for adopting different strategies to weaken the host responses that may restrict pathogen development. Resistance to fungal pathogens may be enhanced in different ways: (i) transformation of host plants for biosynthesis of a novel protein with adverse effect on pathogen growth; (ii) activation of expression of endogenous gene(s) normally induced following infection; (iii) transfer of gene(s) from other sources to direct the synthesis of a novel low-molecular-weight antimicrobial compound(s); and (iv) introduction of gene(s) to detoxify or deactivate pathogen factors required for pathogenesis. The development of plants resistant to fungal pathogens depending on the effective interference in the process of assembling pathogen cell wall

and membrane, and/or degrading them after assembly by introducing the gene(s) encoding the synthesis of antifungal compounds, formed the most frequently applied approach. Introducing pathogenesis-related (PR) proteins with chitinase or β -1,3-glucanase activities has been found to be more effective in arresting development of fungal pathogens. Biosynthesis of chitinase is governed by single genes; it may therefore be comparatively easier to transfer these genes than compared to the multiple genes that control other defense-related compounds such as phytoalexins and lignins. Chitin constitutes one of the major components of the cell walls of many fungal pathogens such as *Rhizoctonia*, and is hydrolyzed by chitinase. *Brassica napus* var. *oleifera* plants transformed with the endochitinase gene from tomato showed a greater level of resistance to *Phoma lingam*, *Sclerotinia sclerotiorum*, and *Cylindrosporium concentricum* compared with nontransformed control plants under field conditions (Grison et al. 1996).

Trichoderma harzianum has been employed as a biocontrol agent (BCA) against several fungal pathogens. Various strains of *T. harzianum* produce endochitinases, CHIT31, CHIT33, CHIT36, CHIT37, CHIT42, and CHIT52 which have been reported to be effective against fungal pathogens (Viterbo et al. 2001; Markovich and Kononova 2003). *T. harzianum* TM strain produced CHIT36 activity when expressed in planta. A plasmid containing *chit36* gene under the control of CaMV 35S promoter and the *nptII* selection gene was introduced into polyethylene glycol (PEG-) treated carrot (*Dacus carota*) protoplasts. The transgenic plants expressing CHIT36 were used in resistance assays to determine their levels of susceptibility/resistance to fungal pathogens *Alternaria radicina*, *A. dauci*, and *Botrytis cinerea*. Laboratory-based assays on detached leaves and petioles showed that transgenic carrots had less severe disease symptoms induced by these pathogens. All transgenic clones showed elevated chitinolytic activity. The highest activity observed for one clone (No. 178) was almost double the activity of the other transgenic lines and ten-fold higher than that of the control (nontransgenic parent lines). Comparison of infected leaflet area showed that transgenic clones differed in their reactions to fungal pathogens. Two clones (No. 96 and 178) had significantly enhanced resistance (35% and 19% disease) compared to the parent line. The clone No. 178 was tolerant to three pathogens tested, whereas clone No. 180 showed tolerance to *A. radicina* and *B. cinerea* but not to *A. dauci*. In general, disease severity of transgenic clones expressing CHIT 36 was reduced by approximately 50% relative to the control plants. For plants produced from seeds (Koral), a strong correlation was observed between chitinolytic activity measured in leaf extracts and the susceptibility to *A. radicina* ($r=0.94$; $P=0.008$) and to *B. cinerea* ($r=0.93$; $P=0.11$) (Fig. 12.4). The results indicated that expression of CHIT36 in planta may be an effective approach for improving the resistance of carrot to fungal pathogen (Baranski et al. 2008).

The genes encoding antifungal proteins (AFPs) from antagonistic biocontrol agents (BCAs) have been used to transform plants to improve the resistance to diseases caused by microbial pathogens. The AFPs encoded by the antifungal activity against several economically important fungal pathogens, including *Magnaporthe grisea*, have been identified. The transgenic rice plants constitutively expression *afp* gene were generated via *Agrobacterium tumefaciens* (At-) mediated transformation procedure. The presence of AFP protein in the leaves of transgenic rice plants was detected by Western blot analysis using polyclonal antibodies (PABs) raised against the purified AFP protein. Constitutive expression of the *afp* gene in rice resulted in a higher level of resistance to *M. grisea* in detached-leaf assay. Among the transgenic lines, the line 10* harboring the

Figure 12.4 Reactions of transgenic carrot plants expressing chitinase *CHIT36* gene to the fungal pathogens *Alternaria dauci*, *A. radicina*, and *Botrytis cinerea* following inoculation of detached leaflets and petioles. Values represent the percentage of nontransgenic “Koral” control for transgenic line 96-183. synthetic *afp* gene was more resistant to rice blast pathogen. The level of *afp* expression appeared to be correlated to the level of disease resistance. The resistance of transgenic rice plants was considered to be due to the inhibition of germination of conidia of *M. grisea* at infection site (Coca et al. 2004).

In another investigation, the activity of the promoters from three maize PR genes *ZmPR-4*, *nipi*, and *PRms* in transgenic rice expressing *gfp* gene from *A. giganteus* was evaluated. The *ZmP4* promoter was strongly induced in response to infection by *M. grisea* and also treatment with fungal elicitors and mechanical wounding, as revealed by histochemical assays of GUS activity in transgenic rice plants. The *nipi* promoter was responsive to infection and wounding. On the other hand, *PRms* was not responsive to any of the treatments tested. The transformants expressing the *afp* gene under the control of *ZmPR4* promoter exhibited resistance to *M. grisea* to different degrees (Moreno et al. 2004). Proteomics analysis of rice phylloplane-secreted proteins was performed to identify proteins secreted during infection by the rice blast pathogen *Magnaporthe grisea*. Apoplastic proteins were analyzed by two-dimensional electrophoresis and MALDI-TOF mass spectrometry. The biological functions of proteins induced by *M. grisea* infections were related to metabolism (47%), stress/defense (36%), and proteolysis (13%). Most secreted proteins were predicted to retain a signal peptide and were highly expressed in incompatible interactions. A domain of unknown function 26 (*OsDUF26*) apoplastic protein was most abundantly secreted in response to rice blast infection. Transgenic rice and *Arabidopsis* plants expressing *OsDUF26-promoter::GFP* were generated to assess the role of *OsDUF26* in response to biotic stress. The *OsDUF26* promoter was activated in response to *Xanthomonas oryzae* pv. *oryzae*, *M. grisea*, and fungal elicitor. The results indicated that plant apoplastic proteins might have key roles in plant responses to biotic stress (Wu et al. 2014).

Fungal pathogens produce endopolygalacturonases (endo-PG) which have an important role during early stages of pathogenesis, spreading into the host tissues in advance of the invading mycelium. Polygalacturonase-inhibiting proteins (PGIPs) are basic proteins present in the cell wall of most dicotyledonous plants. PGIP is structurally similar to several resistance gene products, as it belongs to the superfamily of leucine-rich repeat (LRR) proteins (Matthei et al. 2001). The apple PGIP inhibited PGs secreted by *Verticillium dahliae* grown on cell walls and pectin. The usefulness of apple PGIP to confer resistance against wilt disease caused by *Verticillium dahliae* affecting potato was therefore assessed. Transgenic potato cultivar BP1 plants containing apple *pgip1* gene under the control of the constitutively enhanced CaMV 35S promoter were generated. The PCR and Southern blot analyses confirmed the stable integration of the apple *pgip1* transgene into the potato genome. The extracts prepared from all transgene lines except one effectively inhibited PGs of *V. dahliae*. Active PGIP1 was expressed both in the leaves and roots of transgenic potato plants. Apoplastic localization of PGIP 1 activity in the *pgip1* transgenic potato plants was observed. Six transgenic potato lines showed reduced intensity of disease symptoms compared with controls and other lines grown in sick soil. However, the reduction in disease intensity could not be attributed to inhibition of *V. dahliae* PGs, although a high level of expression of PGIP1 occurred in transgenic potato plants (Gazendam et al. 2004).

Puroindolines (PINs) form the principal components of wheat grain hardness locus (Ha) and have in vitro antimicrobial activity against bacteria and fungi. The effect of variation in PINA and/or PINB content on the inhibition of *Penicillium* spp., causing wheat seed rot, was assessed. Seed-germination assays were performed after incubating seeds in soil contaminated with *Penicillium* sp. As the first step, wheat genotypes consisting of two sets of transgenic isolines created in the varieties Bobwhite and Hi-Line having overexpression of PINA and/or PINB were tested. Another set of genotypes consisting of near-isogenic lines (NILs) varying for mutations in PINA or PINB created

in varieties Explorer and Hank was also tested. Transgenic wheat seeds overexpressing PINA in both Hi-Line and Bobwhite and both PINs in Hi-Line, when incubated in *Penicillium* sp.-contaminated soil, exhibited significantly reduced fungal infection and increased seed germination. No significant differences in pathogen infection or germination rates could be seen in seed of NILs. The results indicated that puroindolines might increase seed viability and that, when overexpressed as transgenes, the puroindolines might function as effective antifungal proteins, resulting in reduction of disease incidence (Kim et al. 2012).

Fusarium graminearum, incitant of Fusarium head blight (FHB) disease of wheat, produces the mycotoxin deoxynivalenol (DON) which is a potent inhibitor of eukaryotic protein synthesis and is believed to have a role in the pathogenesis of diseases affecting cereal crops. The 60S ribosomal protein L3 (RPL3) was suggested as the putative site of actions of the toxin. The rice cDNA encoding the ribosomal protein RPL3 was modified so that the amino acid 258 was changed from tryptophan to cysteine, a change considered to confer resistance to similar mycotoxins in yeast. Both types of the rice *Rpl3* genes were introduced into two species of tobacco by *Agrobacterium tumefaciens* (At) cocultivation and expressed under the control of a constitutive promoter. When cells, tissues, and protoplasts of these transgenic tobacco plants were compared for growth in the presence of DON, a significant difference in growth rate and the ability to undergo differentiation was observed among those plants expressing the modified version of the *Rpl3* gene (Rpl3:c258) compared to those expressing the wild-type *Rpl3* gene. The results indicated a possible mechanism of enhancing host plant resistance to *F. graminearum* among the susceptible cereal crop plants based on the expression of modified *Rpl3* genes (Harris and Gleddie 2001).

The rice cultivar Pusa Basmati 1 was transformed with the gene for Acc-AMP 1 from onion coding for an effective antimicrobial protein CAMP homologous to plant non-specific lipid transfer proteins (Ns-LTPs). The Acc-AMP1 protein was cloned under an inducible rice phenylalanine-ammonia lyase (PAL) or Ub1 (a constitutive maize ubiquitin) promoter. Accumulation of Acc-AMP1 predominantly in the extracellular space in transgenic rice plants was demonstrated by immunolocalization using antibodies against Acc-AMP1. This protein caused morphological deformation of the growing pathogen hyphae of the blast pathogen *Magnaporthe grisea* by membrane permeabilization. The transgenic rice lines exhibited enhanced levels of resistance, as reflected in a reduction of 86% in disease severity induced by *M. grisea*. In addition, the transgenic rice lines expressing Ace-AMP1 also showed resistance to other economically important diseases; the disease severities of sheath rot disease caused by *Rhizoctonia solani* and the bacterial leaf blight disease caused by *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) were reduced by 67% and 82%, respectively. The transgenic rice lines also possessed the desirable attribute of retaining all agronomic parameters of nontransformed parent Pusa Basmati without any recognizable adverse effect on the rice plant phenotype (Patkar and Chattoo 2006).

Rice blast disease management using cultivars with *R* gene-mediated resistance has been shown to be an environmentally sustainable approach. A unique *R* gene of rice was identified on the chromosome 11 of *Oryza sativa* ssp. *indica* cultivar Tetep. Using complementation assay, the functional validation of the *Pi-K^h* (*Pi54*) gene was obtained. The blast resistance candidate gene *PiK^h* (*Pi54*) was cloned into a plant transformation vector and the construct was used to transform a japonica cultivar of Taipei 309 susceptible to rice blast pathogen, *Magnaporthe grisea*. Transgenic lines containing *Pi54* gene

showed a high degree of resistance to diverse isolates of *M. oryzae*. The deposition of callose in transgenic and nontransgenic rice lines was compared. In transgenic rice lines showing incompatible interaction, callose deposition was found to be widespread at infection sites. Successful complementation of *Pi54* gene revealed the role of this gene in the development of resistance to rice blast pathogen. The gene *Pi54* was pathogen-inducible, but expressed constitutively. Callose deposition in the resistant plants containing *Pi54* gene indicated the involvement of callose in the initiation of integrated defense responses to infection by *M. grisea* (Rai et al. 2011).

Plants produce several compounds such as phytoalexins involved in the enhancement of resistance to diseases. Stilbenes, a class of phytoalexins known to be present in grapevines and peanut (groundnut), are produced by the enzyme stilbene synthase. The gene for stilbene synthase was transferred from grapevine into the protoplasts of the japonica cultivar Nipponbare, using the polyethylene glycol (PEG-) mediated direct gene transfer technique. The stilbene synthase gene was stably integrated into the genome of the transgenic rice plants and was also inherited in the offspring. The transgenic rice plants exhibited a greater level of resistance to the rice blast disease (Stark-Lorenzen et al. 1997). The *Rop* proteins of plants, small GTPases (guanosine triphosphates), are important molecular switches in plant signal transduction and the *Rop* gene is also referred to as *Rac* gene. Overexpression of the constitutively active form of *OsRac1* in rice led to a hypersensitive reaction (HR) at points of infection by *Magnaporthe grisea* race 007 and consequently to disease resistance via reactive oxygen species (ROS) production. In contrast, overexpression of dominant negative forms of *OsRac1* consistently resulted in increased susceptibility to *M. grisea* (Kawasaki et al. 1999; Ono et al. 2001). The gene *OsRacB* cDNA was isolated to determine its function through gene expression and transgenic approach. In the rice genome, *OsRacB* present as a single gene shared 98% identity with *HvRacB* at the amino acid level. Strong expression of mRNA of *OsRacB* was recorded in the rice leaf sheath and panicles, while its expression in young and mature leaves was weak. Upon inoculation with *M. grisea*, the transgenic rice plants showed a dramatic regulation in the *OsRacB* transcripts. Overexpression of *OsRacB* resulted in enhancement of symptom severity. In addition, fluorescence microscopy of green fluorescent protein (GFP):*OsRacB*-transformed onion cells and *Arabidopsis* protoplasts revealed the association of *OsRacB* with plasma membrane. The results suggested that functioning of *OsRacB* may require its localization in plasma membrane and its function as a potential regulator for a basal disease resistance pathway in rice (Jung et al. 2006).

The usefulness of fungal viruses to improve the resistance of crops to diseases caused by fungal pathogens causing wheat smut diseases was demonstrated. The presence of “killer proteins” (KPs) in *Ustilago maydis* viruses was detected and the possibility of employing KPs to enhance resistance of wheat to smut fungi was indicated. Three non-homologous genes from three different viruses encoding *KP1*, *KP4*, and *KP6* with antifungal properties were identified. *KP4* was used to transform two Swiss spring wheat varieties Golin and Greina susceptible to stinking smut disease caused by *Tilletia caries*. Specific antifungal activity of the *KP4* gene product in the transformed lines was demonstrated in vitro and in planta in the glasshouse (Clausen et al. 2000). In a later study, the transgenic lines expressing *KP4* protein did not segregate for the transgenes and they were considered to be homozygous for *KP4* gene. The antifungal specificity of the KP system was observed in both transgenic plants. *KP4* in transgenic wheat plants inhibited the growth of *T. caries* and *Ustilago tritici*, incitant of loose smut disease.

The transgene functioned as a quantitative resistance gene and was highly specific for fungal pathogens belonging to Ustilaginales. The antifungal effect of *KP4* was indicated by an enhanced level of resistance of transgenic lines under field conditions (Schlaich et al. 2006).

The improvement of resistance to rice sheath blight disease caused by *Rhizoctonia solani* of transgenic rice lines was attempted by overexpressing the rice *oxalate oxidase 4* (*Osoxo4*) gene in a green tissues-specific manner which breaks down oxalic acid (OA), the pathogenesis factor secreted by *R. solani*. Transgenic plants showed higher enzyme activity of oxalate oxidase (OxO) than nontransgenic control plants which could be visualized by histochemical assays and SDS-PAGE technique. Transgenic rice leaves were more tolerant than control rice leaves to exogenous OA. Transgenic plants showed a higher level of expression of other defense-related genes in response to pathogen infection. A higher level of durable resistance to *R. solani* in transgenic rice leaves was their most desirable attribute. Overexpression of *Osoxo4* in rice did not affect any phenotypic or agronomic parameters. The results indicated that rice OxO could be utilized effectively in plant genetic manipulation for sheath blight resistance and possibly to other diseases caused by necrotrophic pathogens secreting OA (Molla et al. 2013).

In another investigation, the rice basic chitinase gene (RCH10) and the alfalfa β -1,3-glucanase gene (AGLU1) were tandemly inserted into transformation vector pB1101 under the control of 35S promoter with its enhancer sequences to generate a double-defense gene expression cassette pZ100. The pZ100 cassette was used to transform rice cultivar Taipei 309 by *Agrobacterium tumefaciens* (At-) mediated transformation. More than 160 independent transformants were obtained and confirmed by PCR. Northern analysis of inheritable progenies revealed similar levels of both RCH10 and AGLU1 transcripts in the same individuals. Disease resistance to both sheath blight and blast was challenged in open field inoculation. Immunogold detection revealed that RCH10 and AGLU1 proteins were initially located mainly in the chloroplasts and they were delivered to the vacuole and cell wall upon infection, suggesting that these subcellular compartments act as the gathering and execution site for these antifungal proteins. In addition, transgenic seeds showed reduction in seed germination and seedling vigor, indicating that enhancement of resistance might occur at the expense of plant development (Mao et al. 2014).

12.3.2.3 Transgenic Resistance to Bacterial Diseases

Alternate strategies involving biotechnological methods have been found to be useful for developing crop cultivars resistant to bacterial diseases for which traditional breeding procedures were either ineffective or difficult. The *Xa21* locus conferring resistance to all known races of *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) occurring in the Philippines and India was transferred from *Oryza longistaminata*, the wild relative of rice to the rice cultivar IR24. The *Xa21* gene coding for a receptor kinase-like protein was inherited as a single gene in transgenic progenies (Song et al. 1995; Wang et al. 1995). Transgenic plants expressing *Xa21* were resistant to 29 of 32 isolates of *Xoo* from SE Asian countries, including India and Nepal, and Colombia. In a further study to improve the level of resistance to different strains of *Xoo*, an elite *indica* rice cultivar IR72 was transformed with a cloned *Xa21* gene. The transformed rice lines showed higher levels of resistance to rice bacterial leaf blight (BLB) disease due to pyramiding of *Xa21* with *Xa4* which had already been transgressed into the rice cultivar IR72 (Tu et al. 1998). In a later investigation, rice genotype IRBB13 was transformed with a

DNA fragment encompassing the *Xa13* candidate, including the promoter region isolated from another rice cultivar IR 64 and 29 independent transformants were produced. In order to characterize the function of *Xa13*, the expression of *Xa13* or *xa13* was suppressed in rice lines using an RNA interference (RNAi) strategy. The level of resistance to BLB in the cultivar Zhonghua 11 to PX099 strain was significantly increased in 9 of the 12 transgenic lines containing *Xa13*, as indicated by the reduced accumulation of *Xa13* transcripts. With significant reduction in the expression of *Xa13* or *xa13*, the transgenic plants had reduced fertility which was associated with male sterility. The *Xa13* recessive allele conferring BLB resistance plays a key role in both disease resistance and pollen development (Chu et al. 2006).

Attacins constitute a class of antimicrobial peptides detected in the insect haemolymph in response to bacterial infection (Engstrom et al. 1984). Attacins act on the outer membrane of Gram-negative bacteria by altering permeability and protein synthase activity (Carlsson et al. 1998). Attacin genes have been identified in the haemolymph of the giant silk moth *Hyalophora cecropia* (*attacin E*), *Drosophila melanogaster* (*attacin A*), and *Trichoplusia ni* (*attacin A*). Transgenic *Citrus sinensis* cultivar Hamlain plants expressing attacin A gene (*attA*) were generated via *Agrobacterium tumefaciens* (*At*-) mediated transformation for improving the resistance to citrus canker disease caused by *Xanthomonas axonopodis* pv. *citri* (*Xac*). The cDNA clone was used to construct a binary plasmid vector (pCattA2300) and the construct included the native signal peptide (SP) responsible for directing the introduced protein to the extracellular space, where the bacterial pathogen is likely to accumulate in vivo. The presence of the transgene in citrus was confirmed by PCR and Southern blot hybridization analyses in regenerated plants. The transcription of *attA* gene could be established by Northern blot analysis in all transgenic plants. When inoculated with *Xac* (10^6 CFU mL⁻¹), 7 out of 8 transgenic lines exhibited significant reduction in the susceptibility to citrus canker disease. However, no correlation could be seen between disease resistance and level of transcription of *attA* (Boscariol et al. 2006).

The rice *Xa21* gene has been used to transform rice plants to enhance resistance to bacterial leaf blight (BLB) disease. Sequences of citrus genome (52) were shown to have high similarities to the rice *Xa21* gene, with amino acid sequence identity ranging over 54.9–59.7% (Deng and Gmitter 2003). Transgenic lines of four sweet orange cultivars (Hamlin, Natal, Pera, and Valencia) expressing the rice *Xa21* gene were evaluated for their resistance to canker disease. The *Agrobacterium tumefaciens* (*At*-) mediated transformation was performed and the transgene integration was confirmed by Southern blot analysis. The transgenic lines were propagated and challenged with citrus canker pathogen *Xanthomonas axonopodis* pv. *citri* and a nontransformed plant of each cultivar was used as control. All seven transgenic lines of cultivar Hamlin showed significant reduction in susceptibility to canker pathogen. The transformed plants had undergone 1–3 independent transgene integration events. The genetic transformation efficiency was 18.6% for Valencia sweet orange. Transgene transcription was confirmed by Northern blot analysis in most transgenic lines analyzed. Transgenic lines with a higher level of resistance to citrus canker were identified for cultivars Hamlin, Natal, and Pera. The lowest diseased leaf area values were detected for transgenic lines of Natal or Pera which were considered moderately resistant to citrus canker in the fields, indicating the influence of cultivar genetic background on the effectiveness of the *Xa21* gene restricting the incidence and spread of rice BLB disease (Fig. 12.5). The results indicated that the resistance conferred by the transgene was added to the original

Figure 12.5 Northern blot analysis revealing transcription of *xa21* gene of rice in *Citrus sinensis* cultivars (a) Hamlin; (b) Pera; (c) Natal; and (d) Valencia leaves. Lanes 1–8: transgenic lines expressing *xa21* mRNA; lane C: nontransgenic plant (control). Source: Mendes et al. (2010) and with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

resistance level of the cultivar. Integration and expression of the rice *Xa21* gene in citrus could be achieved and the possibility of employing *R* genes for the management of citrus canker disease in a heterologous genetic background was indicated in this investigation (Mendes et al. 2010).

The possibility of producing grapevine cultivars resistant to crown gall disease caused by *Agrobacterium vitis* was explored. Grapevine cultivar Chardonnay was transformed with a construct containing two antimicrobial peptides (AMPs): Magainin-2 and PGL. Five lines expressing Magainin-2 showed enhanced level of resistance to two strains of *A. vitis*: TM4 and CG450. The effects of nine AMPs on the in vitro growth of four grapevine pathogens, *A. tumefaciens* and *A. vitis* (bacterial pathogens) and *Botrytis cinerea* and *Erysiphe necator* (fungal pathogens), were investigated. Cecropin B, MSI-99, and Shiva 1 were most effective against the bacterial pathogens, while ESF-12 had no effect. The growth of *A. vitis* strain TM4 was arrested by the AMPs to a greater extent than that of strain CG450, a pattern parallel to the levels of resistance to crown gall disease among transformants expressing Magainin-2. *B. cinerea* required more than M a-Purothionin, PGL, or ESF 39 for effective growth inhibition. None of the AMPs showed a consistent inhibitory effect on the conidial germination or lesion formation of *E. necator*. MSI-99 and Cecropin B were found to be more potent to provide increased resistance to crown gall disease in grapevine (Rosenfield et al. 2010).

Crop Disease Management**Biological Management Strategies**

Crop plants at different stages of development from seed germination to harvest of the crop produce are exposed to a large number of microorganisms that may be pathogenic or beneficial to plant growth. Some of the microorganisms present along with the microbial plant pathogens in the same environment have been found to be our allies in the fight against pathogens. These microorganisms have the potential to restrict pathogen development to different degrees. The biological management strategies applicable to crop disease management seek to be a component of a synergistic orchestrated symphony, the benefit of which has to reach both the producer and consumer. The biological management may be defined as “the utilization of biotic and abiotic agents that act through one or more mechanisms to reduce the potential of the microbial pathogens directly or indirectly by acting on the host defense systems to reduce disease incidence and/intensity.” Several investigations have demonstrated that the combination of biotic and abiotic agents may result in synergism and consequent improvement in the effectiveness of disease suppression and enhancement of crop yield (Narayanasamy 2013).

Biological control agents effective against diseases caused by microbial pathogens – oomycetes, fungi, bacteria, phytoplasmas, viruses, and viroids – may be divided into two major groups as (i) biotic agents and (ii) abiotic agents. Biotic biological control agents are nonpathogenic living organisms that are antagonistic to potential microbial pathogens causing economically important crop diseases in various agroecosystems. They may suppress the pathogen development through one or more mechanisms. Abiotic agents are derived from inorganic or organic sources. The abiotic agents may also act on the microbial pathogens directly by inhibiting their growth and/reproduction or indirectly act on the host plants by activating their defense systems. The abiotic agents may be classified based on their chemical constitution or on the mode of action on the target microbial pathogen(s). Some of the abiotic agents have been synthesized for application against the plant pathogens and are available as commercial products. The microbial pathogens causing seed- and propagule-borne diseases are known to exist in the form of several races and strains, differing in their pathogenic potential (virulence). Likewise, biotic biological control agents (BCAs) also vary in their efficacy against the target pathogens. Strains or subspecies of the same morphologic species of the biological control agents differ in their biocontrol potential due to their differing sensitivity to environmental conditions, adaptation to new locations, rhizosphere competence, and the nature and quantity of antibiotics, enzymes, or toxic metabolites

produced by them. The precise identity of the effective BCAs therefore has to be established accurately by applying efficient techniques based on their biological, biochemical, and genomic characteristics. The biocontrol efficacy of the strains existing in a location has to be assessed by employing appropriate screening methods performed under in vitro, greenhouse, and field conditions to select the most efficient species/strains for large-scale application.

13.1 Evaluation of Biotic Agents for Biological Control Potential

13.1.1 Fungal Biological Control Agents

Dual culture procedure was applied to evaluate the biocontrol potential of eight isolates of *Trichoderma harzianum* and two isolates each of *T. atroviride* and *T. koningii* to suppress the development of *Pyrenophora tritici-repentis*, causing tan spot disease of wheat. The efficiency of inhibition of mycelial growth by *Trichoderma* spp. varied over 50–74%. The growth inhibition by the fungal biocontrol agents (BCAs) might be due to plasmolysis of conidia and hyphal cells of *P. tritici-repentis*, as observed under the microscope (Perelló et al. 2003). Two yeast strains *Cryptococcus* sp. OH71.4 and *C. nodaensis* OH 182.9 and two bacterial strains *Bacillus subtilis* AS43.3 and *B. subtilis* AS43.4 were evaluated for their efficacy in suppressing the development of Fusarium head blight (FHB) disease of wheat caused by *Fusarium graminearum* (teleomorph *Gibberella zeae*), using two cultivars of durum wheat under greenhouse and field conditions. All antagonists reduced FHB severity on cultivar Renville and three of the four strains reduced disease severity on cultivar Ben. *B. subtilis* strain AS43.3 decreased FHB severity to the maximum extent (90%). All antagonists/production medium combinations (except one) were effective in reducing disease on both durum cultivars. Of the six antagonists tested at field sites, *Cryptococcus* sp. OH71.4 and *C. nodaensis* OH182.9 reduced disease severity by as much as 57% at one site (Peoria, IL), while *Cryptococcus* sp. OH18.1 reduced disease severity by 59% at another location (Langdon, ND). The bacterial antagonist strains *B. subtilis* AS43.3 and AS43.4 were generally more effective in reducing disease in the greenhouse environment than the yeast antagonists, regardless of the durum cultivars. Conversely, the yeast antagonists *Cryptococcus* sp. OH71.4 and *C. nodaensis* OH182.9 were more effective under field conditions. The relative performance indices for four antagonists in the greenhouse and field sites showed that the location, but not the cultivar, influenced the relative performance of the antagonists. The yeast biocontrol agents seemed to have greater potential for reducing the FHB disease on durum wheat in the field (Schisler et al. 2002).

The biocontrol potential of isolates of *Clonostachys rosea* was evaluated against seed-borne pathogens *Alternaria dauci* and *A. radicina* in carrot seeds. The suspension of the spores of *C. rosea* was used to coat the seeds of carrot. Biopriming with addition of *C. rosea* reduced the incidence of *A. radicina* and *A. dauci* to <2.3% and 4.8%, respectively, in seeds with initial infection levels of 29% and 11%, respectively. With low initial infection level (4.7%) in seeds, biopriming of seeds reduced the incidence to less than 0.5%. In addition, biopriming enhanced seedling stand, compared with hydroprimed or nonprimed seeds. The biopriming of carrot seeds with *C. rosea* IK726 transformed with a green fluorescent protein (GFP) reporter gene revealed the presence of the BCA covering the seeds with a fine web of sporulating mycelium of *C. rosea* when observed

under the microscope. Biopriming with *C. rosea* was able to provide protection to healthy and infected seeds without any risk of adverse effect on seedling establishment (Jensen et al. 2004). In a later investigation, the comparative efficacy of fungal and bacterial antagonists, physical methods (hot water, aerated steam, electron treatment), and natural agents (resistance inducers, plant products) was assessed for suppression of the development of *A. dauci* and *A. radicina*, infecting carrot. Based on the average of five field trials, *Clonostachys rosea* strain IK726 and *Pseudomonas* sp. strain MF 416 were the most effective against both fungal pathogens. Hot water treatment, when combined with *C. rosea* IK726 or *Pseudomonas* sp. strain MF416 treatment, was more effective in suppressing the pathogen development (Koch et al. 2010).

Rhizoctonia solani, a soilborne fungal pathogen, causes stem canker and black scurf disease in potato plants and tubers, accounting for significant quantitative and qualitative losses. Six fungal endophytes isolated from Norway maples were screened for their ability to suppress the development of *R. solani*. The endophytes were identified based on the morphological characteristics and sequences of internal transcribed spacer (ITS) regions of rDNA as *Alternaria longipes*, *Epicoccum nigrum*, *Phomopsis* sp., and *Trichoderma atroviride*. Both *T. atroviride* and *E. nigrum* inhibited the mycelial growth of *R. solani* to a greater extent than other endophytic fungi tested, with greatest inhibition zone observed for *E. nigrum* in dual cultures. However, the culture filtrates of *T. atroviride* induced greatest inhibition. Under greenhouse conditions, the disease index differed significantly among different treatments, ranging from 0.1 for *T. atroviride*, 1.13 for *E. nigrum* E18, 1.86 for *Phomopsis* sp., to 2.86 for *A. longipes* with 1.00 for control (uninoculated). The in situ interaction between the pathogen *R. solani* and the endophytic BCAs was visualized using the confocal microscope. *T. atroviride* was able to establish close contact with the hyphae of *R. solani* by coiling. The coils were very dense and appeared to encircle the pathogen hyphae tightly. After 7 days of contact with the pathogen, the BCA penetrated into the pathogen hyphal cells which lost their turgor. The results indicated that *T. atroviride* functioned as a mycoparasite and a competitor for nutrients. On the other hand, *E. nigrum* and *A. longipes* acted on the pathogen by producing secondary metabolites toxic to the pathogen, whereas *Phomopsis* sp. competed for nutrients and space. *T. atroviride* and *E. nigrum* improved the potato yield significantly and decreased the stem disease severity index in sensitive potato cultivar, as indicated by greenhouse assessment (Lahlali and Hijri 2010).

A fungal isolate identified as *Aspergillus niger* var. *niger* was able to transform the phytotoxin, thaxtomin A produced by the potato scab pathogen *Streptomyces scabies*, into much less toxic compounds. The rate and extent of transformation of thaxtomin A was assessed under a variety of conditions including different growth media, quantum of biomass, incubation periods, and shaker speeds. Under optimum conditions, the fungal isolate converted thaxtomin A into two major and five minor metabolites which were fully characterized by a combination of mass spectral and nuclear magnetic resonance techniques. When assayed on aseptically produced minitubers, the major metabolites proved to be much less phytotoxic than thaxtomin A (Lazarovits et al. 2004). The potential of ten strains of wild yeasts isolated from vineyards in Washington State, USA, was assessed for protecting potatoes against *Phytophthora infestans*, causal agent of potato late blight disease. Potato leaf assays and dual culture assay in plates were performed for determining the efficacies of *Metschnikowia pulcherrima*, *Curibasidium pallidicorallinum*, and *Candida saitoana* in restricting lesion development on potato leaves and suppression of pathogen growth in culture plates. *M. pulcherrima* was the most effective in suppressing the development of disease symptoms in a manner suggestive of

induced resistance when applied prior to inoculation with *P. infestans*. Other yeast species also suppressed development of disease symptoms (Hadwiger et al. 2015).

Isolates of *Trichoderma* (23) were screened to select the isolates for effective suppression of four genetically distinct isolates of *Phytophthora capsici*, infecting bell pepper (*Capsicum annuum*) under greenhouse conditions. Three isolates GL12, GL13, and Th23 suppressed the pathogen development in at least two assays. These isolates were compared with *Trichoderma virens* isolates GL3 and GL21 for suppression of the pathogen in the presence and absence of the harpin-based natural product, Messenger. Isolates GL3 and Th23 provided significant suppression of disease development in 3 of 4 assays, whereas GL12, GL13, and GL21 were effective only in 2 of 4 assays. Messenger application was not found to be beneficial in any of the assays performed. The *Trichoderma* isolates were differentiated using phylogenetic analyses (Roberts et al. 2010). The biocontrol potential of *Clonostachys rosea*, a saprophytic strain of *Fusarium oxysporum*, and strains of *Pseudomonas putida* against *Colletotrichum lindemuthianum* causing anthracnose in bean, and *Ascochyta* spp. causing Ascochyta blight of pea, was assessed. *Bacillus subtilis*-based formulations provided the most effective protection against anthracnose, while *P. putida* and saprophytic *F. oxysporum* were also effective against bean anthracnose pathogen. None of the treatments significantly suppressed the development of Ascochyta blight pathogen. A strain of *C. rosea* showed some antagonistic activity against *Ascochyta* sp. (Tinivella et al. 2009).

Banana Fusarium (Panama) wilt disease caused by *Fusarium oxysporum* f.sp. *cubense* (FOC) is an economically important disease, negatively impacting banana production in all countries. Isolates of *Fusarium oxysporum* including the biocontrol agent (BCA) Fo47, nonpathogenic isolates from banana rhizosphere, and two field strains of *Trichoderma* (T2 and T5) were evaluated for their biocontrol potential against FOC. The pathogen was multiplied on millet seeds and the inoculum was used to infest sterilized soil in which banana plants treated with test BCAs had been planted. Disease development was determined by cutting the rhizome open using a scalpel, and recorded based on the disease severity rating as per Inihab's Technical Guidelines. The nonpathogenic isolates and Fo47 effectively suppressed the development of banana Fusarium wilt disease (Nel et al. 2006). In a later investigation, the biocontrol potential of nonpathogenic *Fusarium oxysporum* endophytes isolated from healthy banana roots were evaluated for their efficacy in suppressing *F. oxysporum* f.sp. *cubense*. The nonpathogenic *F. oxysporum* isolates were identified and grouped into 14 haplotypes by employing PCR-RFLP analysis. Representative isolates were evaluated for the control of the banana wilt disease. Under greenhouse conditions, 10 nonpathogenic *F. oxysporum* isolates reduced the wilt disease significantly. The isolate that protected banana plantlets most effectively in the greenhouse tests and *Pseudomonas fluorescens* WCS417 were tested under field conditions. Neither the nonpathogenic *F. oxysporum* isolate, *P. fluorescens*, nor their combinations could reduce the wilt disease under field conditions. The lack of control of the disease to the desired levels was attributed to the soil microbial populations and chemical composition and reduced survival of biocontrol organisms in banana roots (Belgrove et al. 2011).

13.1.2 Bacterial Biological Control Agents

The isolates of bacterial biocontrol agents (BCAs) obtained from seeds/planting materials, soil, or other substrates are evaluated for their biocontrol potential against the target

pathogen(s) under laboratory, greenhouse, and field conditions. Bacterial strains (52) and six *Trichoderma* spp. isolated from the wheat rhizosphere were evaluated for their biocontrol potential against *Fusarium graminearum*, causal agent of Fusarium head blight (FHB) and seedling blight of wheat, under in vitro and greenhouse conditions. Isolates differed in their capacity to inhibit the mycelial growth of *F. graminearum* in agar plate bioassays by 0–79%, but this characteristic was not related to the biocontrol efficacy in vivo. All isolates were initially tested in the greenhouse on wheat cultivars Klein Centauro (moderately resistant) and ProINTA (susceptible) planted in sterilized soil artificially infested with *F. graminearum*. Among the 25 bacterial strains and 6 fungal isolates that exhibited suppressive effect, the most efficient 10 isolates were further assayed on 8 cultivars potted in cultivated-inoculated soil. Among the antagonists, only *Streptophomonas maltophilia* was able to improve the plant stand, height, and dry weight in eight cultivars, compared to other antagonists. *S. maltophilia* reduced disease incidence to nonsignificant level only. Three *Bacillus cereus* and one isolate of *Trichoderma harzianum* decreased the percentage of infection in some wheat cultivars (Dal Bello et al. 2002).

Fusarium graminearum caused several epidemics in Argentina and has been a devastating disease, causing extensive yield and quality losses, due to the contamination of grains with mycotoxins (mainly deoxynivalenol, DON). Potential biocontrol agents (BCAs) isolated from wheat anthers were evaluated in Argentina. A total of 354 bacterial strains were screened in two selection steps using index of dominance (ID) assay, considering environmental parameters such as temperature and water activity in the interaction between pathogen and antagonist. Among the antagonists, 22 strains reduced the production of DON on irradiated grains by 60–100%. The ability of these strains to reduce FHB and DON production was evaluated under greenhouse conditions. Nine strains (40.9%) significantly reduced the disease severity by 49–71% ($P=0.05$). The DON content in spikes produced by plants in the greenhouse trial was significantly reduced by 32–100% compared with control. Five strains belonging to *Brevibacillus* sp. BRC263 and *Streptomyces* sp. BCR87B decreased mycotoxin content in wheat grains to undetectable levels, indicating their effectiveness and potential for use against *F. graminearum* (Palazzini et al. 2007).

The efficacy of 18 bacterial isolates was evaluated for suppressing the development of *Fusarium graminearum* under in vitro and greenhouse conditions. One isolate each of *Bacillus subtilis* MAA03 and *Pseudomonas fluorescens* MAA10 were identified using International Identification Keys and Biolog System. These two isolates were selected based on their effectiveness against *F. graminearum*. The 16S rDNA sequences of these isolates had more than 99.5 identity to the strains already described. When used individually or in combination as a mixture, *B. subtilis* and *P. fluorescens* significantly increased final seed germination percent, the mean daily germination, and germination index of wheat cultivar, while the mean germination time was significantly reduced relative to the infested control. The final infection percent, the mean daily infection, and infection index were decreased, while the mean infection time was significantly increased compared to the infested control. *P. fluorescens* was more efficient than *B. subtilis* or in combination. The best application method of the bacterial BCAs was seed coating. Application of *B. subtilis* and *P. fluorescens* separately or in combination, as seed coating or seed soaking treatments, increased the root length, while soil drench treatment nonsignificantly reduced root length. Likewise, root and shoot fresh and dry weights were also increased by seed coating or seed soaking treatment with these two bacterial antagonists (Moussa et al. 2013).

Rhizoctonia solani infects several crops including potato and lettuce, causing appreciable yield losses. Three potato-associated ecto- and endophytically growing strains of *Pseudomonas fluorescens* B1 and B2 and *Serratia plymuthica* B4 were evaluated against *R. solani* in potato and lettuce. Disease suppressive ability of the bacterial biocontrol agents (BCAs) was assessed in growth chamber as well as in the field. All three BCAs entirely or significantly limited the dry mass (DM) losses on lettuce and disease severity (DS) caused by *R. solani* on potato sprouts in growth chamber assays. Strain B1 was the most efficient strain in suppressing pathogen development (52%) in potato. Under field conditions, the disease severity on both potato and lettuce which were bacterized decreased significantly and the biomass losses on lettuce decreased significantly. The strain B1 was more effective (37%) in suppressing the development of *R. solani* under field conditions than B2 strain (32%) and B4 strain (31%). The marketable potato tuber yield was increased up to 12% by B1 strain, compared to 6% by B2 strain and 17% by B4 strain under high disease pressure conditions. The strain B4 was the most effective in all experiments, indicating its suitability for development as a commercial product against *Rhizoctonia* diseases (Grosch et al. 2005).

Strains of fluorescent pseudomonads (303) isolated from roots and rhizospheric soil of tomato plants were tested in vitro against *Clavibacter michiganensis* subsp. *michiganensis* (Cmm), causative agent of bacterial canker disease of tomato. Strains showing high antagonistic capacity were evaluated for their ability to colonize tomato roots. The most effective fluorescent pseudomonads were present in the rhizoplane soil and endorhizosphere. Among the 42 spontaneous antibiotic-resistant mutants obtained by treatment of the wild-type isolates with antibiotics (rifampicine, nalidixic acid, ampicillin, and chloramphenicol), 28 isolates could colonize the roots of all tomato seedlings efficiently. All wild-type isolates (42) were used for in vitro screening using cotyledon test. Eight of 42 isolates reduced the disease incidence and severity significantly ($P < 0.001$) when applied as seed and root treatments (Amkraz et al. 2010). Citrus canker disease caused by *Xanthomonas citri* pv. *citri* (Xcc) was suppressed by *Pseudomonas* sp. strain LV. The antibiotic activity of the BCA was demonstrated using scanning electron microscope (SEM) and transmission electron microscope (TEM). The antibiotic activity of dichloromethane phase (DP) was greater than all other fractions from vacuum liquid chromatography (VLC), as reflected by inhibition of the pathogen development. The toxic metabolites produced by the BCA prevented formation of biofilms by *Xcc* and destroyed exopolysaccharides (EPS) present around *Xcc* cells. The cells of *Xcc* were found to be shrunken. Finally the cell wall and cytoplasmic membrane of *Xcc* became indistinct, followed by apparent lysis of pathogen cells. Lack of EPS production and formation of biofilm resulted in reduction in lesion formation in plants treated with metabolic fractions of *Pseudomonas* sp. LV (de Oliveira et al. 2011).

Detached-leaf assay was performed to determine the antagonistic activity of isolates of *Bacillus subtilis* against *Phytophthora* blight of red pepper (*Capsicum annuum*) caused by *Phytophthora capsici*. The suspensions of bacterial isolates (10^8 cell mL⁻¹) were sprayed individually on the detached leaves and they were placed in the petriplates lined with moistened filter paper. Spore suspension (10^6 spores mL⁻¹) of the pathogen was sprayed on the leaves already treated with different bacterial isolates. The leaves were incubated in a growth chamber at 20°C with 12h of light and dark periods for 10 days. Disease severity in different treatments was determined using 0–4 disease rating scale as follows: 0 = no visible symptom; symptom severity: 1 = 1–12%; 2 = 13–25%; 3 = 26–50%; and 4 = 51–100% of leaf area covered by the disease. All the antagonistic

isolates showed varying levels of antagonism against *P. capsici*. Two isolates R33 and R13 were more effective in suppressing the disease severity by 86.8% and 71%, respectively, under in vivo. Based on the 16S rDNA sequencing, these two isolates were identified as *Bacillus subtilis*. In addition, the root and shoot length of plants were increased by the isolates of *B. subtilis* (Lee et al. 2008).

Strains of *Paenibacillus polymyxa* (25) were screened for their antimicrobial activity against *Phytophthora capsici*. Based on the inhibitory activity 15 strains were categorized as strongly antimicrobial, among which the strain GBR-462 was the most active, and 5 strains each as weakly or no antimicrobial activity. The antimicrobial activity was influenced by the initial inoculum density. The strains of *P. polymyxa* with a strong antimicrobial activity (including the strain GBR-462) showed antimicrobial activity against *P. capsici* and could only form biofilm when they were applied at the higher initial population levels of 10^8 CFU mL⁻¹ of *P. polymyxa* GBR-462. However, formation of sporangia and release of zoospores were significantly reduced at the lower population levels. Further, the sporangia showed aberrant structures with no or few healthy nuclei, indicating that sporangium and zoospore formation was inhibited at the lower levels of BCA density, as revealed by the light microscopy examination. Application of *P. polymyxa* GBR-462 into potted soil suppressed the disease development and also the disease severity by 30%, compared with untreated control treatment (Kim et al. 2009).

Paenibacillus polymyxa E681 strain produces fusaricidin, a cyclic depsipeptide with antifungal property. *P. polymyxa* E681 effectively suppressed the development of Phytophthora blight disease of pepper caused by *Phytophthora capsici*. The effects of fusaricidin on the pathogen development and disease suppression were investigated. The minimal inhibitory concentration (MIC) of fusaricidin was 16 ppm against *P. capsici*. Application of fusaricidin at 0.1 ppm concentration reduced disease severity significantly (40%) compared with water-treated control (81.7%) on postinoculation, whereas the disease severities on pretreatment were 45% and 83.3% in fusaricidin treatment and control, respectively. Fusaricidin was effective in suppressing the disease severity when applied as soil treatment or foliar spray at 1.0 ppm concentration. The results indicated that fusaricidin might protect plants functioning as an antibiotic directly or *P. polymyxa* might secrete elicitors of disease resistance against plant pathogens (Lee et al. 2013).

The effectiveness of *Paenibacillus ehimensis* KWN38 in suppressing the development of Phytophthora blight disease of pepper caused by *Phytophthora capsici* was assessed. The BCA grown in a grass medium showed high antifungal and lytic enzyme activities. Under greenhouse conditions, 1 month old pepper plants were treated with the strain KWN38 or fungicide. The shoot dry weight was increased and zoospore infection was reduced in plants treated with the bacterial BCA, compared to control treatment. The plants survived better due to treatment with BCA strain or fungicide. Soil cellulase activity was promptly increased shortly after zoospore infection and reached the maximum in BCA-treated plants. Likewise, the β -1,3-glucanase activity of BCA-treated plants increased to the maximum level after zoospore infection. The results indicated that inoculation of the strain KWN 38 in the root zone of pepper plants in the pots resulted in enhancement of plant growth and alleviation of the root death caused by infection by *P. capsici* zoospores (Naing et al. 2014).

Isolates of fungi, actinomycetes, and bacteria (342), isolated from soil and plants from a potato field in which wild oat (*Avena strigosa*) had been precultivated, were screened to select the microorganism(s) effective against *Streptomyces turgidiscabies*, causative agent of potato common scab disease. Based on the initial pot trials, 26 isolates were

selected as antagonistic candidates with disease suppressive potential. After a second pot trial, five actinomycetes isolated either from the rhizosphere soil of wild oat or the soil adhering to potato stolons and tubers, were selected as antagonists because of their consistent suppressive activity. Based on the partial sequence analysis of the 16S rRNA genes from the five isolates, they were assigned to the genus *Streptomyces*. Of these five isolates, WoRs-501 was found to be the most effective in inhibiting the growth of *S. turgidiscabies* and was also the most effective in suppressing potato common scab disease development in the field trial. In the pot trial, a 10% (v/v) mix of WoRs-501 (6.2×10^8 CFU g⁻¹ dry mass) decreased the disease severity by 78–94% compared to the untreated control at the pathogen inoculum of 5×10^4 to 5×10^6 CFU g⁻¹ dry soil. The isolate WoRs-501 showed desirable level of biocontrol potential for the control of potato common scab pathogen *S. turgidiscabies* (Kobayashi et al. 2012).

Root-associated/endophytic (RAE) bacterial isolates (72) obtained from main peanut (groundnut) -producing provinces of China were evaluated for their biocontrol potential against *Aspergillus parasiticus* causing peanut aflaroot disease, which produces the mycotoxin aflatoxin in peanut kernels harmful to humans and animals. The 16S rRNA sequence and phylogenetic analyses placed the RAE bacterial isolates in the class Bacilli (49 isolates) and Gammaproteobacteria (23 isolates). The majority of bacteria belonging to Bacilli belonged to two genera *Bacillus* (48) and *Lysinibacillus* (1), while those isolates in Gammaproteobacteria belonged to the genera *Enterobacter* (7), *Serratia* (11), *Stenotrophomonas* (3), and *Pseudomonas* (2). *Lysinibacillus xylanilyticus* was found for the first time to be an effective antagonist against *A. parasiticus*. All the selected RAE bacteria exhibited antagonistic activities against the growth of *A. parasiticus* and/or aflatoxins (AFs) production in visual agar plate assay and tip culture method. Majority of RAE bacterial strains (96%) reduced the mycelial growth significantly or AFs production levels by >50%. Further, 22 strains (50%) could degrade colloidal chitin on the chitin medium plate. Ten selected chitinolytic RAE bacteria significantly reduced the mycelial growth of *A. parasiticus* and AFs production by >90%. The results indicated the presence and wide distribution of bacteria capable of suppressing the development of aflatoxin production by *A. parasiticus* (Wang et al. 2013).

Detached-leaf assay was performed to assess the biocontrol potential of bacterial strains to suppress the development of potato late blight pathogen *Phytophthora infestans*. The bacterial antagonist was applied at a concentration of 10^8 CFU mL⁻¹ into the Russet Burbank potato leaflets by dipping and incubating for 5 h at room temperature. The leaflets were challenged by applying the pathogen (20 μ L droplets of 10^4 zoospores mL⁻¹ suspension) into the lower surface of the leaflet. The inoculated and control leaflets were then placed on moist sterile filter paper kept in a covered sterile petridish and then transferred to a moist chamber to provide high humidity (95%) for the development of the pathogen. The bacterial-broth supernatant was prepared by inoculating the nutrient broth in flasks and keeping them on a shaker for 3 days continuously at room temperature. After centrifuging at 4500 rpm for 10 min, the supernatant was decanted and frozen. The effect of supernatant bacterial nutrient broth was assessed, as in the case of live bacterial cells. The inoculated leaves treated with live bacteria or water were scanned using the image analysis software Asses® to determine the area of leaflets infected by *P. infestans*. The percentage of inhibition of disease development was calculated using the formula:

$$\text{Percent inhibition} = 100 - \left[\left(\frac{\text{BP}}{\text{WP}} \right) \times 100 \right]$$

where BP is infected area in leaflets treated with bacteria/supernatant and WP is infected area in leaves treated with water (control). The disease intensity is expressed using a rating scale of 1–5 as follows: 1 = <10%; 2 = 10–20%; 3 = 21–40%; 4 = 41–75%; and 5 = >75%. Some isolates of *Pseudomonas fluorescens* DF37 and *Bacillus pumilus* W1 were effective inhibitors of *P. infestans* in vitro, but they did not provide any protection in detached potato leaves when applied as suspension, and had no effect in treated leaves when challenged with *P. infestans*. In contrast, their culture filtrates provided protection against *P. infestans*. *B. pumilus* W1 induced 47% systemic protection, even though it did not provide any local protection against *P. infestans* on either detached leaves or whole plants. The detached-leaf technique might be useful to study the mechanism of action of the biocontrol agents isolated from different substrates (Daayf et al. 2003).

Native bacterial strains were evaluated for their efficacy in suppressing the development of *Colletotrichum falcatum*, causing the devastating red rot disease in sugarcane under greenhouse and field conditions. The antagonistic bacterial strains of *Bacillus subtilis* NH-100, NH-160, *Bacillus* sp. NH-217, and NH-69 effectively suppressed the development of red rot disease under greenhouse conditions. The performance of these four strains was assessed under field conditions, using two sugarcane cultivars SPF-234 and CO 1148, for 3 consecutive years. Two different trials were carried out. The red rot pathogen was inoculated by different methods to determine the extent of suppression as well as induction of systemic resistance by the bacterial antagonists. Three strains reduced the disease incidence by 45–49% in sugarcane plants challenged by pathogen inoculation in the stem and by 48–56% in plants inoculated in soil near the roots. The results indicated the usefulness of the bacterial strains existing in the location concerned (Hassan et al. 2012).

Infection of wheat seeds by *Fusarium graminearum* and related species of *Fusarium* cause wheat Fusarium head blight and scab and maize ear rot and also the produce of mycotoxins such as deoxynivalenol and zearalenone, which induce ailments in humans and animals. The biocontrol potential of a patented endophytic bacterial strain *Bacillus mojavensis* RR101 was assessed in growth rooms. All strains of *B. mojavensis* were antagonistic to *F. graminearum*, *F. pseudograminearum*, and *F. verticillioides*. Seed germination percentage of the highly susceptible wheat cultivar 2552 was increased from 77 to 97% due to treatment of seeds with the BCA, followed by planting in *Fusarium* spp.-infested soil. The seedling emergence was also substantially increased from 20 to 82% following treatment of seeds with the BCA strains. Seed treatment with bacterial antagonists might provide effective protection against the mycotoxin producing fungal pathogens (Bacon and Hinton 2007).

Phytoplasmas are wall-less pathogenic bacteria belonging to the class Mollicutes and are capable of causing several diseases in economically important fruit trees, vegetables, ornamentals, and cereal crops. They are phloem-limited and transmitted by leafhoppers and psyllids (Weintraub and Beanland 2006; Bertaccini 2007). Biological management of phytoplasma diseases introduces the fourth component, the biological control agents. The effectiveness of using bacterial biocontrol agents for the suppression of chrysanthemum yellows phytoplasma (CYP) was assessed. The biocontrol potential of *Pseudomonas putida* SPIf1Rif strain was determined by measuring plant biomass, root architecture, symptom severity, phytoplasma titer, and viability in CYP-inoculated and control plants. The pathogen reduced plant growth and root development. The CYP titer in young apical leaves was not reduced by treatment with *P. putida*, which however

improved the growth of CYP-infected plants. The phytoplasmal viability was reduced over time, regardless of the presence of the BCA in treated and untreated control plants. The phytoplasma cells in fully developed leaves of CYP-infected plants often appeared to be degenerated following treatment with the BCA. The results indicated that the BCA might alleviate adverse effects of the disease, although it could not affect the viable phytoplasmas in young leaves of infected plants (Gamalero et al. 2010).

Antagonistic interactions among strains of “*Candidatus* Phytoplasma mali” infecting apple were investigated by graft-inoculating *Catharanthus roseus* and *Nicotiana occidentalis* (bioindicators) with mild strains 1/93Vin and 1/93Tab as suppressors and three aggressive strains as challengers. Inoculation of suppressors was carried out either in the cross-protection mode prior to grafting of the challengers or by inoculating suppressors and challengers. Multiplex real-time PCR assay was employed to monitor the presence/movement of the suppressors/challengers. In long-term cross-protection experiments with *C. roseus*, the presence of suppressor 1/93Vin was detected in all root and randomly collected stem samples over the entire observation period. In contrast, the challengers were never detected in such stem samples and rarely in the roots. Following simultaneous inoculation, the suppressor successively colonized all stem and root regions whereas detection of challenger AT steadily decreased. However, this strain remained detectable in up to 13 and 27% of stem and root samples, respectively. In the cross-protection experiments with *N. occidentalis* similar results were obtained. Comparison of the symptomatology of infected apple trees with the presence of putatively suppressive strains indicated that the suppression of severe strains also occurred in apple. Phylogenetic analysis using a variable fragment of AAA + ATPase gene AP460 of “*Ca. P. mali*” revealed that suppressors 1/93Vin and 1/93Tab, together with several other mild strains maintained in apple, cluster distantly from obviously nonsuppressive strains that were predominantly highly virulent (Schneider et al. 2014).

The efficacy of plant growth-promoting rhizobacteria (PGPR) has been examined for suppressing the development of virus diseases affecting various crops and providing different degrees of protection to treated plants. Single strains of PGPR were applied as seed treatments to cucumber and tomato for protection against *Cucumber mosaic virus* (CMV), which has a wide host range. There was a delay of 7 days in the onset of symptoms in some PGPR-treated plants compared with nonbacterized CMV-inoculated control plants. The PGPR-treated plants that did not develop symptoms at 7 days post-inoculation (dpi) remained symptomless for 4 weeks (end of experimentation) and did not contain a detectable concentration of CMV in noninoculated top leaves. In tomato plants grown from bacterized seeds, the area under disease progress curve (AUDPC) was reduced relative to the nonbacterized CMV-inoculated plants, indicating that the protection of tomato plants against CMV was due to induction of resistance by PGPR strain. Protection was observed when tomato plants were treated with PGPR strain followed by inoculation with CMV in the greenhouse and later transplanted in the field. The induced resistance was sustained under field conditions (Zehnder et al. 2000).

Due to the variability in efficacy of single PGPR strains, combinations of two strains of PGPR formulations with the carrier chitosan (biopreparations) were evaluated for their potential to promote plant growth and to enhance resistance to infection of tomato plants by CMV. Each PGPR combination included GB03 strain of *Bacillus subtilis* and one of the following PGPR strains of *B. pumilus* SE34: *B. amyloliquefaciens* IN937R; *B. subtilis* IN937b; *B. pumilus* INR7; or *B. pumilus* (T4). Tomato plants treated with each of the biopreparations appeared phenotypically and developmentally similar to

nonbacterized control plants that were 10 days older (older control). The biopreparation significantly enhanced the growth parameters of treated plants. CMV disease severity ratings were lower for biopreparation-treated tomato plants at 14 and 28 dpi. Accumulation of CMV in young noninoculated leaves was significantly less for all biopreparation-treated plants. The results indicated that the biopreparations promoted the growth of treated plants and also protected them from CMV infections in a manner that mimics natural (adult) plant resistance that is exhibited by most plant species as they become older (Murphy et al. 2003).

13.1.3 Viral Biological Control Agents

Virus infections in all organisms from prokaryotic bacteria to human beings are known. The possibility of using viruses as the biological control agents of fungal and bacterial plant pathogens has been explored in some pathosystems. Viruses and virus-like particles have been detected in plant pathogenic fungi and bacteria and have been evaluated for their biocontrol potential for application against phytopathogens.

Among *Fusarium* spp., causing various kinds of diseases of crops, the presence of ds-RNA mycoviruses (viruses infecting fungi) was detected in *Fusarium graminearum*, causal agent of Fusarium head blight (FHB) disease of cereals. Colonies of *F. graminearum* with unusual morphology, slow growth, amoeboid mycelia, and increased pigmentation were observed (Chu et al. 2002). Derivatives of strain DK21 free of the ds-RNA required only 3 days to cover the plates as against 9 days needed for virus-infected isolates of *F. graminearum*. Conidial production by the hypovirulent (with reduced virulence) was significantly reduced and elimination of ds-RNA through conidial passage resulted in faster mycelial growth and less pigmentation. Isolates of *F. graminearum* carrying ds-RNA produced much less mycotoxins (DON) compared to the ds-RNA-free isolates. Development of FHB disease in plants inoculated with isolates carrying ds-RNA was much slower. As there are several vegetative compatibility groups (VCGs) of *F. graminearum*, this condition may serve as a major obstacle for transmission of ds-RNA to virus-free isolates (Chu et al. 2002).

Cycloheximide, which inhibits RNA synthesis, may be able to cure the fungi carrying ds-RNA mycoviruses. *F. graminearum* hyphae containing ds-RNA were transferred to potato dextrose agar (PDA) medium amended with cycloheximide (5–70 ppm) and incubated for 10 days at 25°C. The hyphal tips were transferred to fresh PDA medium and incubated again for 10 days at 25°C. The hyphal tips from these colonies were found to be free of viral ds-RNA as revealed by electrophoresis technique, indicating the ability of cycloheximide to inhibit the ds-RNA virus synthesis in fungal pathogens (Aminian et al. 2011).

The presence of the ds-RNA mycovirus FgV-ch9 in *Fusarium graminearum* (Fg) isolate China-9 infecting wheat and maize was detected and hypovirulence characteristics were studied. Single conidia-originating cultures of Fg China-9 contained high, medium, or low amounts of viral ds-RNAs. At high and medium ds-RNA concentrations, the Fg China-9 isolates showed reduced mycelial growth rate and conidial production, abnormal colony morphology, and disorganized cytoplasm. Virulence of the infected Fg isolates showed significant reduction when inoculated onto wheat and maize plants. No recognizable symptoms could be seen when the pathogen isolates containing low titers of ds-RNAs were used for inoculation. However, the presence of the RNA segments of FgV-ch9 could be detected by RT-PCR technique. Transfection of the virulent

F. graminearum PH-1 isolate with purified virus-like particles (VLPs) of FgV-ch9 resulted in reduction in sporulation, perithecial production, and pathogenicity to wheat and maize by many folds. The results showed that FgV-ch9 induced hypovirulence in *F. graminearum* (Darissa et al. 2012).

Alternaria alternata infects many crops such as bean, soybean, and sunflower, causing substantial losses in yields as well as in quality. The presence of ds-RNA-1, ds-RNA-2, ds-RNA-3, and ds-RNA-4 was detected in the *A. alternata* strain EG35-193 which showed impaired growth phenotype. Cycloheximide inhibited ds-RNA synthesis, resulting in the elimination of mycovirus from hyphal tips taken from infected colony. The ds-RNA mycovirus might be involved in modulating traits of *A. alternata*. The ds-RNA encoded a single open reading frame (ORF) (3447-nt) containing conserved motifs of viral RNA-dependent RNA polymerase (RdRp) which was related to the ORF encoded by ds-RNA-1 of *Aspergillus* mycovirus 341. All of the encoding strands of the four ds-RNA genomes had 3'-poly (A) tails ranging from 33 to 50-nt in length. The virus infecting *A. alternata* was named *Alternaria alternata virus-1* (AaV-1) (Aoki et al. 2009). A simple and rapid method of detecting the mycovirus pathogenic to *Magnaporthe grisea* (*oryzae*), causal agent of rice blast disease, was developed. A sterilized toothpick was used to obtain the *Magnaporthe chrysovirus 1-A* colonies growing on the growth media in plates. The virus was detected and identified by employing direct one-step RT-PCR assay. This procedure could be employed for direct detection of the virus in the lesions in rice leaves induced by *M. grisea* (Urayama et al. 2015).

Bacterial viruses, designated bacteriophages, are capable of infecting some of the economically important bacterial pathogens. Bacteriophages (phages) have been evaluated for their efficacy in suppressing the development of plant bacterial diseases. An extract from decomposed cabbage tissues was demonstrated to have inhibitory principle (filterable virus) arresting the growth of *Xanthomonas campestris* pv. *campestris*, causing cabbage black rot disease (Mallmann and Hemstreet 1924). Several studies have indicated the possibility of employing bacteriophages as biocontrol agents against bacterial pathogens as an alternative disease management strategy, either to replace or reduce the use of chemicals. The relative ease of preparing phages and low cost of production of the phages are the desirable factors for considering bacteriophages as candidates for wider application. Phages are abundant in most natural ecosystems so a high genetic diversity of phages may be expected (Rowher 2003). Phages are likely to be present in large populations in environments where there is a high density of metabolically active bacteria. A metagenomic approach has been applied for assessing the diversity of phages that may be antagonistic to bacterial pathogens present in the soil and plant rhizosphere (Fierer et al. 2007; Kim et al. 2008).

As the phages are natural components of the biosphere, their use as biocontrol agents against bacterial pathogens is ecologically acceptable. Phages are nontoxic to plants and animals, so may be preferable for application in situations where chemical control is not permissible due to legal regulations. The specificity of phages may allow their application in combination with antagonistic bacteria that have been already employed as biocontrol agents. The development of bacterial strains resistant to phages may become a major limiting factor for successful management of bacterial diseases. The process to employ a mixture of host range mutant phages (h-mutants) for disease control was developed and patented. The h-mutants could lyse all bacterial strains that were resistant to the mild-type strains, while still being capable of lysing

the wild-type bacterial pathogen strain. The phage mutants had an extended host range compared to the parent phage alone. A mixture of four phages, including wild-type and h-mutant phages, were applied twice weekly in the early morning prior to sunrise. The combination of phages suppressed the development of tomato bacterial spot disease caused by *Xanthomonas campestris* pv. *vesicatoria* more effectively (Jackson 1989). Phages are specific to host bacterial species/strains, destroying only target bacterial species without affecting other organisms that may be beneficial to plant growth. Bacteriophages were rapidly degraded under field conditions and practically disappeared from tomato canopy at 2 days after application for the control of bacterial spot disease caused by *X. campestris* pv. *vesicatoria*. In order to improve the efficacy of the phage three formulations were tested: (i) 0.5% pregelatinized corn flour (PCF); (ii) 0.5% casecrete NH-400 + 0.5% sucrose + 25% PCF; and (iii) 0.75% powdered skim milk + 0.5% sucrose. These formulations significantly increased the phage longevity on tomato plant surface under greenhouse conditions. The nonformulated PCF, casecrete-, and skim milk-formulated phage mixtures reduced the disease severity on plants compared with the controls by 1, 30, 51, and 62%, respectively. These three formulations increased the concentrations of the phage populations by a factor of 4700, 38,500, and 100,000, respectively, at 2 days after application. The protective formulations increased the efficiency of phage treatments in suppressing the development of tomato bacterial spot disease (Balogh et al. 2003).

Bacteriophages specific to *Ralstonia solanacearum* which is pathogenic to many crops such as pepper, tomato, and potato were isolated from rhizospheres of plants infected with *R. solanacearum*. A host specificity analysis of 15 phage isolates using 9 strains of *R. solanacearum*, including race 1 (biovars 3 and 4) and race 3, indicated great phage diversity even in a single soil. A filamentous phage PE226 had a relatively wide range of host bacterial infection. The phage isolates PE226 and TM227, isolated from pepper and tomato, respectively, were pathogenic to all 9 strains of *R. solanacearum* tested by producing clear plaques (clear spots in a lawn of bacterial pathogen grown in petridish). These two strains might be closely related, as indicated by transmission electron microscope (TEM) observations and genomic characteristics. The isolate PE226, an *Inovirus*, had a long flexible filamentous shape, carrying a circular (+) sense single-stranded DNA genome of 5475 nucleotides. DNA sequences of PE226 exhibited 9 open reading frames (ORFs) that were not highly similar to those of other phages infecting *R. solanacearum*. The phage PE226 carried unique ORF encoding zot-like protein with toxic activity and was also highly virulent to *R. solanacearum* strain SL341. The phage PE226 might be a typical temperate phage carrying both lytic and lysogenic activities (Murugaiyan et al. 2010).

The effectiveness of bacteriophages to suppress the development of grapevine Pierce's disease pathogen *Xylella fastidiosa* (*Xf*) was assessed. A functional *Xylella* phage named Xfas53 was evaluated. The plate overlay method was employed to screen a 30 × 30 matrix, using each isolate as an indicator to test supernatant of isolates grown on PW-M broth. Plaque production due to dissolution of *Xf* cells was observed on plates seeded with pathogen cells. Individual plaques were excised from the overlay, suspended in phage buffer and titered. High titer lysates (10^{10} PFU mL⁻¹) were obtained by harvesting overlays of plates exhibiting confluent lysis. Observations under transmission electron microscope (TEM) revealed that the phage Xfas53 belonged to the family Podoviridae with a head diameter of 55 nm and a short noncontractile tail with a diameter of 12 nm. The isolates of *X. fastidiosa* from different locations were

sensitive to phage Xfas53. The results indicated the effectiveness of phage Xfas53 in suppressing the development of the pathogen *X. fastidiosa* and Pierce's disease in grapevine effectively (Gonzalez et al. 2008).

Bacteriophages specific to *Streptomyces scabiei*, causal agent of potato scab disease, isolated from soil samples were investigated by analyzing their genomes. The DNA fragment profiles obtained from restriction enzyme digestion were compared. Two genetically distinct phages infecting *S. scabiei* were designated Stsc1 and Stsc3. Phage morphology was recorded using electron microscopy. The phages Stsc1 and Stsc3 had a binal symmetry with an icosahedral head and a long striate tail. The phages Stsc1 and Stsc3 infected 81% and 75% of the pathogenic strains of *S. scabiei* strains tested. The phages suppressed the development of symptoms of infection by *S. scabiei* under in vitro conditions, indicating the potential of the phages which have to be tested under field conditions (Goyer 2005).

Two bacteriophages were able to lyse the cells of *Burkholderia plantarii* and *B. glumae* and to suppress the development of rice seed rot and seedling blight diseases caused by these bacterial pathogens. Phage BGPP-Ar more effectively suppressed disease development than the bactericides available in the market. The ratio of seedlings exhibiting infection to the total number of seedlings examined after treatment with BGPP-Ar (1×10^8 PFU mL⁻¹) were 0.0 for seed rot and 2.0 for seedling blight, compared to the ratios of 14.3 and 15.0 for chemical treatments (ipconazole and copper II hydroxide) for seed rot and seedling blight, respectively. BGPP-Ar treatment was highly effective in suppressing seedling rot of rice, even at a low concentration of 1.0×10^5 PFU mL⁻¹. The best BGPP-Ar phage treatment effect for sterilizing seed was achieved indoors to avoid phage inactivation by UV irradiation. Seed treatment with phage was effective in reducing seedborne infection by *B. glumae* and *B. plantarii* (Adachi et al. 2012).

Pantoea ananatis, incitant of bacterial palea browning disease of rice infects during flowering and degrades the quality of rice appreciably in Japan. Phages lytic to both pathogenic and nonpathogenic isolates of *P. ananatis* were isolated from the inflorescence of eulalia (*Miscanthus sinensis*), a graminaceous weed. One of the phage isolates was sprayed with and without a nonpathogenic isolate of *P. ananatis* on rice plants at the flowering stage. Coapplication of the phage and nonpathogenic *P. ananatis* suppressed the disease in sunlight. Application of the light-labile phage itself was able to suppress development of bacterial palea browning disease. The phage retarded the growth of the pathogen on rice plants and also on LB medium. The nonpathogenic *Pantoea* strains were present abundantly on rice panicles at flowering stage and could be hosts of the phage. The optimum infection period of rice with *P. ananatis* was found to be the flowering stage. The disease suppression was therefore considered to be due to the combined activities of the phage and naturally inhabiting nonpathogenic bacteria during the short period of susceptibility of the inflorescence to bacterial infection (Azegami 2013).

13.1.3.1 Mild Strains as Biological Control Agents

Mild strains of a virus have been demonstrated to protect plants against infection by severe strains of the same virus or related virus(es). This phenomenon of cross-protection has been effectively exploited as a practical disease management tactic in the case of diseases caused by *Citrus tristeza virus* (CTV) and *Tomato mosaic virus* (TMoV). The mild strains may be selected from naturally occurring strains or may be generated

artificially by exposure to chemicals, UV-irradiation, or unusual temperature (high or low) regimes. Systemic infection of a plant with a mild or attenuated strain inhibits or restricts secondary infection by a related or more virulent strain of the same virus. The absence of additional symptoms due to the challenging virus was considered to indicate that the protecting and challenging virus isolates are related, whereas the production of symptoms due to the challenging virus isolate is indicative of a lack of relationship with the protecting (challenged) strain of the virus (Narayanasamy 2002). Cross-protection as a management strategy was most successfully applied by inoculating citrus plants with a mild strain of *Citrus tristeza virus* (CTV). In Brazil, 3 of 45 mild strains of CTV were able to offer satisfactory levels of protection against severe strains of CTV in Pera sweet orange, two strains in Galigo lime, and one strain in Ruby grapefruit cultivars. No evidence of breakdown of cross-protection was observed in about 5,000,000 preimmunized citrus planted during a period of 10 years (Costa and Muller 1980). Cross-protection of citrus plants employing mild strains of CTV was adopted on a commercial basis in several countries such as Australia, Japan, and South Africa. However, the need to carefully adopt the cross-protection as a disease management strategy was highlighted by later investigations. Constant monitoring of the strain composition in a geographical location has to be carried out. Sensitive and precise molecular techniques have to be employed for detection and identification of CTV strains occurring in different locations, as the traditional biological indexing requires a long time to provide results. The limited sensitivity/specificity of detection procedures has hampered their usefulness to determine the pathogenic potential of unknown isolates of *Citrus tristeza virus* (Garnsey et al. 2005; Sideburth et al. 2005).

Preimmunization of Marsh grapefruit trees with the mild strain (PB61) of *Citrus tristeza virus* (CTV) protected the plants for 35 years against the severe strains, causing stem pitting (Broadbent et al. 1995). The efficacy of the mild strains PB61 to protect seedlings against superinfection with a severe grapefruit stem-pitting isolate PB219 or two orange stem-pitting (OSP) isolates PB155 or PB235 was assessed in the glasshouse. Symptom development was monitored by visual observations and the presence of each isolate was determined using isolate-specific restriction fragment length polymorphism (RFLP) analysis of amplicons generated by RT-PCR assays. Preimmunization with PB61 provided partial protection against superinfection using aphid-inoculation and delayed superinfection through graft inoculation. Preimmunization with PB61 did not ameliorate the expression of OSP symptoms once superinfection with OSP-inducing isolates was initiated. The results suggested that mild strain cross-protection (MSCP) did not prevent movement of the challenge virus since, once superinfection has occurred, the challenge virus could be detected both in the shoots and feeder roots, indicating systemic movement of the challenge virus (Zhou et al. 2002).

Bark chips from six container-grown citrus trees infected with nondecline-inducing *Citrus tristeza virus* (CTV) isolates and maintained in a vector-free greenhouse for 10 years were used as sources of virus inoculum. A total of 15 commercial grapefruit (*Citrus paradisi*) trees and 16 commercial sweet orange (*C. sinensis*) trees were used to inoculate 3 indicator plants each of sweet orange cultivar Madam Vinous, sour orange (*C. aurantium*), grapefruit cultivar Duncan, Mexican lime (*C. aurantifolia*), Swingle citrumelo, and sour orange grafted with sweet orange cultivar Hamlin. All source plants tested positive by ELISA tests for Florida decline-inducing isolates of CTV, using MAB MCA13. All inoculated trees (except Swingle citrumelo resistant to CTV) were positive for CTV by ELISA after 6 months in vector-free greenhouses. Some indicator plants

were inoculated with the inoculum of decline-inducing strain from 9 of the 37 bark chip source plants. Some of the ELISA-positive indicator trees exhibited vein clearing symptoms, characteristic of severe isolate of CTV. None of the control, noninoculated indicator trees in the same greenhouse was infected by mild or severe strain of CTV. The results indicated that decline-inducing isolates of CTV might be present as a minor component of a mixture at levels undetectable by ELISA and the decline-inducing strains could be detectable later by ELISA or by symptom expression in indicator plants (Powell et al. 2003).

The mild strain of CTV PB61 protected preimmunized seedlings more effectively against OSP isolate PB235 than PB155. The nucleotide sequence identity between PB61 and PB235 (97.6%) was much greater than between PB61 and PB155 (91.2%). Cross-protection seemed to be more effective if the nucleotide sequence identity is greater between the interacting CTV isolates. RNA-mediated defense was suggested to be involved in the cross-protection between CTV isolates (Zhou et al. 2002). The mild isolates of CTV had to be accurately differentiated from the isolates inducing severe symptoms of seedling yellows (SY) and or stem-pitting (SP) in grapefruit or sweet orange. A quantitative real-time PCR assay was developed to identify 56 biologically characterized CTV isolates from 20 countries. This procedure, employing a general primer set and three TaqMan-locked nucleic acid (LNA) probes, was found to be effective in estimating the ratio of different genotypes of CTV present in virus populations in samples from different geographic locations (Ruiz-Ruiz et al. 2009).

Grapevine crops are seriously affected by *Grapevine fan leaf virus* (GFLV) transmitted by the nematode vector *Xiphinema index*. Mild isolates of GFLV and the closely related *Arabidopsis mosaic virus* (ArMV) were identified by comparative performance analysis of grapevines infected with different strains and comparative symptom severity on assay host (*Chenopodium quinoa*) of GFLV. Healthy scions were grafted onto rootstocks that were healthy or infected with mild protective strains of GFLV-GHu or ArMV-Ta. Challenge inoculation using the nematode vector was monitored over 9 consecutive years in control and ArMV-Ta-cross-protected vines using DAS-ELISA format employing GFLV-specific antibodies. Immunocapture (IC-) RT-PCR-RFLP technique was applied to detect GFLV infection in GFLV-GHu-cross-protected grapevines. Cross-protected vines showed a significantly low challenge infection rate consistently. However, both mild strains reduced fruit yield by 9% (ArMV-Ta) and 17% (GFLV-GHu) over 8 years and had limited adverse effect on fruit quality. Use of mild strains for the protection of grapevines against GFLV therefore did not appear to be an acceptable alternative for the management of grapevine fan leaf virus disease (Komar et al. 2008).

Sweet potato feathery mottle virus strains cause russet crack and skin discoloration of storage roots of sweet potato (*Ipomoea batatas*), making the tubers unacceptable to consumers. Strains of SPFMV were distinguished based on symptoms, amino acid sequence identities, and serological properties. A mild isolate 10-0 of SPFMV rarely caused skin discoloration of storage roots, and russet crack symptoms were not observed as in the case of infection by severe strains of SPFMV-S. Sweet potato plants inoculated with the mild strains 10-0 did not contract latent infection by SPFMV-S as indicated by RT-PCR-RFLP analysis. The mild strain 10-0 did not reduce the yield of storage roots compared with that of healthy sweet potato plants. The coat protein (CP) gene of 10-0 encoded 315 amino acids and showed sequence identities of 91.1% at the nucleotide level and 95.6% at the amino acid sequence level with the corresponding region of SPFMV-S. Based on the nucleotide sequence of its 3' noncoding region and CP gene,

the strain 10-0 was genetically shown to have greater similarity to SPFMV-S. Sweet potato was rarely infected with 10-0 strain under natural conditions. Hence, *Ipomoea nil* plants were graft-inoculated with 10-0 to prepare cuttings infected by the strain 10-0. The mild strain 10-0 could be maintained in sweet potato in subsequent generations and the characteristics of infection by the mild strains were stable in infected plants. The results indicated that the mild strain had the potential for wide application for the protection of sweet potato plants against SPFMV-S strain (Yamasaki et al. 2009).

Plant virus strains with reduced virulence may be generated by exposing infected plants to high or low temperatures for predetermined duration or to treatments with chemicals such as nitrous acid or UV-irradiation. The variants with low virulence are evaluated for their ability to protect plants against severe strains of the same virus. The mutant MII-16 of *Tomato mosaic virus* (TMoV) was generated by artificially exposing the purified virus preparation to nitrous acid. The mutant MII-16 was mechanically inoculated onto tomato seedlings using a spray gun with adequate pressure (Fletcher and Rowe 1975). The mutant strain has been extensively used to protect tomatoes grown in glasshouses in England and Netherlands. An increase in yield of tomatoes up to 10% was obtained by protecting the tomato plants with the mutant strain MII-16 (Channon et al. 1978). An attenuated strain LIIA of TMoV was found to be effective in protecting tomatoes against severe strains (Motoyoshi and Nishiguchi 1988). Attenuated mutants of *Potato virus Y* (PVY) necrotic strain were generated by nitrous acid treatment and also by a novel method of mutagenesis-in-tissue culture. The procedure relied on the natural or experimental generation of virus sequence variants within an infected plant followed by isolation of the mutants by serially cloning them in plants. A total of 15 attenuated mutants was generated. Nucleotide and amino acid sequences of the genomes of the attenuated mutant populations were compared with the wild-type isolates and the amino acid changes in relevant genomic regions for viral attenuation were inferred. Many of the mutations were located in the protein 1 (P1) and helper component proteinase (HC-Pro) encoding regions. Amino acid changes mostly involved simultaneous changes in two or more protein encoding regions, one of which was often in the HC-Pro encoding region. The attenuated mutants M-MY10 and N-NA10 were effective in providing protection against the wild-type parent isolate NTND6 of *Potato virus Y* (Ogawa et al. 2013).

Attenuated strains of *Soybean mosaic virus* (SbMV) were generated by exposing infected soybean plants to low temperature. The soybean seedlings inoculated with SbMV were maintained at 15°C for 14 days or alternatively for 30 days. Two attenuated strains of SbMV, Aa15-M1, and Aa15-M2 generated in this way showed similar serological and biochemical properties as the parent strain Aa of SbMV. However, the attenuated strains induced different types of symptoms and varied in aphid- and seed-transmissibility and accumulation in soybean plants. When the soybean plants preinoculated with attenuated virus isolates were challenged with wild-type parent strain, they produced mild mottle symptoms on seeds with a normal colored seed coat (Kosaka and Fukunishi 1993). The effectiveness of attenuated *Soybean mosaic virus* (SbMV) Aa15-M2 in protecting black soybean seedlings under field conditions was assessed. After protective inoculation with SbMV Aa15-M2 strain, about 20,000 and 78,000 seedlings of black soybean cultivar Shin Tambaguro were planted in 1990 and 1991, respectively, in seed farms in Japan. The incidence of virulent strains of SbMV was effectively suppressed by the attenuated strain. Seeds virtually free of SbMV were produced in both years. Black soybean seedlings grown from these seeds were widely

transplanted in growers fields in 1991 and 1992. The incidence of virulent strains of SbMV in late July (preflowering stage about 40 days after transplanting) was 1.3% in 1991 and 0.8% in 1992, whereas the rates of SbMV incidence in earlier years was over 60%. The attenuated SbMV strain Aa15-M2 was found to be very effective in suppressing the infection of soybean plants by severe strains and also in reducing seed transmission of SbMV to subsequent generation (Kosaka and Fukunishi 1994).

A similar approach was adopted for protecting gladiolus plants against *Bean yellow mosaic virus* (BYMV) using a low-temperature treatment procedure to generate attenuated strain(s). A promising attenuated isolate M11 of BYMV was obtained after the low-temperature treatment of severe isolate originally obtained from gladiolus. An efficient method for inoculating mericlone gladiolus seedlings with M11 isolate was developed to prevent severe symptoms on gladiolus (Nakazono-Nagaoka et al. 2004). The effects of cross-protection by *Bean yellow mosaic virus* (BYMV)-M11 obtained after low-temperature treatment against six BYMV isolates derived from gladiolus, broad bean (*Vicia faba*), and white clover (*Trifolium repens*) were determined by employing Western blotting and RT-PCR assay. The levels of cross-protection differed based on the challenge virus isolates. The attenuated strain provided complete protection against BYMV isolates from gladiolus, whereas only incomplete protection was conferred against BYMV isolates from other hosts. Infection by an isolate of *Clover yellow vein virus* was partially suppressed by BYMV-M11 strain. Higher homology of nongladiolus isolates appeared to be the crucial factor determining the extent of cross-protection by the attenuated strain. Phylogenetic analyses indicated that the five gladiolus isolates clustered together, completely separated from three BYMV isolates from other hosts. A comparison of the amino acid sequences between M11 and its parental isolate IbG and analysis of recombinant infectious clones between M11 and IbG showed that an amino acid at position 314 was involved in the alteration of *Bean yellow mosaic virus* (Nakazono-Nagaoka et al. 2009).

The attenuated strains obtained from severe parental strains of *Cucumber mosaic virus* (CMV), *Zucchini yellow mosaic virus* (ZYMV), and *Watermelon mosaic virus 2* (WMV-2) were evaluated for their effectiveness in cross-protecting plants against the respective viruses. No significant difference could be seen between single and multiple inoculations in the cross-protection by the attenuated virus isolates against their respective virulent strains, in spite of virus accumulation. This indicated that the cross-protection effect of an attenuated virus isolate was not affected by the presence of unrelated attenuated virus particles in the same plant. In addition, the protecting strain exhibited its efficacy when it had reached a minimum concentration or before it reached its highest concentration. The degree of cross-protection was correlated with the concentration of the protecting strain in the plants. The cross-protection effectiveness of CMV-mild and ZYMV-mild was not as good as that of WMV-mild which provided complete protection against severe strain under greenhouse conditions. Multiple inoculation of cucumber with mild isolates might be effective for reducing losses due to concurrent infection by CMV, WMV-2, and ZYMV, which might lead to greater losses than would occur due to multiple inoculations of mild isolates (Kosaka and Fukunishi 1997). Another attenuated strain ZYMV-2002 was isolated from a virulent isolate of ZYMV after repeated exposure to low-temperature treatments at 12.5–15°C for about 2 months, followed by five cycles of single plant transfer. This isolate ZYMV-2002 differed from the wild-type isolate in its inability to produce local lesions on *Chenopodium quinoa* and its ability to induce very mild or no symptoms on

cucurbit plants. Cucumber plants preinoculated with ZYMV-2002 isolate showed delayed and suppressed expression of mosaic symptoms and/or deformed leaves characteristic of challenge isolates. Plants preimmunized with ZYMV-2002 had fruit productivity similar to that of healthy control plants under field conditions. Poor aphid transmissibility of ZYMV-2002 isolate was considered as a desirable attribute of attenuated viruses to minimize the risk of economic losses due to natural spread of the mild isolate to other crops in which it might become virulent (Kosaka et al. 2006).

The attenuated strain CM95 of *Cucumber mosaic virus* (CMV) was evaluated for practical application to protect cucumber plants against severe strain of CMV under field conditions. The molecular technique RT-PCR-RFLP was employed to differentiate strain CM95 from severe isolates of CMV rapidly. In cross-protection tests, the effectiveness of protection by CM95 was evaluated by RT-PCR-RFLP procedure on challenge-inoculated leaves at 14 days after preimmunization. The results were corroborated by those of a concomitant experiment conducted to assess symptom expression on upper leaves at 1 month after inoculation. The RT-PCR-RFLP protocol provided reliable results on the cross-protective ability of CM95 in 15 days, whereas the traditional bioassay required 30 days to obtain the results (Nakazono-Nagaoka et al. 2005). *Cucumber mosaic virus* (CMV) encodes the 2b protein, a suppressor of RNA silencing, triggered following infection of susceptible host plants. The 2b protein could also act as a symptom determinant and induces disease symptoms by interfering with microRNAs-mediated gene regulation (Lewsey et al. 2007).

Genetic engineering of viruses may provide a means of designing and generating mild, potentially cross-protective, virus strains. If RNA silencing is the mechanism operating in plants cross-protected by mild strains, then a mutant virus strain lacking the ability to express a silencing suppressor would be a potent cross-protecting agent which might act as a trigger of silencing against its own RNA and homologous viral RNA sequences. The ability of the CMV mutant CMV Δ 2b which could not express 2b silencing suppressor protein (2b) to protect plants against CMV strains was assessed. A CMV mutant of the subgroup IA strain Fny (Fny-CMV Δ 2b) could not express the 2b silence-suppressing protein cross-protected tobacco and *Nicotiana benthamiana* plants against disease induction by wild-type Fny-CMV strain. However, protection was most effective only if inoculation with Fny-CMV Δ 2b and challenge inoculation with wild-type CMV was performed in the same leaf. In addition, Fny Δ 2b mutant also protected plants against infection by TC-CMV, a subgroup II strain not closely related to Fny-CMV. In situ hybridization analysis showed that Fny-CMV Δ 2b and Fny-CMV wild-type isolate could coexist in the same tissues, but tissues contained zones of Fny- Δ 2b-infected host cells from which Fny-CMV, the wild-type strain, appeared to be excluded. The results suggested that protection by mutant isolate lacking CMV-2b protein expression was operated through either induction of very highly localized RNA silencing or by competition between strains for host cells or resources (Ziebell et al. 2007).

Attenuated strains generated by genetic modification of a locally prevalent severe strain may result in greater level of cross-protection. Three amino acid changes, Arg₁₈₀ $\rightarrow$ Ile₁₈₀ (GA mutation), Phe₂₀₅ $\rightarrow$ Leu₂₀₅ (GB mutation), and Glu₃₉₆ $\rightarrow$ Asn₃₉₆ (GC mutation) of the conserved motifs of the helper component, protease (HC-Pro) of a severe strain TW-TN3 of *Zucchini yellow mosaic virus* (ZYMV), were generated from an infectious cDNA clone that carried a green fluorescent protein (GFP) reporter. These three mutants induced milder symptoms on squash plants. Single substitution in these three amino acids apparently affected the virulence of the mutants and also significantly

reduced accumulation of GFP. The GAC mutant conferred complete cross-protection against the parental virus at 5 days after protective inoculation. Accumulation of challenge virus (parental virus) was inversely related to the increase in the length of protection, as shown by the absorbance values of ELISA tests. The GAC mutant was stable, as reflected by the observation that no revertants with severe strain sequences were found after nine passages through squash plants after a period of 9 months. The results indicated the potential of the GAC mutant for effective protection of squash plants against severe strain of ZYMV (Lin et al. 2007).

An attenuated mutant strain of *Zucchini yellow mosaic virus* (ZYMV) without the GFP reporter derived from GAC mutant was evaluated for its aphid transmissibility and effectiveness of cross-protection in cucurbits. Apterous aphids *Myzus persicae* were provided a 10 min acquisition access on plants inoculated with a severe strain of TN3 or attenuated ZAC strain. The mutant ZAC isolate was not transmitted by the aphid vector, even though the level of virus acquisition was equally high as that of the severe strain. Squash plants protected with ZAC strain remained symptomless and appeared normal. The presence of the severe strain T3 could not be detected in plants protected by ZAC strain at 5 and 10 days after challenge inoculation with the severe strain T3 using ELISA tests, indicating that protection provided by the attenuated strain was complete. The results of ELISA tests also revealed that replication of the challenging strain T3 was entirely inhibited in protected plants. The ZAC mutant could protect other cucurbit crops, watermelon (*Citrullus lunatus* cultivar Fu-Bo No.2), cucumber (*Cucumis sativus* cultivar Da-fong No. 2), and oriental melon (*Cucumis melo* cultivar Silver Light) grown in Taiwan. The lack of aphid transmissibility of the mutant could be an additional desirable factor for its use to cross-protect the cucurbit crops (Chao et al. 2010).

The attenuated strain KM3 of *Chinese yam necrotic mosaic virus* (CYNMV) selected from among CYNMV field isolates induced a mild mosaic symptom on leaves of Chinese yam (*Discorea opposita*) cultivar Nagaimo during the early stages of growth and the severity of symptoms decreased with plant growth. Aphids were used to inoculate KM3 to protect yam plants against severe strains of CYNMV YS117 and IW5. The RT-PCR-RFLP procedure was applied to differentiate KM3 from other field isolates of CYNMV. The nucleotide sequence of attenuated strain KM3 offering effective protection against severe strain of CYNMV under field conditions was determined for use in the identification of the mild strain (Kondo et al. 2007). Another attenuated strain T-3 of *Japanese yam mosaic virus* (JYMV) was evaluated for its cross-protection potential against virulent (native) strains in Chinese yam (*D. opposita*) grown in farmers' fields in Japan. The presence of native strains of JYMV could be detected by PCR-based assay in all Chinese yam plants grown from virus-free tubers in the first growing season in the fields, but the native strains were detectable in only one of 50 plants grown from tubers preimmunized with T-3 strain during 6 years of experimentation. The preimmunized plants yielded significantly more than the unprotected plants, indicating the effectiveness of the attenuated strain T-3 of JYMV not only in protecting the Chinese yam plants but also in increasing the yield from protected plants (Kajihara et al. 2008). The effectiveness of an attenuated strain in protecting Chinese yam (*Dioscorea opposita*) against infection by *Chinese yam necrotic mosaic virus* (CYNMV) was assessed under field conditions. The attenuated strain protected the Chinese yam plants against CYNMV strain effectively for 5 years under field conditions. In addition, yields of total tubers and grade A tubers were increased by 25 and 57% in protected crops compared with unprotected crops after 5 years of cultivation. Plants protected by KM3 strain produced

greater yield (31%) over that of unprotected plants grown from virus-free seed tubers. The results showed that the attenuated strain KM3 could be employed to reduce the infection by CYNMV in Chinese yam (Kondo et al. 2015).

13.1.4 Mechanisms of Action of Biological Control Activities of Biotic Agents

Biotic biological agents (BCAs) may act directly or indirectly on plant pathogens/host plants by one or more mechanisms: (i) the ability to inhibit or destroy the pathogen by producing toxic metabolites (antibiosis); (ii) competition between the antagonist and the pathogen for essential food materials such as carbohydrates, nitrogen, growth factors and/or space; (iii) parasitism of the pathogen by the antagonist, resulting in necrosis or death of the pathogen; (iv) prevention of pathogen colonization of host tissues; and (v) induction of resistance in host plants.

13.1.4.1 Mechanisms of Action of Fungal Biological Control Agents

The biocontrol activity of *Trichoderma harzianum* against *Phytophthora capsici* was investigated. *T. harzianum* inhibited the spread of mycelial growth of *P. capsici* in petriplates. It also invaded the whole surface of the pathogen colony later and sporulated over the pathogen. The hyphae of *P. capsici* were surrounded by those of *T. harzianum*, resulting in their subsequent disintegration and eventual suppression of the growth of *P. capsici*, as observed under the scanning electron microscope (SEM) (Ezziyyani et al. 2007). In a later investigation, the interaction between *T. harzianum* T472 strain and *Gibberella zeae* (anamorph *Fusarium graminearum*) was studied using scanning electron microscope (SEM). In the presence of T472 strain in the inoculated wheat straw, *G. zeae* produced only an average of 15 perithecia as against an average of 167 perithecia in the absence of T472. At 15 days after inoculation (dai), mycelia and numerous spores of T42 could be visualized covering the surface of the perithecia of *G. zeae* and colonization of the perithecia by T472 could be clearly viewed under SEM. The BCA colonized the substrate rapidly and out-competed the pathogen. The results revealed that the suppression of *G. zeae* development was effected through parasitism (Inch and Gilbert 2011).

Fusarium head blight (FHB) disease of wheat and other cereals caused by different *Fusarium* spp. has been a difficult problem without effective solution because of the complexities involved. The usefulness of the biotrophic mycopathogenic *Sphaerodes mycoparasitica* was assessed for the control of *Fusarium* pathogens. Germination of ascospores of *S. mycoparasitica* was greatly increased in the presence of *F. graminearum* strains, indicating a compatible interaction between the BCA and pathogen strains. A quantitative real-time PCR was developed employing the *Fusarium*-specific (Fg16N) and trichothecene *Tri5* (TOX-1/2) -specific primer sets. The amounts of DNA of *F. graminearum*, 3-acetyldeoxynivalenol (3-ADON), and 15-acetyldeoxynivalenol (15-ADON) strains were reduced in the presence of *S. mycoparasitica*, indicating a significant reduction in pathogen population, when the BCA and the pathogen were coinoculated. *S. mycoparasitica* was able to germinate in the presence of *F. graminearum* culture filtrates and also establish biographic mycoparasitic relations with two *F. graminearum* chemotypes, suppressing their growth in vitro (Vujanovic and Goh 2011).

Alcohol percentage test (APT) and real-time PCR quantification of DNA were employed to evaluate the efficiency of *S. mycoparasitica* to replace an array of pathogenic/toxigenic *Fusarium* in cultures. Shifts in *Fusarium* mycelial growth and

hydrophobicity measured (APT) at the interaction zone with *S. mycoparasitica* indicated the degree of *Fusarium* mycelial replacement by the mycoparasite ($P < 0.05$), while qRT-PCR estimated changes in DNA quantities of *Fusarium graminearum*. The 3-ADON and 15-ADON chemotypes were challenged with *S. mycoparasitica*. HPLC analysis also revealed a considerable reduction in mycotoxin (DON, 3-ADON, 15-ADON, and zearalenone) concentrations at the contact zone. Estimated shifts in the DNA quantity and mycotoxin production, assessed by qRT-PCR and HPLC respectively, correlated with an alteration in APT values, demonstrating the effectiveness of the mycoparasite under natural conditions (Vujanovic and Chau 2012). *Gibberella fujikuroi* (anamorph *Fusarium moniliforme*), causing bakanae disease of rice, is seedborne. *Talaromyces* sp. KNB-422 isolate was evaluated for its biocontrol potential against *G. fujikuroi*. The fluorescent protein marker GFP and RFP were used to visualize cell-to-cell interactions between the BCA and the pathogen. In slide culture, the hyphal cell wall of *G. fujikuroi* collapsed, and fluorescence of its cytoplasm disappeared at 3 days after contact with the hyphae of *Talaromyces* sp. On inoculated plants, both fungi occupied the same regions of coleoptiles and roots, where the mycoparasite activity might be exerted on the pathogen (Kato et al. 2012).

Sclerotinia sclerotiorum is an economically important pathogen infecting oilseed rape and many other crops, accounting for substantial losses. The process of mycoparasitism of *S. sclerotiorum* infecting *Brassica* by green fluorescent protein (GFP-) transformed *Trichoderma harzianum* ThzID1-M3 strain was studied. A specific PCR primer/probe set for detecting the GFP-transformed isolate was generated. Quantitative real-time PCR was evaluated along with epifluorescence microscopy and image analysis to investigate the dynamics of colonization of sclerotia in nonsterile soil. It was possible to quantify the amounts of ThzD1-M3 DNA and *S. sclerotiorum* DNA from individual sclerotia using the real-time PCR assay. Epifluorescence from the transformant was quantified using computer image analysis to estimate colonization on a per-sclerotium basis. Colonization of sclerotia of *S. sclerotiorum* by *T. harzianum* on agar plates was observed using confocal laser scanning microscopy. The GFP-fluorescing hyphae of *T. harzianum* could be clearly seen. This procedure, although highly labor-intensive, provided high spatial resolution of colonization dynamics. Both methods quantified colonized sclerotia by the BCA over a period of time. The real-time PCR assay provided a more precise assessment of the extent of sclerotial colonization and could be more easily applied to sample entire sclerotia (Kim and Knudsen 2011).

Aspergillus strain ASP-4 belonging to the *Aspergillus aculeatus* clade of the black aspergilli was isolated from a field plot where oilseed rape had been planted for the past 20 years. The mycoparasitic activity of the strain ASP-4 on *S. sclerotiorum* was evaluated both in the laboratory and field plots over a 3 year period. The results clearly revealed the highly significant effect of the mycoparasite in reducing the numbers of germinating sclerotia and subsequent spread of the pathogen. Since *Aspergillus* sp. ASP-4 infected the sclerotia of the pathogen, it might be possible to fix the critical time and method of application of the BCA for the suppression of *S. sclerotiorum*. The results showed that the spore suspension of the BCA could be sprayed at early-mid-flowering season on the soil and after harvest (Hu et al. 2013b).

Rice seeds were found to be contaminated with mycotoxin citrinin produced by several fungi associated with rice seed. An average of 6.79×10^4 fungal spores per gram seeds was present, belonging to 47 species in 28 genera of which *Aspergillus*, *Cladosporium*, and *Penicillium* were predominantly found. *A. niger* and *A. flavus*

occurred more frequently than other fungi associated with rice seeds. Of the 30 rice seed samples, 10 samples were contaminated with mycotoxin citrinin. *Penicillium viridicatum* produced the highest amount of citrinin on glucose ammonium nitrate salts broth and rice grains. The fungal biocontrol agents *Trichoderma hamatum* reduced the amount of citrinin to the maximum extent. The growth of *T. hamatum* infecting *P. viridicatum* increased with lapse of time. The viability of *P. viridicatum* conidia was decreased by *T. hamatum* with an increase in the incubation period. Chitinases and β -1,3-glucanase activities of *T. hamatum* also increased with increased incubation period on *P. viridicatum* mycelia up to maximum values for 72 h and 84 h, respectively. Treatment of rice grains with *T. hamatum* infested by *P. viridicatum* reduced production of citrinin in rice grains relative to the control seed sample (Abd-Allah and Ezzat 2005).

Fusarium head blight (FHB) disease pathogens *Fusarium graminearum* and *F. culmorum* infecting wheat, maize, and barley produce the trichothecene mycotoxin, deoxynivalenol (DON). *Trichoderma viride* P1 is antagonistic to several plant pathogens as it produces an array of cell-wall-degrading enzymes (CWDEs) that act synergistically to advance parasitism. The endochitinase ECH42 is the most important among the CWDEs produced by the BCA and is encoded by *ech42* gene, whereas an N-acetyl- β -D-glucosaminidase was encoded by *nag1* gene. Disruption of the *ech42* gene reduced the biocontrol activity of the strain P1. The *nag1* gene was induced by low-molecular-weight chito-oligosaccharides and its own catabolic products, while *ech42* expression was indirectly induced by carbon starvation and other stress conditions (Mach et al. 1999; Woo et al. 1999).

The expression of these genes contributing to biocontrol activity was monitored in vitro and on crop residues of two maize cultivars by using *goxA* reporter gene fusions. The pathogen toxin DON repressed expression of *nag1* gene in *T. viride* P1. Expression of this gene was reduced by 50% in maize residues when the antagonist was placed in competition with DON-producing strains of *F. culmorum* and *F. graminearum*. By adding synthetic DON to assay mixtures with *Fusarium* strains that otherwise had no effect on the BCA, DON-induced repression could be reproduced, confirming the adverse effects of the pathogen on the expression of key enzyme involved in the biocontrol activity of strain P1. On the other hand, expression of *ech42* gene was neither positively nor negatively affected by DON or contact with *Fusarium* spp. The negative signaling could be an additional factor that might contribute to the inconsistent performance often observed with biocontrol agents (Lutz et al. 2003).

The interaction between the fungal pathogen *Fusarium moniliforme*, infecting maize kernels, and two antagonistic isolates of *Trichoderma harzianum* was investigated in respect of their secondary metabolites fusaric acid (FA) and 6-pentyl- α -pyrone (6PAP). Among 10 isolates of *F. moniliforme* screened for production of FA, isolate 8 produced a higher amount of FA. The mycelial growth and conidial production of both *Trichoderma* isolates T16 and T23 were retarded by increasing concentrations of FA in agar medium. Both *T. harzianum* isolates were able to degrade FA in potato dextrose medium and the isolates T23 and T16 reduced FA production by 51.4% and 88.4%, respectively, at 9 days postinoculation. The antifungal metabolite 6PAP isolated from *T. harzianum* T23 cultures reduced FA contents per gram mycelial dry weight significantly, compared to control. Dosages of 300 and 400 mg L⁻¹ of 6PAP in cultures retarded FA accumulations by 62.5% and 77.2%, respectively, providing evidence that the antifungal activity of *T. harzianum* was derived from the presence of 6PAP which might degrade FA, resulting in the reduction in the contents of *Fusarium* toxin FA (El-Hasan et al. 2008).

The biocontrol activity of *Clonostachys rosea* against *Fusarium culmorum* was shown to be associated with the secretion of cell-wall-degrading enzymes (CWDEs), including chitinases and expression of *N*-acetyl- β -glucosaminidase-encoding gene *cr-nag1* in *C. rosea*. Enzymatic assays and RT-PCR showed that the NAGase activity of *C. rosea* was specifically repressed in medium containing high glucose contents and was expressed in media containing chitin or *F. culmorum* cell walls, as sole carbon sources. *C. rosea* inhibited the mycelial growth of *F. culmorum* and the high expression of *cr-nag1* occurred only in the interaction between *C. rosea* and *F. culmorum*, but not with another fungal pathogen *Pythium ultimum*. The results indicated that the chitin-hydrolyzing agents targeted the cell walls of *F. culmorum*, resulting in the suppression of the mycelial growth of the pathogen (Mamarabadi et al. 2009).

A strain of *C. rosea* ACM 941 (American Type Culture Collection ATCC 7447) was evaluated for antibiosis against *Gibberella zeae* in vitro and for the control of Fusarium head blight (FHB) disease of wheat under greenhouse and field conditions, in comparison to the registered fungicide Folicur (tebuconazole). The strain ACM941 reduced mycelial growth of the pathogen by 52.6% in dual culture after 6 days and completely suppressed spore germination for 6h when cocultured with a macroconidial suspension of *G. zeae*. Strain ACM941 reduced *G. zeae* perithecial production by more than 99% in the leaf disk assay, 60–77% on infected corn kernels, and 32–57% on spikelet debris in the field. These effects of *C. rosea* strain ACM941 on *G. zeae* were similar to those induced by the fungicide. The mechanism of action of *C. rosea* on *G. zeae* was through antibiosis, resulting in the suppression of development of *G. zeae* infecting wheat and maize (Hue et al. 2009). In another investigation, the extracts from 11 isolates of *T. harzianum* and cell-free filtrates were screened for antifungal activity against perithecial development. Isolates T472 and T22 significantly reduced numbers of perithecia produced by more than 70%. Several compounds unique to T472 and T22 capable of suppressing perithecial development were isolated, indicating that these compounds might have a role in suppressing the development of *G. zeae* causing FHB disease of wheat (Inch et al. 2011).

A nonpathogenic *Fusarium oxysporum* antagonistic to *Sclerotinia sclerotiorum* was isolated from the suppressive soil. The antagonistic activity of *F. oxysporum* strain S6 was observed in dual culture plates. The toxic nonvolatile metabolites from *F. oxysporum* S6 strain were detected and differentiated using chromatographic techniques. They were purified and identified as cyclosporine A by spectroscopic methods. The antifungal activity against *S. sclerotiorum* was correlated with the presence of cyclosporine A by a dilution plate assay. The BCA also induced a similar adverse effect on mycelial growth and sclerotial production by *S. sclerotiorum*. Germination percentage of sclerotia was significantly reduced due to infection of sclerotia by the BCA. In the greenhouse experiment, the number of surviving soybean plants significantly increased when the BCA and pathogen were coinoculated. The results indicated that the fungal activity of *F. oxysporum* S6 against *S. sclerotiorum* was primarily due to secretion of cyclosporine A by the BCA (Rodriguez et al. 2006). In another investigation, inhibition of mycelial growth by *Trichoderma* spp. was attributed to production of volatile and nonvolatile inhibitors under greenhouse and field conditions. *T. koningii*, *T. virens*, *T. ceramicum*, and *T. viridiscens* provided maximum protection to potatoes against stem rot caused by *S. sclerotiorum* (Ojaghian 2011). Another fungal biocontrol agent *Clonostachys rosea* BAFC3874 strain isolated from soil suppressive to *S. sclerotiorum* effectively inhibited the infection of the pathogen in pot-grown lettuce and soybean plants. The production

of antifungal compounds against *S. sclerotiorum* with secondary metabolism by the BCA strain was observed. *C. rosea* BAFC3874 produced a microheterogenous mixture of peptides belonging to the peptaibols family. In addition to its ability to secrete the antifungal compounds, the strain BAFC3874 also showed mycoparasitic activity against *S. sclerotiorum* in the dual culture assays (Rodriguez et al. 2011).

The antagonists *Trichoderma* spp., nonpathogenic *Fusarium* spp., and isolates of *Clonostachys rosea* consistently suppressed sporulation of the pathogens *F. culmorum*, *F. graminearum*, *F. proliferatum*, and *F. verticillioides* causing wheat head blight or maize ear rot diseases. These biocontrol agents (BCAs) significantly reduced the colonization of stalk pieces by pathogen *Fusarium* spp. at several sampling dates. The results indicated that wheat head blight/maize ear rot pathogens might be suppressed by the competition with BCAs for nutrients available in plant tissues (Luongo et al. 2005). The colonization pattern of nonpathogenic *Fusarium oxysporum* endophytes was investigated by using *F. oxysporum* isolates transformed with green fluorescent protein (GFP) and red fluorescent (DsRed) genes. Root and rhizome tissue colonization by transformants were similar to that of wild-type isolates. DsRed transformants were difficult to visualize in tissues colonized by them. On the other hand, GFP-transformation was useful to differentiate the transformants from other saprophytic fungi present in the rhizosphere (Paparou et al. 2009).

The contamination of maize (corn) grains with *Aspergillus flavus* is of great concern due to the harmful effects of the mycotoxins secreted by the pathogen. The efficacy of two nonaflatoxigenic isolates of *A. flavus* CT3 and K49 in reducing aflatoxin levels in maize grains was assessed. These two nonaflatoxigenic isolates decreased the aflatoxin levels by 61% and 76%, respectively. The strain K49 capable of producing sclerotia grew rapidly and had greater ability to colonize maize grains than nonsclerotia producing CT3 strain following inoculation of maize grains, indicating its greater ecological (sphere) competence. The native strain K49 exhibited potential for application as a biocontrol agent for reducing aflatoxin levels in maize grains (Abbas et al. 2006).

Biofumigation with *Muscodor albus*, which produces volatile compounds inhibitory to the development of fungal pathogens, was evaluated for the suppression of development of smut pathogens. The effects of these volatiles on dormant and physiologically active teliospores of smut fungi *Tilletia horrida*, *T. indica*, and *T. tritici*, which cause kernel smut of rice, Karnal bunt of wheat, and common bunt of wheat, respectively, were assessed. Dormant and physiologically active teliospores were fumigated in dry petriplates using reactivated culture of *M. albus* for up to 5 days at 22°C. The germination of all three *Tilletia* spp. was totally inhibited when fumigated for 5 days. Biofumigation of smut fungi affecting rice and wheat using *M. albus* resulted in the inhibition of spore germination to a different extent when dry loose teliospores were exposed to the volatiles produced by the BCA. Teliospores within intact sori were not affected by the volatiles produced by *M. albus*. The results suggested that *M. albus* might be effective as seed or soil treatment for controlling seedling-infecting smuts whose infection is initiated by germinating teliospores prior to seedling emergence (Goates and Mercier 2009).

Helminthosporium solani, incitant of potato silver scurf disease, causes significant widespread economic losses. *Acremonium strictum* present along with *H. solani* in infected tubers showed distinct parasitic potential by reducing sporulation, spore germination, and mycelial growth of the pathogen, compared with control culture without *A. strictum*. The mycoparasite reduced conidial production of *H. solani* on minitubers,

resulting in a decrease in inoculum for further infection. *A. strictum* was able to protect healthy minitubers, but not the tubers already infected with *H. solani*. Scanning electron microscopic observations revealed shriveled and shrunken conidia of *H. solani* when contaminated with *A. strictum*, indicating that the mechanism of action of *A. strictum* on *H. solani* might be either direct parasitism or antibiosis by production of toxic metabolites (Rivera-Varas et al. 2007).

Microorganisms (fungi, bacteria, and actinomycetes) were isolated from soil using vegetable tissues as baits. Of the 70 microorganisms tested, 16 were able to produce substances in culture fluids with the capacity to suppress the development of rice blast pathogen *Magnaporthe grisea*. *Fusarium solani* KS-F14 secreted compounds with the potential to activate resistance in rice leaves and was selected for further testing. The resistance-inducing substances were effective at a range of pH values from 5 to 10 and were stable under high temperatures, maintaining the same level of activity even after autoclaving for 20 min. After application, the resistance induced in rice leaves persisted for 14 days. The majority of the secreted resistance-inducing compounds were hydrophilic and some were hydrophobic. The compounds inducing resistance produced by *F. solani* possessed the potential to be developed as a commercial product for the management of rice blast disease (Chern et al. 2014).

13.1.4.2 Mechanisms of Action of Bacterial Biological Control Agents

The bacterial biocontrol agents (BCAs) may act on the plant pathogens directly or indirectly by different mechanisms such as antibiosis, competition for nutrients, colonization of specific sites required for establishing infection, and inducing resistance to pathogens by activating host defense systems. Antagonism exhibited by bacterial BCAs depends predominantly on the ability to produce compounds inhibitory to the development of bacterial and fungal plant pathogens infecting various crops, or adversely affect pathogen development in other ways. Many bacterial BCAs belonging to different genera exhibit metabolites-mediated antagonism, resulting in the suppression of development of fungal and bacterial pathogens and consequently expression of disease symptoms. Root colonization is a process by which bacterial BCAs introduced through seeds or propagules or into the soil are distributed along roots. The plant growth-promoting rhizobacteria (PGPR) have dual roles in promoting plant growth and also in suppressing the development of phytopathogens, resulting in healthy and vigorously growing plants. The PGPR species belong to the genera *Pseudomonas*, *Bacillus*, *Paenibacillus*, *Streptomyces*, and *Achromobacter*.

Among the antibiotics produced by the bacterial BCAs, the presence of phloroglucinols has been more commonly detected in the substrates. The antibiotic 2,4-diacetylphloroglucinol (2,4-DAPG), among phloroglucinols, has been investigated intensively. Two major phenotypic groups of 2,4-DAPG producers have been differentiated based on the production of antifungal compounds. One group produces 2,4-DAPG, HCN, and pyoluteorin and another group synthesizes only 2,4-DAPG and HCN (Raaijmakers and Weller 1998). The genes required for the biosynthesis of 2,4-DAPG by *Pseudomonas fluorescens* Q2-87 have been cloned and the biosynthetic locus includes *phlA*, *phlB*, *phlC*, and *phlD*. The limited distribution of *phlD* among bacteria facilitated its use as marker gene for 2,4-DAPG-producing *Pseudomonas* spp. present in the soil and other environmental samples to be detected by polymerase chain reaction (PCR) assay (McSpadden Gardener et al. 2001). Strains of *P. fluorescens* were screened for the production of 2,4-DAPG by using PCR-based screening procedure employing primers

Phl2a and Phl2b. A fragment of 745 bp characteristic of the biosynthetic genes was amplified. The purified antibiotic 2,4-DAPG from the BCA culture suppressed the development of *Xanthomonas oryzae* pv. *oryzae* (Xoo), causing rice bacterial leaf blight (BLB) disease. This antibiotic suppressed the BLB pathogen development up to 59–64% in the greenhouse and field trials (Velusamy et al. 2006).

The biocontrol potential of *Bacillus subtilis* NSR589-24 strain to suppress the development of two important rice pathogens *Magnaporthe grisea* and *Rhizoctonia solani*, causing rice blast and sheath blight diseases, respectively, was assessed. Antifungal compounds in the culture filtrates of the BCA strain inhibited the mycelial growth of *M. grisea* and *R. solani* and they remained stable after autoclaving, indicating their heat stability. In addition, heat labile β -1,3-glucanase was also purified from the culture filtrates of the strain NSR589-24. Both the purified enzyme and the antibiotic extract from the culture filtrate of the strain NSR589-24 separately inhibited *R. solani* and *M. grisea* with minimum inhibitory concentration (MIC) values of 12.5 and 6.25 mU mL⁻¹ and 3.13 and 1.56 μ g mL⁻¹, respectively. The glucanase enzyme in combination with antibiotic showed a strong synergistic inhibitory effect on the hyphal growth of both fungal pathogens. The results indicated that NSR589-24 could effectively restrict the development of rice blast and sheath blight diseases because of the synergistic activity of the bioactive compounds produced by the biocontrol agent (Leelasuphakul et al. 2006).

A bacterial strain GC-B26 showing strong antifungal and antioomycete activity was isolated from a grassland soil in Korea. Based on the morphological, physiological, and biochemical properties, the strain GC-B26 was identified as *Pseudomonas aeruginosa*. The antibiotic G26A capable of suppressing the development of *Phytophthora capsici* was isolated from the culture filtrates of the strain GC-B26 using different chromatographic techniques. The EI mass and UV spectral analyses indicated that G26A was an analogue of phenazines. On the basis of NMR spectral data, G26A was confirmed as phenazine-1-carboxylic acid. *P. capsici* was highly sensitive to G26A, with mean inhibitory concentration (MIC) value of c. 5.0 μ g mL⁻¹. Treatment with the antibiotic effectively protected pepper plants against infection by *P. capsici* and also by anthracnose disease of cucumber caused by *Colletotrichum orbiculare*. The efficacy of the antibiotic produced by *P. aeruginosa* compared well with the fungicides metalaxyl and chlorothalonil (Lee et al. 2003).

The bacterial BCAs *Paenibacillus polymyxa* and *Bacillus subtilis* from commercial products were assessed for their antagonistic activity against *P. capsici*. *B. subtilis* inhibited the mycelial growth of *P. capsici*, whereas *P. polymyxa* suppressed formation of zoosporangium by *P. capsici*. The release of zoospores from zoosporangium was significantly reduced by both BCAs. The secondary metabolites of the BCAs targeted the pathogen at different stages of its life cycle (Kim et al. 2009). *Paenibacillus polymyxa* E681 strain suppressed the development of *Phytophthora capsici*, causing *Phytophthora* blight of pepper. Fusaricidin, a cyclic depsipeptide isolated from *P. polymyxa* E681 inhibited the development of *P. capsici*, with a minimum inhibitory concentration (MIC) of 16 ppm. The disease severity induced by *P. capsici* in plants treated with 0.1 ppm fusaricidin was 40%, whereas the severity of disease in water-treated control plants was 81.7% on post-treatment. Significant disease suppression ($P < 0.05$) was observed on treatment with fusaricidin (0.1 ppm) by foliar spray and soil drench. The disease severity was drastically reduced to 3.3% by soil drench of fusaricidin (0.1 ppm), while disease severity was as high as 83.3% in water-treated control in one of the two experiments conducted. In the second experiment, the effectiveness of fusaricidin was

considerably reduced in treated plants (Lee et al. 2013). The effectiveness of *Paenibacillus ehimensis* KWN38 in suppressing the development of *P. capsici* was assessed in a grass medium. High antifungal and lytic enzyme activities of *P. ehimensis* KWN38 on *P. capsici* were observed. The BCA strain consistently suppressed the development of Phytophthora blight disease under pot trial conditions (Naing et al. 2014).

The efficacy of *Pseudomonas chlororaphis* strain PCL1391 and *P. fluorescens* WCS365 in suppressing the development of three races of *Colletotrichum lindemuthianum* infecting bean plants was assessed. The strain PCL1391 was more effective in suppressing the development of bean anthracnose disease, while the strain WCS365 did not show any improvement over positive control. Further, combination of the two strains of the biocontrol agents (BCAs) was not more effective than *P. chlororaphis* alone. *P. chlororaphis* inhibited the growth, sporulation, and conidial germination of all three races of *C. lindemuthianum*. The antibiotic activity of *P. chlororaphis* was considered to be due to its ability to produce phenazine-1-carboxamide which was detected using the thin-layer chromatography (TLC) technique. The results revealed the effectiveness and the mechanism of action of *P. chlororaphis* in suppressing the development of the pathogen and the anthracnose disease induced by *C. lindemuthianum* in bean (Bardas et al. 2009). The strain PA23 of *P. chlororaphis* effectively protected canola and sunflower against *Sclerotinia sclerotiorum*. The BCA strain produced nonvolatile antibiotics phenazine and pyrrolnitrin as well as the volatile antibiotics nonanal, benzothiazole, and 2-ethyl-1-hexanol. In the greenhouse, the role of the nonvolatile antibiotics on root colonization and biocontrol potential of the strain PA23 against *S. sclerotiorum* on sunflower was investigated. Application of the strain PA23 alone or in combination with phenazine- and pyrrolnitrin-deficient *Tn* mutants resulted in significantly higher ($P=0.05$) root bacterial number and suppression of *Sclerotinia* wilt disease. The bacterial population decreased considerably and appeared to be negatively correlated with the number of antibiotics produced by PA23 strain. The results did not indicate any clear role of phenazine or pyrrolnitrin for the biocontrol activity of *P. chlororaphis* strain PA23 against *S. sclerotiorum* (Athurkoral et al. 2010).

Six endobacteria capable of producing a variety of volatile compounds were isolated from different plant species. Two isolates LCB01 and AVA02 produced volatile compounds inhibiting the mycelial growth of *Fusarium oxysporum* f.sp. *cubense* race 4 (Foc R4). The volatile compounds secreted by LCB01 (*Herbaspirillum* spp.) were the most effective with 20.3% inhibition of banana wilt pathogen. Volatile compound profiles indicated that inhibition of Foc R4 was due to single compounds such as 2-pentane-3-methyl, methanethiol, and 3-undecane or their synergistic action. The isolate AVA02 produced methanethiol and 3-undecene only and not 2-pentane-3-methyl, the absence of which might have resulted in lower level of inhibition (1.4%). Likewise, the absence or low levels of the three compounds in other four isolates of endobacteria resulted in their inability to inhibit the growth of Foc R4. The results suggested that the volatile compounds might be required to be produced in concentrations sufficient to inhibit pathogen growth effectively (Ting et al. 2011).

Pseudomonas aeruginosa LN strain, capable of producing bioactive compounds, was evaluated for its inhibitory effects of *Xanthomonas axonopodis* pv. *malvacearum* (*Xam*), *X. axonopodis* pv. *Phaseoli* (*Xap*), and *X. axonopodis* pv. *citri* (*Xac*). The antibiotic activity of the compounds produced by *P. aeruginosa* was assessed under greenhouse conditions and by visualizing the effects under electron microscope. Chromatographic fractions EAP, VLC3, VLC4, VLC3d, and VLC4f were tested by disc diffusion assay.

Electron microscopic observations indicated that VLC4f affected the biofilm formation by the pathogen and cell morphology. The partially purified fractions of the compounds secreted by LN strain, when sprayed on the plants under greenhouse conditions, suppressed the development of disease symptoms. VLC4f fraction was the most effective and reduced the number of lesions induced by *Xam* and *Xac* on cotton and orange leaves, respectively, by 94% and reduced the disease severity caused by *Xap* in bean leaves by 73%. The results showed that fractions purified from culture filtrates had potential for use as an alternative to conventional bactericides applied for the management of diseases caused by *Xanthomonas* spp. (Spago et al. 2014).

The biocontrol efficacy of *Pseudomonas* strain LBUM223 in suppressing the development of potato scab disease caused by *Streptomyces scabies* was assessed. The pathogen produced the toxin thaxtomins involved in the induction of disease symptoms on tubers. The involvement of phenazine-1-carboxylic acid (PCA) in repressing thaxtomin biosynthetic genes *txtA* and *txtC* and suppression of potato common scab disease were investigated by employing a mutant deficient in PCA production (LBUM223 *phzC*⁻). Treatment of seed tuber treatment with strain LBUM223 prior to planting in pathogen-infested soil suppressed the disease development. A relationship was observed between PCA-producing ability of strain LBUM223 and its capacity to inhibit the growth of *S. scabies* and its ability to repress the biosynthetic genes *txtA* and *txtC*, and consequently in limiting the surface area of progeny tubers covered with common scab lesions (St-Onge et al. 2011).

The strain LBUM 300 was evaluated for its antagonistic efficacy to suppress the development of *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*), incitant of tomato bacterial canker disease. The strain LBUM300 produced both DAPG and HCN on *Cmm* under in vitro and in planta conditions. Nonsynthesizing isogenic mutants of producer strains were generated to dissect the role of individual metabolite on biological control of *Cmm*. *Pseudomonas* sp. strains LBUM223 and LBUM300 significantly repressed the growth of *Cmm* in vitro, while their respective nonproducing mutants showed less or no significant antagonistic activity. In planta, only the strain LBUM300 reduced disease development and *Cmm* rhizospheric populations. The results suggested that the production of DAPG and HCN contributed to the antagonistic potential of the strain LBUM300. Simultaneous production of DAPG and HCN by LBUM300 was considered as a desirable factor for commercialization of this strain for large-scale application for the control of tomato bacterial canker disease (Lanteigne et al. 2012).

Antibiotics-producing strains DF190 and PA23 of *Pseudomonas chlororaphis*, strain DFE4 of *Bacillus cereus*, and strain DFE of *B. amyloliquefaciens* were evaluated for their ability to suppress the development of canola black leg disease caused by *Leptosphaeria maculans* (anamorph *Phoma lingam*). The strains PA23 and DF190 produced phenazines (phenazine-1-carboxylic acid, 2 hydroxyphenazine) and pyrrolnitrin, while the strains DFE4 and DFE16 produced the lipopeptide antibiotics iturin A, bacillomycin D, and surfactin. The tests with representative strains PA23 and DFE4 showed a small but significant reduction in disease severity via a systemic response. The local split-inoculation (SPI) of the extract (for direct antagonism) indicated a significantly higher level of reduction of disease severity which was also consistent with the SPI of bacterial cells, establishing a more important role for the antifungal metabolites present in the culture filtrates for the direct suppressive activity on black leg symptoms. The BCAs could be effective due to successful colonization of the infection site which, in turn, most possibly

Figure 13.1 Induction of resistance to tomato late blight by application of *Pseudomonas fluorescens* SS101 or massetolide A to leaves of tomato cultivar Moneymaker and its transgenic derivative *nahG*. Effect on (a) lesion area (mm²) and (b) disease severity (%) determined at 7 days postinoculation with *Phytophthora infestans*; asterisk (*) indicates significant reduction in disease severity relative to control ($P < 0.05$); filled columns: control; blank columns: SS101 strain; lined columns: massetolide A. Source: Tran et al. (2007). Reproduced with permission of John Wiley & Sons.

acts as a suitable delivery system for the antifungal metabolites. Direct antifungal activity at the site of infection appeared to be the dominant mechanism mediating control of canola black leg disease (Ramarathnam et al. 2011).

Pseudomonas fluorescens SS101 strain produced a surfactant identified as massetolide A which suppressed the development of *Phytophthora infestans*, incitant of late blight disease of potato and tomato. *P. fluorescens* SS101 effectively prevented infection of tomato leaves by *P. infestans* and also restricted the expansion of lesions already formed and sporangial production. A massetolide A-deficient mutant 10.24 had significantly reduced biocontrol activity compared with wild-type strain (Fig. 13.1). When applied to the lower leaf, the mutant was significantly less effective in reducing the lesion area than the wild-type SS101 strain or massetolide A. Further, the lesion area was significantly reduced in lower leaves of *nahG* transgene treated with SS101 or massetolide A, demonstrating values similar to that obtained in the wild-type progenitor tomato cultivar Moneymaker. The results suggested that *P. fluorescens* SS101 or massetolide A might induce resistance in tomato plants, independent of SA signaling. Application of massetolide A on tomato leaves and roots effectively protected the treated plants against infection by *P. infestans*, indicating the important role of massetolide A in the biocontrol potential of *P. fluorescens* SS101 (Tran et al. 2007).

In a later investigation, the efficacy of the biosurfactant produced by *Pseudomonas koreensis* strain 2.74 in protecting potato plants against infection by *P. infestans* was assessed using the detached-leaf assay. Development of disease on treated leaves challenged with the zoospores of *P. infestans* was reduced significantly. The biosurfactant inhibited the motility of the zoospores, but caused only a minor reduction in mycelial growth rate. No adverse effect on the rate of sporangia production in pure culture was evident following treatment with bacterial surfactant (Hultberg et al. 2012a, b).

The antimicrobial activities of culture filtrates and selected metabolites of *Bacillus* spp. were assessed in vitro against *Xanthomonas campestris* pv. *campestris* (Xcc), causing cabbage black rot disease. All three species, *B. amyloliquefaciens*, *B. subtilis*, and *B. pumilus*, were found to be efficient producers of metabolites toxic to Xcc when they were grown at half-strength of trypticase soy broth (TSB) or cabbage broth (CB). TSB stimulated greater synthesis of metabolites compared with the control. *B. amyloliquefaciens* isolates produced surfactin, iturin, bacillomycin and/or azalomycin F, whereas *B. subtilis* isolates produced mostly surfactin and arthrobactin. The culture filtrates of *B. pumilus* contained surfactin, amphomycin, arthrobactin, and valinomycin. All three species of *Bacillus* produced surfactin in their cultures (Wulff et al. 2002). The ability of *B. subtilis* to inhibit the mycelial growth of *Fusarium verticillioides*, causative agent of Fusarium head blight (FHB) disease of wheat, and to reduce the accumulation of the mycotoxin fumonisin B1 was assessed in vitro. *B. subtilis* strain CE1 was the most efficient in inhibiting the mycelial growth of the pathogen as well as production of mycotoxin. The antibiotic activity of CE1 strain was negatively correlated with the population of *F. verticillioides* in the greenhouse tests (Cavaglieri et al. 2005). *Bacillus amyloliquefaciens* Lx-11 strain exhibited biocontrol activity against rice bacterial leaf streak (BLS) pathogen *Xanthomonas oryzae* pv. *oryzicola*, and secreted three kinds of lipopeptides including surfactin, bacillomycin D, and fengycin which inhibited the development of the pathogen. The antibacterial activity could be associated with surfactin and lipopeptides. The surfactin-deficient mutants lost their biocontrol activity, indicating that the surfactin was the principal compound involved in the suppression of the BLS disease development. Further, the defense-related genes *PR-1a*, *PR-1b*, *NPR1*, and phenylalanine-ammonia-lyase (PAL) were concurrently expressed in rice leaves following treatment with Lx-11 strain. Results suggested that Lx-11 might trigger systemic resistance in treated rice plants. *B. amyloliquefaciens* Lx-11 strain significantly reduced the incidence of rice bacterial leaf streak disease, the efficacy of disease suppression ranging over 60.2–70.6% which was better than what could be achieved by applying bismethiazol under field conditions (Zhang et al. 2012).

Bacteriocins are proteinaceous compounds secreted by bacterial species and exert harmful effects on closely related bacterial competitors present in the same substrate/environment. These toxic metabolites form a structurally and functionally diverse group with antimicrobial properties. Bacteriocin production by biocontrol agents such as *Pseudomonas* spp. may contribute to their rhizosphere competence (Parret et al. 2005). A bacteriocin-like substance (BLS) produced by *Bacillus licheniformis* P40 inhibited the soft rot bacterium *Erwinia carotovora*. The BLS exhibited a bactericidal effect on *E. carotovora* cells at $30\mu\text{g mL}^{-1}$. Observations under transmission electron microscope revealed wrinkled bacterial surfaces and shrinkage of whole cells due to treatment with BLS, indicating plasmolysis. BLS prevented spoilage of potato tubers by *E. carotovora* when tubers were treated at $240\mu\text{g mL}^{-1}$ or above concentrations. Development of soft rot was totally blocked when BLS at 3.7 mg mL^{-1} was used to treat the tubers. The results

indicated that *B. licheniformis* suppressed the soft rot of tubers induced by *E. carotovora* by producing bacteriocin-like compound (Cladera-Olivera et al. 2006).

Different bacterial species with biocontrol potential have been reported to produce antibiotics, lytic enzymes, and siderophores which are involved in the suppression of microbial plant pathogens to a different extent. Enzyme-mediated antagonism has been shown to be the principal mechanism of pathogen suppression in some crop–pathogen combinations. *Pseudomonas chlororaphis* strain PA23 was effective in suppressing the development of canola stem rot disease caused by *Sclerotinia sclerotiorum*. The pathogen produces ascospores from germinating sclerotia and they infect the flowers of canola. The ability of the strain PA23 to induce activities of chitinase and β -1,3-glucanase was assessed by spraying BCA suspensions on plants twice at 30 and 50% bloom, followed by challenge inoculation with *S. sclerotiorum*. The BCA-treated canola plants had significantly higher chitinase and β -1,3-glucanase activities. On the other hand, the activities of these enzymes were less in healthy control, ascospore-inoculated control, and strain PA23-treated plants. The activities of β -1,3-glucanase reached the peak at 6 days after inoculation (dai) and at 4 dai for chitinase. The activities of these enzymes declined slowly with time after ascospore inoculation (Fernando et al. 2007a).

The possible involvement of enzyme-mediated antagonism of *Phytophthora capsici* and *Rhizoctonia solani* by fluorescent *Pseudomonas* isolates GRC3 and GRC4 was examined. The antifungal potential of *Pseudomonas* was assessed by using dual culture technique on solid and liquid media. The activities of chitinases and β -1,3-glucanases and antifungal metabolites of nonenzymatic nature were negatively correlated with the inhibition of *P. capsici* and *R. solani*, indicating that the isolates of *Pseudomonas* might suppress the fungal pathogens through enzyme-mediated antagonism (Arora et al. 2007). *Bacillus pumilus* SG2 inhibited the mycelial growth of *Fusarium graminearum* and *Bipolaris sorokiniana*. The role of chitinases produced by *B. pumilus* in its biocontrol potential against the wheat pathogens was investigated. When grown in salt medium with colloidal chitin, *B. pumilus* SG2 strain secreted two chitinases into the medium, resulting in the inhibition of mycelial growth of *F. graminearum* and abolition hyphal elongation of *B. sorokiniana*. In the presence of glucose as carbon source however, the chitinases were not produced and the antifungal activity of *B. pumilus* SG2 was entirely abolished. The results showed that the expression of the chitinases in *B. pumilus* was under the control of two types of regulation: special regulation by chitin and global regulation by glucose. Chitinases were the principal compounds involved in the biocontrol activity of *B. pumilus* SG2 strain (Shali et al. 2010).

The rice blast pathogen *Magnaporthe grisea* was strongly inhibited by *Bacillus subtilis* KB-1122 strain in agar diffusion assays. The suppressive activity of *B. subtilis* was investigated using comparative proteome analysis. The cellular and culture supernatant (CSN) proteins were prepared from the cocultures of the pathogen and the biocontrol agent (BCA) and subjected to two-dimensional PAGE analysis. Proteome analysis revealed the presence of 33 cellular and 18 CSN proteins. The cellular proteins from *M. grisea* were downregulated, whereas upregulated proteins were derived from *B. subtilis*. The results suggested that glyceraldehyde-3-phosphate dehydrogenase and serine protein kinase might contribute to antifungal activity of *B. subtilis* KB-1122. The endo-1,4- β -glucanase involved in the degradation of polysaccharides was identified among the CSN proteins and was upregulated consistently at different times of incubation. This enzyme might play an important role in the interaction between *B. subtilis* KB-1122 with *M. grisea* P131 (Zhang et al. 2014).

The ability of *Achromobacter xylosoxidans* AUM54 strain was evaluated for the suppressive activity against rice blast pathogen *Magnaporthe grisea*. The antagonistic activity of AUM54 strain was revealed by the inhibition of mycelial growth of the pathogen under in vitro conditions. The BCA strain was able to survive in the spermosphere and spermaplane and was able to move systemically through roots and stems. Furthermore, plants treated with *A. xylosoxidans* AUM54 followed by inoculation with *M. grisea* showed a significant increase in the activities of defense-related enzymes such as polyphenoloxidase (PPO), peroxidase (POD), and phenylalanine ammonia lyase (PAL) and chitinase. Treatment of rice plants with *A. xylosoxidans* AUM54 significantly enhanced the growth of the plants (3–10% plant height) and yield (11–13%) of inoculated rice plants under conditions of no disease and disease in the greenhouse (Joe et al. 2012).

Paenibacillus kribbensis PS04 strain was evaluated for its biocontrol activity against the rice sheath blight pathogen *Rhizoctonia solani*. Microscopic observations on hyphal structures revealed that the morphology of the mycelium was strongly affected by *P. kribbensis* PS04 strain. Proteomic approach was applied to understand the inhibitor mechanisms. Using the two-dimensional gel electrophoresis technique, the differentially expressed proteins from *R. solani* GD118 in response to the association with *P. kribbensis* PS04 were identified. Protein profiling was employed to identify 13 differentially expressed proteins. Of these proteins, 10 were found to be downregulated while 3 were upregulated. These proteins were involved in material and energy metabolism, antioxidant activity, protein folding and degradation, and cytoskeleton regulation. Among them, material and energy metabolism was differentially regulated by the BCA. Protein expression was separately inhibited by *P. kribbensis* in oxidation resistance, protein folding and degradation, and cytoskeleton regulation. Assessment of proteome changes in the mycelium facilitated a better understanding of the direct suppression of the fungal pathogen by the bacterial biocontrol agents (Wang et al. 2014).

The antagonistic activity of *Streptomyces philanthi* RM1-138 strain isolated from the rhizosphere soil of pepper (chilli) in Thailand was assessed using the dual culture method against the rice sheath blight pathogen *Rhizoctonia solani* and other rice pathogens. The RM1-138 strain suppressed the mycelial growth of all pathogens tested with inhibition percentages varying over 82–89.2%, the inhibitory effect being most pronounced on *R. solani*. Heat treatments ranging over 40–100°C for 30 min and 121°C for 15 min did not affect the inhibitory effect of the culture filtrate of *S. philanthi* on *R. solani*, indicating the heat stability of the culture filtrate. The effective dose (>80% inhibition) of culture filtrate in liquid culture was at 5.0% (v/v), while it was 10% (v/v) on solid medium. The suppressive effect of the culture filtrate of *S. philanthi* on *R. solani* was similar to those of four fungicides tested. Observations under scanning electron microscope revealed that the metabolites of *S. philanthi* induced alterations in the cell-wall structure of *R. solani*, resulting in the loss of cytoplasmic materials by partial lysis. The greenhouse tests showed that culture filtrate or autoclaved culture filtrate of *S. philanthi* could be applied for effective suppression of development of rice sheath blight disease (Boukaew and Prasertsan 2014).

Resistance to crop diseases may be induced in plants by applying appropriate biotic or abiotic agents alone or in combination. Induced resistance may be broadly differentiated into two types: systemic acquired resistance (SAR) and induced systemic resistance (ISR). The SAR process is initiated in response to pathogen infection or chemical application, whereas colonization of plant roots by nonpathogenic plant growth-promoting

rhizobacteria (PGPR) leads to ISR. The PGPRs are capable of suppressing the disease development in aerial plant parts which are separated from the roots that are treated with BCA by eliciting ISR in several plant species (van Loon et al. 1998; Kloepper et al. 2004). The potential of *Pseudomonas fluorescens* 89B61 to induce ISR in tomato against late blight disease caused by *Phytophthora infestans* was evaluated. This strain elicited systemic protection against the late blight pathogen and reduced disease severity to a level equivalent to the SAR induced by the chemical inducer β -aminobutyric acid (BABA) in greenhouse experiments. Lack of colonization of tomato leaves by the BCA strain suggested that the ISR was due to systemic protection by this PGPR strain and not attributable to a direct interaction between the pathogen and the BCA strain (Yan et al. 2002). Treatment with *Paenibacillus illinoisensis* KJA-424 strain reduced root mortality by about 84% in pepper plants inoculated with *Phytophthora capsici*, incitant of Phytophthora blight disease. In pepper plants inoculated with *P. capsici*, peroxidase (POD) and superoxide dismutase (SOD) were significantly increased by 36.7% and 27.7%, respectively, at 7 days after inoculation. Treatment of pepper plants with KJA-424 strain inoculated with the pathogen resulted in an increase in the activities of POD and SOD at 5 days, but returned to the original level as in noninoculated plants. In addition, catalase activity fluctuated but again increased over a 7 day period. The results indicated that the BCA KJA-424 alleviated root mortality and suppressed the elevated activities of POD and SOD in pepper roots (Jung et al. 2006).

Fluorescent *Pseudomonas* strains (FPs) have been reported to be effective in suppressing the development of plant diseases via different mechanisms. Five isolates of *Pseudomonas fluorescens* applied as sett and soil treatment significantly reduced sugarcane red rot disease caused by *Colletotrichum falcatum* (teleomorph *Glomerella tucumanensis*) by inducing systemic resistance (ISR). The *Pseudomonas*-mediated ISR was significantly expressed at a higher level in the susceptible sugarcane cultivars than in the moderately resistant and moderately susceptible cultivars. Among the five *Pseudomonas* strains evaluated for their biocontrol potential against red rot disease at an endemic location, the strains CHA0, EP1, and Pf1 significantly reduced the red rot disease incidence in sugarcane under field conditions (Viswanathan and Samiyappan 2002). Another bacterial biocontrol agent *Pseudomonas chlororaphis* PA23 strain was shown to have multiple mechanisms of biocontrol activity in suppressing the development of canola stem rot disease caused by *Sclerotinia sclerotiorum*. In addition to its ability to suppress the pathogen development by antibiosis, two applications of the strain PA23 induced resistance against *S. sclerotiorum* in canola. Enhanced accumulation of PR proteins and oxidative enzymes including chitinase and β -1,3-glucanase by PA23 strain in canola leaf tissues might account for reduction in infection by *S. sclerotiorum*. The combination of antibiotic production with induction of ISR by *P. chlororaphis* PA23 strain could act synergistically and restrict the pathogen growth and colonization, resulting in significant suppression of disease incidence and intensity (Fernando et al. 2007b). Black leg disease of canola caused by *Leptosphaeria maculans* (anamorph *Phoma lingam*) was suppressed by *Bacillus cereus* DFE4 strain and *B. amyloliquefaciens* DFE 16 strain by producing the lipopeptide antibiotics iturin A, bacillomycin D, and surfactin, and also by inducing systemic resistance. The direct antifungal activity of antibiotics was considered a more dominant mechanism of black leg disease suppression (Ramarathnam et al. 2011).

Paenibacillus illinoisensis strain KJA24 was evaluated for its biocontrol potential for the suppression of *Phytophthora capsici*, infecting pepper (chilli) plants. The growth

response of pepper plants and kinetics of pathogenesis-related (PR) protein production were determined after challenge inoculation with *P. capsici* and combined inoculation with the pathogen and the biocontrol agent (BCA). Root mortality of plants treated with BCA and inoculated with *P. capsici* was significantly reduced. The activities of β -1,3-glucanase, cellulase, and chitinase were significantly increased in plants inoculated with the pathogen and BCA to greater levels compared with plants inoculated with the pathogen alone. The activities of these defense-related enzymes were negatively correlated with root mortality. The fresh weight of plants treated with *P. illinoisensis* strain KJA24 was increased, indicating that the bacterial BCA strain induced resistance to *P. capsici* in addition to promoting the growth of pepper plants treated with BCA (Jung et al. 2005). *Paenibacillus polymyxa* MB02-1007 strain exhibited antagonistic activity against *Ralstonia solanacearum* infecting several crops including potato and tomato. Most of the strains (14 of 16) did not interact with the pathogen directly by producing any inhibitory compounds in dual cultures. The chitinase activity was enhanced by *P. polymyxa* and chitosan (a known inducer of resistance to pathogens in treated plants) in the presence or absence of the pathogen. *P. polymyxa* increased chitinase activity as a soil drench or seed treatment by 68% and 78%, respectively. Changes in β -1,3-glucanase activity induced by the BCA were less marked compared with those of chitinase activity. The growth of plants treated with the bacterial BCA was substantially increased, in addition to suppression of the development of disease symptoms induced by *R. solanacearum* (Algam et al. 2010).

13.1.4.3 Mechanisms of Action of Mild Strains of Viruses

Different mechanisms of action of viral biocontrol agents have been indicated by various investigations. Cross-protection is the major mechanism by which the viruses protect the plants against virulent/severe strains. Different mechanisms of cross-protective activity of mild strains have been suggested to explain the suppression of severe symptoms induced by severe strains of the wild-type virus. The exhaustion of precursors for virus replication was proposed as a mechanism of action of mild strains of viruses such as *Tobacco mosaic virus* (TMV). In preimmunized plants, the mild strain may utilize all available precursors required for the establishment of the challenge virus, resulting in the failure of development of severe strain to reach titers sufficient to produce the characteristic symptoms of severe strain. Evidence for this suggestion was indicated by the finding that a significant correlation was shown between the decrease in the amount of microsomal RNA and the degree of cross-protection between the two strains of TMV (Hageman 1964). However, all viruses and strains have been reported to replicate in susceptible plants, utilizing the same amino acids and nucleotides available in plant hosts. The unavailability of these basic materials for virus replication being a limiting factor does not seem to be a possible mechanism of action of mild strains.

The virus strain used for preimmunization may occupy the specific site(s) required for its replication, resulting in the exclusion of the severe (challenging) strain from the same site(s) and consequent failure of infection by the severe strain. Requiring different sites for replication, the unrelated viruses may be able to infect the plants already infected by the mild strain used for preimmunization (Bawden 1950). The virus-specific RNA polymerase may be a site for which there may be competition between the protecting strain and challenging strain and the latter may have a competitive disadvantage with the strain already established in plant (Barker and Harrison 1978). The specificity

of ribosome-binding may be altered by the virus-induced polypeptide in favor of the protecting viral RNA. The mRNA of the protecting strain may occupy most of the available ribosomes, creating an unfavorable condition for the development of the challenging strain (Ziemiecki and Wood 1976). The phenomenon of cross-protection is generally observed between closely related viruses or strains, implying the existence of virus nucleotide sequence similarity required for competition. The results of investigation of cross-protection between strains of *Grapevine fan leaf virus* (GFLV) support the hypothesis of competition between virus strains as a mechanism of cross-protection. The rate of GFLV infection was markedly lower in plants initially infected with GFLV-GHu strain (19%) than in those initially infected with ArMV-Ta strain (40–55%) (Komar et al. 2008). The GAC mutant of *Zucchini yellow mosaic virus* (ZYMV) involving amino acid changes conferred complete cross-protection against the wild-type (parent) strain of ZYMV. The squash plants were resistant to ZYMV at 5 days after inoculation with GAC mutant. The definitive reaction was triggered as the mild strain initiated the infection process (within 5 days after protective inoculation). After stimulation of defense systems of the host plant, the defective (mutated) HC-Pro proteins of the GAC strain was unable to arrest the plant's defense responses, resulting in sharp reduction in accumulation of mild strain. Low levels of mild strain could be detected at this stage, indicating the ability of mild strain to survive. The low titer of the mild strain continued to stimulate and maintain the plant defense responses, resulting in a high level of protection against the severe strain of ZYMV. In the initiation stage of cross-protection, the protective action may result from competition for replication factors that are already used by the protective strain. At the maintenance stage, cross-protection is virus-dependent and a low titer of the protective virus is needed to stimulate the plants to continuously synthesize host factors to maintain the protection mechanism at the required level (Lin et al. 2007; Chao et al. 2010).

The phenomenon of cross-protection by mild strain against severe strain of the same virus has been suggested to be due to posttranscriptional gene silencing (PTGS). The protecting strain induces RNA silencing against its own RNA and homologous sequences of the closely related strains, and it may function as an elicitor of a natural antiviral response RNA silencing (Goldbach et al. 2003). Preimmunization of citrus with *Citrus tristeza virus* PB61 strain protected sweet orange seedlings more effectively against orange stem-pitting (OSP) isolate PB235 and OSP isolate PB155, possibly because PB235 had close nucleotide sequence homology to PB61 than to PB155. This hypothesis based on RNA-mediated defense was proposed to account for the cross-protection provided by the mild isolates of CTV. Infection with protective strain triggered the host to produce a ds-RNA-specific nuclease which targeted the viral RNA for degradation to low concentrations. This condition may lead to the formation of small nucleotide fragments such as those detected during PTGS. Other transcripts – homologous or those similar to the silenced gene – may also be degraded if they infect the plant after establishment of PTGS initiated by the CTV mild strain (Zhou et al. 2002). Involvement of posttranscriptional gene silencing as a mechanism for cross-protection of plants by mild strain against the severe strain was also indicated in other host–virus combinations. Posttranscriptional gene silencing was considered to be functionally involved in the cross-protection of gladiolus by the attenuated isolate of M11 of *Bean yellow mosaic virus* (BYMV) against the parent strain (Xu et al. 2006). Infection of plants by a mutant strain of *Cucumber mosaic virus* (CMV) resulted in the generation of a strong systemic silencing signal directed against CMV-specific RNA

sequences. It is more likely that protection occurred through either induction of very highly localized RNA silencing or by competition between strains for host cells or resources (Ziebell et al. 2007).

13.1.5 Improvement of Biological Control Potential of Biotic Agents

The efficacy of various biotic agents in suppressing the development of phytopathogens has been assessed by different methods under in vitro, greenhouse, and field conditions. The genetic potential of biological control agents (BCAs) may be expected to be important in its antagonistic activity against the plant pathogens. The genetic diversity of a BCA has to be determined by subjecting all available isolates to analyses by different molecular techniques such as RAPD, DNA fingerprinting, and PCR-based assays. If genes controlling the biosynthesis of antimicrobial compounds or enzymes can be identified, such information may facilitate the development of methods to enhance the biocontrol potential of the microorganism(s) selected as the most efficient for genetic manipulation. Attempts have therefore been made to improve the biocontrol potential of the microorganisms through various biotechnological methods. Some of the approaches examined to enhance the efficacy of biotic agents in suppressing the development of plant pathogen(s) include: genome analysis; identification of genes controlling the production of metabolites with antifungal and antibacterial activity; characterization of gene products; induction of mutation, detection, or transfer of gene(s); increasing the copy number of basic gene(s); and protoplast fusion. Widespread application of biotic biocontrol agents for the management of crop diseases has not been possible because of variable levels of control provided by them and commercial conditions that are to be satisfied, as in the case of chemicals that are recommended for different crop diseases. Enhancement of biocontrol potential of the biotic agents is therefore essential if they are to be acceptable as alternative products to chemicals. Information on the genes controlling the biosynthesis of antimicrobial compounds or enzymes may facilitate the choice of suitable methods to enhance the biocontrol potential of microorganism(s) selected for genetic manipulation. Genetic modification through biotechnological methods has been attempted to improve the performance of the most effective naturally occurring strains of biocontrol agents.

Superoxide dismutases (SODs) are considered as the important line of antioxidant enzyme defense systems by removing the superoxide anion, since the superoxide anion initiates a radical chain reaction that results in other reactive oxygen species (ROS) provoking damage to DNA, proteins, and membrane lipids (Krutika and Subramanian 2007). In order to increase the tolerance levels to temperature and salt concentration, *Trichoderma harzianum* was transformed with the SOD gene via *Agrobacterium tumefaciens* (At) transformation technique with an efficiency of 60–110 transformants per 10^7 spores. The successful transfer of SOD gene consisting of 751 bp sequence of nucleotides in transformants was confirmed by Southern blotting. No adverse effect on the growth of transformants was observed, while the biocontrol activity of the transformants was not altered. The genetically modified *T. harzianum* strain by SOD recombinant technology exhibited greater tolerance to salt and heat, facilitating its survival in adverse environments where it had to act on the pathogen *Sclerotinia sclerotiorum*. Antifungal activities of the transformants were assessed under abiotic stresses. The transformants exposed to 40°C for 3 days and 2 mol L⁻¹ NaCl at 27°C for 5–10 days

were tested for their antifungal activity. The inhibition rates of transformants compared with the wild-type strain were 83.96 and 60.13, respectively, after exposure to 40°C and 2 mol L⁻¹ NaCl, indicating the higher levels of tolerance of the transformants to heat and salt stress (Yang et al. 2010).

Biocontrol agents may be applied alone or in combination with fungicides to enhance the effectiveness of crop disease control. It is therefore essential that BCAs are tolerant to the fungicides to enable them to provide additive effects to reduce disease incidence and/or severity. UV mutagenesis and protoplast fusion techniques were combined for the production of fungicide-resistant strains of the cold-tolerant strains of *Trichoderma harzianum* and *T. atroviride*. The methyl-1-(butylcarbonyl) benzimidazole-2-yl carbamate (MBC-) resistant mutants of both species of *Trichoderma* showed total cross-resistance to benomyl and thiabendazole fungicides, whereas the wild parent strains could not develop in the presence of 20 µg mL⁻¹ of the fungicides. The possible mechanism of development of MBC resistance in UV-induced mutants could be a nucleotide substitution in the *tub2* β-tubulin gene. Interspecific protoplast fusion was carried out between carbendazim- and tebuconazole-resistant mutants of both parental strains. Putative haploid recombinants with stable resistance to both fungicides were produced in the case of *T. atroviride*. The fungicide polyresistant fusants exhibited a satisfactory level of antagonism against *Fusarium culmorum* and *Microdochium nivale*, causal agents of wheat Fusarium head blight disease complex and also other fungal pathogens *Pythium debaryanum* and *Fusarium oxysporum*. The results indicated that the combination of UV mutagenesis and protoplast fusion techniques could be used as tools for improving multiple-fungicide resistance in *Trichoderma* strains with desired levels of biocontrol potential against economically important plant pathogens (Hatvani et al. 2006).

Acidovorax citrulli, causal agent of cucurbit bacterial fruit blotch (BFB), is seedborne and affects the fruit production substantially in many countries. A *A. citrulli* nonpathogenic strain with type III secretion system AACOO-1ΔhrcC was generated. This mutant was nonpathogenic to watermelon, but retained its ability to colonize germinating watermelon seed. Treatment of watermelon seed naturally infested with *A. citrulli* with its mutant reduced the seed-to-seedling transmission of BFB pathogen by 81.8% compared to control seeds. Another *A. citrulli* antagonist *A. avenae* strain AAA99-2 was able to reduce BFB seedling transmission by 74.6% in seed samples from the same lot. In addition, when the female watermelon blossoms were protected with AACOO-1/ΔhrcC and subsequently challenged with AACOO-1, the resulting seed lots displayed only 8% BFB seedling transmission. This reduction was not significantly different from seeds from blossoms protected with AAA99-2 (4%), but significantly less than those from blossoms treated with 0.1 M phosphate-buffered saline (36%). The results suggested that the nonpathogenic *A. citrulli* showing a higher level of biocontrol potential might be a potential candidate for seed treatment in a comprehensive BFB management program (Johnson et al. 2011).

13.1.6 Transformation Crop Plants with Genes of Biological Control Agents

Different *Trichoderma* species have been shown to suppress many plant pathogens effectively by producing antibiotics and enzymes such as chitinases, proteases and glucanases that directly affect the mycelial growth of fungal pathogens. Various strains of *T. harzianum* produced endochitinases CHIT-31, CHIT-33, CHIT-37, CHIT-42, and CHIT-52 which differed in their molecular weights and structure

(Markovich and Konova 2003). Transgenic plants overexpressing endochitinase (CHIT) from *T. harzianum* were found to be tolerant to fungal diseases. The effect of expression of CHIT-36 in carrot plant (*Daucus carota*) tissues was investigated. Transgenic carrot plants constitutively expressing CHIT-36 endochitinase were generated. A plasmid containing *chit36* gene under the control of CaMV 35S promoter and the *nptII* selection gene was introduced into polyethylene glycol (PEG-) treated carrot protoplasts. All transformed plants contained the transgenes, as revealed by PCR assay with *nptII*- and *chit36*-specific fragments, respectively. In vitro assays using detached leaves and petioles of transformed carrot plants showed less severe symptoms of infection by *Alternaria dauci*, *A. radicina*, and *Botrytis cinerea*. The resistance response depended on the transgenic clone. However, all clones had significantly enhanced tolerance to *A. radicina* and *B. cinerea* on an average of 50%. Progress of disease induced by *A. dauci* was slower only in two transgenic lines, whereas other clones showed enhanced level of susceptibility to *A. dauci*. The results indicated that the levels of resistance of carrot to *A. radicina* and *B. cinerea* might be improved by transformation of carrot clones with chitinase gene(s) of biocontrol agent *T. harzianum* (Baranski et al. 2008).

13.2 Evaluation of Abiotic Agents for Biological Control Potential

The abiotic agents of plant and animal origin, which are naturally derived products, have been evaluated for their effectiveness in suppressing the development of diseases caused by microbial plant pathogens infecting various crops cultivated in different agroecosystems. The seeds or propagules may be infected by soilborne and airborne pathogens, in addition to the pathogens carried in and/or on the seeds and propagules. It is essential to understand the complex conditions existing in the soil. The host plants interact with the microbial pathogens which adversely affect plant growth, whereas other microorganisms associated with rhizosphere may be either beneficial for plant growth directly, or antagonistic to soilborne pathogens and indirectly reduce the adverse effects of plant pathogens, providing conditions for better yields. The soils that suppress pathogen development and consequent failure of disease incidence are known as suppressive soils. In contrast, soils that favor disease development are termed conducive soils, resulting in reduction of yield of grains and other products. Soil suppression is a property primarily conferred by the soil microbial community (Narayanasamy 2013).

13.2.1 Effects of Addition of Organic Matter

The application of organic matter to the soil improves crop yield mainly by enhancing soil fertility rather than through provision of nutrients to the plants. In addition, many microorganisms antagonistic to plant pathogens are activated following addition of organic matter to the soil, leading to suppression of disease development. Organic matter incorporated into the soil is called amendment, whereas organic matter placed or spread on the soil surface is known as mulch. Organic amendments added to the soil promote biological destruction of pathogen inoculum through germination-lysis

mechanism and intensification of microbiological activity, resulting in the decay of pathogen propagules. The potential of organic amendments to suppress *Ralstonia solanacearum* race 3 biovar 2, causing potato brown rot disease of tubers, was assessed in Dutch sandy and clay soils as well as in sandy soils of Egypt. Organic amendments significantly increased disease incidence and pathogen survival in Dutch sandy and clay soils, which correlated with high organic carbon in the organic Dutch soils. Cow manure amendment significantly reduced disease incidence in organic Dutch sandy soils, but did not affect the bacterial populations. However, cow manure reduced bacterial population densities in Egyptian sandy soils, most probably due to microbial competition. A clear shift in population was detected by denaturing gradient gel electrophoresis (DGGE) technique in Dutch sandy soils after application of cow manure. Suppressiveness of soil towards *R. solanacearum* might be related to soil characteristics and microbial communities which exhibit variations depending on the soil type and organic matter content. Disease suppression was lost following treatment of the soil with methyl bromide fumigation or heat, indicating that a biological principle could be the main factor in enhancing soil suppressiveness towards soilborne pathogens such as *R. solanacearum* (Messiha et al. 2007a, b).

Effective alternate management practices have to be developed for soilborne potato diseases transmitted through seed tubers, since they remain persistent problems. Compost amendments, along with two biocontrol agents (BCAs) *Bacillus subtilis* and *Rhizoctonia solani* hypovirulent isolate (Rhs1A1), were evaluated alone or in combination for their efficacy in reducing soilborne diseases and increasing the tuber yield over three seasons. Both BCAs reduced multiple soilborne diseases, namely stem and stolon canker by 20–30%, black scurf by 30–58%, and common scab by 10–34%, compared to the untreated controls. The combined treatment of *B. subtilis* and *R. solani* hypovirulent isolate provided nominally better control than individual treatments. However, these treatments did not have any effect on tuber yield. On the other hand, all compost amendments from different sources increased total and marketable tuber yield substantially (11–37% and 17–51%, respectively) relative to the controls. Compost treatments did not reduce incidence of black scurf and common scab diseases, but some reduction in *Rhizoctonia* canker was observed. The combination of compost-BCA treatments did not provide significantly better effect than individual treatments, but combined beneficial effects from both components were indicated in this investigation (Larkin and Tvantzis 2013).

The effects of compost amendment and grafting bell pepper onto resistant or partially resistant rootstocks on the incidence of *Phytophthora* blight disease caused by *Phytophthora capsici* were assessed under artificially or naturally infested soil using five sweet pepper cultivars – Fenice, Sienor Marco, Fiume, Kaiman, and Cuneo – as non-grafted controls. Disease incidence in the control plots ranged over 73–100%. The cultivars Cuneo and Kaiman grafted onto Tecnico F1 rootstock provided complete suppression of the disease development. By grafting all susceptible cultivars onto Robusto, Brutus, Snooker, and Capsifort, disease incidence was reduced by 68–93%, 86–100%, 67–100%, and 55–78%, respectively. Under natural infestation conditions, the addition of compost to the soil and the interaction of compost-amended soil with grafting were significant factors contributing to the reduction of disease incidence. The effect of grafting was significant in reducing the percentage of diseased plants in all trials. The addition of compost to the soil was an effective and low-cost disease management option, particularly when combined with susceptible not-grafted hybrids of bell pepper or when partially resistant rootstocks were cultivated (Gilardi et al. 2013).

Cultivation and incorporation of specific green (manure) crops into the soil as a means to manage specific biologically active resident soil microbial communities has been evaluated for the control of soilborne plant pathogens that are capable of infecting seeds/propagules when planted later. The effects of green manure crops buckwheat and canola and crop sequences on potato scab caused by *Streptomyces scabies* and Verticillium wilt induced by *Verticillium dahliae* were assessed in field trials conducted for 2 years. Densities of indigenous streptomycetes and in vitro pathogen inhibitory activities were also determined. Tubers grown in buckwheat-treated soil had significantly lower Verticillium wilt ratings, while tuber yield was increased significantly. Potatoes grown in soils planted with corn or alfalfa in the previous year had significantly lower Verticillium wilt incidence and potato scab ratings, as well as higher yields than in soil previously planted to potato. *Streptomyces* from soils collected from green manure (GM-) treated plots tended to have greater in vitro pathogen inhibitory activity on *Streptomyces* than those from the soils from fallow-treated plots. In addition, pathogen inhibitory activity of *Streptomyces* was often negatively correlated with plant disease incidence and positively correlated with potato yield. The streptomycete communities in GM-treated soils were consistently in greater proportions of pathogen antagonists than in communities in fallow-treated plots in the second season of experimentation. The GM crops may selectively favor the abundance or activity of antibiotic producers within the soil microbial community (Wiggins and Kinkel 2005).

The relative increase in inhibitory activity of the streptomycetes community was frequently associated with a decrease in disease development and an increase in potato yields. The effect of application of cultivars Jubilee Sweet corn and Jubilee Super sweet corn as green manure was investigated for suppressing the development of Verticillium wilt disease of potato induced by *Verticillium dahliae*. The sweet corn cultivars reduced the disease incidence by 60–70%. These treatments did not reduce the pathogen populations directly, but the colonization of potato feeder roots and in potato tissues of stem pieces by *Verticillium dahliae* was reduced. Feeder-root colonization was positively correlated with Verticillium wilt incidence ($P \leq 0.05$) and negatively correlated with yield. In addition, corn green manures increased populations of several fungi such as *Ulocladium* and *Fusarium equiseti*. When potato was grown consecutively for 2 years, the beneficial effects of sweet corn green manure was entirely lost; however, following 2 consecutive years of potato, a single sweet corn crop was enough to restore the original benefit and enhancement of tuber yield by four-fold. The results clearly showed the increases in potato tuber yields could be sustained by incorporating the sweet corn plant materials as green manures into the soil (Davis et al. 2010).

Disease suppressive potential of composts to suppress the development of onion black mold caused by *Aspergillus niger* was assessed by testing the leachates prepared from alfalfa and sunflower stalks. The onion seeds were treated with the leachates of composts at 10 and 20% concentration, and their ability to induce production of antifungal compounds and to suppress the black mold disease incidence was determined. The leachates reduced the disease incidence in sets, but not disease severity in onion seedlings. The antifungal activities of the fractions of the leachates, obtained using thin-layer chromatography, did not differ. The presence of fluorescent pseudomonads and *Pantoea agglomerans* was detected in the leachates of alfalfa and sunflower stalk composts. The sunflower compost leachate had higher populations of *P. agglomerans* compared to alfalfa compost leachate. Both leachates inhibited mycelial growth of the

pathogen in agar tests, indicating that the bacterial BCAs might have a role in the induction of antifungal compounds effective against onion black mold disease (Özer and Köycii 2006).

Compost amendments incorporated into soil or planting mixes have been reported to provide protection not only to soilborne plant pathogens but also to airborne plant pathogens infecting aerial plant organs, such as foliage and inflorescence/seeds. The efficacy of composted cannery wastes and yard wastes in suppressing bacterial spot disease caused by *Xanthomonas vesicatoria* and *X. axonopodis* pv. *vesicatoria* was determined. The disease incidence was reduced by composted yard wastes when disease pressure was high in the conventional tomato production system. Marketable yield was increased by 33% in compost-amended organic plots, whereas no increase in marketable yield could be realized in compost-amended conventional plots (Abbasi et al. 2002). The effectiveness of tomato or pepper residue composts combined with cattle or chicken manure to suppress bacterial canker of tomato caused by *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*) was assessed. Application of composts reduced the disease incidence by 70–100% under natural infection of mature plants and artificial inoculated conditions. Populations of *Cmm* in composts declined to undetectable levels within 15–20 days, while those in peat remained high for 35–40 days. Likewise, colonization of compost-grown tomato plant tissues by the pathogens was reduced to 0–20% compared to plants growing on peat or perlite which showed 53–90% colonization. The results indicated that application of compost could be an effective component of integrated management system for bacterial canker disease affecting tomato (Yogev et al. 2009).

13.2.2 Effects of Products from Plant Sources

Plant tissues contain secondary metabolites such as essential oils, and extracts of various plant tissues have been shown to have antifungal, antibacterial, and antiviral properties. Various nonhosts of plant pathogens have therefore been screened for the presence of antimicrobial compounds that may be useful for the management of crop diseases. The leaf extracts of *Arbus precatorius* alone or in combination with *Pseudomonas fluorescens* Md1 were evaluated for their ability to suppress the development of *Colletotrichum falcatum*, incitant of sugarcane red rot disease. The plant extracts and the bacterial BCA were used to treat the sugarcane setts (planting material) planted in pots under greenhouse conditions. Red rot incidence was reduced to 24.2% and 20% in setts treated with plant extract and bacterial BCA, respectively. Treatment with plant extract was not effective in reducing red rot infection under field conditions. However, the combination of plant extract and *P. fluorescens* applied as foliar spray or soil drench reduced the incidence of red rot disease to the minimum level (3%). The results indicated the effectiveness of the combined application of *A. precatorius* extract and *P. fluorescens* Md1 for the suppression of red rot disease in sugarcane (Jayakumar et al. 2007).

The biocontrol potential of dravya, a commercially produced aqueous plant extract, was assessed for suppression of cotton bacterial blight caused by *Xanthomonas campestris* pv. *malvacearum*. Seed soaking in dravya (1:500) followed by foliar spray three times at intervals of 10 days commencing from 20 days after sowing (das) reduced the bacterial blight disease incidence by 66%, 70%, and 74% as determined at 40, 60, and 80 das, respectively. The mechanism of action of dravya appeared to be through

induction of resistance in cotton plants against cotton bacterial blight disease. The results indicated that the plant extract had potential for use as an ecofriendly component of the integrated management system for cotton bacterial blight disease (Raghavendra et al. 2007).

The inhibitory effect of Chinese leek (*Allium tuberosum*) on banana Fusarium wilt pathogen *Fusarium oxysporum* f.sp. *cubense* (*Foc*) was determined. Treatment of soil in pots with Chinese leek extract reduced disease incidence and disease severity index by 58% and 63%, respectively, in the banana cultivar Baxi (AAA) and by 79% and 81%, respectively, in the cultivar Gungfen No. 1 (AAB) under greenhouse conditions. In the plate assays crude extracts of Chinese leek entirely suppressed the mycelial growth of *Foc* race 4, inhibiting the proliferation of spores by 91%, and caused 87% mortality of conidia. Adopting a rotational crop system including Chinese leek reduced the Fusarium wilt disease incidence and severity index by 88–97% and 91–96%, respectively, under field conditions. In addition, inclusion of Chinese leek as a rotational crop improved the crop value by 36–86% in areas heavily infested with *Foc* during 2007–2009. The results revealed the potential of Chinese leek in suppressing the development of banana Fusarium wilt disease and also improving the quality of banana fruits (Huang et al. 2012).

Products extracted from plants have been evaluated for their inhibitory activity against plant pathogens. Volatile antimicrobial compound allicin (diallyl-thiosulfinate) present in garlic juice inhibited the germination of sporangia, encysted zoospores, and subsequent germ tube elongation in *Phytophthora infestans*, causative agent of late blight disease, both in vitro and in vivo on tomato leaf surface. Disease severity in infected seedlings was reduced by spraying garlic juice containing allicin ($55\text{--}110\mu\text{g mL}^{-1}$) with an effectiveness of c. 45–100% mortality (Portz et al. 2008). The inhibitory activity of garlic juice was also assessed against other plant pathogens. Allicin effectively suppressed the development of seedborne pathogens *Alternaria* spp. infecting carrot, *Phytophthora infestans* causing late blight in tomato and tuber blight in potato, and *Magnaporthe grisea* infecting rice. Reduction in diseases was apparently due to the direct action of allicin on these pathogens (Slusarenko et al. 2008). The inhibitory effects of the root exudates of two garlic cultivars Gailiang (G064) and Gangshan (G025) on *Phytophthora capsici*, infecting pepper, were investigated. Different concentrations of root exudates (25–100%) of cultivar G025 showed lower inhibitory effect than that of cultivar G064. At 100% concentration of root exudates, G064 and G025 showed inhibition of mycelial growth by 69.24% and 49.06%, respectively. High-performance liquid-chromatography (HPLC) analysis showed that the root exudates from G064 contained greater amounts of allicin than that present in root exudates of cultivar G025. The pathogen hyphae treated with root exudates of G064 were mishappened, fragmented, and had a smaller diameter as well as empty cytoplasmic contents in the cell wall, as revealed by scanning electron microscope. These adverse effects were not observed in the control and G025 treatments. The results indicated that the root exudates of cultivar G064 had significant fungicidal effect on *P. capsici* (Azam Khan et al. 2011).

Essential oils, a group of plant-derived compounds, contain a mixture of different terpenoid compounds and their oxygenated derivatives. These oils have a wide spectrum of antifungal activity against plant pathogens. The essential oils (EOs) oregano, thyme, dictamnus, marjoram, lavender, rosemary, sage, and pennyroyal were evaluated for their inhibitory activity against *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*) using plate assays. The multiplication of *Cmm* was entirely inhibited by oregano, thyme, dictamnus, and marjoram essential oils at relatively low concentrations ($85\text{--}300\mu\text{g mL}^{-1}$).

Thymol was the main component of oregano oil, while thyme, dictamnus, and marjoram oils were rich in carvacrol (Daferera et al. 2003). Five essential oils extracted from *Cymbopogon citratus*, *Monodora myristica*, *Ocimum gratissimum*, *Thymus vulgaris*, and *Zingiber officinale* were evaluated for the comparative inhibitory effect on five seedborne bacteria, namely *Acidovorax avenae* subsp. *avenae*, *Burkholderia glumae*, *B. plantarii*, *Xanthomonas oryzae* pv. *oryzae*, and *X. oryzae* pv. *oryzicola*. The essential oils (EOs) at 1:1 dilutions showed different degrees of inhibition of the bacterial pathogens, as deduced from inhibition zones using agar diffusion method. Among the EOs tested, *O. gratissimum* and *T. vulgaris* oils were more effective with mean inhibition zones of 14 mm and 10 mm in diameter, respectively, against all five bacterial pathogens tested. The EOs from *O. gratissimum* and *T. vulgaris* were evaluated for their ability to reduce the seed transmission of *A. avenae* subsp. *avenae* (Aaa) and seed infection of *X. oryzae* in naturally infected seeds by the cassette holder method and liquid assay, respectively. EO applied as a slurry significantly reduced the seed transmission of Aaa by 60–80% and from seeds with infection by 32% on three rice cultivars. The vigor of rice seedlings growing from treated seeds was significantly enhanced. Treatment with EOs reduced the total cell counts of bacteria (92–97%), while the percentages of germination of treated seeds were increased by 13–23% (Nguefack et al. 2005).

The effectiveness of essential oils, organic acids, extracts of stinging nettle and golden rod, Biosept (grapefruit extract), and Tillecur to suppress the development of seedborne pathogens was assessed. Thyme oil, oregano oil, cinnamon oil, clove oil, and Biosept inhibited the development of *Xanthomonas campestris* pv. *campestris*, *Clavibacter michiganensis* subsp. *michiganensis*, *Alternaria dauci*, and *Botrytis aclada* to the maximum extent. The fungal pathogens were inhibited to a lesser degree by organic acids compared to bacterial pathogens. Treatment of cabbage seeds for 30 min with selected essential oils or Biosept at 0.1–1.0% eliminated >99% of the total bacterial populations associated with cabbage seed. They also reduced the percentage of seeds contaminated with fungi from 70% to less than 10%, as indicated by blotter tests. Cinnamon oil and Biosept at >1% affected seed germination. Organic acids exhibited variable antimicrobial effects, but the organic acids ascorbic acid, propionic acid, acetic acid, and lactic acid at concentrations of 2.5% or higher generally reduced the seed-associated bacteria. Among the organic acids, only propionic acid reduced seed germination at concentrations >1.0%. Thyme oil was the most effective natural compound, showing potential for the suppression of seedborne pathogens tested (van der Wolf et al. 2008). Hydrodistilled essential oils and n-hexane extracts from *Origanum acutidens*, *O. rotundifolium*, and *O. vulgare* were analyzed by GC and GC-MS techniques to determine their chemical composition. Essential oils and hexane, chloroform, acetone, and methanol extracts were evaluated for their antibacterial activity against 25 phytopathogenic bacterial strains. The wide spectrum antibacterial activity of essential oils was due to the phenolic compounds such as carvacrol and thymol. The compounds carvacrol and thymol possessed higher antibacterial activity. The results suggested that the essential oils might be valuable antibacterial agents that could be used as seed disinfectant (Dadasoglu et al. 2011).

The inhibitory effects of clarified neem oil (CNO) in 0.1% Triton on aflatoxigenic *Aspergillus* spp. were determined using submerged cultures containing either 0.5 mL or 0.1 mL of CNO. Fungal growth and aflatoxin B1 production were determined in an atmosphere of volatiles emitted from 0.25–1.0 mL CNO added to the plates. The radial growth of *Aspergillus* sp. was reduced by 7–29% and aflatoxin B1 production by 0–67%. GC/MS assessments of the head space volatiles of the CNO indicated that the reduction

in pathogen growth and aflatoxin B1 was probably due to low-molecular-weight hydrocarbons, aldehydes, alcohols, and sulfur compounds emitted at 30% in dry culture (Zeringue et al. 2001). Plant-derived gum biopolymers containing plant growth-regulating hormones have been evaluated for their effect on the development of plant diseases. The effect of application of xanthan gum on the development of *Bipolaris sorokiniana* infecting barley was assessed. Barley plants of cultivars 127, 128, and 129 were treated with xanthan gum and the plants were challenged with the pathogen at different periods after treatment. The treated plants exhibited an increase in the levels of proteins, as well as in the activity of β -1,3-glucanase when compared with the extract from healthy plants. The most important macromolecules in the defense-related functions were demonstrated to be pathogenesis-related (PR-) proteins which accumulated following accumulation of the resistance inducer (Castro and Bach 2004).

Gum biopolymers containing plant growth-regulating hormones with priming potential without any side effects were evaluated for their inhibitor activity against pearl millet downy mildew pathogen, *Sclerospora graminicola*. The gum exudates of *Acacia arabica*, *Moringa oleifera*, *Carica papaya*, and *Azadirachta indica* were evaluated for their synergistic effect. Seed priming with exuded gum biopolymer combined with metalaxyl (Apron 35 SD) fungicide was performed to determine their effect on pearl millet seed quality, growth parameters, and resistance to *S. graminicola*. Seeds of cultivar 7042S were primed with gum biopolymers and metalaxyl 35SD. Seed germination and vigor were synergistically enhanced using gum biopolymers solution (1:2 w/v) with 3 g kg^{-1} metalaxyl 35SD. *A. arabica* and *A. indica* gum polymers alone or with fungicide resulted in seed germination of >91%. Seed priming with fungicide (6 g kg^{-1}) gave 89% seed germination and was not significantly different from control. A similar trend in vigor was recorded among all treatments. Seed priming with gum biopolymers alone provided different levels of disease protection when compared with control. Treatment with the combination of *A. arabica* or *A. indica* gum and metalaxyl at 3 g kg^{-1} was superior in protecting pear millet plants against the downy mildew disease with 86% reduction in disease incidence and better growth of plants (Sudisha et al. 2009).

Durum wheat bran contained various monomeric forms of phenolic acids of which ferulic acid was found to be the most abundant. The effect of natural phenolic acids from wheat bran on the biosynthesis of the mycotoxin type B trichothecene by *Fusarium culmorum* was assessed in vitro. When the liquid cultures of *F. culmorum* were supplemented with a natural wheat bran extract, the production of trichothecene was completely inhibited. The phenolic acid treatment resulted in a drastic reduction in the expression level of structural trichothecene biosynthetic genes. The inhibitory efficiency of the natural phenolic acids extract was significantly higher than that of a reconstituted mixture containing similar concentrations of monomeric forms. To elucidate the full repression of type B trichothecene production induced by natural phenolic acid from wheat bran, two possibilities were therefore suggested: (i) a synergistic impact of monomeric and dimeric forms of phenolic acids; and (ii) involvement of an unidentified oligomeric form able to efficiently repress toxin yield. The most abundant dimer of ferulic acid, the 8-5'-benzofuran dimer, was synthesized and inhibited the trichothecene biosynthesis to the same extent as the monomer of ferulic acid (Boutigny et al. 2010).

Microdochium majus, incitant of snow mold, seedling blight, and foot rot of small grain crops, causes severe losses in yield and quality. As options for the control of plant diseases in organic cultivation system are limited, aqueous extracts of botanical powders prepared from chamomile, meadow sweet, thyme, and Chinese galls were evaluated for

their inhibitory effects on conidial germination and mycelial growth of *M. majus*. Based on the in vitro results, three botanicals were tested under controlled environmental conditions by applying them as powders with different seed coating adhesives. Seed treatments with warm water, a bacterial product, or a botanical were evaluated under field conditions for 3 consecutive years. The Chinese galls treatment was the most effective in suppressing conidial germination and mycelial growth by 97% and 100%, respectively, and the treatment reduced the disease incidence from infested seeds by 59%. Grain yield was increased by treatment with Chinese galls, the bacterial product, and warm water to the extent of 19, 10, and 10%, respectively, compared to the control plots. The results indicated that Chinese galls might be useful for application to organic crops against infection by *M. majus* (Vogelgsang et al. 2013).

13.2.3 Effects of Products from Animal Sources

Chitosan is the most commonly tested product of animal origin for its efficacy in suppressing the development of pathogens infecting various crops. Chitosan, a deacetylated form of chitin, is a natural biodegradable fiber (polymer) derived from crustacean shells such as crabs and shrimps. Chitosan has antifungal properties, leading to direct suppression of the development of fungal pathogens. In addition, chitosan has been shown to induce resistance to pathogens by stimulating defense mechanisms naturally operating in plants. Defense responses have been shown to be triggered following activation of signaling pathways involving salicylic acid (SA) and jasmonic acid (JA) in most compatible plant-host-parasite interactions. The effects of SA and methyljasmonate (MeJA) applied to *Tilletia laevi*-inoculated wheat (*Triticum aestivum*) seedlings at 1, 2, or 3 weeks following emergence on infection were assessed. Further, transcript levels of defense-related genes were determined. Application of SA or MeJA coordinately activated transcripts of different groups of defense-related proteins and reduced common bunt infection. Three patterns of defense gene expression following SA and MeJA treatments were differentiated. Transcripts of Chi1, Chi3, Chi4, PR-1, PR-1.2, Glu1, and a lipase that were upregulated in response to MeJA treatment, their expression potentiated by infection by *T. laevis*, and the highest transcript levels were associated with the 3 week seedling stage. Transcripts of Glu2 responded almost exclusively to SA were not potentiated by infection, and the highest expression was observed at the 3 week seedling stage. Transcripts of ns-LTP-1, ns-LTP-2, and Glu3 were upregulated in response to both SA and MeJA, not potentiated by infection, and the highest transcript levels were observed at the 1 week seedling stage (Lu et al. 2006).

The antibacterial properties of two kinds of chitosan with different molecular weights and degrees of *N*-acetylation were evaluated for the antibacterial activities against rice bacterial pathogens *Xanthomonas oryzae* pv. *oryzae* (Xoo) and *X. oryzae* pv. *oryzicola*, causing bacterial leaf blight and leaf streak diseases. Both kinds of chitosan solutions showed strong antibacterial activity against both rice bacterial pathogens and significantly reduced disease incidence and severity when compared with control under greenhouse conditions. However, the interaction between chitosan and rice pathogens was influenced by the type and concentration of chitosan, the bacterial species, and the contact time between chitosan and bacteria. The direct antibacterial activity of chitosan may be attributed to both membrane lysis and destruction of biofilm. In addition, both chitosan solutions significantly increased the activities of phenylalanine ammonia lyase (PAL), peroxidase, and polyphenol oxidase in rice seedlings following inoculation of

two bacterial pathogens compared with control. Chitosan protected the rice plants against rice bacterial pathogens causing leaf blight and streak diseases through direct antibacterial activity and indirectly by induced resistance (Li et al. 2013).

The ability of chitosan as seed treatment to induce resistance in durum wheat (*Triticum durum*) against seedborne fungal pathogen *Fusarium graminearum*, one of the main causal agents of root and foot rot in wheat, was assessed. The efficacy of seed treatment with chitosan was evaluated by biochemical analyses including the following treatments: seed treated; seed treated and inoculated with pathogen; seed not treated and inoculated; and seeds not treated and not inoculated. The enzymatic activities of some enzymes involved in defense mechanisms were analyzed. Seed treatment induced changes in the activities of guaiacol peroxidase (POD), ascorbate peroxidase (APX), polyphenol oxidase (PPO), and phenylalanine ammonia lyase (PAL) and increased the phenol contents. Disease incidence on plants was significantly reduced by chitosan treatment under greenhouse conditions. Under field conditions, seed treatment with chitosan reduced the disease severity and enhanced quantitative yield parameters, indicating the effectiveness of chitosan seed treatment as effective disease management strategy by improving plant defense responses to the disease caused by *F. graminearum* (Orzali et al. 2014).

Oligochitosan is prepared by hydrolysis or degradation of chitosan. It is water soluble and more effective than chitosan in eliciting multiple plant defense responses, such as H_2O_2 production and stimulation of defense-related enzymes. *Phytophthora capsici* with no chitin in its cell wall was highly sensitive to oligochitosan with EC_{50} and MIC values of 100 and $580 \mu g mL^{-1}$, respectively. Oligochitosan at low concentrations inhibited pathogen development at different stages in the life cycle of *P. capsici*, including zoosporangia production, zoospore release, cystospore germination, and induction of rupture of released zoospores. The addition of ATP did not reduce inhibition of zoospore release and zoospore rupture by oligochitosan. Treatment with oligochitosan induced leakage of electrolytes from the mycelium of *P. capsici*, indicating that oligochitosan might also act on the cell membrane by upsetting osmotic pressure as for chitosan. Transmission electron microscopic observations showed slight distortion of some hyphal cell walls of *P. capsici* in the presence of oligochitosan ($10 \mu g mL^{-1}$). The most pronounced structural alteration of the hyphae treated with oligochitosan ($10 \mu g mL^{-1}$) was found to be disruption of endomembrane system, especially vacuole and secretory vesicles such as plasmalemmasomes in hyphal tips. The polycationic nature of oligochitosan might contribute to the antifungal and multiple modes of action, including induction of disease resistance in treated plants (Xu et al. 2007).

The effectiveness of chitosan in suppressing the development of potato common scab disease caused by *Streptomyces scabies* was assessed when applied alone or in combination with *Streptomyces melanosporofaciens* strain EF76, producing geldanamycin. The combined application of chitosan and strain EF76 was the most effective treatment in reducing common scab incidence under greenhouse conditions, but field application of EF76 strain did not allow the selection of geldanamycin-resistant actinomycetes (GRA) in the bulk soil during the potato-growing season. However, the number of GRA on harvested potato tubers was significantly increased in treatments containing chitosan than in other treatments, suggesting that chitosan might promote the establishment of the antagonistic actinomycetes on progeny tubers. The results showed that combined application of chitosan and EF76 might suppress the development of potato common scab disease by direct effect on the pathogen and indirectly by inducing resistance in potato plants (Prévost et al. 2006).

A naturally occurring spontaneous recovery of plants infected by phytoplasmas is a known phenomenon. Hence, a strategy to facilitate recovery of plants from severe phase by stimulating the plant defense systems was evaluated for potential application for the management of grapevine Bois noir (BN) disease. Five commercial products consisting of chitosan (ChitoPlant, ChitPro), Phosetyl-Al (Aliette), two different mixtures of glutathione (Kenal and Valagro), and oligosaccharines (Olvis) and BTH (Bion) were evaluated for their efficacy by applying aqueous solutions on the canopy on BN-infected grapevine plants. Of the 744 plants treated, 214 were PCR-positive for the presence of BN and showed typical symptoms of BN. In 2007, all treatments increased the percentage of recovered plants in comparison to the control. Bion, Olvis, Kendal, and Aliette yielded the highest percentages of recovered plants which were significantly ($P \leq 0.05$) greater, the recovery ranging from 23.8% (Aliette) to 147.2% (Kendal). None of the plants treated with inducers of resistance showed phytotoxic symptoms. PCR assays failed to detect BN phytoplasma in recovered vines. The results indicated the usefulness of resistance induced to different degrees by different chemicals (Romanazzi et al. 2009).

13.2.4 Effects of Organic Compounds

The ability of various organic compounds to suppress the development of diseases incited by microbial pathogens in different crops has been assessed; most of them have been shown to lack direct inhibitory effect on pathogen development, but have the potential to stimulate the defense mechanisms of host plants. These compounds induce the same spectrum of systemic acquired resistance (SAR) genes to levels comparable with those induced by the biotic inducers of disease resistance (Ward et al. 1991). A wide range of organic compounds has been reported to have the potential for use as inducers of systemic resistance to many economically important crop diseases.

The mechanism of induction of systemic resistance by salicylic acid (SA) has been studied using the model plant *Arabidopsis thaliana*. The SAR regulatory protein non-expressor of PR genes (*NPR1*) is activated by salicylic acid (SA) through redox potential. These changes drive systemic expression of antimicrobial PR proteins and facilitate their secretion by upregulating protein secretory pathway genes (Mou et al. 2003; Wang et al. 2005). Exogenous application of salicylic acid (SA) triggers the translocation of *NPR1* into the plant cell nucleus. The expression of a large number of genes is altered, following SA treatment (Yao et al. 2003). Induction of many genes by SA via the endogenous *NPR1* was confirmed by RNA blot analysis and real-time RT-PCR assay (Wang et al. 2005). The mechanism of treatment of potato tubers with acetyl salicylic acid (aspirin) for protection against soft rot disease caused by *Erwinia carotovora* subsp. *carotovora*-225 (Ecc-225) was assessed. Acetyl salicylic acid was applied at five concentrations from 0.0125 to 0.05% (w/v) at pH 7.0 which did not inhibit the bacterial growth. This compound at concentrations 0.0125, 0.025, and 0.05% in water adjusted to pH 7.0 were able to produce considerable reduction of soft rot. The results indicated that inhibition of development of soft rot disease in potato tubers could be achieved by applying acetyl salicylic acid (López-López et al. 1995).

Exogenous application of salicylic acid (SA) and methyl jasmonate (MeJA, biologically active derivative of jasmonic acid) induced resistance in wheat against common bunt disease caused by *Tilletia laevis*. The responses of the defense-related pathogenesis-related (PR-) genes of wheat seedlings treated with SA and MeJA on infection at 1, 2, or 3 weeks following emergence of seedlings were investigated. Application of SA or

MeJA coordinately activated transcripts of different groups of defense-related proteins, resulting in reduced infections by *T. laevis*. Transcripts of *chi1*, *chi3*, *chi4*, *PR-1*, *PR-2*, *Glu1*, and a lipase were upregulated due to MeJA treatment and their expression was potentiated by infection by *T. laevis* (Lu et al. 2006). Perception of both general and specific pathogen-associated molecules triggers defense responses in plants via signal transduction cascades and transcriptional activation of numerous genes. In chickpea (*Cicer arietinum*), putative genes potentially involved in defense responses including the rapid synthesis of PR-proteins, the presence of an oxidative burst, and synthesis of a putative cell-wall-strengthening proteins and antimicrobial proteins have been identified (Coram and Pang 2006). The responses of three chickpea genotypes treated with defense-signaling compounds SA, MeJA, and aminocyclopropane carboxylic acid (ACC) to *Ascochyta rabiei* causing Ascochyta blight disease were investigated using microarray technology. The observations were validated by quantitative RT-PCR assay. The coregulation of transcripts between treatments for each genotype with varying levels of disease resistance showed that large proportions of transcripts were independently regulated by ACC, MeJA, or SA (Jalali et al. 2006).

The effect of exogenous application of salicylic acid (SA) on host resistance to rice blast pathogen *Magnaporthe grisea* was determined. Rice leaves were treated with SA at 8 mM concentration. Blast lesion production in treated rice leaves was suppressed. Activities of defense-related enzymes peroxidase and polyphenoloxidase were stimulated in SA-treated rice leaves. Analysis of crude leaf extracts of leaves indicated the presence of rice phytoalexins, oryzalexin A, C, and E, and momilactone A following root application of SA. The hydrolysates of conjugated antifungal compounds from SA-treated rice plants caused greater inhibition of conidial germination of *M. grisea* than those from control plants. The results showed that exogenous application of SA to rice plants might result in an increase in the concentrations of compounds involved in the resistance as well as antifungal compounds, which might inhibit the pathogen development directly (Daw et al. 2008).

The potential of salicylic acid (SA), a key phytohormone required for defense against some biotic and abiotic stresses, was assessed for reducing infection by *Plasmodiophora brassicae*, an obligate parasite causing club root disease of broccoli (*Brassica oleraceae* var. *italica*) with a number of survival and dissemination strategies. Experiments were conducted under controlled conditions in growth chambers, glasshouse, and field conditions. Exogenous application of SA to the leaves where it promoted the upregulation of the pathogenesis-related genes *PR-1* and *PR-2* in a systemic acquired resistance (SAR-) like response was observed as early as 24 h post-treatment under controlled conditions. Concentrations of SA >20 mM significantly reduced both shoot and root weights when applied exogenously, but lower concentrations had little measurable effect on plant growth. When SA was applied at >5 mM to plants, there was a significant reduction (25–65%) in gall formation at 6 weeks postinoculation with *P. brassicae*, indicating that the pathogen development could be suppressed by application of SA. A combination of SA and jasmonic acid (JA) also reduced disease severity (25–35%) induced by *P. brassicae*. The results indicated that application of SA could reduce the disease severity appreciably (Lovelock et al. 2013).

The efficacy of organic compounds in inducing resistance against virus diseases has been assessed in some pathosystems. Elimination of viruses from infected plants or propagules has been demonstrated to be an effective virus disease management strategy. Thermotherapy has been successfully applied to eliminate the viruses from

plants and propagules. Enhancement of thermotolerance of plants by treating with chemicals may be a useful approach to increase the chances of obtaining a higher percentage of virus-free plants. The ability of salicylic acid (SA) to increase the thermotolerance of potato microplants infected with *Potato virus X* (PVX) was assessed. Potato microplants were cultured with or without 10^{-5} M SA for 4 weeks, then subcultured without SA and exposed to 42°C for 30 days. Survival of SA-treated microplants was more consistent compared to untreated control plants. SA treatment also improved the post-thermotherapy subculture. All of the surviving microplants treated with SA were virus-free compared to 40–65% of virus-free microplants in the controls. In another group of 30 potato genotypes infected with PVX, 98% of the surviving SA-treated microplants became PVX-free after thermotherapy compared to 75% of untreated control plants. SA-treated plants had lower catalase activity and higher H_2O_2 levels (López-Delgado et al. 2004).

A nontoxic synthetic analogue of salicylic acid (SA), benzo (1, 2, 3)-thiadiazole-7-carbothioic acid-S-methyl ester (BTH) has been demonstrated to be an effective inducer of resistance in many crops against diseases caused by microbial pathogens. Fusarium head blight (FHB) disease caused by *Fusarium graminearum* occurs in most countries cultivating wheat. The possibility of improving the resistance of wheat plant to the FHB pathogen using BTH was explored. Wheat spikes were treated with BTH prior to anthesis, and transcript accumulation and resistance to FHB were determined. BTH-treated wheat spikes were examined for the expression of six defense response genes (*PR-1*, *PR-2*, *PR-3*, *PR-4*, *PR-5*, and peroxidase) and five wheat chemically induced (WCI) genes that were induced by BTH wheat leaves. All five WCI genes were induced by BTH in spikes. However, none of the six defense-related genes was induced in the spikes. In contrast, the defense-related genes were induced by *F. graminearum* infection, whereas the WCI genes were not induced. The results indicated that the pathway for induction of the defense response genes by *F. graminearum* was distinct from the BTH-induced pathway. Disease assessment showed that BTH did not provide significant Type I or Type II resistance to wheat spikes spray- or point-inoculated with *F. graminearum*, respectively, and that the application of BTH for FHB management was an ineffective approach (Yu and Muehlbauer 2001).

The responses of two rice cultivars Tetep (resistant to *Magnaporthe grisea* (Mg), rice blast pathogen, and *Cochliobolus miyabeanus* (Cm) rice brown spot pathogen) and Nakdong (susceptible to both pathogens) to BTH treatment and conidial germination fluid (CGF) of *Cm* were assessed. Treatment with CGF induced rapid cell death in both cultivars, possibly due to phytotoxins produced by *Cm*. Pretreatment with CGF induced significant resistance to *Mg* in cultivar Nakdong, but not to *Cm*. Likewise, BTH significantly enhanced resistance to only *Mg*, but it failed to protect cultivar Nakdong against *Cm*. Enhancement of resistance in cultivar Nakdong to *Mg* by BTH or CGF treatment was correlated with more rapid induction of three PR genes. The results suggested that rice defense mechanisms against rice brown spot disease were distinct from those against blast disease and their expression patterns in response to *Cm* infection were nearly identical in both susceptible and resistant cultivars. It appeared that rice might employ distinctly different mechanisms for its defense against these two fungal pathogens (Ahn et al. 2005).

Elicitors of systemic acquired resistance (SAR) have been shown to reduce disease incidence and/or severity in different crops. Benzo (1, 2, 3) thiadiazole-7-carbothioic acid-S-methyl ester (BTH), acibenzolar-S-methyl, and the rhizobacteria *Pseudomonas*

aeruginosa KMPCH and *P. fluorescens* WCS417 were evaluated for their potential to induce resistance in susceptible and moderately resistant bean (*Phaseolus vulgaris*) to anthracnose pathogen *Colletotrichum lindemuthianum*. BTH induced local and systemic resistance when bean leaves were immersed in BTH solutions at (10^{-3} to 10^{-7} M BTH) concentrations 3 days before the challenge inoculation. BTH at high concentration (10^{-3} M) induced resistance to anthracnose disease, although it induced phytotoxic symptoms at this concentration. Soil and seed treatment with 1 mg kg^{-1} BTH protected beans against anthracnose. BTH-mediated resistance was effective in both susceptible and moderately resistant plants. *P. aeruginosa* KMPCH strain could only induce resistance to *C. lindemuthianum* in a moderately resistant interaction. On the other hand, KMPCH-567, a salicylic acid (SA) mutant of KMPCH, failed to induce resistance, indicating that SA was required for induction of resistance in bean against the anthracnose pathogen. In contrast, *P. fluorescens* WCS417 could induce resistance to *C. lindemuthianum* in both susceptible and moderately resistant interactions in bean-anthracnose pathosystem (Bigirimana and Höfte 2002).

The effect of BTH, an elicitor of SAR in chickpea against blight disease caused by *Didymella rabiei*, was assessed under field conditions. Multiple foliar applications of BTH were effective under economic threshold levels. However, multiple applications reduced the yields. The reduction in yield could therefore be compensated for by applying a combination of BTH and the contact fungicide mancozeb. One spray of BTH (50 ppm) followed by one spray of mancozeb (0.2%) significantly increased the grain yield to 1.241 t ha^{-1} , compared to 0.922 t ha^{-1} obtained with three sprays of BTH alone (Sharma et al. 2001).

Acibenzolar-*S*-methyl (ASM, a derivative of BTH) has been reported to be effective in inducing resistance in several crops against different diseases caused by microbial pathogens. The plant resistance activator ASM, the signaling molecules salicylic acid (SA), and methyl jasmonate (MeJA) were evaluated by seed treatment for their ability to protect melon seedlings against gummy stem blight and white mold diseases caused by *Didymella bryoniae* and *Sclerotinia sclerotiorum*, respectively. Infection of melon seedlings by *D. bryoniae* was entirely suppressed by MeJA application. Necrotic lesions similar to hypersensitive response (HR) appeared on all inoculated seedlings and prevented pathogen invasion into healthy tissues. ASM (BTH) seed treatment also effectively restricted *D. bryoniae* infection, although the percentage of necrotic lesions in comparison with water-soaked lesions was significantly lower than that present in MeJA-treated seedlings. ASM (BTH) protected melon seedlings against *S. sclerotiorum* by producing a high percentage of necrotic lesions. A lower level of resistance was also induced by MeJA seed treatment. The enhanced level of resistance of tissues following seed treatment with ASM (BTH) and MeJA was associated with a rapid increase in the activity of the pathogenesis-related (PR) proteins, chitinase and peroxidase. MeJA also induced a rapid and transient accumulation of lipoyxygenase. Furthermore, ASM (BTH) and MeJA treatments resulted in differential induction of de novo synthesis of particular isoenzymes of these proteins. The results indicated that ASM (BTH) and MeJA applied to melon seeds might activate metabolic pathways in seedlings, leading to induction of resistance against different pathogens (Buzi et al. 2004).

The effectiveness of BTH in comparison with an avirulent strain of *Pseudomonas syringae* pv. *maulicola* (*Psm*) in inducing resistance in canola (*Brassica napus*) against *Leptosphaeria maculans* and virulent strains of *Psm* was assessed. Application of BTH increased systemic resistance (SAR) against *L. maculans* and virulent strains of *Psm*

to a greater extent than localized preinoculation of plants with avirulent strain. Accumulation of PR genes including *BnPR-1* and *BnPR-2* was induced by BTH and avirulent strain of *Psm*. The levels of transcripts of PR genes induced were greater in BTH-treated plants than in plants preinoculated with avirulent strain. Development of SAR in *B. napus* plants expressing a bacterial salicylate hydroxylase transgene (*NahG*) that metabolized salicylic acid (SA) to catechol was appreciably compromised. These plants accumulated only reduced levels of PR gene transcripts compared with nontransformed control. The results indicated that SAR development in *B. napus* had many hallmarks of classical SAR, including long-lasting and broad host range resistance associated with PR gene activation and requirement of salicylic acid (Potlakayala et al. 2007).

The potential of acibenzolar-*S*-methyl (ASM) for its ability to protect pepper (chilli) fruits against infection by *Xanthomonas axonopodis* pv. *vesicatoria* (*Xav*) was assessed following spray application of ASM on pepper plants. Protection offered by ASM could be observed when the inducer was completely degraded. It appeared that the protection was due to the activation of systemic acquired resistance (SAR) (Buonaurio et al. 2002). Pepper plants carrying one or more major genes for resistance (*R*) to *Xav* were sprayed with ASM, followed by challenge inoculation with incompatible strains of *Xav*. At 3 weeks after inoculation, the ASM-treated plants showed significantly fewer lesions induced by both incompatible (hypersensitive) and compatible (susceptible) responses than the number of lesions formed on untreated plants. The results indicated the usefulness of SAR inducer to increase the durability of genotype-specific resistance conferred by *R* genes (Romero and Ritchie 2004). Seed and/or seedling treatment with ASM or the bacterial biocontrol agent (BCA) *Pseudomonas fluorescens* (*Pf*) improved the seed germination and seedling vigor relative to the untreated controls. Under field conditions, a combination of ASM and *Pf* significantly reduced the severity of bacterial spot disease and increased seedling biomass and tomato yield compared to untreated controls (Abo-Elyousr and El-Handawy 2008).

The protective potential of acibenzolar-*S*-methyl (ASM) against tomato bacterial canker disease caused by *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*) was assessed. Pretreatment of tomato plants with ASM reduced the severity of the canker disease and the growth of *Cmm* was reduced in planta. Development of resistance in ASM-treated plants required an interval of 1–7 days between inducer application and challenge inoculation with *Cmm*. The level of protection by ASM reached its maximum when challenge inoculation was performed at 3 days after ASM application. Reduction in disease severity (up to 75%) was correlated with the suppression of growth of *Cmm* during the time course of infection. ASM-treated tomato plants showed higher activities of peroxidase, chitinase, superoxide dismutase, and glutathione-*S*-transferase compared with untreated control plants. ASM appeared to have dual action during interaction with the bacterial pathogen by direct inhibitory effect on the bacterial population and also by enhancement of defense-related enzymes in treated tomato plants, resulting in a higher level of resistance to bacterial canker disease in tomato (Baysal et al. 2003). The effect of ASM and the bacterial BCA *Bacillus cereus* isolate L2-1, applied either alone or in combination, on the suppression of cotton bacterial blight caused by *Xanthomonas axonopodis* pv. *malvacearum* (*Xam*) was determined. Treatment with ASM reduced the disease severity to the maximum extent (57.8%), while L2-1 reduced the severity to 25.48% of the control. The combined application of ASM + L2-1 was less effective compared to ASM treatment alone. Application of ASM

alone induced the maximum increase in the activities of phenylalanine ammonia lyase (PAL), peroxidase, and β -1,3-glucanase as well as lignin deposition, especially at 14 days after treatment (Ishida et al. 2008).

Various kinds of organic compounds have been evaluated for their protective potential against crop diseases. Imidacloprid, a neonicotinoid insecticide, breaks down in plant into 6-chloronicotinic acid which is closely related to the SAR-inducer isonicotinic acid (INA). Soil application of imidacloprid was able to effectively suppress the development of citrus canker disease caused by *Xanthomonas citri* subsp. *citri* (*Xcc*). Potted Swingle citrumelo seedlings (*Citrus paradisi* x *Poncirus trifoliata*) were treated with imidacloprid, isonicotinic acid (INA), and acibenzolar-*S*-methyl (ASM) (known SAR inducers) as soil drenches or with ASM as foliar spray at 1 week prior to inoculation of immature leaves with *Xcc*. Seedlings were reinoculated four times over a 24 week period. Soil application of SAR inducers reduced canker lesions up to 70% compared with untreated inoculated plants. Lesion size was significantly reduced in treated plants, compared with untreated control treatment. Populations of *Xcc* per leaf were reduced following soil treatment with imidacloprid and INA and ASM. SAR induction in treated plants was confirmed by expression of the PR-2 gene (β -1,3-glucanase) (Francis et al. 2009).

The efficacy of inducers of systemic acquired resistance (SAR) acibenzolar-*S*-methyl (ASM), imidacloprid (IMID), and thiamethoxam (latter two are insecticides) in suppressing the development of citrus canker disease caused by *Xanthomonas citri* pv. *citri* (*Xcc*) was assessed by treating the soil. Imidacloprid (IMID), a neonicotinoid, was used to reduce canker disease incidence through control of the leaf miner (*Phyllocnistis citrella*) which could assist the bacterial pathogen to gain entry into the citrus leaf tissue. Thiamethoxam, another soil-applied neonicotinoid used for insect control, was included for comparison. The effects of 1, 2, or 4 soil applications of these compounds were compared with 11 foliar sprays of copper hydroxide and streptomycin applied at 21 day intervals. Canker disease incidence was assessed as the percentage of the total leaves with lesions. All treatments significantly reduced foliar incidence of citrus canker on the combined spring-summer-fall flushes. Sprays of copper hydroxide and streptomycin were effective for reducing canker incidence on shoot flushes produced throughout the season compared to untreated controls, whereas soil-applied SAR inducers reduced foliar disease depending on the rate, frequency, and timing of application. Except for the treatment with four applications of ASM at 0.2 g ai per tree or two applications of imidacloprid, SAR inducers were ineffective in reducing foliar infection by *Xcc* on the flushes that were present during the tropical storm. In 2009, treatments significantly reduced the incidence of foliar canker on the combined spring-summer-fall flushes, but not all treatments of spring-summer-flushes with SAR inducers were effective compared with untreated control. As the occurrence of copper-resistant strains of *Xcc* was observed, soil application of SAR inducers could be an alternative option for the management of citrus canker disease caused by copper-resistant strains (Graham and Myers 2011).

The protective activity of acibenzolar-*S*-methyl (ASM, Bion 50 WG) against *Xanthomonas campestris* pv. *vitians* (*Xcv*), causing bacterial leaf spot in lettuce, was assessed. Aqueous solution of ASM was sprayed on lettuce seedlings (c. 200 μ L of 0.2 mg mL⁻¹ for each seedling). Application of ASM reduced the disease index remarkably. The resistance induced by ASM treatment was discernible up to 11 days after treatment (dat). Plants in control

treatment showed rapid development of disease symptoms. Disease severity was reduced by 75% in ASM-treated seedlings at 7 dat and reduced disease development was observed until 11 dat. ASM treatment resulted in marked reduction in the growth of *Xcv* in plant tissues. The time between initial treatment with ASM and subsequent inoculation with *Xcv* significantly affected the induction of ISR, the optimum interval being 48 h after ASM application. In ASM-treated seedlings, a significantly lower *Xcv* population was recorded up to 96 h postinoculation compared to untreated plants (Yigit 2011).

The nonprotein amino acid, β -aminobutyric acid (BABA), was reported to induce resistance in plants against many diseases caused by plant pathogens. The effect of application of BABA on the development of potato late blight disease caused by *Phytophthora infestans* was investigated using two potato cultivars, Bintje and Pampeana, with different levels of horizontal resistance. Pretreatment of potato foliage with BABA at 30 days after emergence provided 60% protection in cultivar Pampeana against *P. infestans*. The expression of defense molecules such as glucanases, chitinases, and phenolic compounds was stimulated following BABA treatment (Altamiranda et al. 2008). The responses of potato cultivars with different levels of resistance to BABA-induced resistance against *P. infestans* were assessed. The effect of BABA on development of another pathogen, *Fusarium solani*, infecting potato tubers was also determined. Potato plants receiving four applications of BABA over the entire crop cycle, produced potato tubers with greater resistance to both *P. infestans* and *F. solani* than those from nontreated potato plants. Tuber slices from treated plants inoculated with *P. infestans* showed an increase in phenolic and phytoalexin contents. In the potato–*F. solani* interaction, infected tubers from BABA-treated plants exhibited less proteolytic activity than the infected and nontreated tubers. Treatment with BABA improved the growth of potato plants, in addition to providing protection against fungal pathogens. The degree of enhancement of resistance of potatoes depended on the natural (genetic) resistance of potato cultivars concerned (Olivieri et al. 2009).

The potential of β -aminobutyric acid (BABA) to protect potato plants against late blight pathogen *Phytophthora infestans* was influenced by different factors. Under greenhouse conditions, the durability of resistance induced by BABA, the dose–response relationships in susceptible (Bintje) and partially resistant (Ovatio and Superb) cultivars, and the effects of combined application of BABA and fungicides were studied. The lesion size was reduced by treatment with BABA by an average of 40–50% compared with untreated controls. The effect of induced resistance by BABA was progressively reduced at 4–5 days after application. Combined application of BABA and fungicides appeared to have an additive effect in suppressing disease development both under greenhouse and field conditions. With an increase in the concentrations of BABA, the protective effect became stronger proportionately. The partially resistant potato cultivars Ovatio and Superb reacted to lower concentrations of BABA. On the other hand, no significant effect of BABA could be seen under field conditions. However, BABA application compensated for a 20–25% reduction in the dose of fungicide Shirlan, as the combination was as effective as the full dose of Shirlan alone. The results indicated that BABA could be applied as a component of a disease management system against potato late blight disease (Liljeroth et al. 2010).

BABA induced resistance (IR) alone may not be sufficient to suppress the late blight disease development to the required level. Defense responses, such as hypersensitive response (HR), secretion of defense-related proteins, and production of catalase,

Figure 13.2 Effect of BABA application on the development of defense responses in potato cultivars challenged with *Phytophthora infestans*. Note hypersensitive response (HR-) like lesions formation in leaves treated with BABA, irrespective of infection at all intervals after inoculation; i: idioblast; m: mesophyll cells; HR: HR-like lesions in BABA-treated potato cultivar Ovatio at 48 h postinoculation. Source: Bengtsson et al. (2014). Reproduced with permission of John Wiley & Sons.

phenols, and the SA-marker PR-1, were studied in the potato-*Phytophthora infesta* pathosystem using potato cultivars Bintje and Ovatio with different levels of resistance to late blight pathogen. Leaves of cultivars Bintje and Ovatio were analyzed after foliar treatment with BABA. Visibly recognizable HR-like lesions were formed at 2 days post-treatment with BABA, irrespective of levels of infection by *P. infestans*. After staining with trypanblue, observations under the microscope revealed the induction of a small hypersensitive response by callose as well as production of H_2O_2 . When examined under the microscope, these HR-like lesions showed the presence of trypan blue-stained clusters of five or more dead mesophyll cells, both inside and outside the inoculation site, as well as in mock inoculated potato leaves (Fig. 13.2). The HR-like lesions at the site of penetration were enlarged in proportion to the progress of pathogen invasion. Rapid activation of various defense responses and a significant reduction in *P. infestans* growth were observed in leaves treated with BABA. In the more resistant cultivar Ovatio, the activation was both faster and stronger than in Bintje. Molecular and chemical analyses revealed the presence of soluble phenols, such as arbutin and chlorogenic acid, and the activation of PR-1. The role of secreted proteins in the development of resistance to late blight pathogen was investigated. SDS-PAGE analysis of protein secreted in the apoplast of cultivars Bintje and Ovatio showed accumulation of defense marker protein PR-1 (15kDa) at basal level at 2 days post-treatment with BABA at lower concentration (0.1 or 1.0 mM) or water. However, with an increase in concentration of BABA (10 mM), the apoplastic accumulation of PR-1 was appreciably enhanced in both cultivars, the increase in PR-1 level being greater in cultivar Ovatio than in Bintje. The results showed that BABA modulated the defense responses in potato in such a way that did not require release of elicitors from *P. infestans*. The efficiency of BABA-IR might differ based on cultivar differences (Bengtsson et al. 2014).

The comparative efficiency of protecting sunflower plants by BABA, BTH, and 2,6-dichloroisonicotinic acid (INA) against the downy mildew disease caused by *Plasmopara halstedii* was assessed using susceptible (S), partially resistant (MR), and highly resistant (HR) cultivars. By employing *P. halstedii*-specific primers, no detectable pathogen

marker transcript accumulation was recorded in the hypocotyls of S and HR cultivars. However, pretreatments with any one of three resistance inducers reduced the transcript accumulation in both the infected S and MR lines. Pretreatment with BTH before inoculation considerably enhanced defense-related enzyme activities in the infected S and HR genotypes, but not in MR plants. The results indicated that the resistance-inducing compounds might improve resistance in all of the sunflower genotypes to downy mildew disease and increase the activities of peroxidase and polyphenol oxidase, as well as accumulation of mRNAs of glutathione-S-transferase, defensin, and catalase. However, the activation of these enzymes did not correlate with the degree of resistance, but rather with the amount of necrotic tissues (Körösi et al. 2011).

The level of protection provided by BABA to *Brassica napus* (canola) against *Leptosphaeria maculans* was determined. BABA exerted direct inhibitory activity against *L. maculans* in the in vitro assays. The EC₅₀ concentration of BABA was similar to that of the fungicide tebuconazole. Both spore germination and hyphal growth of *L. maculans* were inhibited by BABA. Suppression of disease progression in plants and antifungal activity in vitro were weaker. In contrast to BTH, the effect of BABA on disease development was nearly independent of timing of treatment, indicating possible antifungal activity in plant. Quantification of multiple hormones and an expression analysis indicated that treatment with BABA induced synthesis of salicylic acid (SA) and expression of SA marker gene PR-1. However, no evidence for priming of SA responses to *L. maculans* was obtained. The antifungal activity of BABA against *L. maculans* could be another possible mechanism of action by which BABA might provide protection to *B. napus* (Sašek et al. 2012).

The efficacy of DL-β-aminobutyric acid (BABA) in suppressing the development of tomato bacterial spot disease caused by *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*) was assessed. Tomato plants (3 weeks old) were treated with different doses of BABA (250–1000 μg mL⁻¹), followed by inoculation with the suspension of *Cmm* (10⁸ CFU mL⁻¹). No antibacterial activity of BABA was indicated by in vitro assays. Foliage sprays of 500 μg mL⁻¹ of BABA suppressed disease development by up to 54% at 14 days after inoculation. Populations of *Cmm* were reduced by 84% in planta by BABA, compared with control treatment at 4 days after inoculation. In BABA-treated tomato plants, higher activities of phenylalanine ammonia lyase (PAL) and peroxidase (PO) and higher levels of H₂O₂ were observed at 1 day after application relative to those in control plants. The results suggested that application of BABA might result in induction of defense-related enzymes contributing to the enhancement of resistance in tomato to bacterial canker disease (Baysal et al. 2003).

Maize Fusarium ear rot disease caused by *Fusarium verticillioides* negatively impacts grain yield and quality because of contamination with mycotoxins (fumonisin) which are harmful to humans and animals. The disease management strategy of using chemical elicitors of disease resistance to reduce infection by *F. verticillioides* and mycotoxin contamination was evaluated. Five resistance elicitors, namely BABA, BTH, harpin protein, 2,6-dichloronicotinic acid (INA), and methyl jasmonate (MeJA), and a fungicide containing difenconazole (triazole) and azoxystrobin (strobilurin) as active ingredients were tested for their effectiveness under field conditions in multi-site field trials. After inoculation of maize plants with *F. verticillioides* isolate MRC 826 (high fumonisin producer), disease severity was determined by visual rating and the contents of fumonisins in grains were quantified by HPLC technique. Neither the resistance elicitors nor the fungicide consistently reduced the Fusarium ear rot and/or fumonisin contamination.

Treatment of maize with BTH resulted in significant reduction in ear filling and yield in field trials. Treatment effects on fumonisin content were influenced by maize genotype and trial location. The results showed that the resistance elicitors tested may not be an acceptable option for the management of maize ear rot disease (Small et al. 2012).

The ability of 2,6-dimethoxy-1,4-benzoquinone (DMBQ) to induce resistance in rice against blast pathogen *Magnaporthe grisea* was assessed. DMBQ inhibited spore germination and appressorium formation at concentrations of $>50\text{ }\mu\text{g mL}^{-1}$. When rice leaves were pretreated with DMBQ at $10\text{ }\mu\text{g mL}^{-1}$, lesion formation was inhibited compared with controls and there was no antifungal activity at this concentration of DMBQ. Induction of resistance was at a greater level in the leaf sheaths pretreated with DMBQ. Generation of H_2O_2 and expression of defense-related enzymes PAL, POX, and PR-10 were observed in rice leaves pretreated with DMBQ, indicating that DMBQ might protect rice plants against rice blast disease (Ueno and Yoshikiyo 2014).

Glycerol, an ecofriendly, nontoxic, edible, and biodegradable sugar alcohol, was evaluated for its effectiveness in suppressing development of pod rot disease of cocoa caused by *Phytophthora capsici*, using leaf disc bioassay. Exogenously applied glycerol is absorbed by plant cells and further phosphorylated to glycerol-3-phosphate (G3P) by glycerol kinase in the cytosol. An increase in G3P and decrease in oleic acid levels are considered to be associated with induction of the defense pathway in plants. The effect of exogenous application of glycerol on the endogenous level of G3P within the treated leaves was evaluated using ultrahigh-performance liquid-chromatography mass spectrometry (UHPLC-MS). The cocoa leaves of cultivar SCA6 were treated with glycerol (100, 500, and 1000 mM) or water for 3 days consecutively and inoculated with *P. capsici* after the last treatment with glycerol. All glycerol treatments drastically reduced the average lesion size relative to the control. There was no significant difference in the average sizes of lesions formed on leaves treated with 100, 500, and 1000 mM concentrations of glycerol, indicating that glycerol at 100 mM concentration was sufficient to suppress disease development by inducing resistance to *P. capsici*. Glycerol treatment significantly upregulated the expression genes governing the biosynthesis of a set of pathogenesis-related (PR-) protein in treated plants. Expression of *TcChi1* gene was significantly induced due to application of 100 and 500 mM glycerol application, whereas PR-3Q and PR-5 were not significantly induced. Expression of *TiChi4* was upregulated by a factor of 5 and 30 by 100 and 500 mM glycerol treatments, respectively, compared with water-treated controls. The results indicated that a low-cost and effective strategy of applying glycerol may be useful for managing cocoa pod rot disease caused by *P. capsici* (Zhang et al. 2015).

13.2.5 Effects of Inorganic Compounds

The induction of resistance in crops to diseases caused by microbial pathogens using inorganic compounds has been demonstrated. Phosphites (Phi) are alkali metal salts of phosphorous acid and have the potential to protect plants against infection by pathogens. Seed tubers and foliage of potato cultivars Shepody and Kennebec were treated with Phi to determine their ability to induce resistance against *Phytophthora infestans*, *Fusarium solani*, and *Rhizoctonia solani*. A high level of resistance to *P. infestans* was induced by Phi, whereas the levels of resistance to *F. solani* and *R. solani* were intermediate and low, respectively. Furthermore, seed potato tubers treated with calcium or potassium phosphites (CaPhi and KPhi) as 1% commercial product emerged earlier

than the untreated tubers. Spray application of Phi on the foliage two to four times at different doses provided high levels of protection against *P. infestans* in both potato cultivars. A higher level of protection was observed in cultivar Kennebec when CaPhi was applied, whereas the protective effect of KPhi was greater in cultivar Shepody. Expression of β -1,3-glucanases was induced at different times after treatment, but no correlation between β -1,3-glucanase expression and level of foliar protection could be established. On the other hand, Phi positive protection effects did not produce negative effects on plant growth. Leaves in treated plants were darker green in color than those in untreated plants. Increase in Rubio protein and a delay in setting of leaf senescence in Phi-treated leaves were also seen (Lobato et al. 2008).

The comparative efficacy of potassium phosphite (foliar fertilizer), DL-3-aminobutyric acid (BABA, Bion), and benzothiadiazole (BTH) in suppressing the development of Fusarium head blight (FHB) disease of winter wheat, caused by *Microdochium majus* (= *M. nivale* var. *majus*), was assessed using detached leaves for preliminary assessment. Aqueous solutions of the test chemicals were sprayed on greenhouse-grown winter wheat plants at 7 days prior to inoculation of wheat heads with the pathogen. The number of bleached spikelets per inoculated spike reflected the disease development and severity. Potassium phosphite (KPhi) applied as pretreatment foliar spray reduced the FHB disease development. Spraying plants with foliar fertilizer reduced the disease severity due to *F. culmorum* by up to 40%. Reduced development disease induced by *M. majus* was observed in detached leaves pretreated with the foliar fertilizer. The foliar fertilizer inhibited the mycelial growth of *M. majus* and *F. culmorum*, indicating its fungistatic activity accounting for its inhibitory effect on disease development. No significant reduction in disease development was observed in wheat pretreated with BABA or Bion, although these compounds tended to reduce disease development, especially when applied in combination with other potential resistance inducers. The results showed that an aqueous solution of potassium phosphite was effective in suppressing FHB disease in winter wheat (Hofgaard et al. 2010).

Application of silicon (Si) has been reported to enhance resistance of rice plants to blast disease caused by *Magnaporthe grisea*. The enhanced resistance of rice plants treated with Si appeared to be strongly associated with the production of phytoalexins momilactones A and B. Leaf extracts from plants treated with Si^+ , followed by inoculation with *M. grisea*, contained higher concentrations of momilactone phytoalexins compared with those from untreated rice plants (Si^-). Stimulation of terpenoid pathway occurred more efficiently in Si^+ plants. The lower blast disease severity on leaves of Si^+ plants at 96 h after inoculation with *M. grisea* might be due to stimulation of terpenoid pathway in Si^+ plants (Rodrigues et al. 2005). Silicon induced a rapid, but transient burst of H_2O_2 at 24 h after inoculation. Application of Si to rice plants significantly altered the activity of catalase and lipoxygenase and the concentration of malondialdehyde (indicative of lipid peroxidation) in rice plants. The results suggested that rice plants might respond to Si by increased H_2O_2 accumulation and lipid peroxidation, which in turn may be linked to host defense mechanisms such as lignin production, oxidative cross-linking in the cell wall, phytoalexins production, and hypersensitive reaction (Sun et al. 2010).

The effect of the application of calcium silicate (Si^+) or calcium carbonate (Si^-) on the development of Phytophthora blight disease of bell pepper caused by *Phytophthora capsici* was assessed. Calcium silicate or calcium carbonate was incorporated in No. 2 peat mix and seedlings were planted after 6 weeks. The soil was infested with two

isolates of *P. capsici* (Cp30 and Cp32). The roots and stem samples were examined for the presence of lesions on crown and stems and wilting of plants. The area under disease progress curve (AUDPC) and area under wilting progress curve (AUWPC) were calculated based on the data gathered. Relative lesion extension (RLE) was deduced as the ratio of vertical lesion expansion to stem length at 9 days after planting. An increase of 40% in Si concentration in the roots was observed, but not in the stems of bell pepper plants in the Si⁺ treatment, compared to Si⁻ treatment. The AUDPC was reduced by 15.4% and 37.5%, while AUWPC was reduced by 29% and 33.3% in two experiments, compared with control treatments. RLE values also showed a reduction in Si⁺ treatment. The dry root weights and stem weight also registered increases as compared with control treatment, indicating growth promotion effect due to Si application (French-Monar et al. 2010).

Fusarium (Panama) wilt disease of banana caused by *Fusarium oxysporum* f.sp. *cubense* (Foc) is spread primarily through infected suckers (propagules) which may not exhibit symptoms of infection. It is difficult to manage the disease once the pathogen has been introduced via suckers into the field, where it becomes soilborne. The protective ability of silicon (Si) amendment against the incidence of Fusarium wilt disease was investigated. The banana cultivars Grand Nain (resistant) and Maca (susceptible) were grown in plastic pots with soil amended with Si at 0 or 0.3 g kg⁻¹ of soil (Si⁻ and Si⁺ respectively) and inoculated with Foc race 1. Relative lesion length (RLL) and asymptomatic fungal colonization in tissue (AFCT) were determined at 40 days after inoculation. Si content of roots was significantly increased by 35.3% in Si⁺ treatment compared with Si⁻ treatment, the resistant cultivar showing a greater increase than the susceptible cultivar. Grand Nain and Maca plants in Si⁺ treatment showed significant reductions of 40% and 57.2% for RLL, respectively, compared with plants in Si⁻ treatment. A similar beneficial effect of reduction in resistant and susceptible cultivars due to Si amendment was observed for AFCT compared with unamended control treatments. Si amendment increased the levels of activities of defense-related enzymes in plants, indicating that the mechanism of action of Si might be by inducing resistance in banana plants against Fusarium wilt disease (Fortunato et al. 2012).

The comparative protective potential of sodium nitrite, chitosan, and Tillekur (known elicitors of disease resistance) to suppress seedborne infection by *Didymella lycopersici* in tomato seeds was assessed. Sodium nitrite was highly effective when applied at a concentration of 300 mM L⁻¹ for 20 min. Tillekur showed a similar level of protection as sodium nitrite, while chitosan was less effective in reducing seedborne fungal infection. However, phytotoxicity of Tillekur limited its use for treatment of tomato seeds. The results indicated the effectiveness of sodium nitrite in reducing seedborne infection of tomato seeds by *D. lycopersici*. In addition, the low cost of acidified sodium nitrite could be an additional factor for considering it as an effective candidate for replacing the fungicide applied against seedborne fungal pathogens (Kasselaki et al. 2008).

The effect of calcium nitrate on the development of potato soft rot disease caused by *Pectobacterium carotovorum* subsp. *brasiliense* was investigated under field conditions. Sprouted potato tubers of cultivar BP1 were planted in plots treated with different fertilizer combinations. The harvested progeny tubers were inoculated with *P. carotovorum* subsp. *brasiliense*. Calcium amendment increased the activities of defense-related enzymes, phenylalanine ammonia lyase (PAL), polyphenoloxidase (PPO), and peroxidase (PO) involved in the metabolism of phenolics. Calcium amendments significantly reduced the maceration activity of the bacterial pathogen in tuber tissues. Chlorogenic

acid, caffeic acid, and calcium contents, but not ferulic acid, were significantly higher ($P < 0.05$) in tuber peels or potato plants grown in calcium-treated plots. The reduced maceration could be due to the presence in the tubers of increased levels of caffeic acid and chlorogenic acid which possessed antimicrobial properties (Ngadze et al. 2014).

13.3 Methods of Application of Formulated Products of Biological Control Agents

The effectiveness of different kinds of biotic biological control agents in suppressing disease development has been assessed under greenhouse conditions and some of them under field conditions. Very few of them have been advanced to formulation stage however, because of the many strict requirements to be satisfied and the huge costs involved in obtaining toxicological and environmental data. Biological control agents (BCAs) that have been selected based on their potential for large-scale application for the management of crop diseases are formulated by adopting various procedures. The formulated products are applied to treat the seeds, propagules, or plants as either protective and/or curative treatments, depending on the mechanisms of action of the BCAs. In addition, the BCA formulations may be applied as soil treatment or foliar spray. The efficacy of the formulated products in reducing the disease incidence and/or severity is compared with the unformulated fresh fungal or bacterial species to determine the extent of loss of biocontrol activity, if any, due to the process of formulation and storage for various durations. Commercially available products have to be evaluated by state-owned research institutions and are then recommended for large-scale application by farmers (Narayanasamy 2013).

13.3.1 Treatment of Seeds

Biocontrol agents (BCAs) are applied as liquid, powder, or granular formulations containing single strains or a mixture of strains of fungal or bacterial BCAs. The treatment of seeds and propagules with BCA products has been the more frequently employed method of application since seed/propagule treatment is easier and more economical due to requirement of lesser quantities of BCA product. Soil/foliar applications require large quantities of BCA products to protect seedlings/grown plants against soilborne and airborne pathogens that can infect seeds and propagules later. Seed treatment with BCAs is adopted to suppress soilborne pathogens that can infect young seedlings and become systemic, infecting the inflorescence/seeds at heading stage.

Pseudomonas fluorescens as suspension or talc-based powder was used to coat rice seeds to protect plants against the rice sheath blight disease caused by *Rhizoctonia solani* and blast disease caused by *Magnaporthe grisea*. The bacterial BCA was able to spread to roots, stems, and leaves of plants growing from the treated seeds, offering protection against these important diseases of rice (Mew and Rosales 1986; Vidhyasekaran et al. 1997). In a later investigation, two strains of *Pseudomonas fluorescens* (PF1 and PF2) were applied as talc-based formulation to treat seeds, root, and foliage of rice plants, and to the soil. The talc-based formulations significantly reduced sheath blight disease. The effectiveness of the strain mixture was greater than the individual strains in suppressing the development of sheath blight disease under greenhouse and field conditions. The BCA formulations were equally effective as the fungicide carbendazim.

In the field trials, the maximum disease reduction achieved was 62.1%. Application of talc-based formulations of *P. fluorescens* was also effective against the important rice leaf folder (*Cnaphalocrocis medinalis*) by altering the feeding behavior of the insect and adversely affecting the development of the insect (Radjacommare et al. 2002).

Treatment of barley seeds with *Pseudomonas chlororaphis* MA342 was effective against net blotch caused by *Dreschlera teres*. Soon after seed treatment, the bacterial BCA could be detected under seed glume when the seeds were sown. An irregularly distributed area of bacterial aggregation could be observed, indicating the epiphytic colonization of glume cells. The bacteria were not seen within the embryo. Bacterial aggregates were regularly present in the groove of each seed formed by the base of the coleoptiles and scutellum, suggesting that the BCA could localize the seed tissues with the pathogen which facilitates the action of antifungal compounds produced by *P. chlororaphis* strain MA342 (Tombolini et al. 1999).

The formulated product of *Bacillus subtilis* was used to treat the peanut (groundnut) seeds cultivar Shulamit for the control of the seedborne pathogen *Sclerotium (Athelia) rolfsii*, causing southern blight disease. The adverse effects of *S. rolfsii* on the nodulation, leghemoglobin, and nitrogenase activity of peanut were counteracted by the treatment with *B. subtilis*. In addition, the changes in crop vigor index, total nitrogen content, and survivability of both *Rhizobium* spp. and *B. subtilis* was found to be related to compatibility between them. They showed occasional synergism between them (Abd-Allah and El-Didamony 2007).

The comparative efficacy of three fungal biological control agents (BCAs), *Trichoderma viride*, *T. harzianum*, and *Gliocladium virens*, and five neem products in suppressing the development of anthracnose disease of bean caused by *Colletotrichum lindemuthianum* was assessed. *T. viride* and the neem product Wanis ($1000\mu\text{L mL}^{-1}$) were the most effective in suppressing the mycelial growth of the pathogen. These treatments alone or in combination with carbendazim were evaluated after seed treatment under field conditions, using two bean cultivars Baspa (with high field resistance) and two highly susceptible cultivars grown by farmers. Naturally infected seeds were treated with *T. viride* and Wanis, and these two treatments were effective in reducing seed-borne infection. However, seed treatment alone with biocontrol agent, neem product, and carbendazim were not effective. Disease incidence and severity ranged from 21.22–25.63 and 14.14–17.47, respectively, which were statistically on par under field conditions. Integration of BCA with carbendazim provided maximum protection against bean anthracnose disease (Padder et al. 2010).

The beneficial effect of *Rhizobium* spp. as fixers of atmospheric nitrogen in the root nodules formed in leguminous plants is well known. The capacity of *Rhizobium leguminosarum* biovar *phaseoli* to trigger resistance in common bean (*Phaseolus vulgaris*) against common bacterial blight (CBB) disease was assessed. *R. leguminosarum* bv. *phaseoli* was applied as seed treatment on two tolerant lines Ks 51103 and BF13607 and the susceptible Khomein and line Ks21479 and tested under field conditions. *R. leguminosarum* bv. *phaseoli* reduced the CBB disease severity and improved plant growth in the field trials. The disease severity decreased to the maximum extent at 15 days after inoculation with *Rhizobium*, but under field conditions maximum reduction of CBB disease occurred at 35 dai. Treatment with *Rhizobium* improved the 100 seed weight to the maximum extent in cultivar Khomein (Osdaghi et al. 2011).

Cotton bacterial blight disease caused by *Xanthomonas campestris* pv. *malvacearum* reduces the yield substantially both quantitatively and qualitatively. The bacterial

biocontrol agents (BCAs) *Pseudomonas aeruginosa* strain 7NSK2 and *P. fluorescens* strain CHA0 were evaluated for their ability to reduce disease severity. Cotton seeds were treated with BCA formulations after acid-delinting and neutralization of seeds. Both BCAs effectively reduced the disease severity by inducing resistance to the pathogen and increasing the plant biomass (fresh weight) (Fallahzadeh-Mamaghani et al. 2009). The biocontrol potential of talc-based formulations of *Pseudomonas fluorescens* containing Pf32 and Pf93 strains and *Bacillus subtilis* containing B49 strain in suppressing the development of the cotton bacterial blight disease under greenhouse and field conditions was assessed. The BCA strains survived well as talc-based formulation. Application of mixture of Pf32, Pf93, and B49 to seed, soil, and foliage significantly reduced the bacterial blight incidence, and the plant growth and numbers of bolls were increased by the BCA application under field conditions. The yield levels of bolls from BCA-treated plots were increased due to application of selected strains of *P. fluorescens* and *B. subtilis* (Salaheddin et al. 2010).

Carrot seed infection by *Alternaria dauci* and *A. radicina* results in pre- and post-emergence mortality of seedlings. Isolates of *Clonostachys rosea* were found to be as effective as the fungicide iprodione in protecting the seedlings. Isolate IK26 of *C. rosea* was employed to bioprime a carrot seed lot with high level of seed infection by *A. radicina* (29%) and *A. dauci* (11%), and a seed lot with a low level of infection (4% and 7% respectively). The seeds were primed with water alone (hydropriming) or with the addition of *C. rosea* IK726 (biopriming). During the 14 days of hydropriming, the disease incidence of *A. radicina* and *A. dauci* was dramatically increased to two- and five-fold respectively, regardless of initial level of seed infection. In contrast, biopriming reduced the incidence of *A. radicina* to 2.3% and that of *A. dauci* to 4.8%, while the level of infection by both pathogens was reduced to 0.5% on bioprime seeds with lower level of infection (Jensen et al. 2004).

The integration of good agricultural practices (GAPs) with biological control strategies was considered as a sustainable way of achieving reliable suppression of colonization of maize grains by *Fusarium verticillioides* and mycotoxin (fumonisins) contamination of grains. Field trials were conducted in two locations to assess the effect of seed treatment with *Trichoderma harzianum* strain T22 on *F. verticillioides* kernel colonization and on fumonisin accumulation under various natural conditions. An average reduction of 58% in fungal infestation and 53% in mycotoxin contamination was observed in the 3 year experiments. The results suggested that seed biopriming with *T. harzianum* T22 strain could provide a promising and ecofriendly strategy for the management of *F. verticillioides* affecting maize (Ferrigo et al. 2014).

Clonostachys rosea strain ACM941 parasitized *Gibberella zeae* (anamorph *Fusarium graminearum*), resulting in the reduction in severity of Fusarium head blight (FHB) disease of wheat caused by this pathogen. The efficacy of CLO-1, a formulated product of strain ACM941, in reducing perithecial production on various crop residues was assessed in comparison to the registered fungicide Folicur (tebuconazole) under field conditions. When applied on *G. zeae*-inoculated corn, soybean, and wheat residues in the spring of 2009 and 2010, the formulation CLO-1 significantly inhibited perithecial production on all crop residue types, reducing daily perithecial production (DPP) by 93.1% on corn residue, 94.4% on soybean residue, and 84% on wheat residue compared to untreated control. When applied on naturally infected wheat residues in the autumn of 2009 and 2010, CLO-1 significantly reduced DPP in the following growing season by 72.3% on peduncles, 51.0% on spikelets, and 57.2% on stems. The effects were numerically better but not significantly different from those obtained by the fungicide

used as a positive control. The results suggested that CLO-1 could be an effective bio-fungicide in suppressing the development of FHB disease caused by *G. zeae* by reducing the initial inoculum of the pathogen required for floral infection (Xue et al. 2014).

The biocontrol potential of the fungal biocontrol agent (BCA) *Muscador albus* (capable of producing volatile compounds) applied as seed treatment or an in-furrow soil treatment to suppress the development of wheat common bunt (CB) disease caused by *Tilletia caries* was assessed. For seed treatments, dry rye grain culture of *M. albus* was ground into powder and applied at a rate of 125 mg kg⁻¹ of seed to wheat seed infested with *T. caries* teliospores. The BCA culture was cracked into small particles and applied in the furrows at the rate of 4 g m⁻¹ of row length, along with teliospores-infested seed during sowing. Treatments were evaluated during two growing seasons and two planting dates beginning in early spring, when soil temperatures were optimal for disease development (5–10°C) and then at c. 3 weeks later. In the first year, treatments in the first seeding date reduced the common bunt disease from 44% diseased spikes in untreated controls to 12% and 9% in seed and in-furrow treatments, respectively, and from 6% in control to 0% in both treatments in the second seeding date. In the second year, the disease incidence was reduced from 8% in the controls to 0.5% and 0.25% for seed and in-furrow treatments, respectively, in the first seeding date and from 0.75% in controls to 0% in both seed and in-furrow treatments in the second seeding date. The results indicated the potential of *M. albus* for inclusion as a component of a disease management system in organic crop production where options for CB management are limited (Goates and Mercier 2011).

Formulations containing the plant growth-promoting rhizobacteria (PGPR) *Bacillus megaterium* A6 were evaluated for their biocontrol potential against *Sclerotinia sclerotiorum*, causing serious yield losses in oilseed rape and many other crops worldwide under field conditions. Treatments containing strain A6 in pellet and wrap formulations resulted in the reduction in disease incidence in oilseed rape and seed yields that were similar to those from the chemical-treated plots and significantly greater than the untreated control at two locations. Strain A6 applied to oilseed rape seed in two formulations promoted growth in the greenhouse pot experiments using autoclaved soils. The mean shoot dry weight per pot and mean total N% were increased per plant relative to their respective controls containing formulated oilseed rape seed without A6 strain and the untreated control. Both formulations (pellet and wrap) provided stable *B. megaterium* A6 ($\geq 10^6$ CFU) and seed germination (>85%) over a 6 month period at room temperature. The results indicated that the formulations of *B. megaterium* had the potential for advancement to commercial exploitation (Hu et al. 2013a).

13.3.2 Treatment of Propagules/Transplants

Microbial plant pathogens may be carried by propagules or transplants that may or may not exhibit symptoms of infection. The propagules such as tubers, rhizomes, corms, bulbs, cuttings, or setts have to be treated with formulated products of biocontrol agents (BCAs) to reduce the incidence of diseases in the fields. Sugarcane red rot disease caused by *Colletotrichum falcatum* is primarily transmitted via infected setts. Propagation of disease-free planting materials coupled with different kinds of sett treatments (hot air/hot water) prior to planting is advocated for the management of the red rot disease. Treatment of setts with a suspension of talc formulation of *Pseudomonas fluorescens* for 1 h followed by incubation for 18 h prior to planting was reported to reduce the incidence of red rot disease and also enhance the plant growth (Viswanathan and Samiyappan 2002).

Potato silver scurf disease caused by *Helminthosporium solani* spreads through seed tubers during storage. The minitubers of cultivar Red Norland potato were immersed in a suspension of the fungal BCA *Acremonium strictum* for 3 min and air-dried. The treated and untreated tubers were inoculated with *H. solani* by spraying conidial suspension of the pathogen. *A. strictum* reduced the sporulation and spore germination of *H. solani*. The BCA was effective when applied as a protective treatment on infected tubers (Rivera-Varas et al. 2007). *Phytophthora infestans* causes tuber blight in addition to late blight disease on potato plants in the field. The efficacy of a formulated product of the fungal BCA *Chaetomium globosum* in suppressing the development of disease in potato plants was assessed. The BCA was applied as tuber, soil, and foliar treatment at 1 mL kg⁻¹ of tubers, 1 mL kg⁻¹ of farm yard manure (FYM) as soil application, and 0.7% as foliar spray application. Disease incidence was reduced by 28% under field conditions. Application of *C. globosum* increased the tuber yields in two field trials, indicating the usefulness of the formulated product of *C. globosum* (Shanthiya et al. 2013).

The endophytic actinomycete *Streptomyces griseorubiginosus* strain S96 was evaluated for its potential in suppressing the development of banana Fusarium (Panama) wilt disease caused by *Fusarium oxysporum* f.sp. *cubense* (*Foc*) race 4. The roots of plantlets were immersed in a suspension of strain S96 (10⁶ CFU mL⁻¹) for 1 h before planting, followed by inoculation with *Foc* after 3 weeks. The wilt disease severity was reduced significantly, while the mean fresh weight of the plant was increased (Cao et al. 2005). Tumorigenic strains of *Agrobacterium vitis* infect grapevine, rose, and tomato, causing crown gall diseases. Nonpathogenic *A. vitis* strain VAR03-1 suspension was used to soak the roots of grapevine seedlings for 1 h before planting in pathogen-infested soil. The incidence of tumor formation was significantly reduced by strain VAR03-1 (Kawaguchi et al. 2007). In a later investigation, treatment with VAR03-1 significantly reduced the number of plants infected and disease severity induced by the pathogen in rose and tomato as in the case of grapevines. The strain VAR03-1 was more inhibitory to pathogen development than the nonpathogenic strain K84 of *A. rhizogenes*. Under field conditions, strain VAR03-1 was found to be more efficient in controlling grapevine crown gall caused by *A. vitis*. The BCA strain VAR03-1 could multiply and establish a population averaging 10⁶ CFU g⁻¹ of roots in the rhizosphere of grapevine and persisted on the roots of grapevine for 2 years (Kawaguchi et al. 2008).

The biocontrol potential and plant growth-promoting activity of talc-based formulations of two rhizobacterial strains and their mixtures were assessed for suppressing the development of vascular wilt and corm rot of gladiolus caused by *Fusarium oxysporum* f.sp. *gladioli*. The BCA strains *Bacillus atrophaeus* S2BC-2 and *Burkholderia cepacia* TEPF-Sungal were applied for corm dressing and soil treatment. Treatment with strain mixture resulted in the highest spike and corm production of 100% and 150%, respectively, with less vascular wilt and corm rot incidences by 73.6% and 58.4% over pathogen-inoculated control under greenhouse conditions. In the field experiments the strain mixture also suppressed vascular wilt and corm rot incidence (by 48.6% and 46.1%) over nonbacterized control. The effectiveness of the strain mixture in disease suppression was comparable to the fungicide carbendazim, in addition to enhancement of spike and corm yield with an average of 58.3% and 27.4%, respectively, compared to the control (Shanmugam et al. 2011).

The effectiveness of rhizobacterial strain and a fungal BCA antagonist in suppressing the development of ginger rhizome rot caused by *Fusarium oxysporum* f.sp. *zingiberi*

and soft rot and yellows due to *Pythium splendens* was determined. *Burkholderia cepaica* TEPF-Sungal, *Bacillus subtilis* S2BC-1, and *Trichoderma harzianum* S17TH were evaluated for their efficacy in disease suppression. The rhizomes were treated by soaking them in aqueous solutions of talc-based formulation (20 g L^{-1}) of individual strains and their mixtures. After air-drying, they were planted in endemic fields during 2009–2010. The strain mixtures reduced yellows and rhizome rot by 45.9% and 49.3%, respectively, compared to control. The strain mixture treatment was more effective than the fungicides (carbendazim + mancozeb). Among treatments, the strain mixture S17TH + TEPF-Sungal was more effective than individual BCA strains. This strain mixture also increased rhizome yield (Shanmugam et al. 2013).

13.3.3 Treatment of Soils

The soil environments include several microorganisms interacting with each other and the plants. Organic matter and other nutrients are applied for improving plant growth which is likely to be reflected in the enhancement of crop yields with acceptable levels of quality of the produce. Several fungal/bacterial biocontrol agents (BCAs) have been reported to possess the required level of antagonistic activity in in vitro assays, but very few of them exhibited effectiveness and the potential for utilization in suppressing pathogen development consistently under field conditions. The fungal BCAs *Trichoderma viride*, *T. virens*, and *T. harzianum* have been widely employed for the control of several soilborne pathogens which may become seedborne or propagule-borne accounting for both quantitative and qualitative yield losses. The plant growth-promoting rhizobacteria (PGPRs), such as strains of *Pseudomonas* spp. and *Bacillus* spp., have the capacity to induce systemic resistance in treated plants, providing protection to the plants against diseases caused by microbial pathogens.

Nontoxicogenic *Aspergillus* spp. have been employed to competitively exclude toxigenic fungal pathogens from the soil. Aflatoxin contamination of corn grains could be reduced by introducing competitive non-aflatoxin-producing strains of *A. flavus*. Aflatoxin contamination in corn was reduced by field application of wheat grains preinoculated with nonaflatoxigenic *Aspergillus flavus* strain NRRL 30799. The reliability and efficiency of replacing wheat grains with bioplastic formulation Mater-Bi®, applied to serve as carrier matrix to this formulated BCA, were assessed. Mater-Bi® granules were inoculated with a conidial suspension of NRL30797 strain to achieve a final cell density of approximately 10^7 conidia/granule. Incubation of 20 g soil samples with Mater-Bi® granules for 60 days resulted in 10^{42} and 10^{53} propagules of *A. flavus* per gram of soil in microbiologically active (nonsterile) and sterilized soils, respectively. The degree of soil colonization by the BCA was not enhanced by increasing the number of granules applied to the soil. The bioplastic formulation was highly stable under soil environment. Mater-Bi® granules had the potential for substituting wheat grains as a carrier of application of the BCA strain for reducing aflatoxin contamination in corn (Accinelli et al. 2009). In a further investigation, field application of inoculated bioplastic granules induced a rapid shift in the competition of *A. flavus* with a significant decrease in the relative abundance of indigenous aflatoxigenic isolates. Application of bioplastic granules at 30 kg ha^{-1} was more efficient in replacing aflatoxigenic isolates than a 15 kg ha^{-1} dosage. The aflatoxin contamination was reduced by 86–92% at 30 kg ha^{-1} dosage of bioplastic granules in 2009 and 2010 (Accinelli et al. 2012).

13.3.4 Treatment of Foliage of Plants

Seed infection may be the resultant of interaction between airborne inoculum of fungal or bacterial pathogens infecting aerial plant parts such as leaves, stem, and inflorescence. Biocontrol agents (BCAs) have been used to protect the aerial plant parts to prevent seed infection through local or systemic infections. Seedborne pathogen *Alternaria radicina* causes black rot disease of carrots. *Ulocladium atrum*, the fungal antagonist, was applied to plants at flowering stage in seed production fields. Application of *U. atrum* resulted in reduction in seed infestation by *A. radicina* and no negative effects of the antagonists on seed quality were observed. *U. atrum* acted as a strong competitor during substrate colonization of senescing tissues of carrot plants and the BCA could enter necrotic flower parts before establishment of *A. radicina* on seeds (Kohl et al. 2004). The biocontrol potential of *Pseudomonas chlororaphis* PA-23, *Pseudomonas* spp. DF41, and *Bacillus amyloliquefaciens* BS6 and E16 strains to suppress the development of *Sclerotinia sclerotiorum*, incitant of stem rot disease of canola (*Brassica napus*; infection generally commencing from petals) was assessed. The suspensions of the BCA strains were sprayed at 30 and 50% bloom stages, followed by inoculation with ascospore suspension of *S. sclerotiorum*. *P. chlororaphis* PA-23 and *B. amyloliquefaciens* strain BS6 significantly reduced the disease incidence. The inhibition of ascospore germination and stimulation of host plant defense-related enzymes were observed following application of strain PA-23. The strain PA-23 and BS6 provided protection to canola plants to the same level that could be obtained by applying the fungicide Rovral Flo® (iprodione). Double-spray application of the BCA strains was not more effective in reducing disease incidence than the single spray of the BCA strains tested (Fernando et al. 2007b).

The ability of *Pseudomonas fluorescens* isolated from maize rhizosphere and its formulation was assessed to reduce the incidence of maize ear rot caused by *Fusarium verticillioides* and fumonisin accumulation in maize kernels. *P. fluorescens* was formulated using corn starch, wheat bran, and talc powder, and applied as seed treatment and foliar spray. Pure culture of *P. fluorescens* and the formulations increased plant growth and vigor as reflected by seed germination, seedling vigor, plant height, 1000-seed weight, and yield compared to controls. The pure culture of *P. fluorescens* used as seed- and spray-treatments enhanced the growth parameters and reduced the incidence of maize ear rot disease and the levels of fumonisins to the maximum extent compared with formulated products. The pure culture and formulations of *P. fluorescens* showed potential for reducing fumonisin contamination of maize kernels intended for human and animal consumption (Nayaka et al. 2009).

13.4 Integration of Biological Control with Other Management Practices

13.4.1 Integration with Fertilizer Application

Among the crop management practices, application of fertilizers is of vital importance to sustain better plant growth and consequent higher yields. Combined application of the mycoparasitic biocontrol agent *Coniothyrium minitans*, effective against *Sclerotinia sclerotiorum* and causal agent of stem rot disease of oilseed rape, and the compound

fertilizer (N-P-K) at various concentrations significantly reduced the number of apothecia produced from the sclerotia of the pathogen under field conditions. The compound fertilizer did not adversely affect the ability of *C. minitans* to infect the sclerotia of the pathogen or to suppress the carpogenic germination of sclerotia of the pathogen. *C. minitans* was compatible with the fertilizer when applied at planting of oilseed rape. The combined application of *C. minitans* and the fertilizer could achieve the twin objectives of suppressing development of stem rot disease and increasing production efficiency of oilseed rape, in addition to saving labor costs (Yang et al. 2011).

13.4.2 Integration with Fungicide Application

The strategy of integration of biological control agents with fungicides has been evaluated to reduce the quantity of fungicides applied against fungal pathogens affecting different crops. Microorganisms with biological control potential were found to be ubiquitous in rice ecosystems. The bacterial BCAs *Bacillus* sp. and *Burkholderia cepacia* applied as a mixture reduced the sheath blight disease (*Rhizoctonia solani*) severity by the maximum extent at harvest, compared with individual strains. These strains seemed to exhibit synergism in acting on the pathogen. However, the synergistic effect was not observed consistently in all tests under field conditions. The control efficiency ranged over 50–90% with a high variance. To improve the effectiveness of disease control, a half-dose of the commonly used fungicide/antibiotic such as Jingangmycin in China and validamycin in Vietnam was used as a mix with BCAs. The combination of BCAs and fungicides was found to be effective in suppressing the development of rice sheath blight disease (Mew et al. 2004).

An integrated management system for rice sheath blight disease caused by *Rhizoctonia solani* was evaluated for its effectiveness. *Streptomyces philanthi* RM-1-138, commercial formulation of *Bacillus subtilis* (Larminar®), *B. subtilis* strain NSRS89-24 + MK007 (Biobest), fungicides, carbendazim, validamycin, propiconazole, and mancozeb were applied alone or in combination with *S. philanthi* RM-1-138. All treatments inhibited the mycelial growth and sclerotial production of *R. solani* to different extents under in vitro conditions. The four fungicides did not have any detrimental effect on the BCA, even at high concentrations (up to 100 µg mL⁻¹). All treatments, namely *S. philanthi* RM-1-138, the commercial formulation, or fungicides alone or in combination, provided protection to different extents (47–60%). Combined application of the BCA and carbendazim offered the best protection to rice plants with the maximum reduction of sheath blight disease incidence up to 74% (Boukaew et al. 2013).

Crop Disease Management

Chemical Application

Various disease management strategies such as use of disease-free seeds and propagules, cultural practices, and enhancement of host plant resistance have been applied to prevent the introduction of pathogens and/or buildup of pathogen populations, resulting in reduction in disease incidence and further spread. These methods are indirect and their effects are not readily perceptible, since they act on the host plants and facilitate their vigorous development. On the other hand, pathogen management methods involving the use of biological control agents (BCAs) and chemicals have direct adverse effects on the development of pathogens. The effects of chemical application for disease management either as preventive or curative measure are highly visible and more effective against some pathogens compared with biocontrol agents. However, there are limitations for the adoption of chemical application for disease management, necessitating the need for more economically feasible or ecofriendly methods. Use of chemicals is primarily determined by the increase in the net profit that the farmers can realize. The chemicals may have antifungal, antibacterial, antiviral, insecticidal, and nematocidal properties. High-value crops such as fruit and vegetable crops are protected by frequent application of chemicals, whereas cereals receive only minimum protection by a few applications of chemicals. The blemish-free market demands and economic value per unit of crops such as apples, citrus, grapes, and potatoes may lead to more frequent application of chemicals, resulting in the emergence of strains of the pathogens with tolerance/resistance to certain chemicals. In contrast, enhancement of host resistance and adoption of appropriate cultural practices are the tactics generally applicable to agronomic crops, keeping the chemical application to a bare minimum because of the low unit value of produce from cereals (Narayanasamy 2002).

The application of chemicals may become unavoidable in some situations. If susceptible, high-yielding cultivars have to be grown in environments conducive for disease development, protection with chemicals has to be offered to save these cultivars. During a period of rapid development of epidemics, large-scale application of chemicals has to be resorted to in order to restrict the buildup of pathogen inoculum and secondary spread of the disease. Cultivation of crops under glasshouse conditions leads to disease spread at a faster rate once the pathogen has infected a few plants, which form potential foci of infection. Intensive application of chemicals may be the primary option for keeping the disease at bay under such conditions. Seed crops and seed stocks have to be protected by an effective schedule of chemical application to keep the infection below

tolerance levels prescribed for the disease(s) concerned. Fungicides with specific activity were found to be essential for maximizing yields of crops including staple food crops such as cereals, wheat, rice, and maize (Anderson 1995). Substantial benefits of maintaining food quality may be realized by application of fungicides for the control of fungi-producing mycotoxins such as aflatoxins, ergot toxins, *Fusarium* toxin, patulins, and tenuazonic acid (Pohland 1993; Schneider and Dickert 1994). Cultivars with vertical resistance may need larger amounts of chemicals than the cultivars with horizontal resistance to a pathogen, as in the case of potato late blight pathosystem. Likewise, protection against more virulent (aggressive) strains/races may demand greater frequency of chemical application to reduce the disease severity. Cultural practices such as fertilization, planting density, and irrigation practices markedly influence the microenvironment in the field, which in turn affects the disease development. When the microenvironment is conducive for disease development, the chemical at a particular dosage may become less effective in reducing the disease intensity to the required level. Use of fungicides may be optimized if their application is based on an effective prediction model system developed for the disease concerned, as in the case of potato late blight disease. It may be possible to save on costs of chemicals and labor, since fewer applications may suffice if fungicides are applied based on prediction rather than calendar-based recommendations (Chapter 9).

Among the chemicals used against microbial plant pathogens, fungicides are more numerous than bactericides or viricides. These chemicals may be grouped based on their mode of action, target site of activity, and nature of active ingredients (ai). Based on their activity, they may be categorized as fumigants, protectants, and eradicants (therapeutants). The chemicals may be grouped as nonsystemic (contact) and systemic based on their ability or inability to move from the site of application and act on the pathogen present in plant tissues far away.

14.1 Application of Fungicides

Fungicides may be applied against fungal pathogens as seed treatment, soil treatment, or foliar spray to protect the seeds, reduce the soilborne inoculums, and protect the plants against airborne pathogens that may infect floral parts directly when they are formed.

14.1.1 Seed/Propagule Treatment

Organomercuric compounds were used for treating seeds against seedborne fungal pathogens and for drenching soils against soilborne pathogens. These organomercurials were banned in most countries because of their high mammalian toxicity. Elemental sulfur used previously for seed treatment was replaced by other chemicals because of low levels of effectiveness and their nonsystemic nature. Control of internally seedborne fungal pathogens was a difficult problem, as none of the nonsystemic protectants could offer satisfactory control of these pathogens. When used for seed treatment, benomyl, chloroneb, and thiabendazole were absorbed by soybean seeds. Benomyl (methyl-1-(butylcarbamoyl) benzimidazole-2-yl carbamate (MBC)) has been applied as seed treatment to protect the emerging seedlings against several fungal pathogens. Benomyl was found to localize in the cotyledons (Gray and Sinclair 1971). The presence

of MBC in the seed coat and cotyledons of soybean seeds could be detected when soybean plants were sprayed with benomyl. MBC could move through the stems and pod walls to reach the seeds of soybean plants treated with benomyl (Ellis and Sinclair 1975). Use of organic solvents as carriers of fungicides offered more effective protection to seeds and eliminated pathogens from infected seeds (Papavizas et al. 1978). Infusion of chemicals into seeds is effective especially for elimination of pathogens from small seeds of crops such as tomato, pepper, cabbage, and mustard (*Brassica* spp.). Carrot seed infection by *Alternaria dauci* was effectively reduced by treating the seeds with thiram (0.2%) and iprodione (0.25%) for 24 h (Strandberg 1984). Seedborne fungal pathogen *Phytophthora infestans* in tomato seeds was suppressed substantially by soaking the seeds in 0.05% O-hydroxy diphenyl for 15 min. In the case of crops with small-sized seeds with irregular surface, pelleting may be more efficient in protecting the seeds. It may be possible to provide larger loads of fungicides around the seeds and to vary the spatial orientation of active materials within the pellet. Gum arabic, starch, carboxymethyl cellulose (CMC), gelatin, methyl cellulose, polyvinyl alcohol, and polyoxyethylene glycol-based waxes may be used as binders for pelleting (Agarwal and Sinclair 1996). Paraffin or vegetable oils may be employed as adhesives and water-dispersible fungicides are mixed in water to form a slurry which is coated on seeds (Taylor and Harman 1990; Kitamura et al. 1991).

A survey of the loose smut frequencies in certified barley seed lots in Norway during 1997–2002 revealed the prevalence and occurrence of loose smut disease in greater frequencies than previously presumed. High loose smut infection frequencies were also recorded in fields sown with carboxin-treated seeds, suggesting a reduced effectiveness of the fungicide in eliminating the pathogen *Ustilago nuda* from the seeds. Greenhouse and field experiments were conducted to assess the efficacy of combinations of fungicides for treating two barley cultivars. Seeds of cultivars Otira and Fager with 14.4% and 6.9% infection, respectively, were treated with Fungazil (carboxin + imazalil) and Premis Robust (triticonazole + imazalil). Fungazil (at normal rates) reduced loose smut frequencies by approximately 50% or less. At twice the normal rate, loose smut symptoms in crops growing from seeds treated with fungicides were reduced by 60–80%. Premis Robust was more effective in eliminating the pathogen from barley seed than Fungazil C (Brodal 2006). Seed treatment of barley seed with 2% carboxin effectively eliminated *Ustilago hordei*, causing loose smut disease (van Schmeling and Kulka 1966). Carboxin at 55 g of active ingredient per 100 kg or 110 g ai/100 kg seeds of wheat and barley was applied for the control of loose smut of wheat and barley caused by *Ustilago tritici* and *U. nuda*, respectively. Three isolates of *U. tritici* and two isolates of *U. nuda* were not affected by seed treatment with carboxin at recommended dose (55 g ai) in Canada. However, the incidence of these two diseases was significantly reduced at doubled dosage of carboxin, indicating the development of tolerance of the pathogen isolates to carboxin (Menzies 2008). The effectiveness of preventive activity of the fungicide thiram was compared with biocontrol agent *Trichoderma harzianum* and *Gliocladium roseum* and two products Signum and Natural II to reduce the seed infection by *Verticillium* spp. in spinach seed production crops. Seed treatment with thiram and Signum reduced the seed infection in harvested seeds when applied in the naturally infested and uninfested soil. The soil type had a significant influence on the subsequent disease pressure, and a nonsignificant effect of seed treatment in suppressing the development of *Verticillium* spp. was observed in both years (2010 and 2011) of experimentation (Olesen et al. 2014).

The cereal fungicide Charisma containing fusilazole and famoxate (famoxadone) reduced the infection of wheat grains by *Fusarium culmorum* by 67.0 to 80.3%, whereas tebuconazole, azoxystrobin, and carbendazim could reduce infection by 34 to 67%, 9.6 to 35.8%, and 37 to 44% respectively. Charisma treatment also improved the percentage of seed germination to a level greater than that which could be achieved by treatment with other fungicides. In addition, application of Charisma at early and mid-anthesis stages of crop development resulted in the lowest level of deoxynivalenol (DON, vomitoxin) in wheat grains (Greenfield and Rosall 2001).

In another investigation, metconazole, azoxystrobin, and tebuconazole were evaluated for the management of *Fusarium* head blight (FHB) pathogens infecting winter wheat. The effectiveness of the fungicides was assessed by competitive polymerase chain reaction (PCR) assay based on primers derived from the biosynthetic gene for trichodiene synthase (*Tri5*). No correlation between FHB disease severity and deoxynivalenol (DON) concentrations in harvested grains could be observed. However, the population of trichothecene-producing *Fusarium* strains was positively correlated with DON in grains. Metconazole and tebuconazole reduced *Fusarium* population in grains significantly, while azoxystrobin was ineffective. It was suggested that the fungicides, by altering the proportion of trichothecene-producing *Fusarium* spp., may affect the FHB severity and DON content of grains (Edwards et al. 2001).

Seedborne *Microdochium majus* and *M. nivale* are the primary sources of inoculum for the incidence of *Fusarium* seedling blight disease in wheat. The efficacy of seed treatment with the fungicides fludioxonil and carboxin + thiram and fludioxonil + difenconazole at 4, 8, 12, and 16°C was assessed for the extent of protection provided by the fungicides applied as seed treatment. The combination of fludioxonil + difenconazole showed improved performance compared with fludioxonil alone. Generally seedling emergence was improved and the severity of stem base disease symptoms on emerged seedlings was reduced for both fungal pathogen species by treating the seeds with the abovementioned fungicides (Glynn et al. 2008).

Losses due to *Fusarium* head blight (FHB) disease caused by *Fusarium graminearum* epidemics in spring wheat were common in the Red River Valley of Minnesota and North Dakota, USA. In order to reduce the disease incidence, the efficacy of fungicides applied on spring wheat cultivars with different agronomic and economic characters and resistance levels was assessed. Propiconazole (63 g ai ha⁻¹), tebuconazole (126 g ai ha⁻¹) or propiconazole followed by tebuconazole were applied at Feeks growth stages. The net returns from FHB moderately susceptible (MS) cultivars in low-disease environs was 8% greater than the moderately resistant (MR) cultivars, but differences were not significant when disease was moderate. Deoxynivalenol (DON) accumulation in grain of MS and MR cultivars was not affected by fungicide treatment. The results indicated that MS cultivars were economically more advantageous to grow than MR cultivars in both disease environments. However, MR cultivars consistently produced grains with higher quality compared with MS cultivars, since kernel quality was largely independent of fungicide treatment and was linked to quality characteristics of cultivars. Cultivar selection, rather than fungicide treatment using tebuconazole, was therefore considered to be the most effective tool to be used for producing high-quality grains in disease-prone environments (Hollingsworth et al. 2008).

Strobilurin fungicides and an azole compound were evaluated for their efficacy in suppressing the development of *Fusarium culmorum*, causal agent of *Fusarium* head blight (FHB) disease of wheat. Visual assessment, enzyme-linked immunosorbent assay

(ELISA) for detection of mycotoxin, 1000-grain weight and yield were the parameters used for evaluation. As these parameters were interrelated significantly, they could be employed to assess the efficacy of the fungicides (Chala et al. 2003). Inoculum of a marked *nit*-mutant of *Fusarium moniliforme* inoculum was utilized to evaluate the quantitative significance of seedborne disease transmission. Greenhouse and field experiments showed that seedborne isolates were responsible for up to 50% of ear rot disease caused by *F. moniliforme*. Seed treatment with the fungicide prochloraz reduced seedborne transmission and protected corn plants against seedling blight disease. In addition, elimination of seedborne inoculum reduced incidence of ear (kernel) rot and avoided buildup of soil inoculum associated with the planting of infected corn seeds (Galperin et al. 2003). The Fungicide Technology Initiative created a mechanism for developing, funding, and implementing multistate “Uniform Fungicide Trials” (UFTs) in the USA (McMullen 1998). Data from the UFTs suggested that demethylation inhibitor (DMI) fungicides prothioconazole and tebuconazole may provide superior control of *Fusarium* head blight (FHB) disease and reduce deoxynivalenol (DON) accumulation compared to tebuconazole (Bradley and McMullen 2008).

A meta-analysis, defined as the quantitative synthesis of the results from multiple individual investigations, is regarded as an objective approach for integrating and interpreting results and drawing conclusions. The quantitative research synthesis was performed using data collected from UFTs conducted at multiple locations across the US wheat-growing regions. A meta-analysis of the effect of tebuconazole (Folicur 3.6 F) on FHB disease and DON content of wheat grain was performed using data collected from UFTs. Response ratios (mean disease and DON levels from tebuconazole-treated plots, divided by mean disease and DON levels from untreated check plots) were calculated for each of 139 investigations for tebuconazole effect on FHB index (IND) and field or plot-level disease severity (i.e., mean proportion of diseased spikelets/spike), and 101 studies for tebuconazole effect on DON contamination of harvested grain. Tebuconazole was more effective at limiting IND than DON contamination. Tebuconazole showed greater impact in spring wheat than in winter wheat ($P < 0.01$). There was considerable variability (unexplained) in percentage of disease reduction by tebuconazole (Paul et al. 2007). In a later study, the combination of prothioconazole and tebuconazole was found to be the most effective treatment in suppressing the development of FHB disease (52% over control), followed by metconazole (50%), prothioconazole (48%), tebuconazole (40%), and propiconazole (32%). Metconazole was the most effective in reducing DON contamination (45%), followed by prothioconazole alone (43%) or when combined with tebuconazole (42%), tebuconazole (23%), and propiconazole (12%). The efficiency of fungicides was greater in spring wheat compared to winter wheat in suppressing both FHB and DON contamination. The results suggested that reduced efficacy of fungicides in winter wheat might be related to longer anthesis periods in wheat compared to spring wheat (Paul et al. 2008).

The stage at or near anthesis, or at full head emergence, was generally considered to be the crucial time for fungicide applications, regardless of wheat cultivars for reducing the incidence of *Fusarium* head blight (FHB) disease and mycotoxin accumulation in grains. But the most crucial time for *Fusarium graminearum* infection and mycotoxin accumulation in barley differed between open- (chasmogamous) and closed- (cleistogamous) flowering types. The chasmogamous cultivars were highly susceptible at anthesis, whereas cleistogamous cultivars were considerably resistant to FHB at anthesis but became susceptible shortly after the extrusion of spent anthers, which provided the

initial base for colonization by *F. graminearum*. The optimal timing for chemical application for the management of FHB in barley may vary depending on the flowering type of the cultivar. Thiophanate-methyl was applied at different developmental stages commencing from prior to anthesis to 30 days after anthesis (daa) under artificial inoculation conditions in the field, in which inoculum of spores was provided throughout the experimental asduration. The optimal timing of chemical control of FHB and mycotoxin accumulation was found to be the time around the beginning of spent anther extrusion rather than at anthesis. Application as late as 30 daa was also able to reduce mycotoxin accumulation in grains, but not FHB incidence (Yoshida et al. 2008).

In a later investigation, the impact of the time of spray application of fungicides on the incidence of FHB disease and mycotoxin accumulation in grains of winter wheat at harvest time was investigated under field conditions. In addition, changes in *Fusarium* population composition were also determined in three topoclimatological zones of Luxembourg. FHB incidence and severity were significantly different between locations, the central zone (Christnach) having highest incidence. The wheat grains were contaminated by deoxynivalenol (DON) in all samples tested with a range of 261–1588 $\mu\text{g kg}^{-1}$ seeds. Treatment with prothioconazole, spiroxamine, chlorothalonil, epoxiconazole, fenpropimorph, cyprodinil, and propiconazole and time of spray application had a significant effect on the level of DON contamination. Unexpectedly, a single application of chemicals showed lower DON concentrations, whereas plots treated with three sprays showed greatest DON levels. The *Fusarium* species varied strongly from location to location in their distribution, each one being predominant in different locations (Giraud et al. 2011).

Isolates of *Fusarium asiaticum* and *F. graminearum*, the primary incitants of *Fusarium* head blight (FHB) disease of wheat, showed high resistance to carbendazim (a benzimidazole fungicide, MBC) which was extensively applied for the management of FHB disease in China. In the attempt to overcome this problem, the baseline sensitivities of *F. asiaticum* and *F. graminearum* isolates to pyroclostrobin (quinine outside inhibitor, QoI) and epoxiconazole (a sterol demethylation inhibitor) were determined. The EC_{50} values of pyroclostrobin in inhibiting mycelial growth of 126 *F. asiaticum* isolates and 64 *F. graminearum* isolates were 0.12–0.135 and 0.010–0.105 $\mu\text{g mL}^{-1}$, and in inhibiting conidial germination were 0.047–0.291 and 0.042–0.255 $\mu\text{g mL}^{-1}$, respectively. The corresponding EC_{50} values for epoxiconazole were 0.12–0.95 and 0.16–0.93 $\mu\text{g mL}^{-1}$ for inhibition of mycelial growth and conidial germination, respectively. The results suggested that there was cross-resistance between MBC and pyroclostrobin or epoxiconazole. In the protective and curative applications, pyroclostrobin and epoxiconazole applied at 200 and 300 $\mu\text{g mL}^{-1}$ provided over 75 protective and curative control efficacy in all treatments. Under field conditions, both pyroclostrobin and epoxiconazole applied at 225 g ai ha^{-1} provided over 80% protection in 2010 and 2011 at two sites where MBC resistant isolates were recovered, indicating that effective protection offered by these fungicides could be a pointer for their use as alternatives to MBC compounds (Chen et al. 2012b).

Application of fungicides is one of the most practical methods of managing *Fusarium* head blight (FHB) disease of wheat. However, the effect of fungicide has not been found to be sufficiently high or consistent. Fungicide efficacy varied between years and among locations, even when standard protocols were followed. Further, the fungicide application was less effective in reducing deoxynivalenol (DON) accumulation in grains compared to FHB incidence. Fungicide thiophanate-methyl applied at anthesis (0 daa)

Table 14.1 Effect of timings of fungicide application at anthesis on infection parameters and mycotoxin accumulation in wheat cultivar Norin 61 in 2006 (Yoshida et al. 2012).

Infection parameters	Treatments ^a				P (ANOVA)
	I-1	II-1	II-2	II-3	
Days after anthesis	0	0 + 10	0 + 20	0 + 30	–
FHBI (%)	79	71	75	77	0.660 (NS)
FHBS (0–100)	9	7	9	8	0.773 (NS)
FDK (%)	6.7	5.8	3.3	5.6	0.168 (NS)
DON + NIV (µg g ^{−1})	2.7a	2.0ab	1.1b	1.8ab	0.028 (S)
Control efficacy for FHB S	36	49	38	41	–
Control efficacy for DON + NIV	−15	17	52	25	–

^a Values for each treatment are the mean of three or four replications per treatment; NS: not significant; S: significant.

had a crucial effect on reducing FHB in 2005 and 2006, although the efficacy varied between years. In terms of reducing mycotoxin (DON and NIV) accumulation however, fungicide application was effective in 2005 (control efficacy 50) but had no effect in 2006. When thiophanate-methyl was applied again at 20 days after anthesis, the control efficacy was improved from 50 to 85 in 2005 and from −15 to 52 in 2006 (Table 14.1). The results showed that the fungicide application at 20 daa reduced mycotoxin concentration in mature grain without reducing FHB severity, whereas application at anthesis (0 daa) was crucial for reducing FHB incidence (Yoshida et al. 2012).

The impact of seedborne *Microdochium nivale* var. *nivale* and var. *majus* inoculum and seed treatment with a carboxin + thiram mixture on the development of wheat seedling blight disease and on subsequent stem colonization by the pathogens and growth of winter wheat cultivar Cadenza was investigated at temperatures favorable (3°C) and unfavorable (22°C) to the pathogen development under greenhouse conditions. Seedlings grown at 3°C showed severe blight symptoms and greater colonization of stems of blighted seedling in untreated control when compared with the seedlings grown from fungicide-treated seed. Symptoms did not develop in seedlings grown at 22°C. The vigor of seedlings from fungicide-treated seeds was better than that of untreated control plants. The vigor of seedlings grown at 22°C was not perceptibly affected by the pathogen. Carboxin + thiram seed treatment decreased the extent and severity of stem colonization on plants from seedlings grown at 22°C (Haigh et al. 2009).

Gaseous chlorine dioxide (ClO₂) applied to rice seeds at a concentration of 20 ppm strongly suppressed mycelial growth of *Fusarium fujikuroi*, *F. verticillioides*, and *F. proliferatum*. The incidence of *Fusarium* spp. in dry seed with 87% seed moisture content (SMC) tended to decrease as the concentration of ClO₂ increased from 20 to 40 ppm. In the soil, stem rot was reduced from 56.9 to 15.4%, the number of normal seedlings increased from 0.4 to 25.5% with water-soaked seeds (33.1% SMC) holding moisture in the endosperm and embryo, and the effectiveness of disinfection using ClO₂ increased, even with only 20 ppm for 4 h, suggesting the requirement of moisture for the activity of ClO₂. Removal of palea and lemma from seeds significantly decreased the incidence of *Fusarium* spp. to 3.0%. The results showed that gaseous ClO₂ could be

used to disinfect rice seeds infected with *Fusarium* spp. Effectively, and the presence of optimum moisture level around the pathogens in the seed was an important factor for the disinfestation of seeds by ClO_2 (Jeon et al. 2014).

Winter wheat is seriously affected by dwarf bunt disease caused by *Tilletia controversa* in Canada. The efficacy of seed treatments with fungicides was assessed under inoculated field conditions at two locations in Central Ontario for 3 years, using eight wheat cultivars representing various market requirements. Three rates of two combinations of fungicides, namely difenconazole + metalaxyl-M (Dividend XLTRA) and carbathiin + thiram (Vitaflo 280) and a biological control agent (BCA) *Clonostachys rosea* strain ACM 941 were applied as seed treatments. Dwarf bunt disease incidence was significantly reduced ($P < 0.05$) by all seed treatments compared with untreated controls. Different rates of Dividend XLTRA were highly effective, providing 98–99% control of the disease. Vitaflo 289 and the BCA were less effective, reducing the disease incidence by 50% and 35%, respectively. The chemical seed treatments significantly increased emergence of seedling by 5–8% and yield by 2–4% compared to the control. As there was no significant interaction between wheat cultivars and Dividend XLTRA treatment for all measured parameters, this fungicide was concluded to be an effective tool for the management of dwarf bunt disease in winter wheat in Canada (Xue et al. 2007).

Seedborne infection by barley net blotch pathogen *Stagonospora nodorum* reduced the grain yield substantially. Seed treatment with carboxin + thiram (Anchor) reduced net blotch disease incidence by nearly 100% compared to 81% by imazalil (Fungazil A25), 60% by ipconazole + imazalil (Rancona i-MIX), and 54% by triconazole + prochloraz + pyrimethanil (Rubin TT). In addition, Anchor increased the yield significantly (3–7%), 1000-kernel weight (3–13%), grain volume weight (3–9%), and protein content (1–7%) in the first year of the trial, but not in the second year. The correlation between percent infected kernels in the conventional osmotic method and results of real-time PCR assay was high, showing a potential for complementarity between traditional plate test methods and molecular methods. The fungicide treatment could be used as a preventive measure for reducing the incidence of net blotch disease on the seedlings developing from infected barley seeds (Hysing and Wiik 2013).

The efficacy of fungicides in inhibiting the spore germination and mycelial growth of *Ascochyta rabiei*, causal agent of chickpea blight, was determined in vitro. Of the 13 fungicides tested, treatment of seeds with benomyl + thiram, carbendazim, and carbendazim + chlorothalonil reduced the infection by *A. rabiei* by more than 85% on vacuum infiltration of naturally infected seeds. Coating the seeds with polymers did not increase the effectiveness of protection offered by the fungicides. Azoxystrobin, chlorothalonil, and mancozeb were the most effective under field conditions. With increased disease pressure, the efficacy of the fungicides declined (Demirci et al. 2003).

The effectiveness of cyazofamid, applied as seed treatment, was assessed for the suppression of pearl millet downy mildew caused by *Sclerospora graminicola*. Sporangial production, zoospore release and motility were inhibited by cyazofamid at 0.3 mg mL^{-1} concentration. No phytotoxic symptoms due to treatment with the fungicide concentrations up to 2.0 mg mL^{-1} as seed treatment or $1\text{--}10 \text{ mg mL}^{-1}$ as foliar spray were visually observable. Seed treatment followed by a single foliar application provided effective control of downy mildew disease. Cyazofamid did not have any systemic activity and exhibited strong curative activity, but only moderate translaminar activity with marginal reduction in disease incidence (34.8%). Loss of fungicidal activity over time was very low, indicating stable residual and rainfastness activity. The results indicated

the potential of cyazofamid for use as an effective treatment against pearl millet downy mildew disease (Jogaiah et al. 2007).

Fungicides were applied as seed treatment and foliar spray to reduce the incidence of anthracnose disease caused by *Colletotrichum lindemuthianum* in dry bean (*Phaseolus vulgaris*). Pyraclostrobin and azoxystrobin fungicides were applied under low and high disease pressure conditions at two locations and at four stages of plant growth. For seed treatments, a combination of diazinon + captan + thiophanate-methyl provided superior control of the anthracnose disease on leaf and pod tissue under low and high disease pressure conditions. The combined effect of seed treatments and foliar spray timings improved plant health, extended crop maturity, and increased yield over seed treatment alone. Sequential fungicide treatments were more effective than single applications of fungicides in most environments. Under moderate to severe disease pressure, two fungicide applications and a seed treatment might be needed to maximize economic returns to growers (Gillard et al. 2012). In a further study, seed treatment with metalaxyl-M + fludioxonil + azoxystrobin was found to be equally effective as treatment with diazinon + captan + thiophanate-methyl. The addition of a surfactant to azoxystrobin increased seed yield and net return under high disease pressure. Spray application of pyraclostrobin outperformed azoxystrobin in reducing disease incidence and increased the yield levels under high disease pressure and net return under low and high disease pressure conditions (Gillard and Ranatunga 2013).

The most effective suppression of bacterial fruit blight (BFB) disease of watermelon caused by *Acidovorax avenae* subsp. *citrulli* (*Aac*) is by exclusion of the pathogen from seeds and other sources. Treatment of cucurbit seeds with hydrochloric acid (HCl) was effective in eliminating the pathogen from seed (Hopkins et al. 1996). Peroxyacetic acid (PA) and HCl were evaluated for their comparative efficacy in eliminating *Aac* from watermelon seeds. Peroxyacetic acid at low concentrations eliminated *Aac*, *Didymella bryoniae*, causal agent of gummy stem blight (GSB) disease, and *Fusarium oxysporum* from microbial suspensions. Treatment of seed contaminated with *Aac* and *D. bryoniae* with PA at $1600\mu\text{g mL}^{-1}$ and higher concentrations for 30 min were effective in preventing seed transmission of BFB and GSB pathogens. Exposure of seeds to PA at 3200 and $6400\mu\text{g mL}^{-1}$ for 15 min did not reduce seed germination and the vigor of triploid watermelon seed, even when seeds were not rinsed after treatment. PA at $1600\mu\text{g mL}^{-1}$ was as effective against BFB as the HCl at $10,000\mu\text{g mL}^{-1}$ (Table 14.2). PA was as effective or more effective than HCl in preventing seed transmission of BFB to cantaloupe seedlings as in watermelon. An effective wet seed treatment procedure included a 30 min treatment with PA at $1600\mu\text{g mL}^{-1}$ followed by seed drying at low humidity in a 40°C drying oven for 48 h. Approximately 10 to 100-fold higher concentrations of HCl were required to achieve the efficacy levels in equivalence to PA for the elimination of BFB pathogen from watermelon seeds (Hopkins et al. 2003).

Fusarium graminearum, a cereal pathogen, causes pod blight, seed and root rot, and pre-emergence damping-off of soybean. Seed infection by *F. graminearum* and *F. sporotrichoides* and accumulation of mycotoxins deoxynivalenol (DON) and HT-2 mycotoxins produced by them were detected (Clear et al. 1989). The efficacy of captan, fludioxonil, mefenoxam + fludioxonil, azoxystrobin, trifloxystrobin, and pyraclostrobin applied as seed treatment was assessed using the rolled-towel assay and 2.5×10^4 and 2.5×10^5 macroconidia mL^{-1} of *F. graminearum* for inoculation. All fungicides were able to reduce disease incidence significantly compared to the untreated controls ($P < 0.05$). The effectiveness of treatment was observed in varying levels depending on the fungicide.

Table 14.2 Effect of treatment with PA in combination with different seed drying temperatures on seed transmission of BFB in watermelon (Hopkins et al. 2003).

Treatment ^b	Temperature (°C) ^c	BFB (%) ^a	
		Test I	Test II
Untreated	GH	47b	68b
320 (µg mL ⁻¹)	GH	2c	1d
1600 (µg mL ⁻¹)	GH	0c	1d
Untreated	40	85a	86a
320 (µg mL ⁻¹)	40	0.5c	4c
1600 (µg mL ⁻¹)	40	0c	0d
Untreated	30	48b	66d
320 (µg mL ⁻¹)	30	2c	3c
1600 (µg mL ⁻¹)	30	0.3c	0d
Untreated	25	80a	90a
320 (µg mL ⁻¹)	25	2c	4c
1600 (µg mL ⁻¹)	25	0.8c	0.3d

^a Means of values of four replications followed by the same letters are not significantly different as per DMRT test ($P = 0.05$); ^b BFB-contaminated seeds treated with PA solutions for 30 min; ^c Seed drying temperatures

Seed treated with captan or fludioxonil produced plants with significantly reduced disease severity across all isolates of pathogens and concentrations, while azoxystrobin-treated seeds showed highest disease severity in seedlings. There was no significant difference ($P < 0.05$) between high and low fungicide rates for fludioxonil or captan for disease severity. No significant effect of strobilurin seed treatment on disease severity was observed. Trifloxystrobin and pyraclostrobin treatments had significantly lower disease severity than the untreated seed (Ellis et al. 2011). The efficiency of seed treatments with fungicides for reducing damping-off disease of pea caused by *Rhizoctonia solani* was assessed. Seeds of pea cultivar Mikado were treated with carbendazim, carbendazim + thiram, captan, iprodione, iprodione + thiram, metalaxyl-M + fludioxonil, pencycuron, procymidone, and tolyfluamid. Treated seeds were sown in soil inoculated or uninoculated with *R. solani*. Seedling emergence was reduced in inoculated soil and most effective treatments for the control of *R. solani* were carbendazim, pencycuron, iprodione, and carbendazim + thiram (da Silva et al. 2013).

Planting materials (propagules) have to be protected by applying chemicals prior to planting, although they might have been obtained from disease-free mother plants. Potato tubers may carry fungal, bacterial, and viral pathogens. Preplanting treatments of potato seed tubers with sodium hypochlorite solution (as NaOCl, 500 ppm for 8 min), thiophanate-methyl (TPM, as EsoutTM, 50 g ai/100 kg seed tubers) or a combination treatment with NaOCl followed by TPM were evaluated for their efficacy to reduce the incidence of black scurf disease caused by *Rhizoctonia solani* and common scab caused by *Streptomyces scabies* on potato tubers cultivar Russet Burbank. The treatment with

combination of NaOCl and TPM reduced *R. solani* on progeny tubers at harvest and after storage. However, the incidence of scab on tubers even in untreated checks was low, making the assessment of effectiveness of the chemicals against *S. scabies* unreliable. The combination treatment might have killed the majority of *R. solani* sclerotia on the tuber surface, and the combination treatment with TPM following NaOCl disinfection further suppressed the mycelial growth of *R. solani*. No phytotoxicity symptoms due to combination treatment were observed (Errampalli and Johnston 2001).

Tuber treatment with fungicides has been shown to be effective for reducing the tuber blight of potato caused by *Phytophthora infestans*. Seed tuber treatment with thiophanate-methyl + mancozeb increased plant emergence and uniform stand of potato crop. The foliar fungicides dimethomorph + mancozeb, cymoxanil + mancozeb, or propamocarb + chlorothalonil were also found to be useful for tuber treatment. However, additional foliar spray with fungicides might be necessary to achieve effective suppression of late blight disease development on potato plants at later stages. Sprout treatment with oxadixyl or Ridomil was more effective than treatment of whole tubers with deep incisions or cut tubers (Singh and Pundhir 2004).

The efficacy of fungicides applied alone or in combination as preplanting seed tuber treatment to reduce the incidence of silver scurf caused by *Helminthosporium solani* on daughter tubers was assessed in three field experiments. The most effective fungicides fludioxonil and prochloraz-Zn, applied as low-volume spray, showed control efficiencies of 88% and 82%, respectively. Propineb and mancozeb applied as a dust treatment had control efficiencies of 78% and 79%, respectively. Treatment with azoxystrobin and imazalil were less effective with control efficiencies of 68% and 43%, respectively. None of the fungicides had any effect on crop yields at all three locations (Tsrer and Pertz-Alon 2004). The effectiveness of chemicals thiabendazole (TBZ), fludioxonil, mancozeb, thiophanate-methyl (TPM), azoxystrobin, sorbic acid, and sodium carbonate was assessed to reduce the incidence of silver scurf disease in progeny tubers at four locations in Washington and Oregon in 1998–1999. Following treatment of seed tubers with the chemicals, significant reduction in disease incidence on progeny tubers was observed to a different extent. Seed tubers treated with fludioxonil, fludioxonil + quintozene, azoxystrobin, or thiophanate-methyl + mancozeb showed significantly less silver scurf disease incidence regardless of locations, compared to untreated control treatments at harvest in the spring in both years. Treatments with TPM, sorbic acid, mancozeb, and sodium carbonate were not effective in reducing the disease incidence, which was not significantly different from untreated control at any location or sampling time ($P < 0.05$). Isolates resistant to thiabendazole and thiophanate-methyl were identified for the first time (Geary et al. 2007).

14.1.2 Soil Treatment

Soilborne pathogens may infect the plants at different stages of plant growth from seedling stage and become systemic, reaching floral parts at the time of heading. Nonsystemic and systemic chemicals may be applied on the seeds or in the soil to interact with the pathogens present in the soil. The seeds function as vehicles to carry the fungicides into the soil where they interact with pathogens in the rhizosphere. Systemic fungicides may act from the seed surface against the soilborne pathogens. In addition, these fungicides may also penetrate the tissues of germinating seeds and emerging seedlings and interact with the pathogen structures, if infection has already been established (Maude 1996).

Dosages of chemicals applied as seed treatments and soil application may indicate that relatively small quantities applied to seed may not be able to exert required pressure on the soil microflora/pathogens. However, seed treatments using high rates of chemicals followed by stem base sprays may significantly reduce the disease incidence as in the case of onion white rot disease caused by *Sclerotium cepivorum* (Entwistle 1986). Metalaxyl applied in furrow provided longer protection to soybean plants against root and stem rot disease caused by *Phytophthora sojae* than when metalaxyl was applied as seed treatment. Soybean cultivars with partial resistance, when planted in the fields with environmental conditions conducive for *Phytophthora* root rot development, could benefit from fungicide seed treatment (Dorrance and McClure 2001).

Soil drenches with fungicides have been suggested to protect the seedlings in the main field known to be infected with soilborne pathogens. The practice of using plastic mulch and furrow irrigation favored the incidence of crown and root rot of capsicum caused by *Phytophthora capsici*. Metalaxyl was drenched to restrict the outbreak of the disease in glasshouse crops in southern Italy. The level of sensitivity to metalaxyl was determined using single-hypha isolates of *P. capsici*. More than 80% of the isolates of *P. capsici* from commercial plastic-house crops showed moderate levels of resistance, indicating the loss of effectiveness of metalaxyl application as soil drenches (Agosteo et al. 2000). The optimal timing of application of simeconazole for reducing the incidence of rice kernel smut was determined under field conditions in Miyagi Prefecture, Japan. The fungicide was applied in the form of granules (1.5%) for soil treatment. The submerged application of simeconazole granules (450–600 g ai ha⁻¹) at 1–5 weeks before heading was highly effective against rice kernel smut, with treatments at 1–2 weeks before heading being the most effective. Submerged application of the fungicide at 2–5 weeks before heading was also highly effective in reducing the false smut disease, with treatment at 3 weeks before heading being the most effective. These periods overlap the timing for optimal application of simeconazole to control rice sheath blight and ear blight. It was concluded that treatment with simeconazole at 2–3 weeks before heading could be followed for the control of these diseases of rice (Tsuda et al. 2006).

14.1.3 Treatment of Aerial Plant Parts

Various fungicides and other chemicals with antimicrobial activity have been evaluated for their capacity to reduce disease incidence severity and/or production of mycotoxins/toxic metabolites by the microbial pathogens. The effects of fungicides on the development of Fusarium head blight (FHB) complex due to *Fusarium culmorum*, *F. avenaceum*, and *Microdochium nivale* were investigated under natural and artificially inoculated conditions in the field. The pathogen populations were estimated using quantitative PCR assay and DON contents were also estimated. Tebuconazole selectively controlled *F. avenaceum* and *F. culmorum* and also reduced DON levels, but it was ineffective against *M. nivale*. In contrast, azoxystrobin selectively arrested the development of disease due to *M. nivale* and allowed greater colonization by toxigenic *Fusarium* species, resulting in higher accumulation of DON in grains. No-break azoxystrobin application 2 days postinoculation increased the production of DON per unit of pathogen in artificially inoculated field trial. The results indicated the potential risk of enhanced DON contamination of wheat grains following treatment with azoxystrobin aimed at control of head blight in susceptible wheat cultivars (Simpson et al. 2001).

The systemic fungicide tebuconazole (Folicur®) was applied a few days before and/or after inoculation of wheat earheads with *Fusarium graminearum* under field conditions. Plants in check plots were not inoculated and protected with the test fungicide. Inoculation with *F. graminearum* reduced the yield significantly by 24.2–45.0%. Preinfectional spray of tebuconazole reduced deoxynivalenol (DON) synthesis in the field to an appreciable level and also decreased FHB, glume blotch, and percentage of *Fusarium*-damaged (infected) kernel (FDK). The levels of *Fusarium* kernel infection after harvest clearly reflected the DON content of wheat grain (Homdork et al. 2000).

Structural and cytological changes induced by tebuconazole in the FHB pathogen *Fusarium culmorum* were studied. Mycelial growth of *F. culmorum* was strongly inhibited by the fungicide placed in filter paper strips soaked in $20\mu\text{g mL}^{-1}$ around the point of inoculum in petridishes. Scanning electron microscopic (SEM) observations showed that the fungicide induced irregular swelling and excessive branching of hyphae, thickening of cell walls, excessive septation, formation of incomplete septa, extensive vacuolization, accumulation of lipid bodies, and progressive necrosis or degeneration of hyphal cytoplasm. Nonmembrane inclusion bodies were often detected in hyphal cytoplasm. The formation of new hyphae (daughter hyphae) inside collapsed hyphal cells was commonly seen after fungicide application. Cytochemical procedures showed that the labeling intensities of chitin and β -1,3-glucan in the cell walls of tebuconazole-treated hyphae were more pronounced than in those of untreated control hyphae. In addition, immunogold labeling with antiserum against deoxynivalenol (DON) revealed that DON was localized in the cell walls, cytoplasm, mitochondria, and vacuoles of the hyphae from the control and the fungicide treatment, but labeling density in the fungicide-treated hyphae decreased dramatically compared with control hyphae, indicating that tebuconazole reduced *Fusarium* toxin production by the pathogen (Kang et al. 2001).

In a later investigation, the effect of fungicides on the incidence of *Fusarium* head blight (FHB) disease in durum wheat, infected kernels, and DON concentration in grain was assessed under field conditions. Single application of prochloraz, tebuconazole, epoxiconazole, or bromuconazole at recommended doses was made to wheat cultivars at the beginning of anthesis stage. The fungicides effectively reduced the disease incidence when the disease pressure was low to medium and when the primary pathogens of FHB were *F. graminearum* and *F. culmorum*. Kresoxim-methyl showed low level of effectiveness in suppressing FHB disease development. Tebuconazole, prochloraz, and bromuconazole were effective in controlling *F. graminearum* and *F. culmorum*. DON concentration in grains of plants inoculated with *F. graminearum* and *F. culmorum* was high, averaging 4.2 mg kg^{-1} in untreated control. Application of tebuconazole reduced DON concentration by 43%, while epoxiconazole was ineffective. DON concentration in naturally infected grains was 1.95 mg kg^{-1} grains, which exceeded the tolerance limit of 1 mg kg^{-1} grains (maximum level) allowed in the USA. Prochloraz, bromuconazole, and tebuconazole application under natural infection conditions reduced the DON concentration from 73 to 96%, while epoxiconazole provided the lowest level of protection. A positive correlation was observed between *Fusarium*-infected grains and level of DON contamination of grains (Menniti et al. 2003).

The efficacy of fungicide application at anthesis was assessed for reducing the *Fusarium* head blight (FHB) disease and production of trichothecene mycotoxins by *Fusarium graminearum*, *F. avenaceum*, *F. poae*, *F. culmorum*, *F. tricinctum*, and *Microdochium nivale* under field conditions in soft wheat, durum wheat, and barley. Deoxynivalenol (DON) and nivalenol (NIV) were detected most frequently.

Azoxystrobin significantly decreased *M. nivale* infection levels, whereas treatment with this fungicide was ineffective against *F. graminearum* and *F. culmorum*. On the other hand, metconazole or tebuconazole significantly decreased *F. graminearum* or *F. culmorum* infection levels, but the effect was variable across the years and the type of fungicide applied. DON concentration in wheat treated with tebuconazole and metconazole was reduced by 46% and 48% respectively, while NIV concentration was not reduced in 2002. However, a significant reduction in *F. graminearum* or *F. culmorum* infection levels was not always associated with significant decrease in DON and NIV mycotoxins in 2000 and 2001. Overall, the fungicide application did not reduce the mycotoxins produced in wheat grains (Ioos et al. 2005).

As wheat is highly susceptible to FHB disease around anthesis stage, the effects of timing of fungicide application on the FHB disease incidence and mycotoxin (DON and NIV) accumulation in wheat grain were determined. The late period of grain development (beyond 20 daa) was considered to be important to determine the final toxin contamination level in wheat. Thiophanate-methyl (TPM) was tested under artificial inoculation conditions in which moisture and inoculum of spores were provided throughout the testing period. Eight treatments representing different application timing (0, 10, 20, and 30 daa) and the number of applications (0–2) were tested for 2 years. The results showed that fungicide application timing could affect FHB development and mycotoxin accumulation. Fungicide application at 20 daa reduced mycotoxin concentration in matured grain without reducing FHB severity. On the other hand, application at anthesis was the critical factor for reducing FHB severity (Yoshida et al. 2012).

The comparative efficacy of a strobilurin and an azole compound was determined for the control of *Fusarium culmorum*, causing Fusarium head blight (FHB), by applying strobilurin twice and azole compound once. Visual assessment, enzyme-linked immunosorbent assay (ELISA), a mycotoxin test, 1000-grain weight, and yield assessment indicated the differing levels of the efficacies of the fungicides in arresting disease development and mycotoxin accumulation in grains. Correlation coefficients calculated for the different parameters were significantly higher, indicating their usefulness for determining the effectiveness of the selected fungicides against *F. culmorum* infecting wheat (Chala et al. 2003). In a 2 year investigation, four fungicides were compared for their effect on FHB disease incidence using two wheat cultivars with different levels of resistance to FHB inoculated with 3-ADON and 15-ADON chemotypes of *Fusarium graminearum*. All fungicides tested, namely prothioconazole, tebuconazole, metconazole, and prothioconazole+tebuconazole, reduced FHB index, percent Fusarium-damaged kernels (FDK%) and deoxynivalenol (DON) levels, and increased yield compared with the nonsprayed control in the moderately resistant cultivar Glenn. In the highly susceptible cultivar Robin also, all fungicides reduced FHB index and increased grain yield relative to the control but inconsistent results for FDK and DON contamination were evident. Differences were seen between the two chemotypes of *F. graminearum* for all parameters in both years except for FDK and yield in 2010. The results indicated the need for protection to reduce FHB incidence and DON contamination for obtaining higher level of quality grains (Amarasinghe et al. 2013).

The effectiveness of postanthesis application of prothioconazole + tebuconazole and metconazole was assessed by conducting seven field experiments in Ohio and Illinois during 2011–2013 to reduce Fusarium head blight (FHB) disease and DON contamination in soft red winter wheat. Fungicides were applied at early anthesis (A), 2 (A + 2), 4 (A + 4), 5 (A + 5), or 6 (A + 6) days after anthesis. Additional inoculation of

Fusarium graminearum was provided for six experiments, and the natural incidence of FHB was taken into account in the other experiment. *Fusarium*-damage kernels (FDK) and DON concentration in grain were quantified. Relative to the control, A + 2 resulted in the highest reduction in disease (FHB index, IND) and DON contamination by 69% and 54%, respectively, followed by A + 4 (62% and 52%), A + 6 (62% and 48%), and A (56% and 50%). Treatments A + 2 and A + 6 significantly reduced IND by 30% and 14%, respectively, relative to the anthesis application. DON accumulation was not significantly reduced by postanthesis application of fungicides. The results suggested that application of fungicides made up to 6 daa might provide better protection against FHB and DON contamination (D'Angelo et al. 2014).

The influence of wet rainy conditions during anthesis on the effectiveness of fungicides for reducing *Fusarium* head blight (FHB) disease and deoxynivalenol (DON) contamination of wheat grains was investigated. Tebuconazole + prothioconazole were applied to wheat spikes at anthesis in combination with the nonionic surfactant Induce. Simulated rainfall of a fixed intensity and duration was applied to separate plots at five different times after the fungicide treatment (0, 60, 105, 150, or 195 min). Spike samples were collected at 4 day intervals after fungicide application and assayed for tebuconazole residue. A similar set of greenhouse experiments was conducted using six post-fungicide application rainfall timing treatments (0, 15, 30, 120, or 180 min). All plants in these trials were inoculated at anthesis with conidia of *Fusarium graminearum* and FHB index (IND) and DON were quantified. In four of five trials, all fungicide-treated experimental units (EUs) had significantly lower mean IND and DON than the untreated check, regardless of rainfall treatment. Among all rainfall treatments, EUs that received the earliest rains after fungicide applications tended to have the highest numerical mean IND and DON, but were generally not significantly different from EUs that received later rains or fungicide without rain. In both years, fungicide residue on wheat spike decreased rapidly with time after application of fungicide, but the rate of reduction varied somewhat between years with a half life of 6–9 days. Rainfall did not have a significant effect on the rate of residue reduction or the level of residue at a fixed sampling time after fungicide application. The results showed that tebuconazole + prothioconazole mixed with the nonionic surfactant was fairly rainfast for a fixed set of rainfall characteristics, and tebuconazole residue did not persist for a long time after application to wheat spikes (Anderson et al. 2014). In China, application of tebuconazole at 125 g ai ha⁻¹ decreased FHB severity by 81.80% and 70.54% in 2012 and 2013 and reduced DON contamination by 78.85% and 38.43%, respectively. The yield losses in fungicide-applied plots were much lower in both years. The results indicated that the fungicide tebuconazole could be used for effective reduction of FHB disease and DON contamination levels in wheat grains in China (Sun et al. 2014).

The effects of azoxystrobin (strobilurin fungicide) on infection of wheat by *Mycosphaerella graminicola* (anamorph *Septoria tritici*), causing leaf blotch disease, were assessed using green fluorescent protein (GFP-) expressing transformants. Azoxystrobin at 125 or 250 g ai ha⁻¹ was applied at various stages of infection process under controlled conditions. GFP transformants showed conserved in vitro sensitivity to azoxystrobin and pathogenicity. Azoxystrobin reduced *M. graminicola* infections by over 90% when applied before or during penetration of the pathogen (15% of incubation phase). Azoxystrobin impaired the growth of intercellular hyphae of *M. graminicola* at post-penetration infection stages when applied at up to 50% of incubation phase. Incubating treated leaves showed infections were viable, but the pathogen growth was

impaired. No necrosis was induced in treated leaves under controlled conditions. The efficiency of azoxystrobin at half dosage was not altered in suppressing the development of wheat leaf blotch pathogen (Rohel et al. 2001).

The effects of curative and preventive applications of azoxystrobin in wheat fields against *M. graminicola* were assessed using quantitative PCR assay and visual monitoring. A nonsystemic protectant chlorothalonil and a systemic curative fungicide epoxiconazole were used as references. Asymptomatic infection by *M. graminicola* could be detected by PCR assay at 3 weeks before symptom expression, facilitating the differentiation of the effects of preventive/curative action of fungicides. When applied 1 week after the beginning of infection, curative activity of azoxystrobin was intermediate between chlorothalonil (low effect) and epoxiconazole. When applied preventively, none of the fungicides completely prevented leaf infection. It appeared that azoxystrobin, as preventive treatment, might delay fungal DNA increase more effectively than epoxiconazole at the beginning of leaf infection. Both curative and preventive treatments increased the time lapse between the earliest PCR detection and the measurement of a 10% necrotic leaf area. Azoxystrobin only slightly decreased the speed of necrotic area increase compared with epoxiconazole. The results showed that azoxystrobin activity towards *M. graminicola* was mainly in lengthening the time lapse between the earliest detection by PCR and the measurement of a 10% necrotic leaf area. Based on the results obtained, it would be possible to have optimal positioning of azoxystrobin treatments against wheat leaf blotch disease (Rohel et al. 2002).

Field isolates of *Mycosphaerella graminicola* were classified into four main phenotypes: wild-type strains (TriS); DMI-resistant phenotypes with low (TriLR); moderate (TriMR); and high (TriHR) levels of resistance to representative triazole fungicides (Leroux and Walker 2010). In the absence of highly resistant wheat cultivar to Septoria leaf blotch disease caused by *M. graminicola*, DMIs were the key fungicides applied for the management of this disease. The quantitative (q) PCR assay was employed to evaluate the preventive and curative efficiency of DMI fungicides to control the more frequently occurring genotypes of *M. graminicola*. Prothioconazole treatments significantly reduced the amount of *M. graminicola* DNA by 80% in preventive treatment and were still 70% efficient when applied as curative treatment at 3 days postinoculation (dpi). Electron microscopic observations revealed that after preventive application of prothioconazole, the spores failed to germinate. Applications of prothioconazole at 7–10 dpi resulted in a high loss of efficiency (>50%) of disease control. Preventive treatment was very effective on the susceptible cultivar Alixan with a protection level of 83.6%; this efficiency declined sharply when inoculated at 7–15 days after treatment (dat) with protection level of 42.4% and 27.2%, respectively. No protective effect of prothioconazole was observed after 15 dat. The protocol of qPCR could be used for effectively determining the optimum time of application of DMI fungicides for the management of Septoria leaf blotch of wheat (Selim et al. 2014).

Rice sheath blight caused by *Rhizoctonia solani* is widespread, and it is difficult to obtain an economically sustainable yield. Fluxapyroxad (3-(1-(difluoromethyl)-1-methyl-N-(3'4'5'-trifluorobiphenyl-2-yl)-pyrazole-4-carboxamide) was reported to interfere with succinate ubiquinone reductases in the electron transport chain of fungi. Isolates (128) of *R. solani* collected during 2008–2010 were characterized for baseline sensitivity to fluxapyroxad. The EC_{50} values of boscalid for inhibition of mycelial growth of *R. solani* isolates ranged over 1.89–2.68 $\mu\text{g mL}^{-1}$ and the average EC_{50} value was $2.212 \pm 0.228 \mu\text{g mL}^{-1}$, indicating that isolates of *R. solani* were less sensitive to boscalid

than fluxapyroxad. The fungicide fluxapyroxad exhibited excellent protective and curative activity against *R. solani* by providing 82.6–94.2% protective or curative control efficacy. In the field trials, fluxapyroxad (at 100 g ai ha⁻¹) was applied twice at 15 days and 30 days. After second application of the fungicide, the control efficacy was 83.4–88%. The control efficacy of boscalid at a dosage of 600 g ai ha⁻¹ was at a lower level (51.7–57.0%). The control efficacy of fluxapyroxad was at higher level compared to boscalid or jinggangmycin and has the potential for providing effective protection against rice sheath blight disease (Chen et al. 2014).

Rice false smut caused by *Ustilaginoidea virens* infects several high-yielding and good-quality varieties in most rice-growing ecological regions in China. Chemical control of the disease using fungicides is an important disease management strategy. The ergosterol biosynthesis inhibitor (EBI) fungicides such as prochloraz, difenconazole, propiconazole, and tebuconazole have been extensively used in China for the management of rice blast and sheath blight diseases. *U. virens* isolates (102) were tested for their sensitivity to the four EBI fungicides during mycelial growth stage. The EC₅₀ ranges of values for prochloraz, difenconazole, propiconazole, and tebuconazole inhibiting mycelial growth of 102 isolates of *U. virens* were 0.04–0.75, 0.04–1.08, 0.04–0.38, and 0.03–0.57 µg mL⁻¹ L⁻¹, with the average EC₅₀ values of 0.32 ± 0.08, 0.45 ± 0.08, 0.19 ± 0.03, and 0.21 ± 0.06 µg mL⁻¹ L⁻¹, respectively. The EC₅₀ values suggested that all pathogen isolates were sensitive to all EBI fungicides tested. Results of field trials showed that two sprays of these fungicides were more effective than a single spray for suppressing false smut disease development. Two sprays of 50% propiconazole EC at 300 g ai ha⁻¹ provided best protection against false smut at both sites during the 2 years (2010–2011), with control efficacy ranging over 71.5–74.3%. The sensitivity of the fungal pathogens to fungicide has to be monitored continuously (Chen et al. 2013).

Ascochyta blight disease of chickpea caused by *Ascochyta rabiei* was a major limiting constraint for chickpea production in Canada. Rates and timings of application of chlorothalonil and azoxystrobin separately and in combination were determined under low and high disease pressure conditions. Fungicide application under dry weather, when disease pressure was low, had no effect on blight disease severity in 1998. Under high disease pressure due to wet conditions in 1999 and 2000, a single fungicide application reduced disease severity but had no effect on yield. Two applications (early + midflowering stages) of chlorothalonil (Bravo R 500) at 1 kg ai ha⁻¹, two applications of azoxystrobin at 125 g ai ha⁻¹ or chlorothalonil + azoxystrobin reduced Ascochyta blight and increased yield. Another formulation of chlorothalonil (Bravo Ultrex®) was less effective, but more effective than mancozeb. Fungicide application had a substantial impact on seed yield. A strong relationship between disease severity and seed yield was indicated by regression analysis. Applying azoxystrobin at early + midflowering stages reduced seed infection to 7–9% from 30–48% in control. Fungicide application did not have any effect on other seedborne fungi such as *Botrytis cinerea*, *Sclerotinia sclerotiorum*, and *Fusarium* spp. (Chongo et al. 2003).

The effect of fungicide application frequency, timing, and rotation of different fungicides on the suppression of Ascochyta blight and on yield and seed quality of three chickpea cultivars was assessed during 2002–2004. Five fungicides – chlorothalonil, azoxystrobin, pyraclostrobin, mancozeb, and boscalid – were compared for their efficiency. The disease severity was significantly reduced by fungicide applications to levels below 25% compared to disease severity in untreated controls (21–99%). Increasing the number of fungicide applications was beneficial under high disease pressure conditions, but was not always related to effectiveness of disease suppression.

Application of fungicide at the pre-flowering stage reduced the *Ascochyta* blight severity significantly, increasing the seed yield or 1000-seed weight. No consistent positive impact on seed yield or quality was discernible due to an increase in the number of fungicide applications. Different fungicides showed less improvement in the effectiveness of disease management than the timing and number of fungicide treatments. Inclusion of strobilurin in rotation was beneficial under high disease pressure conditions (Banniza et al. 2011).

The antifungal activity against *Colletotrichum capsici*, incitant of anthracnose and fruit rot of pepper (*Capsicum* spp.), was recorded in in vitro assessments. Greenhouse and field assessments of the efficacy of fungicides showed that foliar spray of propiconazole at 0.1% significantly reduced anthracnose/fruit rot disease of pepper by 70%, followed by difenconazole (0.05%) and carbendazim (0.1%), with a reduction in disease incidence of 58% and 44%, respectively. The fungicides propiconazole, difenconazole, and carbendazim increased fruit yields by 86%, 63%, and 60% respectively (Gopinath et al. 2006). Soybean production is highly hampered because of yield-limiting diseases such as charcoal rot and *Phomopsis* seed decay. Lactofen or azoxystrobin was applied on soybean cultivars and genotypes with different resistance levels to these diseases. Application of lactofen at growth stage R1 and azoxystrobin either at planting, R3 or R6, had no significant effect on severity of charcoal rot, percentage of harvested seed infected by *Phomopsis* spp., or severity of pod blight on genotype Asgrow 4403. PI567562A showed high levels of resistance to charcoal rot and none of the four genotypes was resistant to infection by *Phomopsis* spp. The results indicated that the identification of sources of resistance and the search for new fungicides capable of suppressing the development of diseases seriously affecting soybean production have to be intensified (Cross et al. 2012).

The effectiveness of cyazofamid (4-chloro-2-cyano-N,N-dimethyl-5-p-tolylimidazole-1-sulfonamide) was shown to have specific inhibitory activity against diseases caused by *Phytophthora infestans*. The minimum inhibitory concentration (MIC) was over 60 times lower than that of mancozeb and at least 16 times lower than that of metalaxyl. Cyazofamid at $1.6\text{--}25\text{ mg L}^{-1}$ exhibited not only preventive activity, but also stable residual activity and rainfastness. Cyazofamid at 6.3 mg L^{-1} concentration reduced zoosporangia formation by *Phytophthora infestans* on susceptible host plants by 100%. Cyazofamid also exhibited translaminar and curative activity. Cyazofamid did not show cross-resistance with other commonly used fungicides and, under field conditions, the fungicide provided a high level of control (Mitani et al. 2002). Phosphorous acid (phosphonate or phosphite) is the ionic metabolite of the systemic fungicide aluminum tris-O-ethyl phosphonate (fosetyl-Al). Both phosphorous acid and fosetyl-Al were inhibitory to oomycetes and are systemic in nature (Cohen and Coffey 1986; Ouimette and Coffey 1989).

Phosphorous acid was applied to assess its efficacy in reducing the incidence of potato tuber rots caused by *Phytophthora infestans*, *P. erythroseptica*, and *Pythium ultimum* when applied as foliar spray on potato cultivars at different application timings and rates under different growing conditions in four locations in the Pacific Northwest, USA. Late blight incidence (*P. infestans*) infects tubers after harvest. Foliage of four late-blight-susceptible cultivars and one moderately tuber-blight-resistant potato cultivar was treated with phosphorous acid at 7.49 and $9.37\text{ kg ai ha}^{-1}$. Three applications were not consistently more effective in reducing tuber infection than two applications at the dosage of $9.37\text{ kg ai ha}^{-1}$ when evaluated at three widely separated and diverse locations. Applications at tuber bulking stage beginning were more effective than applications made 4 weeks after initial tuber bulking at one of two locations. Potato

cultivars had an influence on the amount of phosphorous acid required for managing tuber blight, the tuber-blight-resistant cultivar Umatilla Russet needing two applications compared to three required for susceptible cultivar Ranger Russet to achieve the same level of protection. Suppression of pink rot disease (*P. erythroseptica*) by phosphorous acid was not as effective as in the case of late blight disease during the 3 years of investigation. The percentage of reduction in disease incidence was relatively small and three sprays were required for disease suppression in two locations. Control of infection by *Pythium* spp. by phosphorous acid was not up to a recognizable level. The effect of phosphorous acid application on tuber yield was not significant. It was suggested that sound cultural practices such as avoiding excess irrigation of fields, in addition to phosphorous acid application, might be useful for more effective management of tuber rot diseases and a consequent increase in marketable tuber yield (Johnson et al. 2004).

Production of the phytotoxin thaxtomin A is positively correlated with the ability of isolates of *Streptomyces* spp. to induce common scab disease of potato tubers. A strong correlation between the ability of the chemical to suppress common scab symptom development and the ability of the chemical to inhibit thaxtomin A toxicity was indicated. Two isolates of *Streptomyces scabiei* G32 and G20 were used to inoculate the potato tubers. The isolate G32 induced greater severity of common scab disease. The chemicals 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4-dichlorophenoxyacetic acid (amide form, 2,4-Dam), and 2,5-dibromobenzoic acid (2,5-DBB) showed consistent and significant ability to reduce the disease (tuber surface cover) across both cultivars, Russet Burbank (moderately resistant) and Desiree (susceptible), when compared with water control. Another chemical 3,5-dichlorophenoxyacetic acid (3,5-D) was able to suppress the disease severity significantly in five of six experiments. The results showed a clear positive relationship between disease development and thaxtomin A-induced necrosis in tuber tissues, and the extent of disease mitigation using foliar chemicals was strongly correlated with their ability to inhibit thaxtomin A toxicity (Tegg et al. 2012).

Watermelon seedlings are susceptible to gummy stem blight pathogen *Didymella bryoniae* which infects seedlings used as transplants in the greenhouse. Seedlings of bottle gourd (*Lagenaria siceraria*) and interspecific hybrid squash (*Cucurbita moschata* x *C. maxima*) were used as rootstocks for grafting watermelon, and the graft wounds provided the entry points for *D. bryoniae*. Fungicides were necessary to protect the grafted plants grown under misted or high relative humidity (RH) conditions provided for rapid graft establishment. Phytotoxicity symptoms on plants treated with fluopyram + tebuconazole or cyprodinil + difenconazole were observed. Four of the five fungicides that were not phytotoxic reduced the incidence and severity of gummy stem blight on seedless watermelon grafted onto bottle gourd cultivar Emphasis and hybrid squash Strong Tosa. Difenconazole and cyprodinil were more effective than mancozeb or water control ($P=0.01$). Although difenconazole and cyprodinil remained unregistered for use on cucurbits, it was suggested that mancozeb or cyprodinil + fludioxonil might be applied against gummy stem blight disease on watermelon and rootstock seedlings during greenhouse production (Keinath 2013).

14.1.4 Development of Resistance in Fungal Pathogens to Fungicides

Fungicides have to be applied for effective management of crop diseases under certain conditions such as unavailability of dependable sources of resistance to the target disease(s) and existence of conducive environmental conditions for disease development.

However, some undesirable effects due to fungicide use have also been observed, necessitating preclusion of indiscriminate and excessive use of the chemicals. Hazards to human health and environment effects on nontarget microbes, in addition to development of tolerance/resistance to fungicides which has been a great concern for the growers and agencies involved in the development of agrochemicals, resulted in the withdrawal or replacement of fungicides to which tolerant/resistant isolates of the pathogen have been identified.

The application of fungicides at frequent intervals for longer periods has been found to be necessary to protect high-value crops and highly susceptible cultivars. Under such conditions, continued use of the same fungicide for several seasons exerts selection pressure on the pathogens to produce new strains or races that may be insensitive/resistant to the fungicide concerned, leading to the withdrawal of the fungicide from further use against the pathogen(s). Resistance or tolerance to fungicide may be defined as reduction in response of a plant pathogen to a fungicide or chemical as a result of application for the suppression of the pathogen concerned. Development of resistance in pathogen occurs at a faster rate against certain fungicides, whereas no single pathogen is known to develop resistance to different groups of fungicides. Development of strains resistant to nonsystemic fungicides used prior to 1970s was rarely seen, but with an increase in the use of systemic fungicides with narrow-spectrum of activity the incidence of pathogen strains with less sensitivity has been increasing rapidly in number. Fungicide resistance may be of two types: (i) field resistance characterized by the development of resistant strains identified by their reduced sensitivity to the fungicide when used as per label recommendations; and (ii) laboratory resistance recognized under in vitro conditions (Staub 1991). Nonsystemic protectant fungicides have multisite and broad-spectrum action and the chances of fungal pathogens developing tolerance to them are less. In contrast, in the case of systemic fungicides with narrow-spectrum action, the development of resistance by substitution of a single amino acid by suitable changes in pathogen DNA sequence may be possible as in *Rhynchosporium secalis*, causal agent of barley leaf blotch disease. Mutations affecting amino acids at positions 198 and 200 appeared to result in resistance to methyl-1-(butylcarbamoyl) benzimidazole-2-yl-carbamate (MBC) (Hollomon and Butters 1994). As the systemic fungicides offer certain advantages such as requirements of small quantities and fungicidal action inside plant tissues, the use of systemic fungicides has increased despite the possibility of development of resistance in the fungal pathogens.

Carbendazim (MBC) failed to be effective against wheat scab disease caused by *F. graminearum* after about 30 years of application in the eastern coast of China. Presence of MBC resistant isolates was detected frequently in this region. The EC_{50} values and minimum inhibitory concentration (MIC) values of MBC inhibiting the mycelial growth of wild-type isolates were less than 0.9 and $1.4 \mu\text{g mL}^{-1}$, respectively. Both field-resistant and sensitive MBC strains shared similar thermosensitivity, fitness, and virulence on wheat ears. Field-resistant strains and UV-induced mutants showed positive cross-resistance to other benzimidazole derivatives and were mainly at intermediate MBC resistance level. No mutation in β -tubulin was detected in *F. graminearum*, whereas mutation in tubulin has led to MBC resistance in other fungal pathogens (Chen et al. 2007).

The emergence of isolates of *Fusarium graminearum* with lower levels of sensitivity to carbendazim, the major fungicide applied for control of Fusarium head blight (FHB) disease, posed a major obstacle for the continued application of this fungicide. Five isolates representing three phenotypes of different carbendazim sensitivity levels

(S, MR, and HR) were randomly selected to study the inheritance of carbendazim resistance by three genetic crosses under field conditions. Each parent in all crosses was marked with a different class of nitrate nonutilizing (*nit*) mutation. The presence of sexual recombinants indicated that outcrossing had occurred in the crosses. Over 100 putative self-crossing or outcrossing perithecia for each cross were randomly sampled on the surface of the haulms of dead rice for each pair of parents. Results indicated that 5.7–20.9% outcrossing frequency occurred in three crosses and confirmed sexual recombination under field conditions. Most of the sexual recombinants possessed fitness levels comparable with those of their parents. Outcrossing between carbendazim-sensitive and -resistant isolates did occur under field conditions and sexual recombination must play a role in the development of carbendazim resistance in the field (Chen and Zhou 2009).

Resistance to carbendazim has been shown to be conferred by mutations in a single chromosomal β -tubulin gene in *Botrytis cinerea* and most other fungal pathogens, due to several allelic mutations. In contrast, carbendazim resistance in *Fusarium graminearum* was not associated with mutation in the corresponding β -tubulin gene. The β -tubulin gene conferring carbendazim resistance in *B. cinerea* was cloned and connected with two homologous arms of the β -tubulin gene of *F. graminearum* by using a double cross-over at the site where β -tubulin gene of *F. graminearum* is normally located (the β -tubulin gene of *F. graminearum* had been earlier deleted). The β -tubulin gene conferring carbendazim resistance in *B. cinerea* did not express this resistance in *F. graminearum*, since the transformants remained very sensitive to carbendazim (Liu et al. 2010).

In a later investigation, isolates of *F. graminearum* (7261) collected in China during 2010–2012 were evaluated for their sensitivity to carbendazim (MBC). The relationship between trichothecene chemotypes of the FHB pathogen and their MBC-sensitivity was studied. MBC-sensitive isolates were more numerous in nivalenol (NIV) chemotype. 15-acetyldeoxynivalenol (15-ADON) chemotype had a limited number of MBC-sensitive isolates. Most MBC-resistant isolates secreted 3-deoxynivalenol (3-ADON). Trichothecene analyses indicated that MBC resistance increased 3-ADON yield and percentage, especially in site-directed mutants at codon 167 in the β 2-tubulin gene (Zhang et al. 2013a). In order to validate the mechanism of development of resistance in *Fusarium graminearum* (*Fg*), the resistance of field isolates to carbendazim through association with mutations in β -tubulin (*tub*) gene was investigated. Site-directed mutagenesis procedure was adopted, followed by gene replacement to change the β 2-tubulin gene of a carbendazim sensitive field strain of *Fg* at residues 50, 167, 198, or 200. The transformants stably retained the transgressed gene and were tested for their sensitivity to carbendazim. The level of resistance differed depending on the mutation. Biological characteristics of the mutants did not show variations from the parent strain. Mutations at codon 50, 167, 198, or 200 of *F. graminearum* of β 2*tub* could lead to resistance to carbendazim and these codons might form a binding pocket (Qiu et al. 2011). *Fusarium graminearum* (*Fg*) has two β -tubulins (*Fgtub1* and *Fgtub2*), whereas *Botrytis cinerea* and other fungal pathogens have only one tubulin. Even after replacing *Fgtub1* with that of *B. cinerea* (*BctubE198A*), the *F. graminearum* transformants were sensitive to carbendazim. The *Fgtub2* of the mutant 20C1 (*Fgtub1* was replaced with *BctubE198A*) and *Fgtub1* of mutant 20D10 (*Fgtub2* was replaced with *BctubE198A*) were deleted. These mutants were also sensitive to carbendazim. The results indicated that *B. cinerea* β -tubulin could complement the function of the two *Fg* β -tubulins, even when both were deleted and expression of the β -tubulin conferring carbendazim resistance differed between fungal pathogens (Liu et al. 2013).

Sunflower downy mildew induced by *Plasmopara halstedii* was managed by seed treatment with metalaxyl-M, a phenylamide compound. Isolates of *P. halstedii* exhibiting resistance to metalaxyl-M were isolated in Spain during 2000, 2004, and 2006. Populations (60) of the pathogen from the field were characterized by virulence (race) and by reaction to metalaxyl-M applied as seed dressing. Race 310 was found predominantly in 3 years in southern Spain (68% of the populations) and races 100 and 330 were also present. Thirty-one percent of the populations were not controlled by metalaxyl-M when applied at the recommended dose of 2.0 g ai kg^{-1} seed and subpopulations collected on plants growing from treated seed were the same race as those from the initial populations. Doses of metalaxyl and metalaxyl-M varying over $0\text{--}8.0 \text{ g ai kg}^{-1}$ seed were applied to the pathogen population present on seed and the incidence of downy mildew depended significantly on the fungicide dose. A dose response-regression analysis showed ED_{50} values of the populations to be between 2.4 and 4.4. The extended and frequent use of the fungicide was considered as the possible reason for the emergence of populations with resistance to metalaxyl-M in Spain. The presence of virulent populations of *P. halstedii* resistant to the fungicide has to be considered in genetic and chemical strategies for the management of sunflower downy mildew disease (Molinero-Ruiz et al. 2008).

Field isolates of *Gibberella pulicaris* (anamorph *Fusarium sambucinum*), incitant of potato dry rot disease, produce trichothecene mycotoxins and were found to be resistant to thiabendazole, a benzimidazole fungicide. In order to characterize the resistance to this fungicide, homokaryons were derived from single ascospores that were produced in vitro from crosses of thiabendazole-resistant *G. pulicaris* field isolates with sensitive isolates of an opposite mating type. The β -tubulin gene was amplified from these homokaryons using degenerate oligonucleotides synthesized to conserved sequences of the β -tubulin gene derived from related fungi. An open-reading frame containing three putative introns and a deduced amino acid sequence of 446 amino acids exhibited a high level of homology to the β -tubulin gene of other fungi. Although nucleotide and amino acid differences were observed, none of them was linked to the thiabendazole resistance. Linkage analysis confirmed that the isolated β -tubulin gene was a single-copy gene and was not linked to thiabendazole resistance of *G. pulicaris* (Kawachuk et al. 2002).

Seedborne *Didymella bryoniae*, causing gummy stem blight disease, is a very destructive disease of watermelon. The infected seeds form the primary sources of inoculum capable of introducing the strains from different locations. *D. bryoniae* has a history of becoming insensitive to systemic fungicides used for the management of crop diseases. The populations repeatedly exposed to high-risk fungicides present in a location were tested for their sensitivity/resistance to fungicide(s) applied repeatedly at the location concerned. However, the unexpected occurrence of resistant populations in fields where fungicides have never been used suggested the introduction of resistant isolates through seeds/external source. Watermelon seed as a potential source of fungicide-resistant inoculum was therefore investigated. Using direct-plating, sweat box, and blotter assays, 5800 seeds from commercial watermelon seed lots were tested for the presence of isolates insensitive to fungicides boscalid, tebuconazole, azoxystrobin, and thiophanate methyl. Some isolates showed resistance to thiophanate methyl. The results showed that watermelon seed naturally infested with *D. bryoniae* might harbor fungicide-resistant isolates which could be introduced into locations where the fungicide had not been applied earlier (Thomas et al. 2014).

Tridemorph was applied to reduce the incidence of corn smut disease caused by *Ustilago maydis*. Mutants of *U. maydis* with low resistance to tridemorph were isolated in a mutation frequency of 7×10^6 after UV-irradiation and selection on media containing $25 \mu\text{g mL}^{-1}$ tridemorph. Genetic analysis with nine mutant isolates resulted in the identification of two unlinked chromosomal loci, *U/tdm-1* and *Utd-2*. The *U/tdm* mutations were responsible for low resistance levels to tridemorph, based on effective concentration causing 50% reduction in the growth rate (EC_{50}) or minimal inhibitory concentration (MIC). Haploid strains carrying both *U/tdm* mutations showed higher levels of resistance to the fungicide, indicating interallelic interaction between nonallelic genes. Cross-resistance studies with the inhibitors of C-14 demethylase showed that the *U/tdm* mutations were responsible for increased sensitivity to the triazoles, triadimefon, triadimenol, propiconazole, and flusilazole and the pyridine pyrifenoxy. Study of the gene effect on the fitness of *U. maydis* showed that *U/tdm* mutations appeared to be pleiotropic, having more or less adverse effects on pathogen growth rate in liquid culture and pathogenicity on young corn plants (Markoglou and Ziogas 2000).

Carboxin was used to treat wheat and barley seeds to protect the seedlings against loose smut pathogens *Ustilago tritici* and *U. nuda*, respectively. Isolates of *U. tritici* (3) and *U. nuda* (2) isolated in 1997 and 1999 in Canada were found to be insensitive to carboxin, based on teliospore germination assay using carboxin-amended medium. Seeds with or without treatment with carboxin at recommended rate of 55 g ai/100 kg or at 110 g ai/100 kg seed followed by inoculation with the pathogen were sown. The growing plants were assessed at heading stage for infection which was expressed as percentage of smutted spikes. Three isolates of *U. nuda* were not affected by treatment with carboxin at 55 g ai/100 kg seed. However, the incidence of loose smut on their respective hosts by three of these isolates was significantly reduced when seeds were treated at 110 g ai carboxin/100 kg seed. The results suggested that these isolates of *U. tritici* and *U. nuda* were tolerant to carboxin rather than resistant. However, the tolerant isolates might subsequently develop resistance to the higher dose of carboxin sooner or later (Menzies 2008).

Fusarium sporotrichoides, a component of Fusarium head blight (FHB) complex, was investigated for the ability to develop resistance to fungicides. Carbendazim-resistant (RS) and control (CS) strains of *F. sporotrichoides* were exposed to graded concentrations (0, 1, 10, and 100 mg L^{-1}) of azoxystrobin in broth media. Significant strain-fungicide interactions were recorded in trichothecene production following exposure to azoxystrobin. At 4 and 8 days of incubation, addition of 10 mg L^{-1} of azoxystrobin stimulated T-2 toxin synthesis ($P < 0.05$) only in RS cultures. In contrast, T-2 toxin enhancement in the CS cultures occurred only on day 8, but at a lower concentration (1 mg L^{-1}). The stimulation of T-2 toxin synthesis depended on strain and azoxystrobin level. Another toxin diacetoxyscirpenol (DAS) production was affected by a more complex set of interactions. As in the case of T2-toxin, DAS production in CS was stimulated ($P < 0.05$ or better) only at low exposure levels of azoxystrobin. In the case of neosolaniol (NEO), the main effect of strain was significant with CS producing consistently more of the mycotoxin than RS. The results indicated that development of resistance to the fungicide might affect trichothecene production by *F. sporotrichoides* on exposure to a second fungicide (D'Mello et al. 2001).

The primary inoculum for *Fusarium graminearum* (teleomorph *Gibberella zeae*), causal agent of wheat Fusarium head blight disease, comprised ascospores available during anthesis. The application of fungicides containing triazoles at the time of anthesis

was effective in the initial year of introduction. Prothioconazole, metconazole, and tebuconazole inhibited ascospore germination, whereas epoxiconazole had only a minor effect within the range of concentrations tested. The inhibitory effect of epoxiconazole on mycelial growth was strongest in strains isolated in 1987 and decreased with time at an average rate of 0.22% per year. The initial efficacy of triazoles against *G. zeae* ascospores at their market introduction increased by a factor of 2.950 within 10 years (epoxiconazole excluded). During the first 10 years following their introduction, the EC_{50} values for metconazole and tebuconazole increased by factors of 1.391 and 1.393, respectively. The results suggested that the decline in *G. zeae* sensitivity against triazoles was slower in the past decades than the increase in sensitivity achieved by development of new and more efficient triazole analogues (Klix et al. 2007).

Quinine outside-inhibiting (QoI) fungicides have been shown to be effective against some seedborne pathogens. They inhibit mitochondrial respiration of the sensitive fungus by binding to outer quinine-oxidizing pocket of the cytochrome bc1 (*cytb*) enzyme complex. Mutants of *Ustilago maydis* with high resistance to azoxystrobin (based on EC_{50} values) were isolated by guanidine mutagenesis and selection on media containing $1 \mu\text{g mL}^{-1}$ of azoxystrobin, in addition to use of 0.5 mM salicylhydroxamate (SHAM), a specific inhibitor of cyanide-resistant (alternative) respiration. Oxygen uptake in whole cells was strongly inhibited in the wild-type strains (sensitive) by azoxystrobin ($1.5 \mu\text{g mL}^{-1}$) in addition to SHAM (1 mM), but not in the mutant isolates. The criterion of cytoplasmic resistance (of intracellular selection) was fulfilled by experiments on the stability of resistance phenotypes. Cross-resistance studies with other fungicides which also inhibit electron transport through complex III of respiratory chain showed that mutations for resistance to azoxystrobin were also responsible for reduced sensitivity to kresoxim-methyl and to antimycin A which act at the Q_0 and Q_1 sites of the cytochrome bc1 complex, respectively (Ziogas et al. 2002).

Sensitivities of fungal pathogens to quinine-outside-inhibiting (QoI) fungicides may be influenced by the induction of alternative respiration or mutational changes of the cytochrome b target site. The expression and impact of the resistance mechanisms during the conidial germination were investigated. In the absence of a host, alternative respiration provided a >500-fold rescue from azoxystrobin during the germination of conidia derived from four wild-type isolates of *Magnaporthe grisea*, causal agent of rice blast disease. The rescue potential during conidial germination was substantially more pronounced than for mycelial growth. In a comparison of wild-type strain and an alternative respiration-deficient mutation, azoxystrobin efficacies in suppressing symptom development differed by a factor of two, with full disease control achieved for both genotypes at $1 \mu\text{g mL}^{-1}$ azoxystrobin. In contrast, conidia derived from two QoI-resistant target site mutants were highly resistant to azoxystrobin and trifloxystrobin and were fully capable of infecting leaf surfaces protected with $10 \mu\text{g mL}^{-1}$ of azoxystrobin. Both target-site mutants emerged spontaneously in the presence of high azoxystrobin doses when residual mycelial growth was supported by alternative respiration. The effective silencing of alternative respiration in protective applications of QoI-inhibiting fungicides might constitute a strategy of slowing down of the emergence of highly resistant target site mutants (Avila-Adame and Köller 2003).

The emergence of strains of *Magnaporthe oryzae*, causal agent of rice blast disease, showing resistance to QoI fungicides necessitated the development of techniques for rapid, reliable, and sensitive monitoring of the resistant/insensitive strains. A single nucleotide polymorphism (SNP) was detected in a QoI-resistant mutant and a wild-type

strain of *M. oryzae*. Two types of PCR-based DNA markers that facilitate sensitive detection of resistant strains were developed, using DNA templates prepared from filter permeated with the pathogen. This simple, rapid, cost-effective, and reliable procedure required only a few hours to yield results without the requirement of any special equipment (Hayashi et al. 2015).

Microdochium nivale and *M. majus* are involved in the Fusarium head blight (FHB) disease affecting cereals in France. The efficacy of strobilurins was found to be altered in providing protection to the expected level in some field experiments. The sensitivity of French isolates of FHB pathogens to strobilurins and the possible mechanisms of resistance were investigated. Half of the strains collected in 2007 were resistant to strobilurins. In addition, most of the isolates displaying strong resistance were found to be mostly *M. majus* isolates. Positive cross-resistance was observed between all strobilurins tested, but not with the phenylpyrrole derivative fludioxonil and the various classes of sterol biosynthesis inhibitors (SBIs). In most strains, resistance was correlated with the G143A substitution in cytochrome b, the molecular target of strobilurins. Two other mechanisms were also detected at lower frequencies. Strobilurin resistance in *Microdochium* was detected for the first time (Walker et al. 2009).

Isolates of *Fusarium graminearum* (teleomorph *Gibberella zeae*) isolated between 1960 and 2009 in Belgium, Canada, Germany, Italy, Luxembourg, or the USA belonged to the three known chemotypes (3-ADON, 15-ADON, and nivalenol (NIV)) and they were screened for their sensitivity to trifloxystrobin using a liquid culture assay. None of the isolates was completely inhibited by concentrations up to 3 mM of trifloxystrobin. The inhibitory capacity was compared with prothioconazole which inhibited the pathogen growth of a standard isolate of *F. graminearum* at concentrations as low as 0.007 mM. The highest level of inhibition obtained using trifloxystrobin ranged over 14–65% among the strains tested. The sensitivity to trifloxystrobin was not affected by the country of origin or by the chemotype of *F. graminearum*. Significant differences in resistance levels between the countries of origin and chemotypes were detected. In addition, strains isolated before the market introduction of strobilurins in 1996 also showed resistance to strobilurins, indicating that this was largely due to natural resistance of *F. graminearum* isolates and not primarily related to intensive use of strobilurin in agriculture (Dubos et al. 2011).

Azoxystrobin was frequently used for the control of *U. maydis*. The development of mutants resistant to *U. maydis* was observed in several countries. Mutants of *U. maydis* with high resistance to azoxystrobin, an inhibitor of mitochondrial transport at the cytochrome *bc1* complex, were isolated in a mutation frequency of 2.3×10^7 , after nitro-soguanidine mutagenesis and selection on media containing $1 \mu\text{g mL}^{-1}$ azoxystrobin in addition to 0.5 mM salicylhydroxamate (SHAM), a specific inhibitor of cyanide-resistant (alternative) respiration. Oxygen uptake in the whole cells was strongly inhibited in the wild-type strain by azoxystrobin ($1.5 \mu\text{g mL}^{-1}$) in addition to SHAM (1 mM), but not in the mutant isolates. Genetic analysis with nine such mutants led to the production of progeny phenotypes which did not follow Mendelian segregation, but satisfied the criteria of non-Mendelian (cytoplasmic) heredity (Ziogas et al. 2002).

Fungicides that were used regularly for managing gray mold disease of strawberry caused by *Botrytis cinerea* became ineffective in major strawberry production areas in China. *B. cinerea* isolates (486) collected from nine locations in Zhejiang Province were therefore screened for resistance to azoxystrobin, carbendazim, pyrimethanil, and fludioxonil. The majority of the isolates (72.6%) showed resistance to single or multiple fungicides,

whereas 52.3% of the isolates were simultaneously resistant to azoxystrobin, carbendazim, iprodione, and pyrimethanil. All 322 isolates resistant to azoxystrobin (Azo^R) showed the G143 point mutation. Populations of *B. cinerea* could be grouped into types based on the structure of the *cyt b* gene with (12.2%) or without (87.8%) the third introns Bcbi-143/144. The high frequency of *B. cinerea* isolates lacking Bcbi-143/144 intron indicated that populations of *B. cinerea* infecting strawberry possessed a high inherent risk for development of resistance to QoI fungicides (Yin et al. 2015).

Development of insensitivity to azoxystrobin in *Didymella bryoniae*, causal agent of cucurbit gummy stem blight disease, was observed in the eastern USA 2 years after commercial introduction of the fungicide in 1998. Azoxystrobin baseline sensitivity distribution was established in vitro for *D. bryoniae* isolates that had never been exposed to strobilurins (azoxystrobin), and the baseline values were comparable to those of other ascomycetes. The baseline sensitivities of isolates exposed to azoxystrobin for one or more seasons were compared. Sixty-one isolates of *D. bryoniae* collected before 1998 were sensitive. The median EC₅₀ was 0.055 mg L⁻¹ azoxystrobin with a range of 0.005–0.81 mg L⁻¹. Forty isolates collected after exposure during 1998 also were sensitive. On the other hand, 53 of 64 isolates collected in South and North Carolina between 2000 and 2006 were insensitive to 10 mg L⁻¹ azoxystrobin. Sensitive and insensitive isolates could be differentiated based on disease severity on *Cucumis melo* seedlings treated with azoxystrobin (20 or 200 mg L⁻¹). Insensitive isolates of *D. bryoniae* were identified in fields with a history of strobilurin applications (Keinath 2009).

The widespread and highly destructive occurrence of gummy stem blight (GSB) caused by *D. bryoniae* was observed in southeastern USA. The quinone-oxidase-inhibiting (QoI) fungicide azoxystrobin (AZO) initially suppressed the development of the GSB disease very effectively. Azoxystrobin inhibited mitochondrial respiration of the fungal pathogen by binding to the outer quinone-oxidizing pocket of the cytochrome bc1 (*cyt b*) enzyme complex. Resistance to AZO was later observed in *D. bryoniae* isolates from many watermelon-producing regions. Comparison of the DNA sequences of partial *cyt b* genes of four AZO-resistant (AZO-R) and four AZO-sensitive (AZO-S) isolates of *D. bryoniae* revealed the amino acid substitution of glycine by alanine at the 143 codon (G143A) in the AZO-R isolates tested. Allele-specific primers were designed to detect the resistant or sensitive allele at codon 143 of the *cyt b* gene which amplified a 165 bp PCR product from genomic DNA of nine AZO-R and nine AZO-S isolates of *D. bryoniae*, respectively. The primer pairs did not amplify DNA from other pathogens tested. The results indicated that the PCR assays developed in this investigation were specific in differentiating AZO-R and AZO-S isolates and the protocol might be employed for the detection of azoxystrobin resistance in *D. bryoniae* isolates (Finger et al. 2014).

Populations of *Ascochyta rabiei*, causal agent of *Ascochyta* blight of chickpea, resistant to QoI fungicides were detected in the Northern Great Plain of the USA. Assays were performed to assess the fungal sensitivity for two alternative fungicidal mode of action. Isolates (78) of *A. rabiei* collected between 1983 and 2007 were screened to determine the baseline sensitivity to the demethylation-inhibiting foliar fungicide prothioconazole, and 100 isolates collected between 1987 and 2007 were screened for their sensitivity to the methyl benzimidazole carbamate (MBC) fungicide, thiabendazole. Baseline EC₅₀ values for mycelial growth for prothioconazole ranged from 0.0526 to 0.2958 µg mL⁻¹, with a mean of 0.1783 µg mL⁻¹. Isolates of *A. rabiei* collected from 2007 to 2009 from North Dakota chickpea fields exposed to prothioconazole sensitivity were screened using the same assay. Mean EC₅₀ values for these isolates were 0.3544 µg mL⁻¹,

0.3746 $\mu\text{g mL}^{-1}$, and 0.7829 $\mu\text{g mL}^{-1}$ respectively. These values represent an approximate 2- (2007–2008) and 4.4-fold (2009) decrease in intensity from the baseline ranging from 1.192 to 3.819, with a mean of 2.459 $\mu\text{g mL}^{-1}$. No significant decrease in fungicide sensitivity was observed for thiabendazole against *Ascochyta* blight disease to chickpea (Wise et al. 2011).

Genetic modification in *A. rabiei* in response to the development of resistance to QoI fungicides was studied. Isolates of *A. rabiei* exhibiting resistance to QoI fungicides were collected in North Dakota, USA and a fragment of the cytochrome *b* gene from *A. rabiei* from the resistant isolates was characterized. The sequenced genome DNA fragment contained a group I intron immediately after codon 131. The size of the cytochrome *b* gene was estimated to be over 4.6 kb. Multiple alignment analysis of cDNA and protein sequences revealed a mutation that changed the codon for amino acid 143 from GLT to GTC, introducing an amino acid substitution from glycine to alanine (G143A) which is frequently associated with QoI resistance. Based on this mutation, a diagnostic PCR assay was developed using an approach called mismatch amplification mutation assay. This method was validated by testing 38 of 70 *A. rabiei* isolates which were resistant to QoI fungicide. The PCR protocol developed in this investigation could be applied for screening the isolates of *A. rabiei* for their sensitivity/resistance to QoI fungicide (Delgado et al. 2013).

The sensitivity of 50 isolates, including 25 each of the 3-acetyldeoxynivalenol (3-ADON) and 15-acetyldeoxynivalenol (15-ADON) genotypes (chemotypes) from a collection of *Fusarium graminearum* associated with Fusarium head blight (FHB) disease of wheat, to tebuconazole and metconazole was investigated. The effective concentration of tebuconazole leading to 50% reduction in mycelial growth (EC_{50}) was 0.28–8.09 mg L^{-1} , while metconazole had EC_{50} values of 0.05–0.86 mg L^{-1} . The mean sensitivity did not differ between the trichothecene genotype groups. The isolate Gz448NY11 showed the lowest sensitivity to tebuconazole (EC_{50} = 8.09 mg L^{-1}). The level of suppression of FHB and DON accumulation following application of the commercial rate of tebuconazole was significantly reduced in plants inoculated with tebuconazole resistant isolate compared with a sensitive isolate with known aggressiveness and toxigenicity on wheat. Application of metconazole did not have any effect on disease development and toxin accumulation. The number of the population of tebuconazole-resistant isolate recovered from spikes inoculated with an equal mixture of two isolates and sprayed with tebuconazole increased significantly. Monitoring of triazole-resistant isolates to determine the risk which these fungicides pose to disease management and food security is essential (Spolti et al. 2014).

FHB disease of wheat caused by *Fusarium culmorum* was effectively managed by applying azole fungicides, but the occurrence of insensitive strains of *F. culmorum* became a major problem. A tebuconazole-insensitive strain was produced in the laboratory by exposure to higher concentrations of tebuconazole, but the insensitive strain had a lower level of fitness in vitro. The tebuconazole-insensitive strain also showed cross-resistance to nine important azole fungicides. Further, plants inoculated with the insensitive *F. culmorum* strain showed no reduction of FHB symptoms and deoxynivalenol (DON) accumulation in wheat grains after tebuconazole application, compared to plants inoculated with the sensitive strain. Cultivation of wheat cultivars carrying high levels of resistance such as cultivar Toras was considered to be the most effective method of reducing FHB disease severity and DON accumulation. A fungicide mixture that could combine different mechanisms of action on the FHB pathogens might be

used in combination with resistant cultivars to tackle the problem of fungicide resistance in pathogens (Serfling and Ordon 2014).

The azole fungicide prochloraz has been found to be effective in controlling *Fusarium verticillioides* infecting corn in China when applied as foliar spray. The possible resistance risk due to prochloraz treatment was assessed under in vitro conditions. Four prochloraz-resistant strains were generated by successive selection on fungicide-amended media. The mycelial growth rates of the mutants were inversely related to the level of resistance. All four mutants showed cross-resistance to the triazole fungicides, triadimefon, tebuconazole, and difenconazole, but not to the multisite fungicide chlorothalonil or the MAP/histidine kinase inhibitor fungicide fludioxonil. Based on the Y123H mutation in FvCYP51B, the four resistant mutants were subdivided into two genotypes: PCZ-R1 mutants with wild-type FvCYP51B; and PCZ-R2 mutants with substitution Y123H and FvCYP51B. Wild-type FvCYP51B complemented the function of native ScCYP51 in *Saccharomyces cerevisiae* YUG37::erg11, whereas Y123H-mutated FvCYP51B did not. For the PCZ-R2 mutants, disruption of FvCYP51B function by the Y123H substitution caused constitutive upregulation of FvCYP51A expression and consequently to prochloraz resistance (Fan et al. 2014).

The triazole fungicides, sterol demethyl inhibitors, have been the primary systemic fungicides applied on cucurbits to reduce the incidence of gummy stem blight (GSB) disease caused by *Didymella bryoniae*. Isolates of *D. bryoniae* from South Carolina with no exposure to tebuconazole or exposed for several years were tested for sensitivity to tebuconazole and difenconazole. The parameters used were colony diameters, percentages of germination of ascospores, and conidia, and germ tube lengths were determined by growing the isolates (147) of *D. bryoniae* on agar amended with 0.10–10.0 mg L⁻¹ of tebuconazole and 0.01–1.0 mg L⁻¹ difenconazole. All isolates were sensitive to tebuconazole and difenconazole with mean EC₅₀ values of 0.41 and 0.054 mg L⁻¹, respectively. Retention of sensitivity of isolates of *D. bryoniae* to tebuconazole and difenconazole was attributed to the 2 year crop rotation and rotation of systemic and contact fungicides which prevented continuous exposure of the pathogen to tebuconazole and difenconazole. Despite exposure to tebuconazole for up to 9 years, isolates of *D. bryoniae* from South Carolina remained sensitive to triazole fungicides (Keinath and Hansen 2013).

Azoles such as epoxiconazole, propiconazole, prothioconazole, or tebuconazole and imidazoles such as prochloraz belong to the group of demethylation inhibitors (DMIs). Their mode of action is through inhibition of demethylation at 14- α carbon of lanosterol or 24-methylene dihydrolanosterol. Tebuconazole and prochloraz have been shown to be substrates for the cytochrome P450-dependent 14- α demethylase in the biosynthesis of fungal sterols (Gisi et al. 2002). Isolates (about 3000) of *Mycosphaerella graminicola* (anamorph *Septoria tritici*) were assayed in vitro for their resistance to QoI fungicide azoxystrobin and 46 isolates were found to be resistant. On subculturing, only 10 isolates remained resistant. Cross-resistance extended to other QoIs, but varied between different isolates. Application of azoxystrobin was not effective to the required level, especially at lower doses. Propylgallate, an inhibitor of alternative oxidase, potentiated the activity of azoxystrobin in vitro, so that resistance was no longer observed. The growth of resistant strains in the presence of azoxystrobin led to alternative oxidase activation. This increased flexibility in respiration allowed resistant strains to survive in the presence of a QoI fungicide. Under these conditions, selection for target-site mutations could occur. Using QoIs as preventive application reduced the risk of development

of resistance, since alternative oxidase cannot by itself generate all the energy required for spore germination and early infection (Miguez et al. 2004).

Resistance of *Septoria tritici* (teleomorph *Mycosphaerella graminicola*) to QoI fungicides was observed in France and other European countries and reliable suppression of wheat blotch disease was considered to be dependent on inhibitors of sterol 14 α -demethylation (DMIs). Strains of *S. tritici* with reduced sensitivity to DMIs were found to be widespread. Sensitivity assays based on in vitro effects of fungicides on germ tube elongation allowed characterization of seven DMI-resistant phenotypes. In four of them, cross-resistance was not observed between all tested DMIs such as prochloraz, triflumizole, fluquinconazole, and tebuconazole. Further, the highest resistant factors to most DMIs were found only in recently occurring isolates. According to the responses of isolates to prochloraz, two categories were recognized. Molecular analysis showed that DMI resistance was associated with mutations in the *CYP51* gene encoding the sterol 14 α -demethylase. Changes at codons 459, 460, and 461 were related to low resistance levels, whereas at position 381 a valine instead of an isoleucine in combination with previous changes determined the highest resistance levels to all DMIs except prochloraz. Mutations in codons 316 and 317 were also found in some isolates exhibiting low-resistance factors towards most DMIs (Leroux et al. 2007).

The sensitivity of *Septoria tritici* (teleomorph *Mycosphaerella graminicola*) to QoI fungicide trifloxystrobin, azoles propiconazole, tebuconazole, and prothioconazole and nonsystemic fungicides folpet and chlorothalonil was tested in a bioassay using strains isolated in 1999, 2004, or 2008 in the high-disease pressure and high-fungicide input areas between the North and Baltic seas. The percentage of sprays containing at least one demethylation inhibitor (DMIs, azoles) was around 60% at any given point of time in that region where *S. tritici* strains were sampled. The bioassay accurately detected the total loss of sensitivity of *S. tritici* towards trifloxystrobin used as a representative of the QoIs. In 2002, about 80% of the fungicide sprays contained QoIs in a wheat disease monitoring program in northern Germany. After the breakdown of QoI efficacy, use of QoI decreased to about 4% in 2006 and the sensitivity did not recover until 2008, indicating that QoI resistance was not coupled to a significant fitness penalty in *S. tritici*. DMI concentrations inhibiting pathogen growth by 50% decreased on average by $48 \pm 17\%$ between 1999 and 2004 and increased by $132 \pm 42\%$ between 2004 and 2008, compared to 1999. On the other hand, EC_{50} values of the multisite inhibitors folpet and chlorothalonil increased by $128 \pm 25\%$ between 1999 and 2004 and decreased by $40 \pm 11\%$ between 2004 and 2008, but changes over time were nonsignificant for the multiple inhibitors (Beyer et al. 2011). A high proportion of DMI-moderate resistance genotypes ($\geq 94\%$) of *S. tritici* was found in all samples. Distribution of DMI-resistant genotypes was not affected by different levels of resistance of wheat cultivars or by different periods of application of the fungicide prothioconazole. Treatment with prothioconazole significantly decreased the amount of pathogen DNA by 80% in preventive treatment, and they were still 70% efficient when applied curatively at 3 days postinoculation (dpi). The qPCR format was found to be an accurate, specific, and pre-symptomatic quantitative procedure for determining the pathogen population. Correlation between quantity of DNA estimated by qPCR assay and different levels of necrotic surfaces (0–100%) in leaf samples was investigated. *S. tritici* was detected in asymptomatic leaves and the DNA contents increased proportionally with an increase in leaf necrotic areas in the leaves. A high level of correlation ($CF=0.95$) was observed for up to 40% leaf necrotic surface. The DNA contents showed reduction beyond 50% leaf necrotic area and remained constant thereafter (Fig. 14.1) (Selim et al. 2014).

Figure 14.1 Positive correlation between the percentages of necrotic leaf surface on wheat cultivar Maxyl and the copy numbers of tubulin gene (DNA contents) determined by qPCR assay ($F=0.95$). Note the disease progress is proportional to the pathogen development. Source: Selim et al. (2014). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

Variations in the sensitivity to tebuconazole and metconazole of 50 isolates comprising 25 each of 3-acetyldeoxynivalenol (3-ADON) and 15-acetyldeoxynivalenol (15-ADON) from a contemporary collection of *Fusarium graminearum* associated with Fusarium head blight (FHB) disease of wheat were assessed. The effective concentration causing 50% reduction of mycelial growth (EC_{50}) for tebuconazole was $0.28\text{--}8.09\text{ mg L}^{-1}$ ($\mu = 1.12\text{ mg L}^{-1}$), whereas EC_{50} for metconazole was $0.05\text{--}0.86\text{ mg L}^{-1}$ ($\mu = 0.33\text{ mg L}^{-1}$). The mean sensitivity did not differ between the trichothecene genotype groups. Isolate Gz448NY11 of *F. graminearum* from Steuben county was first reported as the tebuconazole-resistant field isolate and had the lowest sensitivity to tebuconazole ($EC_{50} = 8.09\text{ mg L}^{-1}$). FHB suppression and DON production were significantly reduced following application at commercial rate of the fungicide in plants inoculated with tebuconazole-resistant isolate compared with those inoculated with sensitive isolate, which was aggressive and toxigenic. FHB disease and DON production were reduced by application of metconazole. Significantly greater numbers of individuals of the tebuconazole-resistant isolates were recovered from spikes inoculated with an equal mixture of the two isolates and sprayed with tebuconazole. The results indicated the need for constant monitoring of the appearance of triazole-resistant isolates for effective management of FHB disease using fungicides (Spolti et al. 2014).

Intensive application of DMI fungicides led to the selection of several fungal pathogens for different levels of insensitivity/resistance to these fungicides. *Fusarium graminearum* isolates (224) from 13 different German populations, 22 isolates from the UK, and 6 reference isolates from Italy and the USA were evaluated for their levels of sensitivity to propiconazole. Sensitivity within field population was about 80%, suggesting significant potential for selection of resistant isolates at the field scale. Sequence analysis of the pathogen isolates showed that the *CYP51A* and *CYP51C* genes carried several nonsynonymous substitutions, but the *CYP51B* protein was not polymorphic. The nonsynonymous substitutions were randomly distributed among field populations of *F. graminearum* and they showed no relationship with fungicide sensitivity. The results suggested that the contribution of genes outside *CYP51* family might be

more important for development of resistance to DMI fungicides in *F. graminearum* than those in *CYP51* family (Talas et al. 2015).

Phenylamide fungicides have been extensively applied for over three decades to reduce the incidence of oomycete-induced plant diseases. Mefenoxam application effectively suppressed the development of potato late blight disease caused by *Phytophthora infestans*. Isolates of *P. infestans* were collected from Wisconsin from 2009 to 2012. Distribution of clonal lineages, mating types, and sensitivity to the systemic fungicide mefenoxam were studied. The usefulness of analysis of the glucose-6-phosphate isomerase (Gpi) allozyme was assessed for predicting mefenoxam sensitivity to facilitate early transmission of information to the growers for taking appropriate disease management measures. Overall, 143 isolates were collected from 52 locations in 20 Wisconsin counties from 2009 to 2012. Three clonal lineages, US-22, US-23, and US-24 were identified. The US-22 was of the A2 mating type and sensitive to mefenoxam with Gpi 100/122. On the other hand, US-23 and US-24 belonged to A1 mating type and primarily intermediately sensitive to mefenoxam with Gpi 100/100 and 100/111, respectively. The mefenoxam sensitivity could be predicted based on the allozyme assay, because of the close correlation and the unique Gpi patterns for each lineage. The presence of new clonal lineages of *P. infestans* in Wisconsin indicated the need for continued close monitoring of late blight pathogen isolates (Seidl and Gevens 2013).

The insensitivity of isolates of *P. infestans* to phenylamide fungicide mefenoxam was investigated to determine the genetic basis of insensitivity. Crosses were effected between insensitive isolates and intermediate insensitive isolates of *P. infestans*. F1 progeny showed expected semi-dominant phenotypes for mefenoxam insensitivity and suggested the involvement of multiple loci, complicating the positional cloning of the gene(s) conditioning insensitivity to mefenoxam. The primary effect of phenylamide compounds was found to inhibit ribosomal RNA synthesis by the pathogen. The subunits of RNA polymerase I (RNA polI) were sequenced from sensitive and insensitive isolates and F1 progeny. Single nucleotide polymorphisms (SNPs) specific to insensitive field isolates were identified in the gene encoding the large subunit of RNA polI. In a survey of field isolates of *P. infestans*, SNP T1145A (Y382F) showed an association of 86% with mefenoxam insensitivity. Isolates lacking this association belonged predominantly to one genotype of *P. infestans*. Transfer of the allele governing sensitivity RPA190 to a sensitive line resulted in the generation of transgene lines insensitive to mefenoxam. The results demonstrated that sequence variation in RPA190 contributed to insensitivity to mefenoxam in *P. infestans* (Randall et al. 2014).

Development of insensitivity to other groups of fungicides in fungal pathogens has also been reported. The application of scytalone dehydratase inhibitors of melanin biosynthesis (MBI-D) on rice failed to suppress the incidence of rice blast disease caused by *Magnaporthe grisea* in Kyshu in Japan. Isolates of *M. grisea* were collected from Saga prefecture and analyzed for their sensitivity to MBI-D fungicides. Resistant isolates of rice blast pathogen were detected in all prefectures of Kyushu. DNA fingerprinting analysis showed that mutations causing resistance to MBI-Ds had arisen independently in each area. The data suggested that resistant isolates might occur in any area and become dominant under continuous selection pressure for MBI-Ds. However, it would be possible to manage the rice blast disease using reductase inhibitors of melanin biosynthesis (MBI-R) or commercial rice seed disinfectants (Sawada et al. 2004).

Loss of sensitivity to carpropamid in *Magnaporthe grisea* was investigated. The inhibitory activity of carpropamid on scytalone dehydratase (SDH) extracted

from a carpropamid-resistant strain of *M. grisea* was dramatically reduced in comparison with that on SDH extracted from the sensitive strain. A single-point mutation (G to A) located at the upstream region (233bp) downstream from the ATG codon, resulting in a one-amino acid substitution (valine (GTG) 75 to methionine (ATG0:V75M)) was found in the resistant strain. In order to examine whether the V75M mutation was the primary reason for the decrease in sensitivity of SDH to carpropamid, the SDH cDNAs of both the sensitive and the resistant strain were cloned into a GST-fused protein expression vector system. The recombinant SDHs of both strains exhibited the same levels of sensitivity to carpropamid as those extracted from the mycelia of the respective strains. The results revealed that the V75M mutation caused the low sensitivities of the SDHs of the carpropamid-resistant strains and strongly suggested that V75M mutation conferred resistance in these strains to carpropamid (Takagaki et al. 2004).

Resistance to isolates of *Magnaporthe grisea* may be due to a single-point mutation in the scytalone dehydratase gene. This mutation results in a replacement of valine with methionine at codon 75 of the fungicide target protein. PCR-Luminex, a novel system developed for high-throughput analysis of single nucleotide polymorphisms (SNPs), was effectively employed for diagnosis of MBI-D resistance using specific oligonucleotide probes coupled with fluorescent beads. In addition, the PCR-Luminex system was tested for its potential in identifying fungi involved in wheat Fusarium head blight disease. *Fusarium graminearum* (= *F. asiaticum*), *F. culmorum*, *F. avenaceum*, and *Microdochium nivale* were subjected to PCR-Luminex analysis successfully and their involvement in FHB was established in this disease complex in Japan (Ishii et al. 2008).

A novel cyanoacrylate fungicide JS 399-19 (2-cyano-3-amino-phenylacrylic acetate) exhibited specific activity in inhibiting mycelial growth of plant pathogenic *Fusarium* spp. and was evaluated for its efficacy against *Gibberella zeae* (anamorph *Fusarium graminearum*), one of the principal pathogens inducing wheat Fusarium head blight (FHB) disease. Field isolates (43) of *G. zeae* sensitive and 45 isolates resistant to JS 399-19 were evaluated. The resistant mutants were grouped into moderate-level resistance (MR) and high-level resistance (HR) based on the EC₅₀ values. Of the 45 isolates, 17 were MR and 28 were HR. Eight isolates representing three sensitivity-level phenotypes (S, MR, and HR) were randomly selected to investigate the inheritance of resistance in *G. zeae* to JS 399-19 by analyzing the sensitivity of hybrid F1 progeny. A nitrate-nonutilizing mutant (*nit*) was used as a genetic marker to confirm that individual perithecia were the result of outcrossing. Genetic analysis of the crosses indicated that resistance to JS 399-19 was governed by a single major gene in *G. zeae*. The two levels of resistance could be conferred by mutations at two sites or one site with two different mutations in the gene. There was a consistent 1:1 ratio of segregation in the crosses between parents with different resistance levels. The segregation pattern for the two levels of resistance to JS 399-19 in *G. zeae* indicated polymorphism in a single Mendelian gene. There was no positive cross-resistance between JS 399-19 and fungicides belonging to other chemical classes such as ergosterol biosynthesis inhibitors, including tebuconazole and prochloraz, and strobilurins (azoxystrobin). Combining or alternating applications of JS 399-19 with tebuconazole, prochloraz, or azoxystrobin might therefore be an effective strategy for the management of FHB disease of wheat (Chen et al. 2009). The efficacy of JS 399-19 (cyanoacrylate) was assessed for the management of rice bakanae disease caused by *Fusarium verticillioides* (= *F. moniliforme*). The EC₅₀ values for JS 399-19 for inhibiting mycelial growth of the

wild-type *F. verticillioides* strain ranged from 0.162 to 0.559 $\mu\text{g mL}^{-1}$ and the average value was $0.316 \pm 0.072 \mu\text{g mL}^{-1}$. Germination of healthy seeds of selected rice varieties was not affected by treatment with JS 399-19, which could be used as a disinfectant of rice seeds infested by *F. verticillioides*. The results suggested that there was little shift in the sensitivity of *F. verticillioides* isolates to JS 399-19 fungicide (Chen et al. 2012a).

The mechanism of development of resistance to the fungicide JS399-19 in *Fusarium graminearum* was investigated. Fimbrin is an actin-bundling protein and its homolog Sacbp was shown to have a critical role in endocytosis and other cellular process in *Saccharomyces cerevisiae*. *F. graminearum* Y2021A strain was highly resistant to JS399-19. The function of *FgFim* in *F. graminearum* was studied by constructing a deletion mutant of *FgFim*, designated $\Delta FgFim-15$, which showed a dramatic reduction in resistance to JS399-15 in addition to decrease in mycelial growth and other cultural characteristics compared to the wild-type strain. Virulence of the *FgFim* deletion mutant on flowering wheat heads was impaired, while sensitivity to agents that damage cell walls and cell membranes was increased. Reduced virulence was consistent with reduced production of deoxynivalenol (DON) in wheat tissues. All these defects could be restored by genetic complementation of the mutant with the parental *FgFim* gene. Quantitative real-time PCR assays showed that the basal expression of three *Cyp51* genes which encoded sterol 14 α -demethylase was significantly lower in the mutant than in the parental strain. The results indicated the critical role of *FgFim* in the regulation of resistance to JS399-19 fungicide and in other cellular processes occurring in *F. graminearum* (Zheng et al. 2014).

Pepper (*Capsicum* spp.) crop grown in the commercial plastic houses in Calabria (southern Italy) was regularly applied with metalaxyl for suppressing Phytophthora blight disease caused by *Phytophthora capsici*. Single-hyphal isolates of *P. capsici* isolated from the pepper plants were tested for their sensitivity to metalaxyl using different concentrations from 0.1 to 1000 mg L^{-1} incorporated in the potato dextrose agar (PDA) medium. The ED_{50} values for inhibition of mycelial growth of *P. capsici* isolates ranged over 1.41–44.46 $\mu\text{g mL}^{-1}$. More than 80% of the *P. capsici* from plastic house crops showed a moderate level of resistance to metalaxyl (Agosteo et al. 2000).

In a later study, extensive application of metalaxyl was found to result in widespread resistance in *P. capsici* to this fungicide in China. Several fungicides were therefore evaluated for their efficacy in suppressing the development of metalaxyl-sensitive and -resistant *P. capsici* isolates by determining the EC_{50} values. The carboxylic acid amide (CAA) fungicide mandipropamid showed high inhibitory activity against *P. capsici*, leading to suppression of Phytophthora blight disease by 70%. A new fungicide mixture (625 g L^{-1} fluopicolide + 625 g L^{-1} propamocarb) was still more effective in controlling the pepper blight disease caused by metalaxyl-resistant isolates. The results indicated that no cross-resistance between metalaxyl and other tested fungicide apparently existed. These fungicides might therefore be alternatives to metalaxyl for the management of pepper Phytophthora blight disease (Qi et al. 2012).

Phytophthora capsici, causing pepper Phytophthora blight disease, has been difficult to control because the pathogen produces different kinds of propagules capable of initiating infection. The fungicide should therefore be able to inhibit sporangium formation, zoospore germination, and mycelial growth. Carboxylic acid amides (CAA) dimethomorph, flumorph, and pyrimorph were evaluated for their efficacy in reducing the Phytophthora blight disease of pepper (chilli) caused by *Phytophthora capsici*. Isolates (572) of *P. capsici* were collected during 2006–2008 from seven provinces in China. Of these, 90 isolates

without a history of exposure to CAA fungicides were used to determine the baseline sensitivity. The baseline EC_{50} values ranged over $0.122\text{--}0.203\mu\text{g mL}^{-1}$ for dimethomorph, $0.301\text{--}0.487\mu\text{g mL}^{-1}$ for flumorph, and $0.557\text{--}0.944\mu\text{g mL}^{-1}$ for pyrimorph. Four CAA-resistant mutants were generated by repeated exposure to dimethomorph in vitro. The mutants showed similar fitness in hyphal growth, sporulation in vitro, and pathogenicity in vivo. Resistant mutants induced visible lesions on pepper stems or roots treated with recommended dose of dimethomorph. Two cholinephosphotransferase (CPT) genes (*AAPT1* and *AAPT2*), the primary target of CAAs, were sequenced and analyzed. As there was no difference between the amino acid sequences of *AAPT1* and *AAPT2* genes of wild-type and mutants, it was considered that resistance to dithiomorph was not due to mutations in the amino acid sequence of these target genes (Sun et al. 2010).

The effects of three compounds – mandipropamid, dimethomorph, and cyazofamid – on different stages of *P. capsici* life cycle were determined. In addition, the sensitivity and resistance levels of *P. capsici* to these fungicides were also assessed. Forty isolates of *P. capsici* were sensitive to mandipropamid and dimethomorph based on mycelial growth, zoospore germination, and sporangial production. The EC_{50} values for arresting these processes averaged 0.03, 5.70, and $0.02\mu\text{mL}^{-1}$ respectively for mandipropamid, while the average EC_{50} values for dimethomorph were 0.24, 0.10, and $0.46\mu\text{g mL}^{-1}$, respectively. The majority of isolates of *P. capsici* were either resistant or intermediately sensitive to cyazofamid at $500\mu\text{g mL}^{-1}$ or lower concentrations, based on mycelial growth or sporangial production. The results showed that mandipropamid and dimethomorph were effective in suppressing *P. capsici* at all stages of pathogen development. Mandipropamid inhibited mycelial growth and sporangial production at lower concentrations than dimethomorph, while dimethomorph inhibited zoospore germination at lower concentrations than mandipropamid. *P. capsici* populations in Georgia were sensitive to mandipropamid and dimethomorph. On the other hand, the majority of *P. capsici* isolates showed resistance to cyazofamid, indicating the need to select appropriate fungicides for application against this disease (Jackson et al. 2012).

Development of resistance to single-site fungicides occurs more frequently in fungal pathogens. Boscalid is a broad-spectrum fungicide included in the class of succinate dehydrogenase inhibitors (SDHIs). This group, including carboxim, flutolanil, and fluopyram, interferes with the activity of succinate ubiquinone reductase (complex II) or succinate dehydrogenase (SDH) complex, which is a functional part of the tricarboxylic acid (TCA) cycle in mitochondrial electron transport chain (Keon et al. 1991). Boscalid (a pyridine-carboxamide) lost its effectiveness against *Didymella bryoniae* (anamorph *Stagonosporosis cucurbitacearum*), incitant of gummy stem blight disease of cucurbits. Boscalid inhibits fungal respiration by binding to the enzyme succinate dehydrogenase in mitochondria. Boscalid in combination with pyraclostrobin (Pristine) was used against cucurbit gummy stem blight disease, because boscalid component was effective against strobilurin-insensitive isolates of *D. bryoniae* (Seebold and Langstrom Jr 2004). However, several isolates of *D. bryoniae* became insensitive to boscalid at 10 mg L^{-1} and resistant isolates were detected in South Carolina. A total of 201 isolates collected between 1998 and 2009 were tested for sensitivity to boscalid by determining percentages of germination of ascospores and conidia on media amended with boscalid at $0.01\text{--}10.0\text{ mg L}^{-1}$. All isolates collected in 1998, 2002, or 2005 were sensitive to boscalid. Of the 170 isolates collected in or after 2006, 84.7% were insensitive to boscalid including 19 of 30 isolates recovered from greenhouse-grown seedlings. The ascospores

were less sensitive than conidia. Twelve isolates that were insensitive, moderately insensitive, or highly insensitive based on conidial germination did not differ in relative virulence on boscalid-treated muskmelon seedlings, when inoculum suspensions contained only ascospores or mixture of ascospores and conidia. Since *D. bryoniae* produces conidia and ascospores on infected plants, it is essential that both types should be used to determine the sensitivity to the fungicide(s) of pathogens such as *D. bryoniae* that produce different spore forms on their host plants (Keinath 2012).

In another investigation, of the 103 isolates of *D. bryoniae* tested, 82 and 7 were found to be very highly resistant (B^{VHR}) and highly resistant (B^{HR}) to boscalid, respectively. Cross-resistance studies with the new SDHI penthiopyrad showed that the B^{VHR} isolates were only highly resistant to penthiopyrad ($B^{VHR}-P^{HR}$), while B^{HR} isolates appeared to be sensitive to penthiopyrad ($B^{HR}-P^S$). The molecular mechanisms of fungicide resistance in these two phenotypes ($B^{VHR}-P^{HR}$ and $B^{HR}-P^S$) were studied. In addition, their sensitivity to another SDHI fungicide fluopyram was also assessed. A 456 bp cDNA amplified fragment of the succinate dehydrogenase iron sulfur gene (DbSDHB) was initially cloned and sequenced from two sensitive (B^S-P^S), two $B^{VHR}-P^{HR}$, and one $B^{HR}-P^S$ isolate of *D. bryoniae*. Comparative analysis of the DbSDHB protein revealed that a highly conserved histidine residue involved in the binding of SDHIs present in wild-type isolates was replaced by tyrosine (H277Y) or arginine (H277R) in the $B^{VHR}-P^{HR}$ and $B^{HR}-P^S$ variants, respectively. Further, the H/Y and H/R substitutions were present in the remaining $B^{VHR}-P^{HR}$ and $B^{HR}-P^S$ variants, respectively. Analysis of the sensitivity to fluopyram of representative isolates showed that both SDHB mutants were as sensitive to this fungicide as the wild-type isolates. A selection of fungicides for effective management of *D. bryoniae* has to be based on the genotype-specific cross-resistance relationships between the SDHI boscalid and penthiopyrad, and the lack of cross-resistance between these fungicides and fluopyram (Avenot et al. 2012).

Resistance to fungicides may develop in fungal pathogens due to exposure to high-risk fungicides or the introduction of resistant isolates from external source(s). In order to assess the possibility of watermelon seeds being a potential source of fungicide-resistant inoculum of the fungal pathogen *Didymella bryoniae*, causing of gummy stem blight (GB) disease of watermelon and other cucurbits, direct plating, sweat box, and blotter assays were employed. Seeds from commercial watermelon seed lots were visually examined for symptoms of GSB disease. Three isolates of *D. bryoniae* were isolated from two seed lots and were evaluated for their levels of sensitivity/insensitivity to boscalid, tebuconazole, azoxystrobin, and Thiophanate-methyl, which were commonly used for GSB disease management. The isolates were resistant to thiophanate methyl, indicating the existence of fungicide-resistant isolates of *D. bryoniae* in naturally infested commercially distributed watermelon seeds. The results highlight that a new approach for fungicide resistance management in watermelon production is needed (Thomas et al. 2014).

Boscalid was found to be very effective in suppressing the development of *Sclerotinia sclerotiorum*, causing stem rot in oilseed rape. Five boscalid-resistant (BR) mutants were generated by culturing 10 field isolates of *S. sclerotiorum* for 2 weeks on PDA amended with boscalid at $50\mu\text{g mL}^{-1}$. The BR mutant had EC_{50} values of $>9\mu\text{g mL}^{-1}$, while the EC_{50} values of their parents were $<0.3\mu\text{g mL}^{-1}$. The mutants showed cross-resistance between boscalid and carboxin, whereas negative cross-resistance was detected between boscalid and kresoxim-methyl. All laboratory-induced BR mutants formed smaller colonies on fungicide-free potato dextrose agar (PDA) culture plates

Figure 14.2 Comparative abilities of Boscalid-resistant (BR) mutants and their parental isolates in producing sclerotia on PDA medium at 40 days after inoculation. (a–c) Parental isolates; (d–h) BR mutants. Source: Wang et al. (2015). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

and less biomass in potato dextrose broth (PDB). The parental lines produced sclerotia at 40 days in PDA cultures, whereas the BR mutants failed to produce the sclerotia that may be required for their survival during adverse environmental conditions. BR mutants had a slower rate of mycelial growth and lacked the ability to produce sclerotia (Fig. 14.2). In addition, they had lower virulence and oxalic acid content, but they had higher mycelial respiration and SDH activity. DNA sequence analysis revealed that all BR mutants had the same point mutation AIIV (GCA to GTA) in the sulfur protein subunit (SDHB). The expression of the cytochrome *b* (*cyt b*) gene was reduced to varying degrees in BR mutants. The results indicated that the risk of development of resistance in *S. sclerotiorum* to boscalid was low to moderate. Further, the results suggested that boscalid should not be combined or alternated with carboxin because of the cross-resistance between these fungicides (Wang et al. 2015).

14.2 Application of Chemicals Against Bacterial Diseases

Bacterial disease management systems primarily include preventive methods such as use of disease-free seeds and propagules and eradication measures. The effects of physical and chemical treatments on the elimination of *Acidovorax avenae* subsp. *citrulli*, causal agent of watermelon bacterial fruit blotch (BFB) disease, were assessed. Healthy triploid watermelon seed lots were spiked with naturally infected watermelon and melon seeds harvested from three separate diseased fruits. Treatments with acidic electrolyzed water for 30 min eradicated the pathogen most effectively without reducing seed germination or seedling establishment. Treatment with Clorox at 50°C for 20 min, Tsunami 100 for 30 min, or acidified cupric acetate at 50°C for 20 min eradicated the

bacterial pathogen, but significantly reduced seed germination ($P=0.05$) and/or seedling establishment (emergence) (Feng et al. 2009). Common bacterial blight pathogen infecting dry bean is seedborne, which is difficult to control. The viability of the bacterial pathogen after treatment with microwave radiation on navy (cultivars Navigator and Envoy) and pinto (cultivar Ac Ole) bean was tested. The microwave treatment reduced the incidence of seed infection. Under field conditions, microwave and chemical treatments were combined. Cultivars Modern, MB, Ridgtown, and Exter seeds were exposed to microwave radiation and then treated with copper hydroxide (53.8%) and pyroclostrobin + fluxapyroxad + metalaxyl before planting. Microwave treatment reduced emergence of seedlings by up to 7%, but did not affect yield and profit margin. Chemical treatment alone or in combination with microwave treatment provided effective elimination of seed infection, leading to higher yields (Friesen et al. 2014).

Chemicals available for application to seeds and propagules are limited. Copper compounds and antibiotics have been used with limited success. Use of copper compounds may result in reduction in intensity of symptoms, such as in bacterial canker disease of tomato caused by *Clavibacter michiganensis* subsp. *michiganensis*. Seven antibacterial compounds (bronopol, copper sulfate, kasugamycin, oxolinic acid, oxytetracycline, streptomycin, and 8-hydroxyquinoline), three chemical formulates (Antibak RZ, an oligoelements mixture containing copper plus zinc; Orthopol, a potassium soap; and Param, a resistance inducer), and a combination of these compounds were tested for their efficacy in reducing the tomato bacterial canker disease. Treatments containing copper sulfate substantially reduced disease severity in plants inoculated with the pathogen, whereas streptomycin was less effective. In two experiments, the percentage of leaves showing symptoms was significantly lower (2.4% and 11.9%) after treatment with copper sulfate combined with 8-hydroxyquinoline at half-dose, than in inoculated controls (75% and 59.6%). The disease suppressive effect of combination was greater than copper sulfate alone. The results indicated that copper sulfate combined with 8-hydroxyquinoline might be effective in reducing the amount of copper applied to tomato crops (De León et al. 2008).

Copper compounds were applied for the management of cabbage black rot disease caused by *Xanthomonas campestris* pv. *campestris* (*Xcc*) in Trinidad. Native isolates (56) of *Xcc* collected from 12 farming districts and 7 reference strains were evaluated for their resistance to copper in buffered (pH 7.0) and unbuffered (pH 5.6) nutrient agar media. Most of the isolates showed resistance to copper buffered (34) and unbuffered (33) media. All reference strains were highly sensitive to copper. The mean minimum inhibition concentration for the 56 native isolates was 224.6 ppm copper, indicating high levels of copper resistance in *Xcc* isolates. There was a strong association between the length of time of continuous application of copper formulations to treat cabbage against black rot disease and the proportion of the native *Xcc* isolates with copper resistance (Lugo et al. 2013).

Copper compounds were widely applied for the management of citrus canker disease caused by *Xanthomonas citri* subsp. *citri* (*Xcc*), resulting in the emergence of strains showing resistance to copper. Multiple and independent introductions of copper resistance genes into strains of *Xcc* and also in strains of *X. alfalfae* subsp. *citrumelonis* from Florida were investigated. The partial nucleotide sequences of principal copper resistance genes, *CopL*, *CopA*, and *CopB* from *X. citri* subsp. *citri* and *X. alfalfae* subsp. *Citrumelonis*, as well as of strains of other *Xanthomonas* spp. resistant to copper isolated

from 12 different countries and territories, were determined. The *CopLAB* gene cluster was detected in many species of *Xanthomonas* from different parts of the world. Alignment of partial nucleotide sequences of copper resistance genes among the copper-resistant (Cu^{R}) strains of *Xanthomonas* detected homology of >92, >96, and >91% for *CopL*, *CopA*, and *CopB*, respectively. It appeared that the plasmid had been horizontally transferred and various populations mutated based on selection pressure unique to geographic regions. Although high homology of the genes among the strains indicated that the copper resistance in xanthomonads had a common origin, the slight difference in the nucleotide sequences within groups of strains showed that Cu^{R} genes could be independently exchanged among species of *Xanthomonas* throughout the world (Behalu et al. 2013).

Streptomycin sulfate has been the antibiotic recommended for the management of bacterial diseases affecting many crops, including rice bacterial leaf blight (BLB) and streak (BLS) diseases caused by *Xanthomonas oryzae* pv. *oryzae* and *X. oryzae* pv. *oryzicola*, respectively. Inhibition of protein synthesis by the bacterial pathogens resulting in the interference with translational proofreading was the principal mechanism of action of streptomycin. *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) and *X. oryzae* pv. *oryzicola* were isolated from southern China. Single colony isolates (534 and 827, respectively) of these pathogens were tested for their sensitivity to streptomycin. Four strains of *Xoo* isolates from the same county of Yunnan Province were resistant to streptomycin and the resistant factor (the ratio of the mean median effective concentration inhibiting the growth of resistant isolates to that of sensitive isolates) was about 226. Resistance of these isolates in vivo was also observed. Less sensitive isolates of *Xoo* were also recovered in this county. On the other hand, none of the isolates of *X. oryzae* pv. *oryzicola* was found to be insensitive to streptomycin. Mutations in the *rpsL* (encoding S12 protein) and *rrs* genes (encoding 16S rRNA) and the presence of the *strA* gene accounting for resistance to streptomycin in other phytopathogens or animal and human pathogenic bacteria were examined on the sensitive and resistant strains of *X. oryzae* pv. *oryzae* by polymerase chain reaction (PCR) amplification and sequencing. As no mutation in the *rpsL* or *rrs* genes and presence of the *strA* gene could be detected, different mechanism(s) might be involved in the development of resistance to streptomycin in rice BLB pathogen (Xu et al. 2010).

In order to determine the molecular resistance mechanism of *X. oryzae* pv. *oryzicola* to streptomycin, seven streptomycin resistant mutants were obtained by UV irradiation or streptomycin selection on appropriate media. The mutants could grow at $100\mu\text{g mL}^{-1}$ of streptomycin, while the wild-type strain (RS105) could not survive at $5\mu\text{g mL}^{-1}$. Sequence analysis was applied for the detection of the *rpsL* gene encoding ribosomal protein S12, which had 125 amino acid residues. In all resistant strains, a mutation in which AAG was substituted for AGG (Lys $\rightarrow$ Arg) occurred either at codon 43 or 88. Two plasmids pUFRRS and pUFRRX were constructed by ligating the *rpsL* gene into the cosmid pUFR034. The plasmids pUFRRS and pUFRRX containing the Lys $\rightarrow$ Arg mutation of the *rpsL* gene conferred streptomycin resistance to the sensitive wild-type strain by electroporation. Both transformants RS1 and RS2 were able to develop in the medium amended with streptomycin at $50\mu\text{g mL}^{-1}$. A mutation at codon 43 or 88 in *rpsL* might result in resistance of *Xanthomonas oryzae* pv. *oryzicola* to streptomycin (Zhang et al. 2013b).

Development of resistance in the rice bacterial leaf blight (BLB) disease pathogen *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) to bismethiazol was investigated. Three

bismerthiazol-resistant mutants (1-1-1, 2-1-1, and 4-1-1) of *Xoo* were characterized in comparison to their parental strain ZJ173. After repeated subculturing of the mutants on bismerthiazol-free medium, they were pathogenic to rice plants treated with $300\mu\text{g mL}^{-1}$ of bismerthiazol, indicating the stability of the mutants. Bismerthiazol showed protective and curative activities against the wild-type strain ZJ173, but not against the three mutants. In order to determine the extent of natural occurrence of bismerthiazol-resistance in field isolates, 701 isolates of *Xoo* were obtained from 1419 leaf samples collected from eight provinces of China from 2007 to 2009. Rice plants were sprayed with bismerthiazol at $300\mu\text{g mL}^{-1}$ and inoculated with the isolates of *Xoo*. Of the 502 isolates, 62 were considered to be resistant (showing $>70\%$ inhibition relative to the wild-type strain). Frequencies of resistant strains among field populations ranged from 0 to 21%. Resistance to bismerthiazol in field isolates was not related to resistance determined in vitro. Determination of the extent of presence of bismerthiazol-resistant field populations of *X. oryzae* pv. *oryzae* would be useful for rice farmers to select the chemical(s) for application to reduce rice bacterial leaf blight disease (Zhu et al. 2013).

Emergence of strains of *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) resistant to bismerthiazol indicated the need to find an alternative bactericide to suppress the development of rice bacterial leaf blight (BLB) disease in Anhui Province in China. Zinc thiazole was evaluated for its effectiveness against 109 strains of *Xoo* isolated from four counties in Anhui Province. The EC_{50} values of zinc thiazole for inhibition of pathogen growth were $0.53\text{--}9.62\mu\text{g mL}^{-1}$ with average values of $4.82 \pm 1.86\mu\text{g mL}^{-1}$. The minimum inhibitory concentration (MIC) for inhibition of bacterial growth ranged over $5.0\text{--}40.0\mu\text{g mL}^{-1}$ (Fig. 14.3). The protective and curative efficiency of zinc thiazole was determined under field conditions along with bismerthiazol. Zinc thiazole protected rice plants more effectively by providing over 88% control efficacy when applied at $300\mu\text{g mL}^{-1}$ at 1 and 3 days before or after inoculation, compared with bismerthiazol. Zinc thiazole at 375 g ai ha^{-1} provided over 70% control efficacy in 2012 and over 80% control efficacy in 2013 in four field trials conducted at two sites. Zinc thiazole at 250 g ai ha^{-1} was more effective in all field trials than bismerthiazol at 250 g ai ha^{-1} , revealing its potential to replace bismerthiazol against which *X. oryzae* pv. *oryzae* strains had developed resistance (Chen et al. 2015).

The systemic fungicide amicarbazol (2-amino-4-methylthiazol-5-carboxanilide) has been applied against bacterial pathogens to reduce disease incidence. Inhibition of

Figure 14.3 Baseline sensitivity frequency distribution of strains of *Xanthomonas oryzae* pv. *oryzae* to zinc thiazole. Source: Chen et al. (2015). Reproduced with permission of John Wiley & Sons/Blackwell Publishing Ltd, UK.

succinate dehydrogenase (SDH) activities of *Xanthomonas axonopodis* pv. *citri* by amicarbazol was observed. Three amicarbazol mutants – Xuv10, Xuv20, and Xuv40 – were produced by exposure to UV irradiation. The minimal inhibitory concentrations (MICs) of the mutants and the wild-type isolate were 400 and 100 $\mu\text{g mL}^{-1}$, respectively. Assays using triphenyltetrazolium chloride (TTC) showed that the SDH activities of these mutants were significantly lower than that of the pathogen. The complete nucleotide sequences of four subunits (SdhA, SdhB, SdhC, and SdhD) of succinate-ubiquinone oxidoreductase (SQR) were cloned by PCR amplification. An amino acid mutation (His₂₂₉ → Leu₂₂₉) in *sdhB* was found to confer resistance in *X. axonopodis* pv. *citri* to amicarbazol. The mutation might alter the SDH complex in some way that prevents binding of amicarbazol (Li et al. 2006).

In a later study, the molecular mechanism of resistance to amicarbazol in *Xanthomonas oryzae* pv. *oryzae* (*Xoo*) was investigated. The activity of SDH in the wild-type *Xoo* was strongly inhibited by amicarbazol while UV-induced resistant mutants were insensitive, although their SDH activity was decreased, compared to the wild-type sensitive strain without amicarbazol. A mutation of Histidine₂₂₉ (CAC) to Tyrosine₂₂₉ (TAC) was identified in *sdhB* which encoded the iron-sulfur protein subunit of SDH. The *sdhB* from the mutant was ligated into a cosmid pUFR034 to generate pUF034RAX which conferred resistance to amicarbazol when transformed into the wild-type sensitive strain. A mutation of His₂₂₉ (CAC) to Tyr₂₂₉ (TAC) in SdhB was responsible for determining amicarbazol resistance (Zhang et al. 2010).

The formation of biofilms by *Xanthomonas axonopodis* pv. *citri* (*Xac*) was considered to be an important virulence factor playing a critical role in the early stages of infection in *Citrus* spp. The effectiveness of two organic compounds D-leucine and 3-indolylacetoneitrile (IAN) in restricting infection of citrus plants by *Xac* by inhibiting biofilm formation was assessed. D-leucine and IAN prevented biofilm formation by *Xac* on different abiotic surfaces and leaves of citrus at a concentration lower than the minimum inhibitory concentration (MIC). In addition, D-leucine and IAN increased the susceptibility of *Xac* cells to copper by a factor of c. 10 compared with untreated pathogen cells. Spray application of D-leucine (10 mM) or IAN (100 $\mu\text{g mL}^{-1}$) suppressed canker symptom development in grapefruit leaves when applied prior to or along with pathogen inoculation. The effectiveness of D-leucine and IAN was compatible to copper sulfate applied at 100 $\mu\text{g mL}^{-1}$ concentration. D-leucine and IAN appeared to act on *X. axonopodis* pv. *citri* by preventing biofilm formation, resulting in impaired infection and subsequent symptom development (Li and Wang 2014).

Citrus huanglongbing (HLB) disease caused by “*Candidatus Liberibacter asiaticus*” was reported to have affected an estimated 100 million citrus trees in 40 countries, threatening the survival of the US\$ 9 billion citrus industry (Sutton et al. 2005). As no curative treatment for eliminating the HLB pathogen was available, a new combination of antibiotics was evaluated for its efficacy using periwinkle and citrus trees. The combination of penicillin and streptomycin (PS) was effective in eliminating or suppressing “*Ca. L. asiaticus*” and provided a therapeutically effective level of control for a much longer period of time than when the antibiotics were applied separately in periwinkle cuttings. Young grapefruit seedlings (2 years old) were treated by root soaking in solutions of penicillin and streptomycin separately or in combination. HLB-affected 6 year old citrus trees were injected with the antibiotics. The antibiotic combination (PS) effectively eliminated the HLB bacterium from grapefruit seedlings and provided therapeutically effective level of control for 6 months, in contrast to treatment with penicillin (P) or streptomycin (S) alone. “*Ca. L. asiaticus*” population at 30 days after treatment

Figure 14.4 Effect of application of penicillin G (P) or streptomycin (S) individually or in combination (PS) on populations (cells g^{-1} of plant tissue) in huanglongbing (HB-) affected citrus seedlings under greenhouse conditions. Penicillin applied at 1 g L^{-1} and streptomycin at 100 mg L^{-1} ; CK: control (water). Source: Zhang et al. (2011). Reproduced with permission of the American Phytopathological Society, MN, USA.

(dat) for PS (36,733 cells g^{-1} of plant tissues) was significantly lower than the individual (P or S) treatment alone (282,188 and 500,766 cells g^{-1} of plant tissue, respectively). The pathogen population returned to relatively high level at 180 dat (Fig. 14.4). A synergistic and greater prolonged activity was observed due to the combined application of antibiotics. When the 6 year old citrus plants (mandarin x tangelo) were injected with PS, the HLB population decreased from 1,080,349 cells g^{-1} of plant tissue to 78,346 cells g^{-1} of plant tissue, indicating a 13-fold reduction in pathogen titer by PS. At 6 months after treatment, the number of bacterial cells was reduced below the level that could be detected by qPCR assay (<100 cells g^{-1} of plant tissue). The pathogen population was kept at <1000 cells g^{-1} of plant tissue until 14 months after PS treatment (Fig. 14.5). The results demonstrated the curative effects of the new combination of penicillin and streptomycin on HLB-infected citrus plants (Zhang et al. 2011).

The effect of chemical treatment via trunk injection in reducing the incidence/severity of huanglongbing (HLB) disease caused by "*Candidatus Liberibacter asiaticus*" (Las) was assessed. A mixture of streptomycin (250 mg L^{-1}), ampicillin (2.5 g L^{-1}), penicillin G (2 g L^{-1} and BacicureR (2 g L^{-1}) was injected into the trunk of Las-infected pomelo (*Citrus maxima*) trees. The bacterial pathogen DNA in treated trees was quantified by employing quantitative real-time polymerase chain reaction assay. This mixture of chemicals provided the most effective suppression of the pathogen population, as indicated by the assay. The pathogen population, as reflected by the mean threshold (Ct) values, was reduced from 20.8 ($=7.2 \times 10^7$ cells g^{-1} of plant tissues) to 36.6 ($=2140$ cells g^{-1} of plant tissues) in the greenhouse experiments and from 19.4 (c. 1.8×10^8 cells g^{-1} of plant tissues) to 37.8 (c. 969 cells g^{-1} of plant tissues) in the field trials. The effectiveness of the antibiotic treatment persisted for 1 year. Transmission electron microscope observations revealed the response of Las-infected pomelo to treatment with chemicals (Puttamuk et al. 2014).

The synthetic auxin 2,4-dichlorophenoxyacetic acid (2,4-D) is a common herbicide applied to reduce the weed populations that compete with crops for nutrients applied primarily for better growth and yield. Application of 2,4-D to foliage of potato plants

Figure 14.5 Effect of application as trunk injection of combination of penicillin and streptomycin (PS) at different ratios on bacterial pathogen titers (cells g^{-1} of plant tissues) in huanglongbing (HLB)-affected citrus plants under field conditions. PS-5: penicillin 5 g + streptomycin 0.5 g/100 mL; PS-10: penicillin 10 g + streptomycin 1 g/100 mL; PS-0: water control. Source: Zhang et al. (2011). Reproduced with permission of the American Phytopathological Society, MN, USA.

was found to reduce common scab disease caused by *Streptomyces scabies*. Phytotoxic effects of 2,4-D were observed when applied at a concentration of $200 mg L^{-1}$, and the yield of tubers was also reduced. With the minimal significant threshold rates of $8.3\text{--}23.6 mg L^{-1}$ of 2,4-D, the incidence of common scab disease was reduced in pot experiments. 2,4-D application at $10.8\text{--}41.0 mg L^{-1}$ minimized disease severity in all pot and field trials, except in one pot trial. Disease control due to 2,4-D was associated with decreased sensitivity of tubers to thaxtomin A produced by the pathogen required for disease development. The amount of residual 2,4-D left in tubers at harvest varied with cultivar, Russet Burbank accumulating more 2,4-D than Désirée. The results showed that application of 2,4-D at low rates ($<100 mg L^{-1}$) could provide a commercially viable strategy for the management of potato common scab disease (Thompson et al. 2014).

Some bacterial pathogens have multiple modes of transmission; they may be transmitted through infected propagules and also through natural biological vectors. Citrus huanglongbing (HLB) disease caused by "*Candidatus Liberibacter asiaticus*" is transmitted through infected propagules and also by psyllid vector *Diaphorina citri*, while grapevine Pierce's disease incited by *Xylella fastidiosa* is vectored by the glass-winged sharpshooter *Homalodisca vitripennis* (formerly known as *H. coagulata*; Yamamoto et al. 2006; Choi et al. 2010). A three-component disease management system was advocated to reduce the incidence of bacterial diseases and spread by the biological vectors. Thorough eradication of infected plants and plant debris, use of disease-free propagules and intensive chemical control of the pathogen were aimed to reduce the sources of inoculum and pathogen titer in the infected plants from which the inoculum may be spread by the vectors. In addition, by reducing the vector population the rate of spread of disease may be reduced. Management of Asian citrus psyllid (ACP) *D. citri* was considered a vital component of the program targeted at reducing the incidence and spread of HLB disease caused by "*Ca. L. asiaticus*." Eight different insecticides were applied sequentially on a calendar-based interval in individual plots (0.2–0.4 ha), making it a complete program. A reduced insecticide program consisting of five calendar applications of traditional insecticides or a mineral oil program (oil application

every 3 weeks plus 1 dormant insecticide spray) were also adopted. The results indicated that even the complete program was ineffective in preventing the huanglongbing disease spread (Hall et al. 2013). A similar approach for the management of grapevine Pierce's disease caused by *X. fastidiosa* was suggested. Control of the glass-winged sharp shooter on a regional basis or national level could be an important consideration for reducing the disease incidence (Gergerich et al. 2015).

14.3 Application of Chemicals Against Virus Diseases

Various kinds of chemicals have been applied for the inactivation of viruses or reduction of vector populations, and the consequent lower disease spread rate.

14.3.1 Application of Antiviral Chemicals

A variety of chemicals such as dyes, antibiotics, synthetic analogues of the purine and pyrimidine bases, and other organic compounds have been evaluated for their efficacy in suppressing the development of symptoms and/or virus replication. Although some chemicals have been reported to be effective in reducing virus replication, none has reached the stage of commercial production for wide application under field conditions. The principal problems associated with virus disease management through chemicals are: (i) the intracellular location of viruses in the host plants; and (ii) the intimate relationship between virus replication and host synthetic machinery, leading to substantial adverse effects on the host plant development. However, chemicals have been applied either to successfully eliminate the virus from meristem cultures or as a curative treatment of intact plants to produce virus-free plants. Phytotoxicity due to chemicals has been observed in several investigations.

Among the chemicals tested for antiviral activity, synthetic analogues of purine and pyrimidine bases were found to be promising. Virazole (ribavirin), a riboside of guanine, inhibited replication of *Potato virus X* (PVX) in the callus tissue and also in intact plants (Lerch 1977). Application of virazole at 2 days prior to or 8 h after inoculation with *Apple chlorotic virus* resulted in complete inhibition of virus replication (Hansen 1979). When injected into the branches of apple trees, virazole suppressed the symptoms of apple mosaic disease but the virus was not completely inactivated (Cheplick and Agrios 1983). Incorporation of virazole in the medium used for regeneration of orchids to free them of *Cymbidium mosaic virus* and *Ondotoglossum ringspot virus* by meristematic culture or thin-section culture effectively eliminated these viruses, as confirmed by enzyme-linked immunosorbent assay (ELISA) or polymerase chain reaction (PCR) assays (Lim et al. 1993).

Potato virus S (PVS) could be eliminated by a combination of thermotherapy treatment of plants and apical meristem culturing in the medium amended with ribavirin. Several subcultures were needed to eliminate PVS from the potato cultivar Red Pontiac. Potato plantlets generated from the meristem cultures were free of PVS, as confirmed by ELISA test (Kim et al. 1996). Treatments with auxins and antiviral chemicals were shown to be effective for elimination of *Plum pox virus* (PPV). Infected shoots were grown in Murashige-Skoog (MS) medium supplemented with indole-butyric acid (IBA), gibberellic acid (GA), and different concentrations of ribavirin. Regenerated and rooted plants were raised under greenhouse conditions for 2 years. Freedom from PPV was ensured by indexing the plants using DAS-ELISA and IC-RT-PCR procedures.

Phytotoxicity symptoms due to ribavirin at higher concentrations (80 and 100 mg L⁻¹) were recorded (Paunović et al. 2007).

The effect of ribavirin on elimination of *Potato virus A* (PVA), *Potato leafroll virus* (PLRV), *Potato virus S* (PVS), *Potato virus X* (PVX), and *Potato virus Y* (PVY) was assessed. Potato plantlets were cultured on MS medium amended with different concentrations of ribavirin. The plant height and fresh weight were reduced with increasing concentrations of ribavirin from 0 to 150 mg L⁻¹; most of the plants could not survive when the concentration reached 200 mg L⁻¹. Ribavirin was more efficient in eliminating PVA, PVM, PVS, and PVX than PVY and PLRV from the surviving plants. Healthy plants could be obtained with high frequency (up to 100%) by culturing with 75–150 mg L⁻¹ of ribavirin after 2–3 subcultures. On the other hand, only 33–66% of PVY- and PLRV-infected plantlets were found to be virus-free after 3 subcultures with 75–150 mg L⁻¹ of ribavirin. ELISA tests indicated the freedom of plants from viruses, whereas quantitative RT-PCR assays showed that ribavirin could effectively reduce virus content in plantlets. No virus could be detected after eradication stage. No apparent genetic variation in plants following ribavirin treatment was discernible. The results demonstrated that ribavirin treatment could be used for the effective elimination of potato viruses (Yang et al. 2014).

Some systemic fungicides have been shown to reduce the symptom severity of virus diseases. Carbendazim is a fungicide that has been reported to be effective against several fungal diseases. When tobacco plants were watered with aqueous solution of carbendazim, development of mosaic symptoms induced by *Tobacco mosaic virus* (TMV) was suppressed. However, the virus titer was not reduced in the treated plants. The chlorophyll content of leaves of untreated control plants was drastically reduced, whereas chlorophyll content of the carbendazim-treated leaves was not reduced (Tomlinson et al. 1976). A similar ameliorative effect on intensity of symptoms was observed in rice tungro disease (Thomas and John 1980) and peanut green mosaic disease (Gopal and Srinivasulu 1988). Commercial formulations of strobilurins – azoxystrobin, kresoxim-methyl, trifloxystrobin, and pyraclostrobin – were evaluated for their efficacy in reducing *Bean common mosaic virus* (BCMV) under greenhouse and field conditions. Highest seed germination percentage and seedling vigor was recorded in seeds treated with pyraclostrobin (2 g L⁻¹). In the greenhouse trials, 76% protection against BCMV was observed. When pyraclostrobin was applied as seed treatment at 10 g L⁻¹ under field conditions with natural BCMV inoculum, the fungicide treatment resulted in 65% protection against BCMV infection. ELISA assays were used to determine the infection in bean plants and the immunoreactive values were recorded in common bean seedlings raised from seeds treated with pyraclostrobin and kresoxim-methyl. Strobilurins exerted a direct positive physiological effect on common bean plants and also protected bean plants against BCMV infection in greenhouse and field. The fungicides with reduced risk may be useful as potential inducers of resistance against BCMV and growth enhancers, and they could be a beneficial component of integrated disease management system for common bean (Udayashanker et al. 2012).

14.3.2 Chemicals Applied Against Vectors of Viruses

Managing virus diseases through the application of chemicals to reduce the populations of vectors has frequently been reported to be ineffective. Achieving zero population of vectors is not always possible. Further, no insecticide can exert an instant knockdown

effect on aphids and other vectors of nonpersistent viruses which may be acquired and transmitted with short acquisition/transmission feeding periods on virus-infected plants and healthy plants, respectively. A small population of the vectors left after chemical application may be sufficient to spread the virus disease and cause significant crop losses (Simmons and Zitter 1980). On the other hand, the spread of persistent viruses which require longer feeding periods by the vectors for both acquisition and transmission can be significantly reduced by the application of insecticides. For example, the spread of *Potato leafroll virus* (PLRV, persistent virus) could be markedly reduced by application of insecticides, whereas spread of *Potato virus Y* (PVY, nonpersistent virus) could not be reduced by chemical application, despite the fact that the viruses are transmitted by the same aphid species *Myzus persicae* (Webley and Stone 1972; Olubayo et al. 2010; Hansen and Nielsen 2012). Systemic and persistent chemicals have been found to be more effective than contact insecticides, which are easily washed away by rains. Protection of plants by chemicals in the nursery or in the early stages of crop growth may be more important, since young plants are more susceptible to viruses and older plants are likely to develop adult-plant resistance to virus infection (Narayanasamy 2002).

Transmission of plant viruses by their vectors may be prevented or reduced by the application of mineral oils. Aphids (*Myzus persicae*) carrying the nonpersistent (styletborne) *Potato virus Y* (PVY) was unable to transmit the virus when it was fed through a film of oil on the membrane surface. As the infective aphids probed through the film of oil, infectivity was substantially reduced (Bradley et al. 1966). The application of mineral oils has become common practice to provide protection to potato crops against virus diseases, especially to PVY (Olubayo et al. 2010; Fageria et al. 2014). The efficacy of two mineral oils (Superior 70 and Vazyl-Y) in reducing the spread of PVY was assessed by using three concentrations of mineral oils under three spray regimes. The presence of PVY in tubers was determined by employing ELISA tests. In the plots sprayed with Superior 70, PVY spread in treated plots ranged over 2.1–12.2%, while in control plots it ranged over 20.4–37% across three cultivars. In the case of Vazyl-Y, PVY spread in treated plots ranged over 2.1–26.5%, while in the control plots the infection ranged over 49.9–85.7% across three cultivars. The results showed that the PVY incidence was significantly reduced due to application of mineral oils (Fageria et al. 2014). Greenhouse and field trials were conducted to shed light on the mechanism of action of mineral oils bringing about reduction in the incidence of disease caused by *Potato virus Y*. The local and systemic accumulation of PVY^O in susceptible cultivars Shepody and Russet Burbank was investigated. The results suggested that the mineral oils did not influence PVY^O levels in mechanically inoculated leaves or tubers of plants with a secondary infection. However, a reduction in systemic PVY^O titer was recorded in mineral-oil-treated older plants but not in younger plants, suggesting that the mineral oil might inhibit PVY^O movement in an age-dependent manner (Al-Daoud et al. 2014).

The effects of application of mineral oil Sunspray 850 EC alone or in combination with commonly applied aphidicides on the incidence of potato viruses *Potato virus Y* and *Potato virus M* (PVM) were assessed under field conditions. The aphidicides, Mospilan 20SP (acetamprid), Primor 500 (primicarb), and Karate Zeon 050CS (lambda-cyhalothrin) were used for control of aphid population. Mineral oil application was the most effective in reducing the incidence of PVY and offered better protection to potato plants than the aphidicides, although Mospilan 20SP reduced the aphid populations

most effectively. Mineral oils, when used alone or in a mixture with Primor 500WG, were the most effective in limiting PVY infection by 64% relative to the control. Reduction in PVM incidence by mineral oil application was not significant because of low disease pressure. Application of insecticide and mineral oil mixtures was not always as effective as the mineral oil alone. Further, the use of mixtures might not be acceptable to growers since due to the extra cost (Wróbel 2014).

Crop Disease Management

Integration of Strategies

Depending on the nature of microbial pathogens and existing environmental conditions favoring disease development and spread, crop diseases may cause qualitative and quantitative losses of varying magnitudes in cultivars with differing levels of susceptibility/resistance to the disease(s) concerned. In order to limit yield losses, compatible disease management strategies have been integrated to achieve yield levels approaching the biological potentials of the crop cultivars if other crop requirements are satisfied. Integrated disease management systems, involving the use of disease-free seeds and propagules and other strategies in different combinations, have been developed to provide effective protection against various seed- and propagule-borne pathogens.

15.1 Development of Integrated Disease Management Systems

The effectiveness of different strategies is known to vary, so the search for new disease management strategies has been pursued over several years. Prior to the nineteenth century, cultural methods were the mainstay for the control of crop diseases. From the latter half of the twentieth century, chemicals with antimicrobial properties became increasingly available in large numbers and were used either in conjunction with or instead of cultural practices. With the advent of the Mendelian era, the development of cultivars with built-in resistance through breeding provided a strong foundation for effective crop protection against some crop diseases. The limitations of genetic improvement of resistance of cultivars were realized because of the nonavailability of dependable sources of resistance and the rapid development of new race strains/races of pathogens capable of adapting to the resistance genes incorporated into the cultivars. The possibility of employing biological control agents (BCAs) to achieve acceptable levels of disease control have therefore been explored. Commercial formulations containing fungal and bacterial BCAs have been developed for efficiently tackling some crop diseases. The usefulness of biotechnological methods has been demonstrated in improving the levels of resistance of cultivars by incorporating genes from diverse sources which could not be utilized by conventional breeding methods (Narayanasamy 2002, 2011).

Research and extension efforts of plant pathologists provided direction to the integration of different compatible strategies or tactics to improve the effectiveness of management of crop diseases. The term “integrated pest management” (IPM) was first used by the entomologists R.E. Smith and R. van den Bosch (Smith and van den Bosch 1967) based on the concept of Stern et al. (1959). IPM was defined as “applied pest control which combines and integrates biological and chemical control used as necessary and in a manner which is least disruptive to biological control.” On the other hand, from the very inception of plant pathology crop disease management has relied upon integrated disease management (IDM) using basic information on the loss potential, pathogen biology, ecology, and epidemiology. This is clearly demonstrated by searching the USDA-CRIS project database for IDM-related projects from 1985 to 1995; 1755 projects in plant pathology and 1426 in plant entomology were listed in this database (Jacobsen 1997).

The concept of economic injury level (EIL) and economic threshold (ET) introduced by Stern et al. (1959) provided workable bases for insect (pest) control since the populations of insects could be easily estimated. On the other hand, plant pathologists have to assess the populations of microbial pathogens with great difficulty and the assessments do not always result in predictable differential damage. However, in some pathosystems damage may exceed the ET even before symptoms become visible. The ET levels prescribed for insects as pests cannot be used for insects functioning as vectors of viruses. Populations remaining below ET levels are sufficient to spread virus diseases, and it is not economical to maintain zero populations of vectors by application of insecticides to restrict virus disease spread. It has therefore not been possible for plant pathologists to adopt the EIL and ET concepts of IPM meant for insect management. Furthermore, crop disease management generally did not depend at any time on levels of chemical uses that were commonly associated with insect control. Many destructive diseases were managed successfully by integrating various strategies such as sanitation, certification, crop rotation (sequence), selection of suitable sowing/planting date, and use of resistant cultivars if available. The use of fungicides or other chemicals was kept at minimal levels. Although these strategies were commonly employed for insect pest control, greater emphasis was given to chemical control. The term integrated disease management (IDM) has been increasingly used in plant pathology investigations, while the term “pest” is largely confined to insect control. With basic knowledge of pathogen biology and ecology, sources of inoculum, and epidemiological factors favoring disease development, different strategies have to be integrated to effectively reduce the incidence and spread of crop diseases to derive maximum economic benefit to the growers.

15.1.1 Selection of Strategies for Integration

The effects of individual strategies on pathogen development and disease spread were discussed in Chapter 10 (exclusion of pathogens), Chapter 11 (reduction of pathogen inoculum), Chapter 12 (enhancement of genetic resistance of crops), Chapter 13 (biological management of crop diseases), and Chapter 14 (chemical control of crop diseases). These strategies/tactics may be grouped into four categories based on their effects on the pathogen and the development of diseases which may vary due to the prevailing environmental conditions in different agroecosystems.

- i) Programs aimed at preventing the introduction of pathogens into a country, geographic location, or field have to be carried out at different levels by various agencies such as certification agencies, plant quarantines, national or provincial governments, plant protection advisers, extension pathologists, and growers.
- ii) Close coordination, constant surveillance, and efficient technical support for rapid detection and identification of new pathogens and feedback on the effectiveness of corrective measures taken to restrict the spread of the pathogens to neighboring states/fields may ensure the effectiveness of this approach, which is vital for all kinds of diseases caused by microbial plant pathogens.
- iii) The reduction of inoculum buildup may be achieved by choosing suitable geographic locations for planting sites where sources of inoculum are absent or at minimal levels.
- iv) In addition, suitable planting dates, use of disease-free seeds/propagules, treatment of seeds/propagules, modification of cultural practices such as crop rotation, application of organic amendments and mulches, soil solarization, eradication of alternate and alternative host plant species, proper disposal of infected plants and plant debris, and tillage practice may reduce buildup of pathogen inoculum, which has a direct influence on the disease incidence and spread in a newly planted crop. Growers must adopt selection practices that may avoid or reduce inoculum buildup and consequently restrict the use of chemicals.

The rate of spread of crop diseases has to be reduced by adopting effective tactics. Use of resistant cultivars is the most important strategy to reduce the rate of disease spread. Disease development is retarded depending on the levels and durability of resistance possessed by a cultivar to be grown. Cultivars with horizontal resistance may be preferred to cultivars with vertical resistance. Use of cultivar mixtures and multilines has been shown to be effective in reducing disease incidence and/or severity in certain pathosystems. Although several biological control agents (BCAs) have been shown to be effective in some locations, only a few have been shown to have the potential for widespread application under field conditions. Cost-effectiveness and comparative performance, along with commonly used standard fungicides, have to be demonstrated convincingly. Many fungicides have the potential to restrict the spread of crop diseases. However, continued and indiscriminate use of fungicides has resulted in the development of insensitivity/resistance in pathogens against frequently applied single-site systemic fungicides. The cost of using alternative disease management strategies is reported to be far less than the cost of chemical control (Pimentel et al. 1991). Consequently, the approaches to chemical application emphasize not only the efficiency of fungicides and reducing risks of development of resistance, but also their specificity and biodegradability (Maloney 1995). This trend is due to environmental concerns about chemicals in general. Nonchemical disease management methods involving traditional farming systems, use of biological control agents, and induction of resistance in crop plants which are otherwise susceptible have been accepted by all concerned with crop production.

Integration of disease management strategies may result in an increase or decrease in the effectiveness of disease suppression. It is therefore vital to select the strategies that are compatible with each other and do not have any negative influence on other strategies. Efforts to assess the effectiveness of integrated disease management system(s)

have been far less than desirable. The possibility of integrating different management strategies for effective reduction in the incidence and spread of some of the economically important diseases of various crops is discussed in the remainder of this chapter.

15.2 Management of Fungal Diseases

15.2.1 *Fusarium* Head Blight Disease

Fusarium head blight (FHB) disease is caused by different species of *Fusarium* forming a complex, the components of which may vary at different locations. *F. graminearum* (teleomorph *Gibberella zeae*), *F. avenaceum*, *F. culmorum*, *F. poae*, and *Microdochium nivale* are commonly associated with the FHB disease. Crop residues left on the soil surface after harvest forms the principal source of inoculum and infection of spikes takes place at the time of heading. Crop rotation, including soybean prior to wheat crop, resulted in lower incidence of FHB disease. The incidence and severity of FHB were lower in moldboard-ploughed plots than in either chisel-ploughed or no-till plots and the yield also increased (Dil-Macky and Jones 2000). The favorable effect of moldboard ploughing was also observed in a later investigation for reducing the incidence of FHB disease incited by *Fusarium* spp. (Steinkellner and Langer 2004). Application of nitrogenous fertilizer (type and quantity of N applied) had a significant influence on the incidence of FHB and mycotoxins produced by the pathogen. A significant increase in FHB severity and deoxynivalenol (DON) accumulation in wheat grains was observed with an increase in N dosage from 0 to 80 kg ha⁻¹. At higher input levels of N, FHB and DON concentrations did not show appreciable variations (Lemmens et al. 2004). Variable effects of N application on the ear rot disease incidence in maize were recorded. Effects of urea and a slow-release fertilizer did not show significant variations in the contamination levels of grains for zearalenone, fumonisin B1, or ochratoxin A. Ear rot disease incidence and severity were generally higher in ears from plants fertilized with insufficient N, but application of high N fertilizer doses (>300 kg ha⁻¹) significantly increased zearalenone accumulation in maize kernels. In contrast, concentrations of fumonisins were related to nitrogen deficiencies (Blandino et al. 2008). The effect of heat treatment on elimination of *Fusarium graminearum* from wheat and barley seeds, with 84% and 23% infection respectively, was assessed. The pathogen was eliminated from Canadian Western spring wheat seeds treated at 60°C for 15 days, at 70°C for 5 days, or at 80°C for 2 days. In a similar manner, barley seeds were disinfected by heat treatment at 60°C for 21 days, at 70°C for 9 days, or at 80°C for 5 days. Seed germination was not adversely affected by heat treatments (Clear et al. 2003).

The effectiveness of fungal biocontrol agents in reducing *Fusarium* head blight (FHB) disease was demonstrated by some investigations under field conditions. The yeast species, *Cryptococcus* sp. OH71.4 and *C. nodaensis* OH182.9, reduced the FHB disease severity by 57%, but the yeast antagonists did not have any significant effect on the extent of mycotoxin concentration of grains (Schisler et al. 2002). *Fusarium equiseti* strain G, selected as the most effective biocontrol agent, was tested for its ability to reduce FHB disease incidence and the production of mycotoxin deoxynivalenol by *F. culmorum* and *F. graminearum* in wheat grains under field conditions. The BCA strain could reduce the percentage diseased grains by 92% and DON contents by 94%, indicating potential for reducing the disease incidence and mycotoxin production by the pathogen in grains (Dawson et al. 2004). In another investigation performed under

field conditions, *Clonostachys rosea* (IK726) significantly reduced FHB severity. Dried and stored conidia of *C. rosea* suppressed disease development as effectively as freshly harvested conidia of the BCA (Jensen et al. 2000). A mixture of *C. rosea* strain 47 and *Trichoderma atroviride* strain 312 with carboxin, thiram, and triticonazole applied to wheat seeds significantly suppressed the development of *F. culmorum*. The effectiveness of BCA application in reducing FHB incidence was comparable to that of triticonazole under field conditions (Roberti et al. 2006). The plant growth-promoting rhizobacteria (PGPR) pseudomonads showed significant disease suppressive potential against *F. culmorum* under both greenhouse and field conditions. The disease severity and loss in 1000-grain weight were significantly reduced when *Pseudomonas fluorescens* strains MKB158 and MKB249 and *P. frederiksbergensis* strain 202 were applied. In the *F. culmorum* infested fields, treatment with strain MK158 or MKB 249 reduced FHB disease severity in wheat and barley. Further, levels of deoxynivalenol (DON) were also reduced in wheat and barley grains by 74–78%. Protective application of *P. fluorescens* has the potential for large-scale application to reduce FHB incidence and DON accumulation in grains (Khan and Doohan 2009).

The efficacy and stability of integrating fungicide with cultivar resistance to reduce the incidence of Fusarium head blight (FHB) disease of wheat and accumulation of deoxynivalenol (DON) in grains was determined. Data from over 40 trials in 12 US states were analyzed using means of FHB index (index) and DON from up to six resistance-class-fungicide management combinations per trial as parameters. Multivariate meta-analysis and mean log-response ratios across trials were estimated and transformed to estimate mean percent control (C) due to management combinations relative to the susceptible-untreated (S-UT) treatment. All combinations significantly reduced index and DON ($P < 0.001$). Moderate resistance of the cultivar with fungicide treatment (prothioconazole + tebuconazole) was the most effective combination with C of 79% for index and 71% DON reduction relative to S-UT. The combination of fungicide application and resistance to disease was additive in terms of percent control for index and DON contents of grain. Moderate resistance of wheat cultivar treated with fungicide had the mean rank among treatment combinations relative to susceptible without fungicide protection. The results showed that although the magnitude of percent control may vary among environments, integrating a single tebuconazole + prothioconazole application at anthesis with cultivar resistance could be a more effective and stable management practice for both disease index and DON content reduction than either strategy applied alone (Willyerd et al. 2012).

15.2.2 Rice Blast Disease

Rice blast disease pathogen *Magnaporthe grisea* (anamorph *Pyricularia grisea*) occurs as numerous races with varying levels of virulence (aggressiveness) differentiated based on their interactions with differential varieties/genotypes of rice. Cultural practices such as changing planting dates (when disease incidence is less), the application of optimal levels of nitrogenous fertilizer, and maintaining optimum levels of irrigation have been shown to reduce disease incidence and severity. Use of resistant/tolerant cultivars may be a single strategy that may be more effective in reducing crop losses than others. Application of silicon (Si) as sodium silicate in Si-deficient soils reduced the blast disease severity and increased grain yield by about 20–35% compared to nonamended soils. Fungicide edifenphos in combination with Si application increased yield levels. When blast disease pressure was high, Si application followed by treatment with

tricyclazole resulted in reduced loss due to blast disease (Seebold et al. 2004). *Pseudomonas fluorescens* strain Pf1 applied as seed treatment, followed by three foliar applications, significantly reduced the blast disease incidence and severity (Vidhyasekaran et al. 1997) and also increased grain yield (Karpagavalli et al. 2001). The effectiveness of plant activators that stimulate defense responses of plants to develop local/systemic resistance to several diseases has been demonstrated. Exogenous application of salicylic acid (SA) might enhance concentrations of defense-related compounds in treated rice plants, resulting in inhibition of rice disease development (Daw et al. 2008). Likewise, treatment with benzothiadiazole (BTH) enhanced the resistance of cultivar Nakdong (susceptible to blast disease). The PR-genes involved in the development of resistance to *M. grisea* were activated by application of BTH (Ahn et al. 2005). It may be desirable to select the suitable strategies and integrate them to achieve the required level of disease suppression and enhancement of yield, keeping the application of chemicals at a minimum.

15.2.3 Rice Sheath Blight Disease

Rice sheath blight disease caused by *Rhizoctonia solani* is widespread in all rice-growing countries. As the pathogen is soilborne and has a wide host range, adoption of crop rotation including noncereal crops has limited use. Other cultural practices such as proper spacing and application of optimal doses of nitrogen may not favor the incidence of sheath blight disease. Silicon fertilization in silicon-deficient soils (as calcium silicate) was reported to reduce the severity of the disease (Rodriguez et al. 2001). Extensive screening of rice genotypes for identifying resistance sources has not yielded encouraging results. Suppression of sheath blight disease using biotic and abiotic biocontrol agents (BCAs) appears to be a feasible approach. Talc-based formulations containing *Pseudomonas fluorescens* strains PF1 and PF7 either individually or in combination reduced the sheath blight disease incidence to different levels, depending on the strain or strain mixture. Treatment with PF strains, in addition to suppression of disease symptoms, also increased the yield of grains by up to 40.4% (Nandakumar et al. 2001). Furthermore, talc-based formulations of *P. fluorescens* strains PF1 and PF7 in combination with chitin amendment were more efficient in reducing sheath blight disease incidence up to 62% and enhancing the grain yield up to 21% (Radjacommare et al. 2002).

Mixtures of fungal BCAs *Trichoderma harzianum*, *T. viride*, and *Gliocladium virens* provided effective protection against infection by *Rhizoctonia solani* (Tang et al. 2002). The effectiveness of disease suppression offered by the BCAs *P. fluorescens* or *T. viride* was comparable to the level achieved by application of the fungicide carbendazim. The additive effect of combining both BCAs was only marginal on disease reduction and yield increase (Mathivanan et al. 2005). *Bacillus megaterium*-based water-soluble granular formulation applied as seed treatment followed by three sprays at seedling, tillering, and flowering stages reduced the development of rice sheath blight and blast diseases. With proper weed control and an optimal dose of nitrogenous fertilizer, yield of grains was increased compared to untreated control treatment (Kanjamaneesathian et al. 2009). In another investigation, the effectiveness of application of *Bacillus subtilis* strain NJ-18 alone or in combination with a fungicide half-dose of kresoxim-methyl at 225 g ai ha⁻¹ to reduce the incidence of rice sheath blight disease was assessed. The sheath blight disease was more effectively suppressed by the combination of the

bacterial BCA and the fungicide than kresoxim-methyl (50%) alone or the antibiotic Jingtangmycin at 125 g ai ha⁻¹. Treatment with *B. subtilis* alone was also effective in suppressing the development of *R. solani* (Yang et al. 2009). Resistance-inducer BTH, when applied as soil-drench or foliar spray, reduced sheath blight disease development on inoculated leaf sheath and upwards spread to younger leaves (Rohilla et al. 2002). Various fungicides have been tested for their efficacy, but the economic feasibility of applying chemicals seemed to be limited. The results of various experiments indicate that if the effectiveness of the biocontrol agents could be established under different ecological environments, use of BCAs might be the best option for integration with cultural practices.

15.2.4 Late Blight Diseases of Tomato and Potato

Phytophthora infestans, incitant of late blight diseases of tomato and potato, is intensively investigated because of the extensive damage caused by this fungal pathogen in all countries. The pathogen produces different kinds of spore forms and exists in the form of several races with varying pathogenic potential (virulence). The pathogen can infect all plant parts and also tubers in potato, causing tuber blight disease. It has been difficult to suppress disease development in greenhouse tomato crops because of the limited possibility of manipulating the environmental conditions of prolonged periods of leaf wetness and temperature favoring development of the disease. Polyethylene mulch was shown to provide consistent, effective, and highly significant suppression of late blight disease development in tomato, the disease control efficacy being 83.6 ± 5.6%. The combination of polyethylene mulch and fungicide Kocide 2000 plus Neemguard showed an additive effect, the effectiveness being greater than that provided by polyethylene mulch alone. The suppressive effect of polyethylene mulch was due to many factors such as reduction in leaf wetness duration and reduction in sporulation by the pathogen. Additional benefit of using polyethylene mulch was reduction in weed infestation and the consequent saving of irrigation water by up to 30% (Shtienberg et al. 2010).

The effectiveness of organic compounds in suppressing development of late blight disease in potato has been demonstrated. Allicin, present in garlic extract, suppressed seedborne infection of *Phytophthora infestans* in tomato seeds and tuber blight disease development in potato (Slusarenko et al. 2008). Bacterial biocontrol agents *Bacillus pumilus* strain SE34 and *Pseudomonas fluorescens* strain 89B61 protected tomato plants by inducing systemic resistance, the level of which was similar to what could be achieved by application of resistance inducer β-aminobutyric acid (BABA) (Yan et al. 2002). BABA induced different levels of systemic resistance in potato tubers against tuber blight, when potato plants were treated with BABA. In the resistant cultivar Ovatio, the activation of systemic resistance was faster and stronger than in susceptible cultivar Bintje (Liljertoth et al. 2010; Bengtsson et al. 2014).

Among different types of plastic mulches, black polyethylene film and copper hydroxide-treated agricultural textile used to cover the hills reduced the incidence of potato tuber blight compared to controls. The effectiveness of black polyethylene mulch was considered to be due to blocking of water movement through potato hill and the alteration of soil environment within the hills by making hills drier and slightly warmer. However, preventing/reducing foliar epidemics through host resistance strategies have to be applied wherever it is possible (Glass et al. 2001). Potato late blight disease management system possibly represents the culmination of various disease

management strategies to achieve the level of effectiveness that is yet to be fully achieved. Different disease management strategies have been applied alone or in combination to restrict the disease incidence and spread through forecasting models, genetic resistance, cultural practices, biological control agents, and chemical application. Varying degrees of success have been obtained under different environmental conditions by integrating the approaches suitable for the geographical locations concerned. Use of disease-free certified seed tubers is the basic requirement to effectively eliminate the initial sources of inoculum of *Phytophthora infestans*. Production of disease-free tubers depends on the prevention of tuber infection in the previous crop to a great extent. Crop sanitation, selection of appropriate planting date, monitoring of disease incidence, and immediate elimination of all infected plants, including volunteer plants, were effective in reducing the late blight disease incidence (Basu 2009). Strip-cropping of potatoes with cereals or a grass-clover mix was effective in reducing disease incidence (Bouws and Finckh 2008).

Several fungal and bacterial biocontrol agents (BCAs) have been evaluated for their efficacy in suppressing the development of *Phytophthora infestans* under in vitro or greenhouse conditions. The fungal BCAs *Penicillium aurantiogriseum* and *Stachybotrys atra* suppressed the lesion development in greenhouse-grown potato plants to the extent of 93% and 84%, respectively (Jindal et al. 1988). *Pseudomonas putida* and *Serratia plymuthica* suppressed the development of *P. infestans* US-8 clonal lineage, a highly virulent strain, through induction of resistance and antibiosis, respectively, indicating the different mechanism of action by the bacterial BCAs (Daayf et al. 2003). Tuber infection by *P. infestans* could be reduced significantly by treating the potato tubers with strain mixtures of *Pseudomonas fluorescens* (Slininger et al. 2007). Treatment of potato tubers with *Trichoderma harzianum* (5 g kg^{-1}) and *P. fluorescens* (2.5 g kg^{-1}) protected the plants effectively and increased the yield from 13.8 t ha^{-1} in control plots to 19.5 and 19.0 t ha^{-1} , respectively, in treated plots (Basu 2009). A formulated product of the fungal BCA, *Chaetomium globosum*, was evaluated for its efficacy in suppressing the development of late blight on potato plants and tuber blight in tubers. The BCA was applied as tuber, soil, and foliar treatment at 1 mL kg^{-1} of tubers, 1 mL kg^{-1} farmyard manure (FYM), and 0.7%, respectively, under field conditions. Incidence of disease was reduced by 28%. Application of *C. globosum* increased the tuber yield in two field experiments, indicating the effectiveness of the commercial product of *C. globosum* (Shanthiya et al. 2013).

Management of potato late blight continues to be largely dependent on the use of different fungicides in many countries, although emergence of isolates insensitive/resistant to commonly applied fungicides and the possible environmental pollution due to excessive application of fungicides are known. Application of copper-based fungicides even in organic production system has increased, despite the existing ceiling of 6 kg of elemental copper per hectare (Ghorbani et al. 2004). Several organic compounds that can induce resistance in potato plants as alternatives to these fungicides were therefore evaluated for their efficacy. The protective effect of β -aminobutyric acid (BABA) against potato late blight pathogen *Phytophthora infestans* was demonstrated in two cultivars Bintje and Pampeana with different levels of horizontal resistance. Pretreatment of potato plants with BABA at 30 days after emergence provided about 60% protection in cultivar Pampeana against *P. infestans*. Foliar application of BABA stimulated the expression of molecules associated with induction of resistance to diseases (Altamiranda et al. 2008). The degree of enhancement of resistance by BABA depended on the natural level of genetic resistance of potato cultivars to different races of *P. infestans* (Olivieri et al. 2009). BABA treatment could compensate for a 20–25% reduction in the dosage of

fungicide Shirlan needed as the combination of the fungicide and BABA was as effective as the full dosage of Shirlan alone, indicating the possibility of using BABA as a component of potato late blight disease management system (Liljeroth et al. 2010).

Phosphites (Phi), alkali metal salts of phosphorus acid, showed potential for protecting potatoes against fungal diseases. Treatment of seed tubers with calcium or potassium phosphite (CaPhi or KPhi) at 1% commercial product facilitated earlier plant emergence. When sprayed on foliage of two cultivars Shepody and Kennebec, CaPhi or KPhi provided significant protection (2–4 times) to the plants against late blight disease. The cultivar Kennebec was more responsive to Phi application, which was more effective against *Phytophthora infestans* than against *Fusarium solani* (causing dry rot) and *Rhizoctonia solani* (inducing black scurf). Phi application did not induce any apparent adverse effects on growth of potato plants, indicating that Phi had the potential to protect potato plants against *P. infestans* and other fungal pathogens of potato. In addition, leaves in Phi-treated plants had a darker green color and showed delay in setting of leaf senescence compared to untreated control plants (Lobato et al. 2008).

Different levels of multisite- (contact) and single-site (systemic) fungicides have been applied as protective/curative treatments on seed tubers, soil, and potato plants against infection by late blight disease caused by *Phytophthora infestans*. Seed tuber treatment with thiophanate-methyl + mancozeb increased plant emergence and uniform stand of potato crop. Dimethomorph + mancozeb, cymoxanil + mancozeb, or propamocarb + chlorothalonil were effective as tuber treatment and also for foliage application at later stages of crop growth (Singh and Pundhir 2004). Cyazofamid with translaminar and curative activity was specific against *P. infestans* and reduced the formation of zoosporangia. The fungicide did not show cross-resistance with other commonly used fungicides under field conditions, providing high levels of disease suppression (Mitani et al. 2002). Several fungicides were found to be effective against potato late blight disease in the initial years of their introduction. However, *P. infestans* isolates resistant to the fungicides have been recovered after some years. For example, phenylamide fungicide mefenoxam reduced the disease development for over three decades. However, isolates of *P. infestans* insensitive to mefenoxam were collected in Wisconsin from 2009 to 2012. The isolates of US-23 and US-24 clonal lineages belonging to A1 mating type were found to be intermediately sensitive (reduced) to mefenoxam. The sensitivity of the isolates was determined using the analysis of the glucose-6-phosphate isomerase (Gpi) allozyme for predicting the mefenoxam sensitivity of isolates of *P. infestans*. The presence of new clonal lineages of *P. infestans* in Wisconsin emphasized the need for constant monitoring of the development of insensitive strains of the pathogen (Seidl and Gevens 2013). Insensitivity to mefenoxam was governed by the allele RPA190 in the isolates of *P. infestans*. Transfer of this allele RPA190 to a sensitive isolate resulted in generation of transgenic lines insensitive to mefenoxam. Sequence variation in RPA190 was shown to contribute to insensitivity to mefenoxam in *P. infestans* (Randall et al. 2014).

15.3 Management of Bacterial Diseases

15.3.1 Rice Bacterial Leaf Blight Disease

Xanthomonas oryzae pv. *oryzae* (Xoo), incitant of rice bacterial leaf blight (BLB) disease, has the potential for causing considerable losses when environmental conditions are favorable in SE Asian countries. The bacterial biocontrol agent *Lysobacter antibioticus*

strain 13-1 isolated from rice rhizosphere reduced rice BLB disease index by 78.3% and 59.1% in 2005 and 2006, respectively, compared to the control. The bacterial antagonist was more effective than the antibiotic zhongshengmycin with disease suppression efficiencies of 69.4% and 47.7% in 2005 and 2006, respectively. The strain 13-1 was able to colonize rice leaves and stems at 3 weeks after application and reduce the disease development in most rice cultivars, irrespective of their susceptibility levels (Ji et al. 2008). Harpins produced by phyto bacterial pathogens possess the capacity for multiple functions, including induction of resistance to bacterial diseases. The effectiveness of two fragments of harpin (from *X. oryzae* pv. *oryzicola*) HpaG₁₀₋₄₂ and HpaG_{xoo} was assessed for suppression of BLB disease development under field conditions. The activity of HpaG₁₀₋₄₂ was greater than that of HpaG_{xoo} and stimulated resistance to three important rice diseases: rice blast, sheath blight, and bacterial leaf blight disease. The grain yields were increased in 672 experimental plots with nine rice cultivars planted at three locations. HpaG₁₀₋₄₂ applied at 6 µg mL⁻¹ once at nursery seedling stage and three times in the main field after transplanting was the most effective. Incidences of BLB, blast, and sheath blight were reduced by 61.6, 93.6, and 93.3% and 56.4, 76.0, and 55.05% in indica and japonica cultivars, respectively, relative to the untreated controls. Further, grain yields were increased by 22–27% compared to control plots. Application of harpin HpaG₁₀₋₄₂ was as effective as the local management practices, including the use of chemicals. The results revealed the suitability of HpaG₁₀₋₄₂ protein fragment for the efficient management of three major rice diseases and enhancement of the yield levels of rice crops (Chen et al. 2008).

Streptomycin sulfate has been the most frequently used antibiotic against bacterial diseases of crops, but strains showing resistance to streptomycin sulfate have been recovered from different locations. *Xanthomonas oryzae* pv. *oryzae* (Xoo), causal agent of rice bacterial leaf blight (BLB), and *X. oryzae* pv. *oryzicola*, incitant of rice bacterial leaf streak (BLS) disease, were isolated in Yunnan Province, China where streptomycin sulfate had been applied. Four strains of Xoo were found to be resistant to streptomycin. The resistant factor (the ratio of the mean median effective concentration inhibiting the growth of resistant isolates to that of sensitive isolates) was about 226. Less sensitive isolates of Xoo were also present in this region. In contrast, none of the isolates of *X. oryzae* pv. *oryzicola* was found to be insensitive to streptomycin under field conditions. The PCR amplification and sequencing of *rpsL* gene (encoding S12 protein) and *rrs* genes (encoding 6S rRNA) showed a lack of any mutation in these genes considered to be responsible for resistance to streptomycin, indicating the involvement of a different mechanism for development of resistance to streptomycin in *X. oryzae* pv. *oryzae* (Xu et al. 2010). In all strains of *X. oryzae* pv. *oryzicola* showing resistance to streptomycin sulfate a mutation on the *rpsL* gene encoding ribosomal protein S12 had occurred. The amino acid sequence analysis showed that in the mutant strains, AAG was substituted for AGG (Lys → Arg) either at codon 43 or 88, resulting in the development of resistance to streptomycin sulfate in *X. oryzae* pv. *oryzicola* (Zhang et al. 2013). Bismethiazol suppressed the development of rice bacterial leaf blight (BLB) disease caused by *X. oryzae* pv. *oryzae* (Xoo). Bismethiazol showed protective/curative activity against the wild-type strain ZJ173, but not against the mutants showing resistance. Frequencies of resistant strains arising among field isolates ranged over 0–21.1%. Resistance to bismethiazol in field isolates was not related to response induced in vitro using bismethiazol-amended medium (Zhu et al. 2013).

15.3.2 Tomato Bacterial Canker Disease

Various disease management strategies have been evaluated for limiting the incidence of tomato bacterial canker disease caused by *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*). No commercial tomato cultivar with substantial levels of resistance, to ensure the zero-tolerance level emphasized in commercial seed trade to prevent introduction of *Cmm* through seeds (Sen et al. 2015), is available. Soil solarization using transparent polyethylene sheets for covering soil in commercial tomato production areas was applied for 6 weeks in plastic houses. Bacterial canker disease severity was drastically reduced by soil solarization/mulching throughout the tomato-growing season. Soil solarization with polyethylene sheets did not affect the population of *Pseudomonas*, *Bacillus*, and the actinomycete *Streptomyces* antagonistic to *Cmm*, and they could survive in the tomato rhizosphere even in the increased temperature conditions prevailing during soil solarization. The fluorescent pseudomonads isolated from the rhizosphere soil were able to induce resistance to *Cmm* in plants growing from seeds treated with pseudomonads (Antoniou et al. 1995). The biocontrol agents *Bacillus subtilis*, *Trichoderma harzianum*, and *Rhodosporidium diobovatum* were found to be effective in suppressing the development of tomato bacterial canker disease to varying degrees (Utkhede and Koch 2004).

The effectiveness of plant activators capable of inducing resistance to crop diseases have been assessed for their efficacy in reducing the incidence and severity of tomato bacterial canker disease caused by *Clavibacter michiganensis* subsp. *michiganensis* (*Cmm*). Pretreatment with acibenzolar-*S*-methyl (ASM) reduced the severity of canker disease. The development of resistance to canker disease depended on the provision of an interval of 1–7 days between challenge inoculation with the bacterial pathogen and application of ASM. An interval of 3 days between ASM application and pathogen inoculation resulted in the highest level of protection (Baysal et al. 2003; Soylyu et al. 2003). Another disease-resistance inducer DL- β -aminobutyric acid (BABA) was able to induce resistance in tomato against *Cmm*. Foliar sprays of BABA (500 g L⁻¹) reduced canker disease development by up to 54% at 14 days after inoculation. Bacterial populations were reduced by 84% in planta by treatment with BABA, which enhanced the activities of defense-related enzymes in tomato plants (Baysal et al. 2005).

Managing tomato bacterial canker disease using copper compounds was carried out with some success. Antibacterial compounds such as bronopol, copper sulfate, kasugamycin, and 8-hydroxyquinoline, three commercial formulates (Antibak RZ, an oligoelements containing copper plus zinc; orthopol, a potassium soap; and Param, a resistance inducer), and combinations of these compounds were evaluated for their efficacy in suppressing bacterial canker disease development. Treatments containing copper sulfate significantly reduced disease severity in inoculated plants. Streptomycin was less effective. Copper sulfate combined with 8-hydroxyquinoline (at half dose) was more effective than copper sulfate alone in reducing bacterial canker disease in greenhouse-grown tomato plants. This combination of treatments appeared to be ecofriendly since the amount of copper applied could be reduced (de León et al. 2008).

15.3.3 Potato Scab Diseases

Streptomyces scabies and *S. turgidiscabies* cause potato scab and common scab diseases, respectively. These bacterial pathogens are soilborne and can survive in the soil for long periods. Cultivation and incorporation of specific green manure crops have been

suggested as a disease management strategy because of their ability to improve the soil conditions, favoring the buildup of microbial populations antagonistic to these bacterial pathogens. The effects of buckwheat and canola as green manures and rotation crops on potato scab disease (*S. scabies*) were investigated in 2 year field trials. Potatoes grown in soil planted with corn or alfalfa in the previous year had lower incidence of scab and higher yield levels than potatoes grown in soil previously planted with potato. Streptomycetes from soil collected from green manure (GM-) treated plots tended to have greater pathogen inhibitory potential (determined in vitro) than those from fallow-treated plots (without GM). The antagonist populations also showed increases in the GM-treated plots. GM crops appeared to selectively enrich the abundance or activity of antibiotic producers within the soil microbial community (Wiggins and Kinkel 2005). Incorporation of green manures had a favorable effect on potato common scab disease caused by *Streptomyces turgidiscabies*. The number of diseased tubers harvested from soil incorporated with lopsided oat or wooly pod vetch was significantly reduced, compared with tubers obtained from soil planted to oat or continuous potato cultivation in a planter experiment. Under field experiments conducted during 1999–2000, treatment with lopsided oat followed by lopsided oat or wooly pod vetch was significantly more effective in suppressing the disease severity than oat and continuous potato cultivation ($P < 0.001$). A significantly greater increase in marketable tuber ratio was also observed in plots treated with lopsided oat compared with plots with oat or potato as previous crop. The results suggested that lopsided oat might be grown as a green manure crop and incorporated prior to cultivation of potato to reduce disease severity and enhance marketable potato tubers (Sakuma et al. 2011).

Among organic compounds of animal origin, chitosan has been demonstrated to be effective in suppressing the development of many crop diseases. The effectiveness of chitosan on the development of *Streptomyces scabies* applied either alone or in combination with *Streptomyces melanosporofaciens* strain EF76, capable of producing the antibiotic geldanamycin, was assessed. Combined application of chitosan and the strain EF76 was the most effective in reducing the scab disease incidence under greenhouse conditions. Under field conditions, the number of geldanamycin-resistant actinomycetes (GRA) on harvested potato tubers was significantly increased in treatments containing chitosan than in other treatments. The results suggested chitosan might promote the establishment of antagonistic actinomycetes on progeny tubers and induce resistance in tubers against infection by *S. scabies*. On the other hand, the strain EF76 might suppress pathogen development through production of the antibiotic geldanamycin (Prévost et al. 2006).

15.3.4 Citrus Canker Disease

Xanthomonas axonopodis (campestris) pv. *citri* causes cankers in all plant organs, including fruits, reducing the market value of fruits of *Citrus* spp. Enforcement of quarantine regulations prevented the introduction and establishment of the canker disease to varying levels in different countries. In the USA, State and Federal regulatory personnel were involved in the eradication of 20 million citrus trees. Infected trees and all plant materials within 125 feet were burnt as per quarantine regulations. The clothes of worker, tools, machinery, and vehicles were thoroughly disinfected (Schumann 1991). Planting disease-free seedlings and plant sanitation are very important to reduce inoculum buildup, in addition to the management of citrus leaf minor, the feeding

injuries of which make way for the easy entry of the citrus canker pathogen. Various kinds of organic compounds have been evaluated for their efficacy in suppressing the development of canker disease.

The protective potential of imidacloprid, a neonicotinoid insecticide which breaks down in the plants into 6-chloronicotinic acid, a compound related to the SAR inducer isonicotinic acid (INA), was assessed. Soil application of imidacloprid effectively suppressed the development of citrus canker. Swingle citrumelo seedlings (*Citrus paradisi* x *Poncirus trifoliata*) were treated with imidacloprid, isonicotinic acid (INA), and acibenzolar-*S*-methyl (ASM), proven SAR inducers, as soil drenches or with ASM as foliar spray at 1 week prior to challenge inoculation of immature leaves with *X. axonopodis* pv. *citri*. Seedlings were reinoculated with the pathogen four times over a period of 24 weeks. Soil application of the SAR inducers (plant activators) reduced disease severity (number and size of lesions) by 70% relative to the untreated control plants (Francis et al. 2009). In a later investigation, the efficacy of imidacloprid, thiamethoxam, and ASM for the suppression of canker disease development on Ray Ruby grapefruit trees was assessed. Foliar infection of *Xac* was significantly suppressed by all treatments on combined spring–summer fall flushes. The recommended practice of applying copper hydroxide and streptomycin (11 sprays at a 3 week interval) reduced the canker disease incidence on shoot flushes produced throughout the season compared with untreated control. The soil-applied SAR inducers also reduced foliar infection depending on the rate, frequency, and timing of application. During a tropical storm, SAR inducers were generally not effective. The protective efficiency of SAR inducers differed depending on the concentration and timing of their application (Graham and Myers 2011).

Copper compounds have been applied widely for the management of citrus canker disease for a long time, resulting in the development of *Xanthomonas axonopodis* pv. *citri* (*Xac*) strains resistant to these chemicals. Multiple and independent introduction of copper resistance genes into sensitive strains of *Xac* and also into strains of *X. alfalfae* subsp. *citrumelonis* from Florida were investigated. The principal copper resistance genes *copL*, *copA*, and *copB* were identified in both pathogens. The *copLAB* gene cluster was present in many species of *Xanthomonas* from different parts of the world. It appeared that the plasmid had been horizontally transferred and various populations had mutated, based on selection pressure unique to the geographic locations concerned. Although high homology of the genes among strains indicated that the copper resistance in *Xanthomonas* had a common origin, the slight differences in the nucleotide sequences within groups showed that Cu^R gene could be independently exchanged among species of *Xanthomonas* throughout the world (Behalu et al. 2013). The need to restrict the use of copper-based chemicals is underscored and adoption of other options for reducing the citrus canker disease incidence may be the feasible approach.

15.4 Management of Virus Diseases

Virus diseases affecting various crops are managed primarily by applying strategies aimed at reduction/prevention of virus infection and spread. Use of virus-free seeds and propagules is the basic requirement to prevent the plants growing from infected seeds/propagules, serving as the potential sources of inoculum for the secondary spread of the disease through the natural biological vectors. Eradication of all sources

of inoculum present within the field/farm as infected volunteer plants or weed species has to be followed strictly. If ignored, these strategies targeting the virus inoculum may result in considerable yield losses in quantity and quality. Protecting the crops against virus infection by using mild strains against severe strain has been successful more frequently in the case of viruses transmitted through propagules than viruses carried by true seeds.

15.4.1 Management of Seedborne Virus Diseases

Soybean mosaic virus (SbMV) is seedborne and is also transmitted by aphids under natural conditions. SbMV occurs in the form of different strains. The effectiveness of using attenuated strains of SbMV to protect soybean plants against severe strains of the virus was assessed. An attenuated strain of SbMV was generated by exposing the infected plants to 15°C for 14 days or 30 days (Kosaka and Fukunishi 1993). The attenuated SbMV isolate Aa15-M2 generated by exposure to 15°C for 14 days was used to cross-protect the susceptible soybean plants. Black soybean seedlings (20,000 in 1990 and 78,000 in 1991) were planted 1–3 days after immunization with the attenuated strain in seed farms in Kyoto Prefecture, Japan. Infection by the severe strain of SbMV was effectively suppressed in the immunized plants. The seeds obtained from the cross-protected plants were virtually free of the virus. As the next step, seedlings growing from the seeds of protected plants were transplanted in the farmers' fields. The incidence of virulent strains of SbMV up to pre-flowering stage (about 40 days after transplanting) was 1.3% in the first year and 0.8% in the second year. The effectiveness of preimmunization of soybean plants by an attenuated strain of SbMV was demonstrated by Kosaka and Fukunishi (1994).

Attenuated strains of *Cucumber mosaic virus* (CMV), *Zucchini yellow mosaic virus* (ZYMV), and *Watermelon mosaic virus* (WMV-2) were produced by exposing the plants infected by the respective viruses to low temperatures. The attenuated strains effectively protected the plants against respective severe strains and no difference in the effectiveness of the attenuated strains in protecting plants was observed. The degree of cross-protection was correlated to the concentration of the protecting strain in the plants. The WMV-mild strain provided a higher level of cross-protection to plants against severe strains than CMV-mild strain and ZYMV-mild strain (Kosaka and Fukunishi 1997). An attenuated strain CM95 of CMV efficiently protected cucumber plants under field conditions. The effectiveness of cross-protection by attenuated strain was assessed by symptom expression assay and RT-PCR-RFLP procedure after challenge inoculation with severe strain. The RT-PCR-RFLP method indicated the level of protection much earlier than the bioassay, which required several days to provide results (Nakazono-Nagaoka et al. 2005). The attenuated strain of *Zucchini yellow mosaic virus*-2002 (ZYMV) obtained after repeated low temperature treatments at 12.5–15°C was purified by five cycles of single-plant transfer. The attenuated isolate ZYMV-2002 protected cucumber plants efficiently and the protected plants yielded as high as healthy plants. They showed very mild or no symptoms following inoculation with ZYMV-2002 under field conditions. The results revealed the potential of the attenuated strain in protecting cucumber plants under field conditions (Kosaka et al. 2006).

Another strategy that has been shown to be effective in restricting the incidence of virus diseases in cucurbits is the use of reflective, metalized plastic mulch with a thin coat of aluminum (Summers et al. 2004). The effectiveness of disease suppression by

integrating the UV-reflective plastic mulch and commercially available resistance-enhancing compound BioYield was assessed. The incidence of *Watermelon mosaic virus* (WMV) infecting summer squash (*Cucurbita pepo* var. *meloepo*) was significantly reduced in plants grown on silver-on-black (UV-reflective mulch) compared to the plants grown on black mulch (control) in the trial conducted during spring. The virus concentration (as determined by ELISA test) was significantly reduced in plants from treated plots compared to controls. The fall trial including highly UV-reflective silver mulch showed that the highly UV-reflective silver mulch treatment was more effective in reducing incidence of WMV compared to silver-on-black and black mulch treatments. However, the yield of squash was greater in plants covered with silver-on-black mulch treatment than from the other two treatments. The application of BioYield was ineffective in either reducing the disease incidence or increasing the yield of squash plants (Murphy et al. 2008).

Some fungicides such as carbendazim have been reported to alleviate the symptom severity in virus-infected plants. The extent of discoloration induced by *Tobacco mosaic virus* (TMV) was reduced by carbendazim by preventing the destruction of chlorophyll in infected plants (Tomlinson et al. 1976). Similar ameliorative effect of fungicides on bean plants infected by *Bean common mosaic virus* (BCMV) was observed. Commercial formulations of strobilurins, namely azoxystrobin, kresoxim-methyl, trifloxystrobin, and pyraclostrobin, were evaluated for their efficacy under screenhouse and field conditions. Seed treatment with pyraclostrobin (20 g L^{-1}) resulted in the highest seed germination percentage and seedling vigor and provided 76% and 65% protection against BCMV under screenhouse and field conditions, respectively. Infection by BCMV in plants growing from seeds treated with pyraclostrobin or kresoxim-methyl was indexed using ELISA tests which showed the protective ability of these fungicides. Strobilurin exerted a direct positive physiological effect on common bean plants. These fungicides with reduced risk could be useful as potential inducers of resistance against BCMV and growth promoters (Udayashankar et al. 2012).

15.4.2 Management of Propagule-Borne Virus Diseases

Viruses transmitted via propagules have the potential to ruin a production system almost entirely, as in the case of *Banana bunchy top virus* (BBTV) and *Citrus tristeza virus* (CTV), if adequate attention is not bestowed upon the selection of healthy propagules. Introduction of the viruses via propagules has to be efficiently prevented by implementing certification and quarantine programs. Several rapid and sensitive diagnostic techniques for detection and identification of virus(es) present in the planting materials are available (Chapter 7). The production of virus-free planting materials through tissue culture techniques and establishment of virus-free nuclear stocks are essential so that growers can begin with clean planting materials to ensure healthy crops and high levels of yield. Virus disease management strategies have the aim of preventing the incidence of diseases, rather than curing infected plants. Restricting the spread of the virus diseases by reducing the populations of biological vectors has limited application, since a small population of vectors left after chemical application may be able to spread the disease to a significant number of healthy plants. All sources of virus infection should be eradicated thoroughly to reduce incidence of new infections. Spread of *Citrus tristeza virus* (CTV) was effectively contained by planting virus-free citrus on citrus-tolerant or -resistant rootstocks, along with eradication of CTV-infected trees by the Central California

Tristeza Eradication Agency (CCTEA) (Yokomi and De Borde 2005). Monocropping generally increases the risk of providing conditions for the virus disease to become endemic. Plant diversification through mixed cropping including cover crops, border plants, intercrops, and barrier (trap) crops along with the primary crop has therefore been found to be useful to reduce the incidence and subsequent spread of virus diseases. The incidence of *Potato virus Y* (PVY) in potato could be reduced by raising sorghum, soybean, or wheat as border crops, which might reduce the movement of aphid vectors (Di Fonzo et al. 1996).

Immunization of crop plants with mild strains against infection by severe strains of the same virus or related viruses has been demonstrated to have practical utility to reduce the adverse effects of severe strains on plant growth and yield. Mild strains are selected from naturally occurring strains or are generated artificially by exposure to chemicals, UV-irradiation, or unusual temperatures (high or low). Cross-protection (immunization) as a virus disease management strategy has been most successfully employed for the protection of citrus plants against *Citrus tristeza virus* (CTV). In Brazil, 5,000,000 preimmunized plants were planted over a period of 10 years with no evidence of breakdown of the level of protection offered by the mild strain (Costa and Miller 1980). This approach for management of CTV was adopted in several other countries such as Australia, Japan, South Africa, and India. Constant monitoring of the strain composition in a geographical location has to be carried out to sustain the effectiveness of this strategy (Garnsey et al. 2005; Sieburth et al. 2005).

The usefulness of cross-protection as a disease management strategy applicable for *Citrus tristeza virus* (CTV) depends on the early detection and accurate identification of CTV isolates. The CTV isolates are usually dispersed to new areas by propagation of infected buds, and the virus is largely spread by different species of aphids in a semipersistent manner. The lack of knowledge of actual genetic determinants of CTV pathogenicity, the presence of mixed populations in field trees, and the lower levels of sensitivity of detection techniques pose considerable problems to be solved (Sieburth et al. 2005). The real-time RT-PCR procedure could be employed for precise identification of 56 biologically characterized CTV isolates from 20 different countries. All mild strains of CTV were identified accurately and differentially from the severe strains causing seedling yellows (SY) and stem-pitting (SP) symptoms. This protocol showed the potential for use by quarantine and certification personnel to avoid introduction or nursery propagation of potentially dangerous isolates in areas where only mild isolates might be prevalent (Ruiz-Ruiz et al. 2009).

Chinese yam necrotic mosaic virus (CYNMV) causes considerable yield losses in Chinese yam (*Dioscorea opposita*) crops. An attenuated strain KM3 of CYNMV was selected because it produced only mild mosaic symptoms on leaves of Chinese yam cultivar Nagaimo. Aphids were used to inoculate the attenuated strain KM3 to protect healthy yam plants against severe strains YS117 and IW5. The strain KM3 provided effective protection against severe strains of CYNMV under field conditions (Kondo et al. 2007). Another attenuated strain T-3 of *Japanese yam mosaic virus* (JYMV) was able to protect the Chinese yam against severe strain of JYMV. The native strains were detected in only 1 of 50 plants grown from tubers preimmunized with T-3 strain during a period of 6 years. The preimmunized plants yielded significantly more marketable tubers than the unprotected plants. The attenuated strain T-3 showed potential for effective protection of yam plants against *Japanese yam mosaic virus* (Kajihara et al. 2008).

Severe strains of *Sweet potato feathery mottle virus* (SPFMV) cause russet crack and discoloration of storage root skin of sweet potato (*Ipomoea batatas*), making them unacceptable to consumers. A mild strain of SPFMV 10-0 rarely induced skin discoloration and russet crack symptom, and this strain was used to protect the sweet potato plants against severe symptoms. The mild strain did not reduce the yield. The strain 10-0 was rarely present in sweet potato plants under natural conditions, so the mild strain was maintained in *Ipomoea nil* by graft inoculation. This mild strain 10-0 showed potential for protecting the sweet potato plants against severe strains of SPFMV (Yamasaki et al. 2009). Nitrous acid treatment procedure was applied for generating attenuated strains (mutants) of *Potato virus Y* (PVY). Among the 15 attenuated mutants of PVY generated, two mutants M-MY10 and N-NA10 were effective in providing protection against the wild-type strain NTND6 which induced necrotic symptoms in potato tubers (Ogawa et al. 2013).

Management of virus diseases in perennial crops requires constant monitoring using sensitive diagnostic assays, eradication of all infected plants and sources of inoculum, replanting with certified virus-free plants/planting materials, and applying chemicals to reduce vector populations to restrict secondary spread of the viruses. A comprehensive integrated management system was applied for the management of *Grapevine leafroll-associated virus 3* (GLRaV-3) in South Africa. The management strategies included planting certified material tested free of detectable viruses, application of herbicide and subsequent removal of infected plants and debris, adoption of fallow periods during which time all volunteer host plants were eradicated, application of systemic and contact insecticides to reduce populations of viruliferous mealy bugs, and consequent reduction in disease spread. Incidence of GLRaV-3 was reduced from 100% infections on 111,431 vines planted in 41.26 ha during 1989–1992 to 0.027% infection (58 of 209,626 vines) in 2012. The reduction in infection by GLRaV-3 could be achieved by replacing fully infected vineyards and rouging out 3105 young infected vines in new vineyards. In the majority of vineyards, growers did not adopt the GLRaV-3 control strategies earlier; the disease was therefore widespread in these areas (Pietersen et al. 2013).

- Detection of *A. avenae* spp. *citrulli* by IMS method, 237
- Detection of *A. avenae* spp. *citrulli* by combination of agar plating and real-time PCR assay, 264
- Detection of *A. avenae* spp. *citrulli* by ELISA formats, 236
- Detection of *A. avenae* spp. *citrulli* by MCH-real-time PCR format, 268
- Detection of *A. avenae* spp. *citrulli* with specific MAb, 235
- Detection of all members of *Tobravirus* by a generic PCR assay, 531
- Detection of ALSV infection of apple flower buds by in situ hybridization assay, 644
- Detection of *Alternaria brassicae* by PCR-based assay, 51
- Detection of *Alternaria* spp. by deep-freezer blotter method, 38
- Detection of *Alternaria* spp. by PCR assay, 38
- Detection of AP phytoplasma by PCR-based methods, 435
- Detection of *Apple latent spherical virus* (ALSV) in apple seed, 475
- Detection of apple proliferation (AP) phytoplasma in apple by TaqMan real-time PCR assay, 338
- Detection of ASPV/CRLV/CNRMV infecting apple and cherry by RT-PCR assays, 527
- Detection of *A. vitis* in grapevine by real-time PCR assay, 314
- Detection of AYRSV in artichoke by RT-PCR assay, 533
- Detection of bacterial pathogens by DNA array technique, 322
- Detection of bacterial pathogens by ELISA tests, 226
- Detection of bacterial pathogens by PCR-based assays, 245
- Detection of bacterial pathogens in tomato and pepper by PCR assays, 297
- Detection of BBTV in field-grown banana plants and aphid vectors by PCR assay, 522
- Detection of *B. glumae* in rice seeds by PCR-based assay, 251
- Detection of *Blackgram leafcrinkle virus* in seeds, 460
- Detection of *Botrytis* spp. by real-time fluorescent PCR assay, 55
- Detection of *B. plantarii* in paddy water and graminaceous weeds, 396
- Detection of BSV in banana by ISEM observation, 516
- Detection of *C. acutatum* by nested PCR assay, 99
- Detection of *Ca. L. asiaticus* in citrus fruit and peduncles, 317
- Detection of *Ca. L. asiaticus* in citrus fruits by PCR assay, 295
- Detection of *Ca. L. solanacearum*, causative agent of potato zebra chip (ZC) disease, 425
- Detection of *Ca. L. solanacearum* in potato tubers by PCR assay, 297
- Detection of *C. capsici* by real-time PCR, 40
- Detection of *C. coccodes* in potato tubers by PCR assay, 96
- Detection of CEVd in leaves and petals of *Imaptiens* and *Verbena*, 577
- Detection of CEVd in seeds of citrus by RT-PCR assay, 577
- Detection of *C. flaccumfaciens* pv. *flaccumfaciens* in bean seed by PCR assay, 250
- Detection of *C. fragariae* by real-time PCR assay, 99
- Detection of CGMMV in cucumber seeds by RT-PCR assay, 491
- Detection of *C. lagenarium* by real-time PCR assay, 54
- Detection of *Claviceps* spp., 48
- Detection of *C. lindemuthianum* by duplex PCR, 40
- Detection of *C. lindemuthianum* by PCR-based assay, 39
- Detection of *C. michiganensis* spp. *michiganensis* by ELISA, 237

- Detection of *C. michiganensis* ssp. *michiganensis* in asymptomatic tomato seed, 258, 403
- Detection of *C. michiganensis* ssp. *sepedonicus* in potato by PCR assay, 283
- Detection of CMV in phloem exudates (PEs) of cucumber, 639
- Detection of *cpnox1* gene of *C. purpurea*, 194
- Detection of CPsV in citrus by TBIA technique, 631
- Detection of *C. purpurea* by RAPD-AFLP analysis, 64
- Detection of CTV by DAS-ELISA test, 498
- Detection of CTV by hybridization of DIG-labeled probes with ds-RNA, 519
- Detection of CTV by ISIA procedure in citrus, 640
- Detection of CTV in citrus by real-time PCR format, 558
- Detection of CyMV/ ORSV in orchids by molecular beacon technique, 563
- Detection of *Dahlia mosaic virus* in seed by PCR assay, 483
- Detection of *E. lata* in grapevine by PCR-based RFLP technique, 100
- Detection of European stone fruit yellows phytoplasma by direct PCR assay, 332
- Detection of *F. circinatum* by real-time PCR assay, 49
- Detection of *F. graminearum* by real-time PCR assay, 46
- Detection of *F. oxysporum* f.sp. *cubense* by real-time fluorescent PCR assay, 49
- Detection of *F. oxysporum* f.sp. *cubense* in pseudostem tissues by PCR-based assay, 98
- Detection of *F. oxysporum* f.sp. *phaseoli* by qPCR assay, 59
- Detection of *F. oxysporum* f.sp. *vasintectum* by PCR assay, 41
- Detection of fumonisins B1, B2 and B3 in corn kernels, 207
- Detection of fungal pathogens using nucleic acid-based techniques, 90
- Detection of *Fusarium* spp. causing FHB disease, 44
- Detection of GFLV in grapevine propagules by RT-PCR assay, 541
- Detection of GLRaV-2 by PAS-ELISA and indirect DIBA tests in grapevine, 505
- Detection of GLRaV-3 in flowers/fruits of asymptomatic grapevine by DAS-ELISA, 504
- Detection of GLRaV-1 in grapevine by DAS-ELISA test, 626
- Detection of GLRaV-5 in grapevine by optimized ELISA test, 504
- Detection of GLRaV-3 in grapevine leaf extracts by ISEM procedure, 641
- Detection of GLRaV-3 using bivalent antibody, 498
- Detection of grapevine virus by ELISA and RT-PCR tests, 541
- Detection of grapevine viruses in planting materials by real-time PCR assay, 557
- Detection of GUS activity in fungal pathogens, 81
- Detection of head infection by *U. tritici* and *U. nuda*, 26
- Detection of *Hibiscus latent ringspot virus* in kenaf seed, 475, 476
- Detection of HLB pathogen in asymptomatic citrus fruit, 422
- Detection of HLB pathogen in asymptomatic citrus tissues by LAMP assay, 318
- Detection of HLB pathogen in different tissue types in citrus fruit, 422
- Detection of HLB pathogen in psyllid vectors, 297
- Detection of HLB pathogen inside the fruit and seed of citrus, 422
- Detection of HPV in biological vector, 471
- Detection of *H. solani* in potato tubers by nested PCR assay, 96
- Detection of HSVD in asymptomatic propagules by RT-PCR assay, 585
- Detection of HSVD in pollen grains of plum plants by RT-PCR assay, 586
- Detection of immunodominant membrane protein in phytoplasmas, 432
- Detection of *Indian citrus ringspot virus* in citrus pollen, 474
- Detection of infection in propagules by bacterial pathogens, 273

- Detection of infection of PNRSV in seed integuments and seed parts by in situ hybridization assay, 643
- Detection of inter-and intra-cellular hyphae of *U. hordei* in barley, 190
- Detection of IPCV-H strain in millet seeds, 468
- Detection of IYSV in onion tissue extracts by indirect ELISA format, 508
- Detection of JYMV by RT-LAMP assay in Japanese yam plants, 566
- Detection of latent infection by *R. solanacearum* by ELISA test, 230
- Detection of latent infection by *X. campestris* pv. *campestris* by ELISA test, 230
- Detection of latent infection of *C. michiganensis* ssp. *michiganensis*, 246
- Detection of latent infection of potato tubers by BIO-PCR assay, 306
- Detection of latent infection of potato tubers by *Erwinia* by immunoassays, 278
- Detection of *Lettuce mosaic virus* (LMV) in commercial seed lots, 460
- Detection of *Little cherry virus, 1* by ELISA in cherry and plum, 506
- Detection of LMV in lettuce seed by DAS-ELISA test, 467
- Detection of LYSV in garlic and leek by ISEM method, 517
- Detection of *Magnaporthe grisea* by real-time PCR assay, 54
- Detection of marked strain in rice seeds, 394
- Detection of microbial plant pathogens, 12
- Detection of mixed infection of citrus by HLB and phytoplasma by nested PCR assay, 340
- Detection of molecular variants of GVA in grapevines, 543
- Detection of multiple pathogens by PCR-based assays, 244
- Detection of multiple pathogens in potato tubers by PCR-based assay, 335
- Detection of multiple pathogens simultaneously by PLPs and dot-blot hybridization assay, 270
- Detection of mycotoxins by immunoassays, 24
- Detection of onion yellows phytoplasma by PCR-based assay, 334
- Detection of oospores of *P. capsici* in soil, 52
- Detection of OYDV in tissue culture-derived garlic plants by ISEM, 516
- Detection of Panama wilt disease of banana in propagules, 98
- Detection of pathogens in spore extracts, 25
- Detection of pathotypes of SqMV in quash seed by qRT-PCR assay, 490
- Detection of *P. brassicae* by nested PCR assay, 97
- Detection of *P. brassicae* in soil, 97
- Detection of PBV in pineapple by PCR assay, 522
- Detection of *P. capsici* by real-time PCR assay, 52
- Detection of PDV by DAS-ELISA format, 502
- Detection of PDV in cherry seedlings by ELISA format, 503
- Detection of *Peronosclerospora sorghi* by RAPD-PCR procedure, 65
- Detection of *P. erythroseptica* in potato tubers by PCR, 91
- Detection of *P. fragariae* by PCR-based assay, 98
- Detection of *P. fragariae* var. *rubi* in raspberry plants, 98
- Detection of *P. halstedii* in sunflower seed powder, 37
- Detection of *P. halstedii* in sunflower seeds, 36
- Detection of phytoplasmas by PCR-based assays, 431
- Detection of phytoplasmas in potato tubers by PCR-based assay, 336
- Detection of plant viruses by Immunoblot assay, 512
- Detection of PLMVd in pollen from infected peach cultivars, 576
- Detection of PLMVd in pollen from peach trees by spot-blot hybridization assay, 650
- Detection of PLRV in potato tubers by RT-PCR assay, 553
- Detection of *P. nicotianae* by PCR assay, 43
- Detection of PNRSV and PDV by RT-PCR assay, 526

- Detection of PNRSV in all flower bud tissues by in situ hybridization assay, 643
- Detection of PNRSV in apricot pollen grains by dot-blot hybridization assay, 642
- Detection of PNRSV in floral organs of stone fruit trees by dot-blot hybridization, 481
- Detection of PNRSV in fruits of apricot by TPH assay, 643
- Detection of PNRSV in infected trees by DAS-ELISA format at different seasons, 502
- Detection of PNRSV in peach tree tissues, 526
- Detection of potato viruses by NASH technique in potato tissues, 519
- Detection of PPV by TAS-ELISA and IC-RT-PCR techniques, 550
- Detection of PPV in anthers of *Prunus* spp., 487
- Detection of PPV in fully ripe seeds/germinating seeds/seedlings, 493
- Detection of PPV in plum germplasm entries by RT-PCR assay, 539
- Detection of PPV pathotypes by array technology, 568
- Detection of PR-proteins in infected rice leaves, 382
- Detection of PSbMV by RT-PCR in ELISA-negative seed samples, 484
- Detection of *P. sojae* by real-time PCR assay, 53
- Detection of PStV and PeMV by IC-RT-PCR assay, 491
- Detection of PStV and PeMV in single peanut seed, 485
- Detection of PSTVd and viruses of potatoes under the same RT-PCR conditions, 587
- Detection of PSTVd in pollen grains by RT-PCR assay, 582
- Detection of PSTVd in reproductive organs of potato, 652
- Detection of PSTVd in seeds by return gel electrophoresis method, 574
- Detection of *P. teres* by PCR-based assay, 50
- Detection of PVY in certified seed potato tuber lots, 529
- Detection of PVY in dormant potato tubers by RT-PCR format, 562
- Detection of PVY in foundation seed potato tubers, 534
- Detection of PVY strains groups by real-time RT-PCR format, 562
- Detection of *Pyrenophora graminea* by PCR-based assay, 50
- Detection of *R. collo-cygni* in barley seed, 139
- Detection of *rhs* family gene homolog in *Xanthomonas*, 249
- Detection of *R. secalis* in barley seed powder, 33
- Detection of *R. solanacearum* by real-time PCR formats, 307
- Detection of *R. solanacearum* in asymptomatic potato tubers by rep-PCR format, 301
- Detection of *R. solanacearum* in ginger rhizomes by real-time BIO-PCR format, 307
- Detection of *R. solanacearum* in potato tubers by PCR assay, 283
- Detection of *R. solani* in rice by qPCR assay, 53
- Detection of *R. solani* in soil extract, 54
- Detection of RYMV in alternative hosts, 470
- Detection of *S. citri* by PCR-based assays, 329
- Detection of seedborne inoculum of BCMV in bean, 476
- Detection of seedborne inoculum of BSMV in barley, 476
- Detection of *S. endobioticum* in soil and tubers, 94
- Detection of serotypes of IPCV in peanut by dot-blot hybridization, 481
- Detection of six viruses in garlic by DTBIA test, 509
- Detection of slow-growing fungal pathogen, 18
- Detection of SMV in asymptomatic soybean plants, 468
- Detection of SMV in soybean seed by DAS-ELISA test, 467
- Detection of SMV in soybean seed with and without mottling symptom, 469
- Detection of *Spongospora* spp. in potato tubers, 88

- Detection of *S. reilianum* isolates using AFLP primer combinations, 69
- Detection of *S. sclerotiorum* by real-time PCR assay, 57
- Detection of *S. septoria*/*S. nodorum* in wheat by PCR assay, 47
- Detection of *S. subterranea* in potato tubers by PCR assay, 92
- Detection of strains of PPV in apricot by TAS-ELISA format, 503
- Detection of strains of *X. campestris* pv. *vesicatoria* with copper resistance, 250
- Detection of *Streptomyces* spp. by PCR in potato tubers, 290
- Detection of subcellular PR-1 protein, 187
- Detection of SVBV based on nucleic acid-based amplification (NASBA), 563
- Detection of SVBV by biological indexing in strawberry, 563
- Detection of sweet potato viruses by PCR assay, 523
- Detection of *T. caries* by DAS-ELISA, 25
- Detection of threshold of detection of *D. bryoniae*, 60
- Detection of *T. indica* by ELISA, 25
- Detection of *T. indica* by real-time PCR assay, 50
- Detection of toxin in culture filtrates, 25
- Detection of TRV in potato tubers by dot-blot hybridization technique, 518
- Detection of TRV in potato tubers by RT-PCR assay, 530
- Detection of TRV in sugar beet by PAC-ELISA format, 474
- Detection of *T. solani* in potato plants and tubers, 97
- Detection of TSWV in *R. asiaticus* tubers by TBIA test, 511
- Detection of *V. dahliae* by quantitative real-time PCR assay, 55
- Detection of *V. dahliae* in certified potato seed tubers, 87
- Detection of *V. dahliae* in potato tubers, 95
- Detection of viral RNA inside generative cell by in situ hybridization assay, 643
- Detection of viroids by physico-chemical methods in seeds and propagules, 574
- Detection of viroids in citrus buddlings imported from other countries by multiplex RT-PCR assay, 585
- Detection of viroids in germplasm collection of fruit trees using poly6 probe in dot-blot hybridization, 580
- Detection of virus by dot-immunobinding assay, 514
- Detection of virus by nucleic acid-based techniques, 517
- Detection of viruses by DNA array technology, 568
- Detection of viruses by in situ immunoassay (ISIA), 515
- Detection of viruses by molecular beacon technology, 562
- Detection of viruses by nucleic acid-based techniques, 480
- Detection of viruses by RT-LAMP technique, 565
- Detection of viruses by small-RNA deep-sequencing analysis, 570
- Detection of viruses in budwood materials by TaqMan real-time RT-PCR assay, 558
- Detection of viruses in dormant potato tubers by microarray method, 569
- Detection of viruses in in vitro-generated plantlets of potato cultivars by DAS-ELISA tests, 507
- Detection of viruses in *Lillium* sp. by DIBA test, 513
- Detection of viruses in propagules by ELISA formats, 499
- Detection of viruses in propagules by immunoassays, 495
- Detection of viruses in propagules by PCR-based techniques, 521
- Detection of viruses in propagules by real-time PCR formats, 556
- Detection of viruses in propagules by TBIA test, 509
- Detection of viruses in seeds/seed extracts, 460
- Detection of viruses in seeds using fluorescent antibody techniques, 477
- Detection of viruses using electron microscope, 479

- Detection of virus infection in apple cultivars, 539
- Detection of *X. axonopodis* pv. *citri* by specific bacteriophage, 275
- Detection of *X. axonopodis* pv. *citri* in citrus by PCR assay, 285
- Detection of *X. axonopodis* pv. *vasculorum* in sugarcane by LFD technique, 282
- Detection of *X. campestris* pv. *campestris* by PCR-based assay, 247
- Detection of *X. campestris* pv. *campestris* in cabbage seeds, 223
- Detection of *X. campestris* pv. *campestris* in tomato and pepper seed washes, 248
- Detection of *X. campestris* pv. *musacearum* in banana by PCR assay, 290
- Detection of *X. campestris* pv. *phaseoli* by rapid PCR-based assay, 246
- Detection of *X. campestris* pv. *translucens* in barley, 224
- Detection of *X. campestris* pv. *vitians* by direct plating, 390
- Detection of *X. citri* ssp. *citri* in citrus flowers, 418
- Detection of *X. fastidiosa* in citrus by PCR assay, 287
- Detection of *X. fastidiosa* in citrus seed coat extracts by real-time PCR assay, 255
- Detection of *X. fastidiosa* in fruit peels and endocarp of citrus, 408
- Detection of *X. fastidiosa* in fruit vascular bundles and seed of citrus by one-step PCR assay, 297
- Detection of *X. fastidiosa* in grapevine/ citrus by LAMP assay, 320
- Detection of *X. fastidiosa* in grapevines by PCR assay, 289
- Detection of *X. fastidiosa* in seedlings, 408
- Detection of *X. oryzae* pv. *oryzae* in asymptomatic rice leaves, 251
- Detection protocol for large scale testing of planting materials for PPV, 559
- Detection *S. citri* in citrus by SYBR Green quantitative PCR assay, 317
- Detection sensitivity of RT-LAMP procedure in comparison to RT-PCR assay, 588

- Nec1 protein inducing necrosis in excised potato tuber, 429
- Necrotrophic phase of *B. cinerea*, 194
- Nested-PCR assay for detection of GLRaV-1 and GRSPaV in grapevine, 541
- Nested PCR assay for detection of *P. cinnamomi*, 99
- Nested PCR assay for detection of *P. fragariae*, 98
- Nested PCR assay for detection of *X. fastidiosa*, 303
- Nested PCR for detection of *Phytophthora* spp., 53
- Nested PCR for detection of *U. virens*, 42
- Nested RT-PCR assay for generic detection of genetically related viruses in grapevines, 543
- nit* mutant of *P. grisea*, 138
- nit* mutants of *V. dahliae*, 74
- Nivalenol and deoxynivalenol chemotypes of *Fusarium* spp., 62
- Nivalenol chemotype, 151
- NIV chemotype of *F. graminearum*, 146
- Nonchromosomal proteins essential for pathogenicity of *X. campestris* pv. *vesicatoria*, 386
- Non-decline-inducing strains of CTV, 625
- Nondefoliating pathotypes of *V. dahliae*, 74
- Nondestructive detection of *Fusarium* head blight (FHB), 20
- Nonmotile mutants of *B. glumae*, 397
- Nonpersistent transmission of viruses, 628
- Nonseptate mycelium, 134
- Northern blot hybridization for detection of CEVd directly in field-grown citrus samples, 578
- Northern blot hybridization for detection of CVd-5 in citrus, 578
- Nuclear targeting of, 2b protein of CMV essential for suppression of PTGS, 639
- Nucleic acid-based detection methods for bacterial pathogens, 242
- Nucleic acid-based detection techniques for detection of phytoplasmal pathogens in propagules, 330
- Nucleic acid-based methods, 7, 12, 242, 282, 517
- Nucleic acid-based techniques for detection of bacterial pathogens, 282
- Nucleic acid-based techniques for detection of viroids in propagules, 577
- Nucleic acid-based techniques for detection of viruses in propagules, 517
- Nucleic acid-based techniques for viroids, 7
- Nucleic acid-based techniques for viruses, 7
- Nucleic acid hybridization assays for detection of viroids in propagules, 578
- Nucleic acid hybridization methods for detection of bacterial pathogens, 242
- Nucleic acid hybridization methods for detection of viruses in seeds, 480
- Nucleic acid hybridization procedures for detection of viruses in propagules, 518
- Nucleic acid hybridization techniques for detection of viroids in citrus, 575
- Nucleic acid subtractive hybridization (NASH) assay for detection of viruses, 519
- Nucleotide sequences of mtDNA of *T. indica*, 31
- Nutrient agar medium for isolation of *A. avenae* ssp. *citrulli*, 225
- Nutritional requirement of fungal pathogens, 134
- Nylon membrane for immobilizing pathogen protein, 29

- Obligate parasites, 19, 28, 134
- Occlusion of vessels of sweet orange by *X. fastidiosa*, 409
- Oligonucleotide-based DNA microarray system for detection of *R. solanacearum*, 416
- Oligonucleotide probes, 29
- One-step accelerated RT-LAMP detection and identification of PPV strains, 567
- One-step fluorescent RT-PCR for differentiation of PVY strains, 624
- One-step multiplex RT-PCR for detection of viroids in citrus collections of NCVEC, China, 585
- One-step PCR format for detection of *P. brassicae*, 97
- One-step RT-LAMP assay as first-line screening of potato for PSTVd RNA, 589
- One-step RT-PCR assay for detection of sugarcane viruses, 549
- One-step RT-PCR assay for detection of viruses of stone fruit trees, 536
- One-step RT-PCR for detection of citrus viroids in forced cuttings, 583
- One-tube duplex RT-PCR assay for assessing distribution of viroids in Washington State, 585
- One-tube RT-PCR assay for detection of CEVd, 648
- One-tube RT-PCR procedure for detection of viruses infecting potatoes, 560
- Oospore density in seeds, 15
- Oospores, 135
- Optical measurements for detection of Fusarium-damaged kernel (FDK), 20
- Optimized ELISA format for detection of GLRaV-2 and GVB in grapevine, 505
- Ornithine decarboxylase (ODC) essential for virulence of *S. nodorum*, 202
- Ouchterlony double diffusion test for detection of *P. syringae* pv. *pisi* in pea seeds, 231
- Outer and inner primers for LAMP assay, 259
- Overwintering of *Ralstonia solanacearum* in plant debris and tubers, 415
- Oxalic acid, a toxic metabolite of *S. sclerotiorum*, 202
- PAb-captured-sandwich ELISA, 236
- Padlock probes (PLPs) and dot-blot hybridization for detection of *A. avenae* ssp. *citrulli*, 269
- PAI marker genes in *S. scabiei*, 291
- Palms lethal yellowing phytoplasma detection by PCR-based assay, 332
- Particle morphology of virus particles, 619
- Pathogenesis genes of *U. maydis*, 191
- Pathogenesis of seedborne fungi, 174
- Pathogenicity assessment by differential lines, 86
- Pathogenicity genes of *M. oryzae*, 204
- Pathogenicity groups of *Fusarium* spp., 84
- Pathogenicity island genes in *S. scabiei*, 291
- Pathogenicity island in bacterial pathogen DNA, 246
- Pathogenicity island in *C. michiganensis* ssp. *michiganensis*, 301, 404
- Pathogenicity island in *P. syringae* pv. *phaseolicola*, 391
- Pathogenicity island in *Streptomyces* spp., 294, 420
- Pathogenicity island of *S. scabiei*, 427
- Pathogenicity of fungal pathogens, 147
- Pathogenic potential of viruses, 458, 620
- Pathogenic specialization in *Fusarium* spp., 146
- Pathogenic variants of *X. axonopodis* pv. *citri*, 286
- Pathogenic variants of *X. citri* ssp. *citri*, 420
- Pathogen mycelium in wheat seed, 137
- Pathogen protease content of infected peanut seeds, 196
- Pathogen-specific antibodies against *S. citri*, 328
- Pathogen-specific primers for PCR assay, 32
- Pathogroups of PPV strains, 623
- Pathotype A strains of *X. citri* ssp. *citri*, 420
- Pathotype-selective ELISA test, 484
- Pathotypes of *Alternaria*, 203
- Pathotypes of *A. rabiei* infecting chickpea, 197
- Pathotypes of bacterial pathogens, 274
- Pathotypes of *C. capsici*, 145
- Pathotypes of CMV isolates infecting banana, 463, 622
- Pathotypes of *M. grisea*, 69

- Pathotypes of *P. teres*, 85
- Pathotypes of *T. indica*, 78
- Pathotypes of *X. citri* ssp. *citri*, causing Asian citrus canker disease, 418
- Pathotype-specific probe for detection of *P. herpotrichoides*, 72
- Pathotyping analysis of strains of *X. oryzae* pv. *oryzae*, 244
- Pathovar of bacterial pathogens, 221
- Pathways of seed infection by *X. euvesicatoria*, 388
- Pattern of phloem colonization by ZC pathogen in potato tubers, 425
- Patterns of hybridization of DIG-labeled PCR amplicons by *E. carotovora* ssp. *atroseptica*, 323
- Patterns of potato tuber tissue colonization by *P. infestans*, 208
- P. capsici* strain transformed with *pgfp* gene, 196
- P. chlamydospora* transformed with *gfp* gene, 87
- P. cinnamomi* detection by MALDI-TOF-MS technique, 81
- PCR amplicons of *T. indica* DNA, 32
- PCR amplification of *Citrus mosaic virus* genome fragment, 522
- PCR assay for detection of *Cephalosporium graminearum*, 34
- PCR assay for detection of *E. carotovora* ssp. *atroseptica* in potato tubers, 283
- PCR assay for detection of *Fusarium* spp., 35, 40
- PCR assay for detection of *P. halstedii*, 36
- PCR assay for detection of *Phoma ligulicola*, 36
- PCR-based detection of sweet potato viruses, 523, 524
- PCR-based restriction mapping method for detection of *T. solani*, 97
- PCR-based techniques for detection of viruses, 483
- PCR detection and identification of *P. syringae* pv. *phaseolicola* strains, 392
- PCR detection of BBTV in banana plants, 521
- PCR-ELISA for detection of *D. bryoniae* in cucurbit seed, 59
- PCR-ELISA procedure for detection of AP phytoplasma in apple, 338
- PCR-ELISA technique for simultaneous detection of viruses in dormant trees, 552
- PCR format for detection of *L. xyli* ssp. *xyli* in sugarcane, 289
- PCR formats for detection of phytoplasmal pathogens in propagules, 330
- PCR inhibitors in plant tissues, 35
- PCR-microplate hybridization technique for detection of PVY in potato tubers, 527
- PCR mimic technique, 32
- PCR/PicoGreen assays for detection of *S. tritici*, 47
- PCR primer sets for detection of *T. walkeri*, 31
- PCR-RFLP analysis of *E. carotovora* subspecies, 305
- PCR-RFLP markers for differentiation of DON chemotypes, 152
- PCR screening of *U. nuda* barley seedlings, 31
- Pea seeds infected by PSbMV, as primary sources of inoculum, 470
- Penetration of host surface by infection hypha of *C. lagenarium*, 148
- Penetration of pericarp walls by *C. variable* in spinach seed, 181
- Penetration of seeds by *P. syringae* pv. *phaseolicola* from pod lesions, 391
- Penetration of wheat spikelets by *E. graminearum*, 201
- Penicillinase-based ELISA test, 467
- Pepper seeds, as primary sources of inoculum, 388
- Peptide nucleic acid (PNA) probe for detection of *S. endobioticum*, 90
- Percentages of spiklets bleached, as measure of disease severity, 154
- Peroxisome synthesis in *C. lagenarium*, 199

- Detached-leaf assay for assessing antagonistic activity of *B. subtilis*, 229
- Detached-leaf assay for assessing biocontrol potential of bacterial antagonists against *P. infestans*, 231
- Detection, identification and quantification of pathogen population, 363
- Detection of ds-RNAs of CMV and PVX in plants for screening of infection by quarantines, 70
- Detection of latent infection of plum by PPV by IC-RT-PCR assay, 59
- Detection of live population of *Ca. L. asiaticus* in citrus and vector tissues, 37
- Detection of mixed infections of grapevine propagative materials by viruses, 72
- Detection of mycotoxins in wheat grains by ELISA tests, 309
- Detection of mycovirus FgV-ch9 in *F. graminearum*, 234
- Detection of OYDV in propagation materials generated through meristem-tip culture, 73
- Detection of *P. ananatis* in lake water using specific phages, 30
- Detection of pathogens in asymptomatic plants and seeds, 4
- Detection of pathogens in seeds using diagnostic techniques, 53
- Detection of pathogens in symptomatic plants, 4
- Detection of presymptomatic infection by *M. graminicola*, 25
- Detection of QoI-resistant and sensitive strains of *M. oryzae*, 330
- Detection of stone fruit viruses by one-step RT-PCR assay, 58
- Detection of *S. tritici* in asymptomatic wheat leaves, 334
- Detection of thiophanate-methyl resistant isolates of *D. bryoniae* in commercial watermelon seed lots, 340
- Detection of transgene-derived small interfering RNA (siRNA) in cowpea transgenic lines resistant to CAMV, 196
- Detection of *V. dahliae* in vascular systems of plants growing from infested soil, 23
- Detection of viruses in imported fruit propagation materials by DAS-ELISA format, 70
- Detection of *X. axonopodis* pv. *alli* in contaminated onion seeds by AFLP analysis, 36
- Determination of critical time of fungicide application for FHB disease control, 310
- Determination of sources of primary or initial inoculum, 8
- Development of citrus canker pathogen strains resistant to copper, 373
- Development of crop plants with transgenic resistance to diseases, 192
- Development of cultivars with durable resistance to diseases, 363
- Development of insensitivity to azoxystrobin in *D. bryoniae*, 331
- Development of isolates of *P. capsici* resistant to dimethomorph, 339
- Development of isolates of *P. capsici* showing resistance to cyazofamid, 339
- Development of mutants of *U. maydis* resistant to azoxystrobin, 330
- Development of resistance in bacterial pathogens to phages, 235
- Development of resistance in fungal pathogens to single-site fungicides, 339
- Development of resistance to benzimidazole fungicide in potato dry rot pathogen, 327
- Development of resistance to bismethiazol in field isolates of rice BLB pathogen, 370
- Development of resistance to bismethiazol in rice BLB pathogen, 343
- Development of resistance to carbendazim in FHB pathogen, 328
- Development of resistance to chemical in plant pathogens, 324
- Development of resistance to metalaxyl in *P. capsici*, 338
- Development of resistance to metalaxyl-M in sunflower downy mildew pathogen, 327
- Development of resistance to nonsystemic fungicides in fungal pathogens, 325

- Development of resistance to streptomycin in rice bacterial pathogens, 370
- Development of resistance to systemic fungicides in fungal pathogens, 325
- Development of soil suppressiveness to *S. scabies* following monoculture of potato, 121
- Development of systems for integrated disease management, 361
- Differences in nucleotide sequences of *X. axonopodis* pv. *citri* strains resistant to copper, 373
- Differential defense responses of rice cultivars resistant and susceptible to blast and brown spot pathogens, 176
- Differential expression of thaxtomin A tolerance in potato tissues, 192
- Differential host plants species/ varieties, 5
- Differential levels of resistance of wheat cultivars to chemotypes of *F. graminearum*, 154
- Differentially expressed genes (DEGs) in rice cultivar resistant to false smut disease, 177
- Differential sensitivity of chemotypes of *F. graminearum*, 319
- Differentials to identify races of *P. oryzae*, 143
- Differential susceptibility of plants at different ages, 39
- Differentiation of *Burkholderia* spp. in rice seeds using real-time PCR format, 56
- Differentiation of isolates sensitive and insensitive to fungicides by PCR assay, 331
- Diffusible signal molecules (elicitors) released by pathogens, 170
- DIG-labeled riboprobes for detection of viruses in tomato seedlings, 69
- Direct adverse effects of chemicals on pathogen development, 306
- Disease assessments to quantify effects of diseases, 5
- Diseased plant affected area (DPAA) for rice sheath blight disease, 157
- Disease intensity dependent on number of ascospores of *D. pinodes*, 11

- Economic threshold (ET) levels, 362
- Effectiveness and risks of fungicide application against potato late blight disease, 368
- Effectiveness of agricultural practices in reducing incidence and spread of wheat FHB disease, 364
- Effectiveness of amicarbazol in protecting plants against bacterial pathogens, 344
- Effectiveness of antibiotics for control of citrus HLB disease, 345
- Effectiveness of antibiotics on rice bacterial diseases, 370
- Effectiveness of application of chitosan against rice bacterial diseases, 269
- Effectiveness of ASM in suppressing development of citrus canker disease, 373
- Effectiveness of attenuated strain of CYNMV for protection of Chinese yam plants against severe strain, 376
- Effectiveness of attenuated strains for protecting against severe strains of CMV/ZYMV and WMV-2, 241
- Effectiveness of attenuated strains in protecting cucurbits against virus infection, 374
- Effectiveness of BABA in suppressing potato late blight disease, 275
- Effectiveness of *Bacillus* spp. in suppressing development of red rot disease of sugarcane, 232
- Effectiveness of bacteriocin-like substance in inhibiting soft rot pathogen, 254
- Effectiveness of bacteriophage for control of cabbage black rot disease, 235
- Effectiveness of bacteriophage treatment for suppressing development of grapevine Pierce's disease, 236
- Effectiveness of barley straw in reducing population of *V. dahliae* infecting potato, 110
- Effectiveness of bean seed treatment with *T. viride* against anthracnose disease, 284
- Effectiveness of bismethiazol in reducing incidence rice BLB disease, 370
- Effectiveness of black polyethylene film and copper hydroxide-coated textile for control potato tuber blight disease, 130
- Effectiveness of boscalid in suppressing cucurbit gummy stem blight disease, 339
- Effectiveness of boscalid in suppressing development of oilseed rape stem rot disease, 340
- Effectiveness of *Brassica* crops, as green manure in reducing potato stem rot disease, 120
- Effectiveness of *B. subtilis* and *P. fluorescens* in suppressing development of *F. graminearum*, 228
- Effectiveness of *B. subtilis* in suppressing FHB disease, 225
- Effectiveness of carbendazim in reducing TMV symptom severity, 375
- Effectiveness of carbon tetrachloride for reducing infection by internally seedborne diseases of pea, 132

- Effectiveness of carboxylic acid amide fungicides for control of pepper Phytophthora blight disease, 338
- Effectiveness of chitosan in inducing resistance against *T. laevi* in wheat, 269
- Effectiveness of chitosan in reducing potato scab disease incidence, 372
- Effectiveness of chitosan in suppressing development of potato common scab disease, 270
- Effectiveness of chitosan in suppressing phytoplasmal diseases development, 271
- Effectiveness of combination of antibiotics for control of HLB disease, 345
- Effectiveness of compost amendments in suppressing *R. solanacearum*, 263
- Effectiveness of control of potato late blight using combination of plastic mulch and fungicide, 367
- Effectiveness of copper compounds in reducing severity of tomato bacterial canker disease, 342
- Effectiveness of copper sulfate + 8-hydroxyquinoline in suppressing tomato bacterial canker disease, 342
- Effectiveness of cotton seed treatment with *P. fluorescens* against bacterial blight disease, 285
- Effectiveness of cryotherapy for production of phytoplasma-free sweet potato plants, 88
- Effectiveness of cryotherapy in eradicating HLB pathogen from citrus plants, 85
- Effectiveness of cultural practices in reducing pathogen inoculum and disease incidence, 100
- Effectiveness of cyanocrylate fungicide for control of wheat FHB disease, 337
- Effectiveness of cyazofamid as seed treatment for control of pearl millet downy mildew disease, 313
- Effectiveness of cyazofamid in reducing incidence of potato late blight disease, 323
- Effectiveness of 2,4-D in reducing potato common scab disease, 347
- Effectiveness of D-leucine and IAN against citrus canker pathogen, 345
- Effectiveness of dry heat treatment for eradication of bacterial fruit blotch pathogen from cucurbits seeds, 126
- Effectiveness of ergosterol biosynthesis inhibitor (EBI) fungicides on rice false smut pathogen, 322
- Effectiveness of formulation of *C. globosum* against potato late blight disease, 287
- Effectiveness of fungicide application in reducing DON and NIV mycotoxins in wheat grains, 319
- Effectiveness of fungicides in suppressing watermelon gummy stem blight disease, 324
- Effectiveness of fungicide treatment of tubers in reducing incidence of potato silver scurf disease, 316
- Effectiveness of fusaricidin applied as soil treatment in suppressing Phytophthora blight disease of pepper, 230
- Effectiveness of heat treatment in eliminating *F. graminearum* from barley seeds, 124
- Effectiveness of hot air treatment of pepper seeds in reducing seedborne infection by fruit rot pathogen, 125
- Effectiveness of hot water treatment for elimination of EY phytoplasma from dormant cuttings, 126
- Effectiveness of hot water treatment in eliminating EY phytoplasma from elm planting materials, 87
- Effectiveness of hot water treatment in reducing transmission of *X. fastidiosa* through pecan scion wood material, 85
- Effectiveness of hot water treatments for elimination of FD phytoplasma from grapevine, 87
- Effectiveness of insecticides in reducing psyllid populations in citrus, 347
- Effectiveness of insecticides in reducing vector populations and virus disease incidence, 350
- Effectiveness of integration of BCAs with fertilizer application, 289
- Effectiveness of integration of BCAs with fungicides treatment, 290
- Effectiveness of limiting PVY infection by mineral oil application, 351

- Effectiveness of *M. albus* applied as soil treatment in suppressing wheat bunt disease, 286
- Effectiveness of MBC-resistant mutants of *T. harizanum* and *T. atroviride* against FHB pathogens, 261
- Effectiveness of MBI-D fungicides for control of rice blast disease, 336
- Effectiveness of micropropagation technique for sanitization of explants of grapevine, 88
- Effectiveness of MII-16 mutant strain in protecting tomato against TMoV, 240
- Effectiveness of mild/attenuated strains for protection against severe strain infection, 374
- Effectiveness of mild strain generated after treatment with nitrous acid against severe strain of PVY, 377
- Effectiveness of mild strain of SPFMV to protect sweet potatoes against severe strain, 239
- Effectiveness of mineral oils in reducing incidence and spread of PVY in potato, 350
- Effectiveness of mixture of BCA strains for control of rice sheath blight disease, 366
- Effectiveness of nonpathogenic *Aspergillus* spp. in suppressing *A. flavus* in wheat grains, 288
- Effectiveness of oligochitosan for protecting pepper plants against Phytophthora blight disease, 270
- Effectiveness of PAP in protecting *P. hybrida* against CMV, 197
- Effectiveness of *P. chlororaphis* in suppressing canola stem rot disease, 257
- Effectiveness of pepper residue composts and cattle/ chicken manures in suppressing tomato bacterial canker disease, 265
- Effectiveness of *P. fluorescens* and *B. pumilus* in inhibiting development of *P. infestans*, 232
- Effectiveness of phage mixtures for control of tomato bacterial spot disease, 236
- Effectiveness of phenylamide fungicides for control of potato late blight disease, 336
- Effectiveness of *P. kribensis* in suppressing development of rice sheath blight disease, 256
- Effectiveness of plant activators in inducing resistance in tomato to bacterial canker disease, 371
- Effectiveness of polyethylene mulch for control of potato late blight disease, 130
- Effectiveness of polyethylene mulch in reducing potato late blight disease incidence, 367
- Effectiveness of postanthesis application of fungicides in reducing FHB incidence and DON contamination of grains, 319
- Effectiveness of preventive activity of thiram against seedborne infection by *V. dahliae* in spinach, 308
- Effectiveness of protection by attenuated strain against wild strain of SbMV infecting soybean, 240
- Effectiveness of *Pseudomonas* LBUM223 in reducing rhizospheric population of tomato canker pathogen, 252
- Effectiveness of *Pseudomonas* sp. against citrus bacterial canker disease, 229
- Effectiveness of radiation treatments for eliminating fungal pathogens, 128
- Effectiveness of ribosome-inhibiting protein (RIP) from pokeweed against viruses, 196
- Effectiveness of root-associated/endophytic bacterial isolates against *A. parasiticus* infecting peanut, 231
- Effectiveness of SA/MeJ application for control of wheat bunt disease, 271
- Effectiveness of seed treatment of cucumber and tomato with PGPR in protecting infection by CMV, 233
- Effectiveness of seed treatment with ASM for protection of melon seedlings against gummy seedling blight, 274
- Effectiveness of seed treatment with ASM for protection of melon seedlings against white mold disease, 274
- Effectiveness of seed treatment with carboxin + thiram mixture on FHB disease, 312

- Effectiveness of seed treatment with fungicides for FHB disease management, 314
- Effectiveness of *S. mycoparasitica* in suppressing FHB disease and accumulation of DON in grains, 245
- Effectiveness of soil application of imidacloprid in reducing citrus canker severity, 373
- Effectiveness of soil solarization using plastic foil mulch for disease control, 130
- Effectiveness of streptomycin sulfate in reducing rice bacterial diseases, 343
- Effectiveness of strobilurin fungicides in suppressing FHB disease development, 309
- Effectiveness of temperature treatments for elimination of FHB pathogen from wheat seeds, 364
- Effectiveness of thermotherapy methods for elimination of GSD from sugarcane, 87
- Effectiveness of treatment of potato tubers with SA in suppressing soft rot disease, 271
- Effectiveness of tridemorph in reducing incidence of corn smut disease, 328
- Effectiveness of trunk injection of antibiotics for control of HLB disease, 346
- Effectiveness of tuber treatment with NaOCl + TPM in reducing potato scurf in progeny tubers, 316
- Effectiveness of using disease-free seedlings and plant sanitation in reducing citrus canker disease, 372
- Effectiveness of UV-reflective silver mulch in reducing WMV infection in squash plants, 375
- Effectiveness of volatile compounds from *M. albus* in suppressing wheat seedborne bunt pathogen, 286
- Effectiveness of yellow polyethylene sheet spread with sticky substance for control of CMV and PVY in bell pepper, 131
- Effective protection of Chinese yam by attenuated strain KM3 under field conditions, 243
- Effective protection of tomato plants against *P. infestans* by massetolide applied on leaves and roots, 253
- Effect of agricultural practices on incidence and spread of onion center rot disease, 34
- Effect of application of chopped maize stalks on infection by *F. graminearum*, 17
- Effect of ASM in suppressing cotton bacterial blight disease, 275
- Effect of BCAs on FHB incidence and DON accumulation in wheat grains, 228
- Effect of calcium nitrate on development of potato soft rot disease, 282
- Effect of calcium on incidence of bacterial soft rot in potato tubers, 114
- Effect of combination of BTH and mancozeb on chickpea blight disease development, 274
- Effect of combination of rotation crops on incidence of potato black scurf and common scab diseases, 118
- Effect of combined application of chitosan and bacterial BCA on potato common scab disease, 270
- Effect of competition among FHB pathogens on trichothecene production, 20
- Effect of cow manure amendment on potato brown rot disease, 111
- Effect of crop rotation on incidence of canola blackleg disease, 120
- Effect of crop rotation on incidence of Phytophthora blight in pepper, 117
- Effect of crop rotation with different crops on incidence of crown rot disease of wheat, 116
- Effect of deep ploughing on soilborne pathogens, 102
- Effect of disease pressure on effectiveness of fungicides, 318
- Effect of 2,4-D on potato common scab disease development, 324
- Effect of elicitors of resistance on development of maize *Fusarium* ear rot disease, 279
- Effect of flooding the soil on infection of banana by *F. oxysporum* f.sp. *cubense*, 106
- Effect of fungicidal application on FHB disease incidence and DON accumulation in wheat grains, 318
- Effect of glycerol application of biosynthesis of PR-proteins in cocoa, 280

- Effect of glycerol on development of cocoa pod rot disease, 280
- Effect of growing rice cultivar mixtures on incidence of brown spot disease, 121
- Effect of heat treatment of wheat seeds on germination and seedling emergence, 125
- Effect of heat treatment on survival of *F. graminearum* in crop residues, 22
- Effect of infection time on FHB disease incidence in wheat, 13
- Effect of infection time on mycotoxin accumulation in wheat grains, 13
- Effect of intercropping on incidence of PVMV in pepper, 123
- Effect of intercropping on incidence of WMV and PRSV-W in pumpkin, 122
- Effect of intercrops on incidence of pepper Phytophthora blight disease, 122
- Effect of irrigation methods on incidence of Phytophthora root rot of pepper, 107
- Effect of irrigation on disease incidence on potato tubers, 108
- Effect of irrigation on potato powdery scab disease, 113
- Effect of lodging on DON and NIV accumulation in wheat grains, 113
- Effect of maize or sunflower as barrier crops on incidence of PVY and CMV in pepper, 122
- Effect of manganese on development of rice blast disease, 114
- Effect of manganese on development of rice sheath blight disease, 115
- Effect of microwave treatment on viability of bean bacterial blight pathogen, 342
- Effect of minimum tillage in combination with crop rotations on potato tuber diseases, 102
- Effect of monoculture on development of potato scab pathogen *S. scabies*, 121
- Effect of multiple cropping on incidence of crop diseases, 121
- Effect of mycovirus application on FHB disease and DON accumulation in grains, 234
- Effect of N application on FHB disease and mycotoxin accumulation, 17
- Effect of nitrogen on susceptibility of rice cultivars to blast disease, 111
- Effect of no-till/conservation tillage on incidence of FHB disease, 22
- Effect of no-till practice on fumonisin accumulation in maize grains, 103
- Effect of oat as a barrier crop on incidence of watermelon mosaic disease, 122
- Effect of origin of seed potatoes on phenotypic structure of *P. infestans*, 117
- Effect of *P. illinoensis* on root mortality due to infection by *P. capsici* in pepper, 257
- Effect of plant age on level of susceptibility/resistance of plants to *A. sesame*, 16
- Effect of plant density on disease incidence and spread, 27
- Effect of plant diversification on incidence of PVY in potato, 376
- Effect of postanthesis fungicide application on FDK and DON contamination in grains, 320
- Effect of potassium on incidence of soybean mosaic disease, 114
- Effect of previous crops in rotation on potato powdery scab disease, 113
- Effect of rainfall on incidence of diseases affecting potato tubers, 108
- Effect of rates of nitrogen fertilizers on potato powdery scab disease, 113
- Effect of reduced/conservation tillage of accumulation of plant residues on soil, 102
- Effect of relative humidity of Asiatic citrus canker disease development, 34
- Effect of ribavirin on elimination of potato viruses in potato plantlets, 349
- Effect of roguing infected onion plants on disease spread, 34
- Effect of silicon on development of Phytophthora blight of pepper, 281
- Effect of silicon on rice blast disease development, 281
- Effect of sowing date on maize kernel infection by *F. verticillioides*, 106
- Effect of strobilurins on symptom severity induced by bean common mosaic disease, 349
- Effect of sunflower as a border crop on incidence of PVY in pepper, 122

- Effect of systemic fungicides on symptom expression of virus diseases, 349
- Effect of temperature on germination of ascospores of *F. graminearum*, 20
- Effect of temperature on infection of linseed by *B.cinerea*/*A. linicola*, 21
- Effect of temperature on initial stage of infection process of *F. verticillioides*, 20
- Effect of temperatures on mycotoxin production, 20
- Effect of tillage on FHB severity, 17
- Effect of tillage on incidence of canola blackleg disease, 120
- Effect of timing of fungicide application on FHB development and mycotoxin accumulation in grains, 319
- Effect of tuber-borne *Streptomyces* on disease incidence in daughter tubers, 29
- Effect of virus infection on growth of *Alternaria* spp., 235
- Effect of wheat flowering types on accumulation of DON and NIV, 13
- Effects of agricultural practices on disease incidence and spread, 363
- Effects of allicin on potato late blight disease development, 266
- Effects of allicin on rice blast disease development, 266
- Effects of amendments on soilborne pathogens, 262
- Effects of antiviral chemicals on virus multiplication, 348
- Effects of azoxystrobin on infection by wheat leaf blotch disease incidence, 320
- Effects of BTH treatment on rice diseases, 273
- Effects of buckwheat as green manure on potato scab and Verticillium wilt diseases, 264
- Effects of Chinese gall treatment on development of *M. majus*, 269
- Effects of compost amendment and grafting bell pepper on Phytophthora blight disease, 263
- Effects of conservation tillage in combination with crop rotations on potato tuber diseases, 102
- Effects of cropping systems on mycotoxin levels in wheat grains, 104
- Effects of cropping systems on wheat FHB disease, 103
- Effects of curative and preventive applications of azoxystrobin on wheat leaf blotch disease, 321
- Effects of cyazofamid on different stages of *P. capsici* life cycle, 339
- Effects of dosages of chemical applied as seed treatment and soil treatment on onion white rot disease, 317
- Effects of dravya applied as seed treatment and foliar spray on cotton bacterial blight disease, 265
- Effects of environmental factors on initial infection by FHB pathogens, 19
- Effects of green manure crops on potato scab disease incidence, 372
- Effects of gum exudates of plants on pearl millet downy mildew development, 268
- Effects of inorganic compounds on development of crop diseases, 280
- Effects of intercropping on aflatoxin contamination of maize kernels, 118
- Effects of irrigation on incidence of *Phomopsis* seed decay of soybean, 107
- Effects of mulch and irrigation on incidence of onion center rot disease, 34
- Effects of mulches on soilborne pathogens, 262
- Effects of nitrogen fertilization on FHB disease development in wheat, 112
