Introduction

The concept of an encyclopedia derives from the Greek words for gathering together or "encircling" knowledge and learning. Indeed, Diderot and the French encyclopedists of the mid 18th century aimed to bring together all of the world's knowledge in one giant publication. Our ambitions today are more modest but "encapsulating" existing knowledge of a defined topic is still a reasonable basis for decision making in the present and planning for the future. The Encyclopedia of Medical Immunology follows in the encyclopedist tradition. At the present time, however, progress is proceeding at such a rapid pace that a static volume, no matter how extensive, could never do justice to this dynamic subject. Thus our present encyclopedia is based on the concept that articles will be linked to current research and updated on a regular basis. The reader needs to gain an understanding of medical immunology not only at the date of publication, but on a continuing basis.

The immune system, as a vital component of normal physiology, participates in establishing and maintaining the well-being of the host. Its core responsibility is to prevent or control infection and malignancy. Immune functions can be divided into constituative and adaptive. Inherited innate immunity takes its origins from most primitive cellular functions of recognition and nutrition. In animals, it evolved through invertebrates as a group of formed barriers and a system of cells and cell products for promptly dealing with harmful invaders or preventing clonal amplification of malignant cells. In vertebrates, in addition to innate immunity, an adaptive immune system provides a more focused and potent response, but one that requires more time to mobilize. It utilizes a novel system of hypermutation and recombination to provide a sufficiently broad repertory of receptors to recognize and eliminate, in principle, any potential microbial invader. In establishing and maintaining such a wide repertory of recognition structures, the adaptive immune system inevitably recognizes many epitopes on molecules within the body of the host. Thus, the same protective effector mechanisms of the healthy immune system, if out of control, can produce harm in the form of the immune mediated disorders described in these Volumes.

The most frequent disorders of the immune system are deficiencies. If the immune system fails to perform its core function of protection, infectious or malignant disease can follow. Most of these immune failures result from germ line inheritance of mutations in genes regulating the innate or adaptive

immune systems. The most frequent sign of an immune deficiency disease is infection due to one or more of the myriad microorganisms that inhabit the human environment.

A second group of immune-related illnesses results from loss of normal immunologic homeostasis. The regulatory devices that normally limit immune responses are inadequate. The failure may result from deficiencies, either inherited or acquired, of the overall regulatory machinery. Rather than a decrease in homeostatic regulation, immune disease can result from augmented immune responses. Powerful adjuvants, providing the non-antigen-specific signals, may overcome even normally functioning immune regulation.

Both types of immune-mediated disease are considered in our encapsulated knowledge. Allergies result from exposures to foreign substances that are harmless in the majority of individuals. As a group, allergic diseases affect at least 10% of the population and appear to be increasing over time in many populations. In contrast to an exaggerated response to foreign antigens, autoimmunity is the consequence of the "forbidden" recognition of some antigens in the host's body. Like allergic disease, autoimmune disease represents an uncontrolled immune response. Because allergic and autoimmune diseases can occur in different organ systems in the body, they can differ greatly in their clinical presentation, even though they share many genetic and regulatory features.

The goal in all medical immunology is to alleviate or prevent illness. If a disease is related to an inadequate immune response or to an overwhelming challenge, an intervention in the form of vaccination is a historically proven approach. Preventive vaccinations may be the most successful public health measure of the 20th century. New vaccines directed to oncoming newly emerging infectants or subtypes remains a major goal of current immunologic research. Potential adverse effects of vaccines also require constant attention. These days vaccines are being tested as a way of limiting or reducing malignant tumors.

Immunotherapy is a more modern success story as biological agents such as monoclonal antibodies and receptor-blocking ligands are increasingly available for control of diseases due to immunological derangement.

The need for an Encyclopedia of Medical immunology is compelling. Our encyclopedia is divided for convenience into the four subject areas discussed above: Immune deficiency diseases, allergic diseases, autoimmune diseases and vaccines. Each of these areas has significant and immediate relevance to medical practice and public health. Each is a growing area of research.

By bringing together these different areas in one comprehensive publication, the encyclopedia illustrates and emphasizes the fundamentals of the immune response. For immunity to play its part in good health, it must maintain homeostasis within itself and with all other physiologic systems. The challenges to maintaining immunologic good health are both internal and external. In the face of changes in the environment, including climate, infectious agents and industrial exposures, human survival places a need for constant recalibration of the immune system. Internally, the effects of aging,

hormonal changes, the microbiome and life cycle events (eg. puberty, pregnancy) also require readjustment of immunologic homeostasis. Interventions are designed to restore immunologic balance, to repair innate or induced deficiencies and to strengthen immune responses.

As Editors-in-Chief, we trust that the users will find this "encirclement" of a body of knowledge will prove helpful for decision making in promoting immunologic health and reducing immunologic disorders.

Editors-in-Chief

Preface

The immune system is the sensory organ that perceives and responds to dangerous alterations in tissue. The major alerts to the immune system are pathogen-associated molecular patterns (PAMPs) expressed by microbes and damage-associated molecular patterns (DAMPs) expressed by stressed or injured tissue. These triggers bind to membranes and cytosolic pattern recognition receptors (PRPs) and galvanize the immune system into action. An immune response begins with activation of an innate immune response and progresses to an adaptive immune response, which is the locus of immune memory. Interestingly, the response may also be communicated to the brain, which can contribute to the regulation of peripheral inflammation and immune responses.

During lymphocyte ontogeny and in the course of any immune response, there is a risk of the generation and/or activation of autoreactive lymphocytes that may cause an autoimmune disease. Development of autoimmune disease is regulated by the complement of genetic risk and protective alleles as well as by exposure to known and unknown environmental insults.

The encyclopedia will introduce the reader to processes of immune activation and quiescence that is required for self-tolerance. Both infectious and non-infectious mechanisms of immune activation are addressed. Moreover, tissue-specific immune function and immune pathologies are addressed in detail.

All authors are experts in their field, and all entries include a bibliography that provides further reading material. This encyclopedia is the first line in learning about specific immune mechanisms in health and disease. It has been designed to be useful to the new learner and to the expert alike.

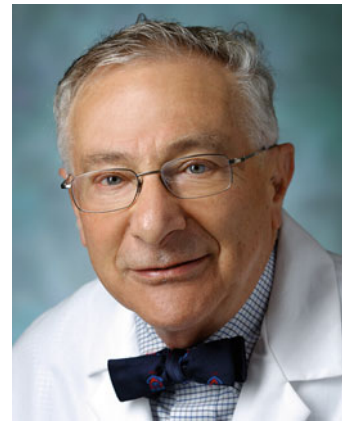
Ian R. Mackay's research career, mostly directed to autoimmunity, began in 1956 in the Clinical Research Unit (CRU) of the Walter & Eliza Hall Institute and Royal Melbourne Hospital (RMH), Melbourne, Australia. It comprehended associations between disorders of immunological function and clinical expressions in diseases of obscure causation. Research laboratories in the Hall Institute and supervision of a 27-bed general medical ward in the adjacent RMH encouraged one to think of autoimmunity holistically rather than via any single disease. A particular interest in autoimmunity and liver and a collaboration with D Carleton Gajdusek pointed to autoimmune responses in causation of two major entities, chronic active hepatitis and primary biliary cirrhosis (PBC). The detection of autoimmune reactivity of a monoclonal plasma paraprotein was a key element in Burnet's formulation of the Clonal Selection Theory of Acquired Immunity. Mackay's later return to PBC in the molecular era (1980s) in research with M Eric Gershwin resulted in cloning and identification of the gene for the disease-associated "mitochondrial" autoantigen of PBC, the E2 subunit of pyruvate dehydrogenase complex (PDC-E2). In autoimmune hepatitis, levels in serum of transaminase enzymes were found to reflect ongoing hepatocellular damage, so providing a monitor of efficacy of immunosuppressive drugs prednisolone and azathioprine and, in the 1960s, the first long-term treatment trial established their benefit. This drug combination remains today as the standard therapy for autoimmune hepatitis.

In the early 1960s, Mackay became sufficiently convinced of the reality of autoimmunity to compile with F MacFarlane Burnet the first authoritative text (1963). Thereafter, he made research contributions on numerous autoimmune diseases, thyroiditis, multiple sclerosis, myasthenia gravis, pemphigus, and gastritis. With "Reg" Strickland, gastritis was separated into Type A (autoimmune) and Type B (later, bacterial) gastritis, foreshadowing bacterial infection in peptic ulcer disease. Mackay became a major protagonist for the early development of the specialty of Clinical Immunology and with Senga Whittingham laid out specifications for the practice of this specialty. In the 1980s, the RMH drew on the CRU to establish an AIDS service, and observations made on human papillomavirus (HPV) infection in rectal swabs of homosexual men led to Ian Frazer's development in Brisbane of an HPV vaccine for prevention of virus-induced cervical cancer.

In 1987, Mackay relocated to the Department of Biochemistry, Monash University, where with Merrill Rowley an autoimmunity laboratory was established for further investigation of PBC, Type 1 (autoimmune) diabetes, and rheumatoid arthritis. The laboratory sought to identify in various autoimmune diseases molecular epitopes (auto-epitopes) using contemporary techniques including antibody screening of phage-displayed random peptide libraries. A notable achievement arising from collaborations at Monash with James Whisstock, Gus Fenalti, and others was the crystallization of both isoforms of glutamic acid decarboxylase (GAD) 65 and 67, revealing the 3D structure and "molecular positioning" of the reactive antibody epitopes of the autoantigenic 65kD isoform and differences from the non-autoantigenic 67 kD isoform. This work is ongoing.



Noel R. Rose received his basic training in microbiology at Yale University followed by PhD and MD degrees at the University of Pennsylvania and State University of New York at Buffalo. He was appointed to the faculty at Buffalo in 1951, where he began his research career. His early studies under the tutelage of Professor Ernest Witebsky searched properties of the organ-specific antigens that characterize the unique functions of normal and malignant cells. In the course of these investigations, he discovered that he could produce an autoimmune disease in the thyroid gland by immunization with the major thyroid protein thyroglobulin. Until that time, it was generally accepted that in only a few "privileged sites" in the body were such pathogenic autoimmune responses possible. These studies opened the modern era of research on the autoimmune diseases and set the direction of Rose's career since that time. In the 1960s, he investigated the requisite conditions for inducing autoimmune disease and the delineation of the basic immunologic and pathological processes. He included studies on other organs, such as the pancreas, as well as allergic diseases. In 1971, he and his colleagues discovered the first major gene that is responsible for susceptibility to autoimmune diseases and proved that it was a member of the major histocompatibility complex. At that time, he moved his laboratory to Wayne State University in Detroit, where he and his colleagues carried out detailed studies on the genes responsible for autoimmune disease of the thyroid gland. He also performed early experiments of the regulatory role of the thymus-derived lymphocytes and other studies related to unique enzymes of specialized cells, especially prostatic cancer. In 1981, Rose moved to Johns Hopkins University, where he created a department devoted to studies of immunity and infection. He directed much of his research to infectious agents and chemicals that induce autoimmune disease. A major effort was devoted to developing an experimental model of autoimmune heart disease produced in genetically prepared mice by infection with a virus that led work to the first identification of a well-defined antigen responsible for cardiac inflammation. Investigations on this model revealed a stepwise process that leads from infection to initial harmless autoimmunity to later life-threatening autoimmune disease.

In addition to his research, Rose has been deeply involved in the clinical practice of immunology. He directs a diagnostic immunology laboratory; he

serves as expert consultant to the World Health Organization and as director of the WHO Collaborating Center for Autoimmune Disorders. He chaired the first committee on clinical immunology of the American Association of Immunologists and was co-founder of the Clinical Immunology Society. He was editor-in-chief of the first six volumes of the Manual of Clinical Immunology co-sponsored by the American Association of Immunologists and the American Society for Microbiology.

Throughout his career, Rose has had the opportunity of working with a number of leading investigators including Pierre Grabar at the Pasteuer Institute, Paris; Henry Isliker at the Swiss Institute for Cancer Research; Sir James Gowans at Oxford University; and Sir Gustav Nossal and Ian Mackay at the Walter and Eliza Hall Institute in Australia. While at the Hall Institute, Rose was invited to prepare a book describing the broad area of autoimmune disorders. He joined with Mackay in producing the first volume of the book, *The Autoimmune Diseases*, which is now in its fifth edition.

At Johns Hopkins, he continues to teach in medicine and public health and directs an active research laboratory. He also heads the Center for Autoimmune Disease Research, which facilitates communication and collaboration among specialists in the different facets of autoimmune disease research.

Editors

Betty Diamond The Feinstein Institute for Medical Research, Manhasset, NY, USA

Adjunct Professor of Microbiology and Immunology and Medicine, Albert Einstein College of Medicine, BX, NY, USA

Ralph and Maureen Nappi, Professor, Department of Medicine, Hofstra-North Shore LIJ School of Medicine, Manhasset, NY, USA

Betty Diamond received an MD from Harvard Medical School in 1973. She performed a residency in Internal Medicine at Columbia Presbyterian Medical Center and then a postdoctoral fellowship in Immunology with Dr. Matthew Scharff at the Albert Einstein College of Medicine. She is currently Head of the Autoimmune Disease Center at the Feinstein Institute for Medical Research and on the faculty of the Albert Einstein College of Medicine.

Dr. Diamond's research has focused on the induction and pathogenicity of anti-DNA antibodies in Systemic Lupus Erythematosus. She received the Outstanding Investigator Award of the ACR in 2001, the Lee Howley Award from the Arthritis Foundation in 2002, and the Recognition Award from the National Association of MD-PhD Programs in 2004 and was elected to the Institute of Medicine in 2006. Dr. Diamond has served on the Scientific Council of NIAMS and the Board of Directors of the American College of Rheumatology. She is past president of the American Association of Immunologists.

Dr. Diamond's laboratory has demonstrated that a subset of anti-DNA antibodies cross-reacts with the NMDA receptor. These antibodies can mediate neuronal apoptosis in the hippocampus leading to a memory deficit or in the amygdala leading to a behavioral alteration. These antibodies are present in serum and cerebrospinal fluid and correlate with symptoms of neuropsychiatric lupus. These studies show that lupus antibodies can cause aspects of neuropsychiatric lupus in a noninflammatory fashion and create a paradigm for antibody-mediated changes in brain function in many conditions. With colleagues at the Feinstein Institute, she has generated a potential therapeutic to prevent neurotoxicity from these antibodies.

Anne Davidson, MBBS, The Feinstein Institute for Medical Research, NY, USA

Anne Davidson, received her MBBS degree from the University of Melbourne, Australia, and is a board-certified rheumatologist. She is currently an Investigator at the Feinstein Institute for Medical Research, New York, and Professor of Molecular Medicine at Hofstra North Shore-LIJ School of Medicine, New York, USA.

Dr. Davidson's research is focused on pathogenesis and therapy of SLE. She has worked extensively with mouse models of SLE, using newly discovered pathways of immune activation to determine the mechanisms of action of novel therapies for SLE. The results of these studies are then used to design mechanistic studies in the context of human SLE clinical trials. A main focus of the laboratory is to understand how B-cell tolerance is dysregulated in SLE. A second area of interest is to understand the mechanisms of inflammation within the SLE kidney, using a combination of systems biology and functional studies. She is a past recipient of the Dubois Award for SLE Research and the ACR Basic Science Distinguished Investigator Award.

Dr. Davidson is a member of the NIH study section PBKD and cochairs the grant review committee of the animal models subsection for the Lupus Research Institute. She is currently the Chair of the Scientific Advisory Council for the Rheumatology Research Foundation of the ACR.

Acute and Chronic Hepatitis B Virus Infection, Immune Response

Mala Maini, Abhishek Das and Anna Schurich
Division of Infection and Immunity, UCL, London, UK

Synonyms

APC Antigen-presenting cell; CHB Chronic hepatitis B; HBV Hepatitis B virus

Definition

Hepatitis B virus (HBV) is a non-cytopathic DNA virus. The immune response to HBV is critically important to define, as it not only has potential to control the virus, but also to mediate liver inflammation and disease.

Immune Response in Acute Hepatitis B Virus Infection

The early immune events leading to clearance or persistence of HBV have been difficult to study. Unlike human immunodeficiency virus (HIV) and hepatitis C viruses (HCV), which are detectable in the periphery within days, HBV uniquely does not undergo a logarithmic phase of replication until 6–8 weeks after initial infection. Virus and viral proteins are undetectable during this incubation period. The clinical course of acute infection reflects this quiescent phase; patients develop symptoms only 10–12 weeks after initial infection or alternatively, remain asymptomatic throughout (Rehermann and Nascimbeni 2005). Therefore, a window of opportunity to study the kinetics of early innate and adaptive immune responses is often missed by the time patients are identified. Despite these setbacks, studies in human subjects identified incidentally (or after accidental inoculation) during the initial few weeks after virus encounter have provided insight into the early immune control of HBV.

Innate Immunity

The innate immune system provides a rapid, non-antigen-specific protection against pathogens, including a variety of viruses, bacteria, and fungi. It is the first line of defense not only in humans but in organisms as far removed as the *Drosophila* fly and *Caenorhabditis elegans* worm, which share evolutionary conserved receptors which recognise molecular patterns on the surface of pathogens as nonself (Akira et al. 2006).

During human infection, viral particles and their replicative intermediates are sensed by these pattern recognition receptors. These include Toll-like receptors, found on the surface and within endosomes of innate cells, and Rig-like helicases and Nod-like receptors within the cytosol. Production of antiviral type I interferons is the hallmark response. All nucleated cells have the capacity to produce these cytokines.

I.R. Mackay, N.R. Rose (eds.), *Encyclopedia of Medical Immunology – Autoimmune Diseases*,
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

Natural killer cells play an important role in the initial stages of antiviral immunity. They are the predominant lymphocytic subset within the liver and can kill virus-infected hepatocytes, cross-talk with dendritic cells and initiate priming of adaptive T cell responses and humoral immunity. In addition, a variety of non-parenchymal hepatic cells including Kupffer cells and liver sinusoidal endothelial cells contribute to viral sensing, making the liver an immunological organ (Bertoletti and Ferrari 2011).

Although this dogma of innate viral clearance is true for many viruses, gene-profiling studies have identified a stark lack of induction of type I IFN responsive genes in the liver of HBV-infected chimpanzees studied serially over the course of early acute infection (Wieland et al. 2005). Absence of type I interferon induction has also been confirmed in human studies of early acute infection (Dunn et al. 2009; Fisicaro et al. 2010). In a transgenic mouse model of HBV, type I interferons efficiently prevent the assembly of viral particles and destabilize existing viral capsids, suggesting that they do have the capacity to neutralize HBV particles when they are released. The absence of this critical innate effector function raises the possibility that HBV is a "stealth virus" which is able to evade innate immunity. Alternatively, there may be active mechanisms, which are suppressing innate immune responses during the initial phases of infection. The evidence for these two alternative hypotheses will be described in the following paragraph.

The idea that HBV avoids innate sensing mechanisms is supported by the fact that its transcriptional template (covalently closed circular DNA) remains within the nucleus of an infected cell and single-stranded RNA and DNA are shielded in viral capsids within the cytoplasm. These mechanisms may circumvent early detection by innate sensing receptors. However, data in human studies of early acute infection have provided compelling evidence that HBV does not completely evade innate immunity. Despite absence of type I interferon induction, several studies have shown an early peak in the frequency of NK and NT cells (T cells which express markers for classical NK cells) during the logarithmic phase of HBV infection and associated NK cell IFN-γ production and cytolytic activity (Fisicaro et al. 2009; Webster et al. 2004).

Alternatively, viral mechanisms may be suppressing early innate responses. HBV infected cells uniquely secretes milligram quantities of HBV proteins, HBsAg and HBeAg, which have no discernible role in viral replication. It is thought that these factors may play a role in modulation of immune responses through inhibition of Toll-like receptor signalling pathways or induction of immunosuppressive cytokines including IL-10. Study of acute infection has identified an early rise in serum IL-10 correlating with the logarithmic phase of viral replication and transient attenuation of NK and T cell responses (Dunn et al. 2009). Furthermore, the HBV X and polymerase proteins have been shown to interfere with type I interferon production (Bertoletti and Ferrari 2011).

Despite the apparent lack of a classical type I interferon response, the majority of patients who are acutely infected with HBV in adulthood resolve spontaneously. It is feasible that innate responses have a potential role in dampening initial viral responses during the incubation phase; however, late clinical presentation of patients has made timely sampling and study of this phase difficult.

Adaptive Immunity

HBV-specific adaptive immune responses are detectable 6–8 weeks after infection, correlating with the logarithmic phase of viral replication. They appear before onset of clinical symptoms and are critical mediators of viral clearance. A strong, polyfunctional, multi-specific T cell response is associated with self-limited infection. Patients who have established chronic infection characteristically have weaker HBV-specific responses, which are under constitutive negative regulation, although it has not been possible to determine whether these are the cause or result of chronicity.

CD4 T cells are required for priming and survival of functional CD8 T cell responses. They appear early during the logarithmic phase of

viremia; robust Th1 responses against multiple epitopes within the core protein have been associated with resolution of acute infection. Through production of IFN-γ and TNF, these cells contribute to non-cytolytic clearance of HBV but may also inadvertently potentiate liver inflammation. Evidence for their importance in early priming of CD8 T cell responses is suggested from chimpanzee studies, in which in vivo depletion of CD4 T cells prior to HBV inoculation resulted in dysfunctional CD8 T cell responses and ultimately, viral persistence (Asabe et al. 2009). CD4 T cells are also critical for induction of humoral immunity and generation of antibodies against the HBeAg.

The critical role for CD8 T cells in antiviral clearance is highlighted by depletion studies in chimpanzees. Depletion of CD8 T cells at the peak of viremia postponed viral clearance and development of hepatitis until reconstitution of T cells (Thimme et al. 2003). Their antiviral mechanisms are twofold. Since the majority of hepatocytes may be infected at peak viremia, non-cytolytic mechanisms, including production of the cytokines IFN-γ and TNF which can interfere with post-transcriptional steps of HBV replication, are important to prevent overwhelming organ damage (Guidotti et al. 1996). Additionally, cytolytic mechanisms include perforin-/granzyme-mediated lysis of infected hepatocytes. These initial mechanisms trigger the subsequent recruitment of a large non-antigen-specific lymphocytic infiltrate that contributes to liver inflammation and damage.

Of note, these findings apply to horizontally acquired adult infection. Over 95 % of individuals who acquire infection in this setting undergo viral resolution. In contrast, patients who are infected through vertical transmission have a much greater likelihood of developing chronic infection. The pattern of immune responses during acute infection following vertical exposure to HBV has not been well characterized.

Humoral Immunity

B cells play a prominent role during the symptomatic phase of infection, 10–12 weeks after initial inoculation. IgM antibodies to the HBV core antigen are a feature of early acute infection. IgG anti-HBc antibodies persist long term in both resolved and chronic infection whereas neutralizing antibodies directed to HBV surface antigen (anti-HBs) are associated with successful resolution of acute infection and contribute to protective immunity. The appearance of antibodies against the e antigen is also temporally associated with disease resolution, although their contribution to viral control is unclear. Furthermore, during chronic infection, production of anti-HBe antibodies marks a transition from a high to low replicative state. The protective potential of neutralizing antibodies is supported by the efficacy of the HBV vaccine; generation of antibodies against the surface antigen is associated with long-term protection against HBV infection. Additionally, the HBsAg used in the vaccine may also be cross-presented to prime T cell responses.

Immune Response in Chronic Hepatitis B Virus Infection

Despite the availability of a preventative vaccine, an estimated 350 million people are persistently infected with HBV according to the World Health Organisation (WHO). This leads to over one million annual deaths caused by HBV-related complications of liver cirrhosis and hepatocellular carcinoma (HCC). There is a 100-fold higher risk of HCC conferred by HBV infection (Beasley 1988); this is one of the top ten causes of mortality worldwide. Current antiviral therapies do not result in sustained off-treatment responses in the majority of individuals, therefore necessitating lifelong treatment and imposing a huge financial burden on the countries most affected. There is an urgent requirement for novel immunotherapeutic strategies which, in conjunction with current therapies, may tip the balance in favor of viral clearance.

Innate Immune Response

NK cells constitute around one third of intrahepatic lymphocytes. They have antiviral potential through their capacity to induce apoptosis of HBV-infected hepatocytes through the

tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) pathway (Dunn et al. 2007) or to non-cytolytically clear HBV via production of IFN-γ. Their antiviral contributions may be more significant in the setting of the exhausted CD8 T cell responses characteristic of CHB. However, NK cells are also partially dysfunctional in CHB, with impaired capacity to produce IFN-γ; these cells may be under negative regulation by immunosuppressive cytokines including IL-10 within the liver environment (Peppa et al. 2010).

Furthermore, NK cells have a dichotomous role in the liver. The effector functions required for antiviral activity also contribute to liver damage and immunopathology. Recruitment of NK cells to the liver as part of a larger non-antigen-specific infiltrate (triggered by HBV-specific mechanisms) may amplify inflammation through TRAIL-mediated hepatocyte damage and potentiate a pro-inflammatory environment.

Adaptive Immune Response

The capacity to detect HBV-specific T cell populations with a combination of intracellular cytokine staining and MHC class I restricted peptides/tetramers has facilitated functional profiling of these cells. These studies showed that HBV-specific CD4 and CD8 T cells are quantitatively depleted in the periphery and dysfunctional in their ability to proliferate and produce Th1/Tc1 type cytokines including IL-2 and IFN-γ in CHB. These weaker, narrowly focused responses fail to achieve adequate viral control.

Within HBV-specific CD8 T cells, an epitope hierarchy exists which varies with the different phases of chronic HBV infection. Core 18–27-specific CD8 T cells are dominant in patients with acute hepatitis (when compared to a limited panel of other HLA-A2-restricted epitopes inclusive of surface and polymerase proteins). Conversely, the same core 18–27-specific CD8 T cells are not detectable in the circulation in patients with CHB with viral loads $>10^7$ copies per ml (Webster et al. 2004); in these individuals, the few detectable responses are predominantly surface or polymerase-specific CD8 T cells. These dysfunctional specificities demonstrate altered tetramer binding and poor antiviral function and may represent persisting tolerized populations.

Although HBV utilizes the error-prone reverse transcriptase enzyme for replication, CTL escape mutations are thought to arise less frequently in HBV than in infections with other highly variable viruses such as HIV and HCV. This may be partially attributable to the weak selection pressure exerted on the virus by an exhausted HBV-specific CD8 T cell response in CHB but is likely also due to the constraints on sequence variation imposed by the overlapping reading frames of the HBV genome. T cell escape mutants have been observed in a few cases of CHB in whom the T cell response was uncharacteristically strong and narrowly focused (Bertoletti et al. 1994). Amino acid mutations have been described within HBcAg 18–27 epitope but not in surface and polymerase epitopes, suggesting a higher selection pressure by HBcAg-specific CD8 T cells.

The role of HBV-specific T cells within the liver has implications for liver immunopathogenesis in addition to antiviral immunity. The inadequate effector functions that fail to control viral load may instead potentiate liver inflammation. Release of IFN-γ has been shown to induce chemokine release by hepatocytes which recruit a large non-antigen-specific lymphocytic infiltrate into the liver (in a transgenic mouse model) (Bertoletti and Maini 2000). In this model of HBV infection, platelets have been found to play a novel role in the recruitment of CD8 T cells initiating HBV-related liver disease (Guidotti and Chisari 2006). Thus, functionally inadequate HBV-specific T cells which persist in CHB infection both fail to control viremia and, as a bystander effect, contribute to pathology (Bertoletti and Maini 2000). A large nonvirus-specific component to the T cell infiltrate has also been noted in patients with poorly controlled CHB (Maini et al. 2000). Many of the T cells constituting the intrahepatic cellular infiltrate in liver diseases such as HCV are now known to have a distinctive "liver-homing" phenotype, with expression of CD161, chemokine receptors such as CXCR6 or CXCR3, and an invariant Vα chain.

These mucosal-associated invariant T cells (MAIT) are prone to production of pro-inflammatory mediators such as IL-17, but their exact role in viral hepatitis remains to be elucidated (Klenerman and Thimme 2011).

Downregulation of the Antiviral T Cell Response in CHB

Virus-specific T cells are quantitatively depleted (inversely correlating with viral load) and profoundly dysfunctional in CHB. Their phenotype resembles that observed in the murine model of chronic LCMV infection, which has been termed T cell exhaustion. T cell exhaustion is characterized by a hierarchical loss of T cell effector functions. The capacity to produce IL-2 is lost early on, with an associated impairment of T cell proliferation. Cytotoxicity is lost next, followed by impaired production of effector cytokines TNF-α and IFN-γ, and finally deletion of the virus-specific T cells (Wherry 2011). In HBV infection, it has been shown that the loss of virus-specific T cells is associated with upregulation of the proapoptotic Bcl-2 interacting molecule (Bim) (Lopes et al. 2008). The few remaining T cells show a narrowly focused antiviral repertoire and in accordance with the exhaustion model, show no IL-2 production, weak or absent proliferative capacity, and impaired cytotoxicity and effector cytokine production. As IFN-γ has been shown to be a potent mediator of non-cytolytic clearance of HBV from hepatocytes, its lack of production is likely to contribute to viral persistence. HBV-specific T cells undergo phenotypic changes attenuating their functionality. The CD3-zeta signalling chain is downregulated as a hallmark of arginine deprivation, while co-inhibitory molecules such as programmed death 1 (PD-1) and cytotoxic T lymphocyte antigen-4 (CTLA-4) are upregulated. The expression of these co-inhibitory molecules thwarts any possible activation of the respective cells. Recent investigations have shown that blocking co-inhibitory pathways in vitro could help to recover T cell cytokine production by patient-derived T cells in many cases (Bertoletti and Ferrari 2011). These findings might help in the development of future immunomodulatory therapies.

The drivers contributing to the changes in phenotype and functional impairment of HBV-specific T cells are thought to be manifold. Firstly, the liver environment in which HBV-specific T cells are likely to encounter their cognate antigen has been described to be immunosuppressive, with low levels of arginine and high levels of the immunosuppressive cytokines IL-10 and TGF-β. Resident hepatic APC, such as liver sinusoidal endothelial cells (LSEC), have been shown to actively induce tolerance in antigen-specific T cells. Interaction with hepatocytes leads to the induction of a pro-apoptotic phenotype and T cell deletion. Many resident specialized intrahepatic cell types including LSEC, stellate cells, Kupffer cells, and hepatocytes themselves can deliver co-inhibitory signals to infiltrating T cells through their expression of ligands like PD-L1.

Secondly, high levels of persistent antigen can lead to tolerance induction in T cells, as shown in murine experiments. In addition to the very high levels of viremia persisting for years in many patients with CHB, HBV-derived antigens such as the HBeAg and subviral particles containing HBsAg are found in extremely high quantities in the circulation of these patients. The production of these noninfectious antigens is thought to constitute a viral immunosuppressive mechanism.

In addition to these mechanisms of T cell exhaustion, a number of other cell types may exert excessive downregulation of antiviral immunity in CHB. CD4 regulatory T cells (Treg) have the capacity to modulate immune responses by suppressing proliferation and effector functions in CD4 and CD8 T cells and interfering with the maturation of dendritic cells. Treg are important in the prevention of autoimmune responses; however, in chronic infections, they potentially hinder antiviral immune responses and consequently viral clearance. Despite numerous studies, there is still some controversy about the importance of CD4 T regulatory cells in HBV (Manigold and Racanelli 2007), which partly reflects the difficulty in reliably identifying these populations in humans. Fox-P3-expressing CD4 Treg are enriched in HBV infection, particularly in the liver, and have the capacity to suppress effector responses; they may therefore

constitute an additional mechanism to prevent excessive tissue damage by limiting the immune response in patients with high viral titers (Alatrakchi and Koziel 2009).

Conclusions

Despite the altered kinetics of HBV replication during the initial phases of infection, recent evidence suggests innate, in addition to adaptive, immune mediators may play a role in viral control. Further human studies and animal models of acute infection are required to define the immune events during the immediate few weeks after inoculation, details of which have remained elusive. Whether or not the endpoint of infection is viral persistence or control is likely decided during these initial few weeks.

Once chronic infection is established, it is perpetuated by a variety of mechanisms that normally serve to limit exuberant immune responses in the immunotolerant liver. A better understanding of these mechanisms has opened new avenues for developing therapeutic approaches to boosting immune control and limiting liver disease in CHB.

Hepatic adaptive immune cells

Definition

The adaptive immune cells of liver includes T cells and B cells, and they possess specificity, diversity, and immunological memory. These cells recognize specific antigenic epitopes. T lymphocytes provide cell-mediated immunity and consist of $CD8^+$ cytotoxic T lymphocytes (Tc) and $CD4^+$ T helper lymphocytes (Th). B lymphocytes are characterized by the production of antibodies raised against specific antigens and participate in humoral immunity. They orchestrate a major role of in both immunity and tolerance in the liver along with other immune cells.

The cardinal features of the adaptive immune system are specificity, diversity, and immunological memory. The adaptive (specific) immune response is orchestrated by T lymphocytes and B lymphocytes, which recognize specific antigenic epitopes. It has immunological memory in that a subsequent exposure to the same antigen leads to a more rapid, sustained, and potent immune response. T lymphocytes provide cell-mediated immunity and consist of $CD8^+$ cytotoxic T lymphocytes (Tc) and $CD4^+$T helper lymphocytes (Th). B lymphocytes are characterized by the production of antibodies raised against specific antigens and participate in humoral immunity. The normal liver contains a population of memory T cells that are involved in immune surveillance both locally and systemically. In response to infection or injury, innate and adaptive immune cells are rapidly recruited to the liver. Chronic hepatitis is characterized by hepatic infiltration with T and B effector cells that are crucial in determining whether inflammation resolves or persists with progression to cirrhosis. In viral hepatitis, liver-infiltrating T cells are crucial in controlling and clearing infection and defects in adaptive immunity lead to viral persistence and chronic hepatitis.

Introduction

The liver is the largest solid organ in the body and receives 75 % of its blood supply from the gut via the portal vein; the rest comes via the hepatic artery. The terminal branches of both drain into the hepatic sinusoids, a low-flow vascular bed where interactions with Kupffer cells, endothelial cells, and hepatocytes facilitate processing of nutrients and soluble antigens from the gut. The liver has an important role in the removal of

pathogens and particulate antigens entering from the systemic circulation via the hepatic artery and from the gut via the portal vein. The liver is thus constantly exposed to nutrients, antigens, and bacterial products and in order to prevent a constant state of immune activation. Mechanisms have evolved that suppress immune responses to harmless antigens while maintaining the capacity to respond to infections such as hepatitis viruses. In inflammatory and autoimmune liver diseases, lymphocytes are recruited, leading to hepatitis, which may become chronic if antigen persists, e.g., viral infection or autoimmune disease. Persistent chronic hepatitis can lead to progressive injury, an aberrant scarring, and cirrhosis. Thus, understanding how adaptive immune cells are activated, recruited, and positioned in the liver and how they respond to the hepatic microenvironment is critical to understanding the immune-pathogenesis of liver diseases.

The Adaptive Immune System

The adaptive immune system evolved to recognize and respond to a vast array of antigens and moreover to remember these antigens, leading to more rapid and vigorous responses on reexposure known as "immunological memory." The ability to recognize so many antigens is a consequence of accelerated somatic mutation and genetic recombination of antigen receptor gene segments which generates a vast number of potential antigen receptors (Siu et al. 1984). These are expressed on individual B and T lymphocytes and inherited by their progeny, allowing "memory" lymphocytes to deliver long-lived specific immunity. Teleologically, the adaptive immune system first appears in jawed fish and the innate immune system is the major system of host defense against pathogens in non-vertebrates (Medzhitov and Janeway 1997). However, the two systems are linked because activation of adaptive immune responses is dependent on signals generated in response to activation of pattern recognition receptors on antigen-presenting cells of the innate immune system by molecular motifs associated with pathogens or damaged cells. The cellular components of the innate immune system include antigen-presenting cells such as macrophages, dendritic cells, and some endothelial cells as well as eosinophils, basophils, and mast cells. In addition, epithelial cells can act as important sensors of tissue damage to activate innate lymphoid cells such as gamma delta T cells (Vantourout and Hayday 2013).

Lymphocytes are responsible for the specificity and memory in adaptive immune responses. They are produced in the bone marrow and mature within the thymus (T cells) or secondary lymphoid organs (B Cells) before emerging into the circulation as naive cells. These cells migrate between blood and secondary lymphoid tissue until they encounter their specific antigen. They express homing receptors that direct their migration between blood and secondary lymphoid tissues, allowing them to provide surveillance throughout the lymphatic tissues where they are most likely to encounter antigen in an environment that promotes optimal conditions for lymphocyte activation and the generation of immune responses (Miyasaka and Tanaka 2004).

CD8 αβ and CD4 T cells include a diverse repertoire of T cell receptors that recognize antigens in the context of MHC class I and II molecules, respectively. On activation by antigen presented by appropriately activated antigen-presenting cells (APCs), naive T cells differentiate into functional effector and memory cells with either T cytotoxic (Tc) or T helper (Th) cell functions (Kapsenberg 2003). Cytotoxic CD8 T cells recognize intracellular viral or tumor antigens presented in association with MHC class-I molecules whereas activated CD4 T cells secrete a range of cytokines depending on how and where they are activated that shape the nature of immune responses, e.g., Th1 responses dominated by Il-12, IFNγ and TNF secretion, Th2 dominated by IL-4 and IL-13, Th17 dominated by Il-17 secretion and Th22 cells that secrete IL-22. In addition, some CD4 T cells have regulatory functions and a specific subset of T follicular helper cells provides help to B cells (Vinuesa et al. 2005). An effective immune

response to most hepatotropic pathogens requires strong and durable CD4 and CD8 T cell responses that can be detected within the liver alongside regulatory T cells that are critical to control the effector immune response and allow resolution once the antigen is cleared (Protzer et al. 2012).

B cells produce antibodies that are secreted as soluble factors and recognize antigens as part of humoral immunity. B cells express a unique B cell receptor (BCR) that allows them to recognize specific antigen. Whereas T cells recognize their cognate antigen in a processed form presented by MHC molecules on APCs, B cells recognize antigen in the native form. If a B cell encounters its specific antigen in the context of additional signals provided by T cells (T cell help), it differentiates into an antibody-secreting plasma cell. Antibodies bind antigens and activate components of the innate immune system including phagocytes and complement. Some plasma cells become long-lived antigen-specific memory B cells primed to produce specific antibodies on reexposure to the pathogen (Table 1).

Adaptive Immune Cells in the Liver, Table 1 Characteristics of human T and B lymphocytes

	T lymphocytes	B lymphocytes
Maturation site	Thymus	Bone marrow
Surface markers	**CD3:** T cell receptor	Surface Ig, CD19
	CD4: Th1, Th2, Th17, Th22, Treg TFH	
	CD8: Tc (cytotoxic T cells)	
Intracellular cytokines	**Th1**: IFN-γ, TNF-α	Plasma cells secrete
	Th2: IL-4, IL-5, IL-13	IgG, IgM, IgA
	Th17: IL17, 22, GMCSF, IFN-γ	
	Th22: IL-22	
	Treg: IL-10	
Function	**Th1**: Kill intracellular microbes	Protect against extracellular microbes
	Th2: Parasitic infection	
	Th17: Fungal infection, autoimmunity	
	TFH: Provide helps for B cells	
	Treg: control other T cells	
Antigen receptor	TCR	BCR/Antibody
Memory cells	Yes	Yes
Antigen specificity	Yes	Yes
MHC recognition requirement	Yes	No

Activation of Adaptive Immunity in the Liver

The liver's well-known ability to promote immune tolerance has evolved to prevent excessive immune responses to nutrients or commensals entering via the portal vein. Some pathogens, for example, malaria and hepatitis C virus, exploit the liver's tolerogenic properties to evade effective immune responses and establish persistent infection. However, in most infections, the liver responds appropriately to pathogens by activating both the innate and adaptive immune responses to clear infections such as hepatitis A and E. The liver is characterized by populations of resident nonprofessional APCs in addition to conventional dendritic cells (DCs) both of which regulate local activation of T cells (Crispe 2012). The ability of liver sinusoidal endothelial cells (LSECs) and hepatocytes to interact with T cells is facilitated by the cellular composition and unique structure of hepatic sinusoids. Sinusoidal endothelial cells can take up, process, and present soluble antigens and apoptotic cells from the sinusoidal blood. Their characteristic fenestrations facilitate solute transport and allow hepatocytes to extend protrusions into the sinusoidal lumen (Warren et al. 2006) where as a consequence of low levels of flow, circulating lymphocytes can interact directly with endothelial cells, Kupffer cells, stellate cells, and hepatocytes during transit through the sinusoids (Benseler et al. 2011). LSEC can directly cross-present antigen to naive $CD8^+$

T cells, and this usually results in tolerance rather than full activation (Knolle et al. 1999; Limmer et al. 2000, 2005). The contribution of LSEC to intrahepatic $CD4^+$ T cell priming is less clear (Knolle et al. 1999; Limmer et al. 2000, 2005). Studies in mice suggest that LSECs have the ability to prime naïve lymphocytes with a regulatory phenotype (Knolle et al. 1999; Limmer et al. 2000), and a recent paper suggests that such activation can imprint responding cells with a gut homing phenotype, providing a potential link between the gut and liver (Neumann et al. 2012). Antigen presentation by hepatocytes leads to T cells entering hepatocytes and being degraded by a process called suicidal emperipolesis (Benseler et al. 2011). Antigen presentation by bone-marrow-derived APCs is regulated by the hepatic microenvironment to favor tolerance, and liver-derived DCs in mice and humans are inherently tolerogenic and express low levels of the co-stimulatory molecules required for full T cell activation (Goddard et al. 2004). Liver-derived DCs also preferentially secrete IL-10 and are capable of inducing peripheral Treg, which suppress immune responses (Thomson et al. 2009; Thomson 2010). Recent studies from the Bertolino group have shown that the liver microenvironment modulates the ability of bone-marrow-derived APC to activate viable effector T cells (Holz et al. 2012; Lopes et al. 2008; Sawa et al. 2009). Such an outcome is not seen in other tissues, suggesting that it is the liver microenvironment that determines this outcome. One factor may be the secretion of IL-7 by hepatocytes, which has been shown to regulate T cell survival (Sawa et al. 2009) or other cytokines such as IL-6, IL-10, or TGFβ secreted by stromal cells (Holt et al. 2009) or Kupffer cells.

The importance of local IL-10 secretion is illustrated by murine studies of the enteric pathogen *Trichinella spiralis* (Douglas et al. 2010). Wild type mice infected orally develop gut infection and local expansion of $CD4^+$ T cells but not hepatitis, whereas IL-10-deficient mice develop severe hepatitis mediated by $CD4^+$ T cells activated in the gut, illustrating the importance of local regulatory networks in the liver in protection against effector responses generated in the gut (Lunz et al. 2007). The constant exposure to bacterial products means that the liver is relatively insensitive to endotoxin, and Kupffer cells, and LSECs respond by preferentially secreting immunosuppressive cytokines, preventing the liver from being in a constant state of inflammation (Uhrig et al. 2005). Plasmacytoid DCs, which are recruited to the liver in response to inflammation, can also induce tolerance through anergy or apoptosis (Goubier et al. 2008) of antigen-specific $CD8^+$ T cells which may contribute to the elimination of antigen-specific cytotoxic T cells during the resolution phase of antiviral immunity.

In response to inflammation, myeloid DCs in the liver become activated and migrate via a parasinusoidal route from the parenchyma to portal tracts, which contain T cells and are therefore a potential site of T cell priming, before migrating to regional lymph nodes (Kudo et al. 1997). This route could explain the formation of portal lymphoid aggregates in many chronic inflammatory liver diseases including viral hepatitis.

Thus, under homeostatic conditions, antigen presentation within the liver favors immune tolerance and the outcome of intrahepatic immune responses is dependent on the local inflammatory microenvironment. When antigen is presented predominantly within the liver, $CD8^+$ T cell tolerance is likely to ensue whereas early antigen expression within secondary lymphoid tissue results in an effective cytotoxic T lymphocyte response.

Lymphocyte Recruitment to the Liver

Lymphocyte recruitment to the liver involves specific combinations of adhesion molecules and chemokines including the atypical endothelial adhesion molecule VAP-1 although no tissue-specific homing receptor has so far been reported for the liver. Circulating memory lymphocytes are widely distributed throughout the body via the blood to peripheral tissues such as the liver where they contribute to the process of immune

surveillance. The hepatic lymphocyte population also contains innate-like lymphoid cells, which include natural killer T cells, and γδ T cells, which play a critical role in first-line immune defense in response to injury or infection forming a bridge between innate and adaptive immunity. Around 15 % of $CD3^+$ lymphocytes from human liver express TCRγδ rather than TCRαβ.

Under normal conditions, lymphocyte recruitment to the liver is restricted to populations of memory T cells that recirculate as part of the process of immune surveillance. Such cells can be detected in portal tracts and scattered throughout the parenchyma and include both conventional lymphocytes, CD4 and CD8 T cells, T cells with αβ_ chain T cell receptors, that recognize antigens in the context of MHC class I and II molecules and a small number of memory B cells. In addition, NKT cells and populations of γδ T cells (both are known as unconventional T cells) and innate-like lymphoid cells including NK cells patrol the normal liver (Doherty and O'Farrelly 2000). Classical NKT cells express a very restricted T cell receptor repertoire Vα24 and Vβ11chains in humans and recognize antigens restricted to the MHC class I molecule CD1d that recognize antigen alpha-galactosyl ceramide. Nonclassical NKT cells encompass TCR_ αβ _ and TCRγ δ T cells, which do not use the T cell receptor Vα14 chain. Both classical and nonclassical NKT cells are abundant in the liver and constitute around 20–30 % of liver-infiltrating lymphocytes (Exley and Koziel 2004). Under non-inflamed conditions, liver-infiltrating lymphocyte comprise 60 % T cells, 30–35 % NK cells, and 5 % of B cells (Racanelli and Rehermann 2006). In response to infection or inflammation, recruitment increases rapidly, resulting in lymphocytic infiltrates in the portal tracts (portal hepatitis) or parenchyma (lobular hepatitis).

Lymphocytes are recruited from the circulation via sinusoidal endothelial cells, which express adhesion molecules and chemokines that support transendothelial migration. Subsequent interactions with stromal cells and extracellular matrix direct migration beyond the endothelium and into tissue. The recruitment of leukocytes to the liver occurs at three sites: (a) portal vein terminal branches, (b) central vein branches, and (c) hepatic sinusoids. Elegant studies in rodents suggest that most recruitment occurs through the sinusoids with subsequent migration onward into portal tracts and hepatic lymph (Xu et al. 2008).

In general, leukocyte recruitment via endothelium follows a four-stage process. Initially, free-flowing leukocytes are captured and tethered to the endothelium by selectins and their glycosylated ligands. However, in the low-flow system of the hepatic sinusoids, selectins have a much lesser role and other molecules including ICAM-1,VCAM-1, and VAP-1 may be involved at this stage (Lasky et al. 1992). Tethering induces rolling and the reduced velocity allows the cell to be activated by signals such as chemokines retained in the endothelial gycocalyx (Tanaka et al. 1993; Mackay 2001). This leads to the clustering and conformational activation of leucocytes integrins that support firm adhesion and arrest. Integrins are transmembrane heterodimers that mediate cell-cell and cell-matrix interactions and promote motility. They are required for transendothelial migration (Shimaoka et al. 2003). Integrins involved in leukocyte-endothelial interactions include αLβ2 (LFA-1) which binds to ICAM-1 and ICAM-2 on endothelium, α4β1 (VLA-4) which binds to VCAM-1 and α4β7 (LPAM-1) which binds to MadCAM-1, an adhesion molecule predominantly expressed in the gut (Butcher and Picker 1996). Integrins exist in an inactive conformation with low affinity for ligand until activated by signals such as chemokines (Campbell et al. 1998) (Table 2).

The adherent cell then undergoes intravascular crawling mediated by chemokines (Phillipson et al. 2006) and integrins followed by transendothelial migration through endothelium. Most transmigrating leukocytes migrate between endothelial cells at cell-cell junctions (paracellular migration) using junctional receptors including members of the JAM family (Nourshargh and Marelli-Berg 2005), but some leukocytes migrate through sinusoidal endothelium via transcellular pores within cells.

Adaptive Immune Cells in the Liver, Table 2 Integrins and their ligands, which are involved in recruitment of hepatic lymphocytes

Integrins on lymphocytes	Name	Ligands on sinusoid	Function
α4β1 (CD49d/CD29)	VLA-4,	VCAM-1, Fibronectin	Cell-matrix adhesion; lymphocyte adhesion
$\alpha_L\beta_2$ (CD11a/CD18)	LFA-1	ICAM-1 to ICAM-4	Leukocyte adhesion to sinusoid; transmigration; T cell-APC adhesion
α4β7 (CD49d/cd104)	LPAM-1	Fibronectin, VCAM-1, MadCAM-1	Lymphocyte homing to mucosal tissue

Both paracellular and transcellular migrations involve chemokines, integrins, and other atypical adhesion receptors including in the hepatic sinusoids both VAP-1 and for some leukocytes the scavenger receptor CLEVER-1 (Lalor et al. 2002; Shetty et al. 2011).

In most vascular beds, the leucocytes then has to cross the basement membrane although in the liver, this is absent and they enter the loose matricellular network of the space of Disse before entering the parenchyma. How cells traverse the space of Disse is poorly understood but probably involves interactions with stellate cells and extracellular matrix (Holt et al. 2009). Once in tissue, the leukocyte follows chemokine gradients to its target cell (Fig. 1).

Chemokines in the Liver

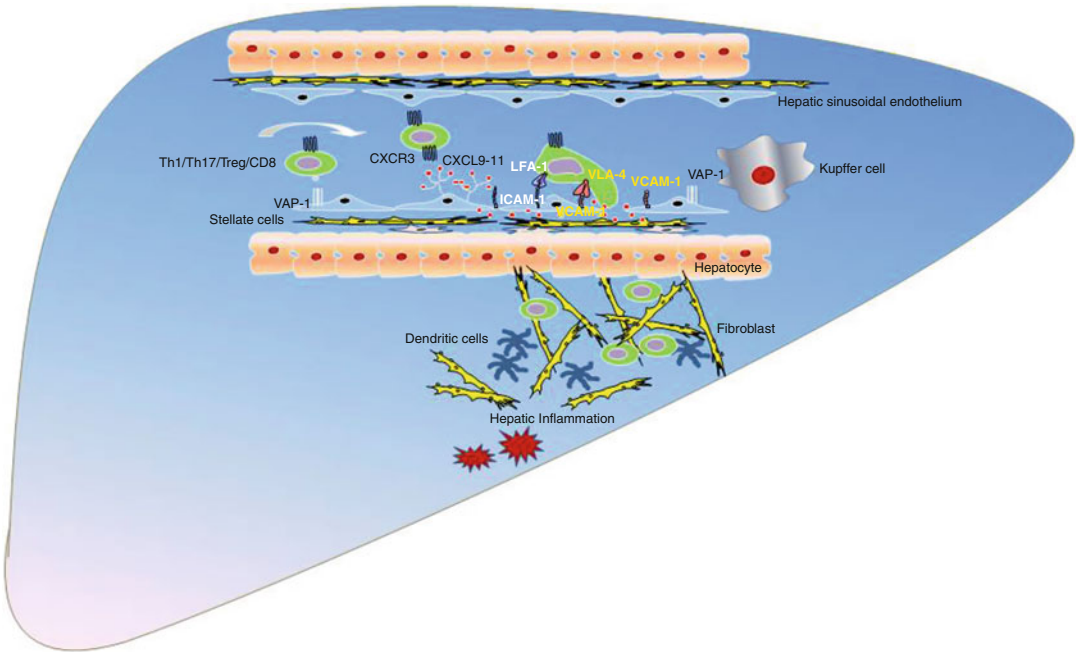
Chemokines are a family of structurally related chemotactic cytokines that regulate leukocyte migration, thereby shaping the outcome of immune responses. Chemokines provide cues for the recruitment of effector and regulatory subsets and are central to the pathogenesis of inflammatory diseases. They bind specific G protein–coupled receptors that activate integrin-mediated adhesion and enhance motility (Oo and Adams 2010). Chemokines are secreted early after infection or injury by endothelial and epithelial cells, stromal cells, and leukocytes and recruit an initial wave of innate immune cells that precedes antigen-specific effector and regulatory T cell recruitment.

Most effector T cells infiltrating the chronically inflamed human liver express high levels of CXCR3, CXCR6, CCR1, and CCR5 consistent with a tissue-infiltrating phenotype; the roles played by these different receptors in recruitment are beginning to be understood. In addition to recruiting different subsets of lymphocytes, there is evidence for compartmentalization of recruitment as well. CCR5 and its chemokine may have a particular role in recruitment to portal tracts, whereas CXCR3 appears to be essential for recruitment into the parenchyma (Table 3).

Chemokines in Lymphocyte Recruitment to the Liver

Expression of CXCR3 on T cells is closely linked to activation and tissue infiltration, and its ligands CXCL9, CXCL10, and CXCL11 are induced by proinflammatory cytokines. Studies have reported increased levels of CXCR3 on CD4 and CD8 effector cells within the liver with increased levels of hepatic CXCR3 ligands in many chronic inflammatory liver diseases. The sources of CXCR3 ligands in liver inflammation include hepatocytes, stellate cells, sinusoidal endothelial cells, and infiltrating leukocytes (Curbishley et al. 2005). The expression of CXCR3 ligands requires stimulation with IFN-γ and TNF-α, which are released by activated hepatic macrophages and the initial wave of infiltrating innate immune cells with an additional contribution from activated $CD4^+$ T cells themselves, thereby amplifying effector cell recruitment.

CXCR3 and two of its ligands CXCL9 and CXCL10 are important for transmigration of effectors T lymphocytes through hepatic sinusoids (Table 3). CXCR3 ligands are secreted by the endothelium but also originate from



Adaptive Immune Cells in the Liver, Fig. 1 The multistep model of leukocyte recruitment in the liver. Leukocyte extravasation into hepatic tissue involves multiple steps. First of all, lymphocytes are captured by carbohydrate-dependent tethering (which in the liver may be mediated by vascular adhesion protein-1 (VAP-1) rather than selectins which are absent from the hepatic sinusoids), allowing the flowing lymphocytes to contact the vessel wall where arrest can be triggered by chemokines CXCR3 on hepatic sinusoids immobilized on endothelial proteoglycans that activate lymphocyte integrins (LFA-1 and VLA-4) and binding to endothelial cell adhesion molecules ligands such as ICAM-1 and VCAM-1. During this stage, the leukocyte arrests on the vessel wall and undergoes intravascular crawling to sites of transendothelial migration. This process may involve migration between or through endothelial cells, and it is mediated by a number of molecular signals including chemokines, integrins, and atypical adhesion receptors such as VAP-1. Once in the tissue, the cell follows chemokine gradients presented on hepatic fibroblasts to sites of hepatic inflammation, using chemokine-mediated changes in the actin cytoskeleton, and adhesion molecules to propel migration

neighboring cells from where they can be transcytosed to the endothelial surface (Middleton et al. 2002). In addition, chemokines secreted "upstream" by other cell types including cholangiocytes in portal tracts can be captured from the slow-flowing sinusoidal blood by proteoglycans within the endothelial cell glycocalyx and presented at the endothelial surface. Thus, chemokines on the endothelium reflect local secretion by many cell types in the inflamed microenvironment (Edwards et al. 2005).

Chronic hepatitis includes nonspecific bystander lymphocytes as well as antigen-specific cells, and both express high levels of CXCR3. Although it was originally thought that CXCR3 expression was a characteristic of Th1 cells, it is now apparent that B cells, Tregs, and Th17 cells also use CXCR3 to enter inflamed tissues, including the liver, and CXCR3 may be viewed as important for tissue infiltration per se rather than being associated with particular types of inflammation.

Chemokines and Lymphocyte Subset Localization in the Liver

In human blood, CXCR6 is expressed on effector CD8 T cells with particularly high levels detected on CD4 and CD8 T cells within the inflamed human liver. The CXCR6 ligand CXCL16 is one of only two chemokines that exist in

Adaptive Immune Cells in the Liver, Table 3 Chemokines and their receptors involved in recruitment, positioning in the liver

Hepatic parenchyma cells	Chemokines	Responding chemokine receptors
Portal vessels	CCL3-5	CCR5
Liver sinusoids	CXCR9, 10, 11	CXCR3
	CXCL16	CXCR6
Biliary epithelium	CCL20	CCR6
	CCL28	CCR10
	CXCL16	CXCR6
Portal-associated lymphoid tissue	CCL19, 21	CCR7

Lymphocytes expressing CCR5 (Th1, CD8) can be recruited across the portal endothelium and this is mediated by the chemokines CCL3-5. Recruitment of lymphocyte subsets (CD8, Th1, Treg, and Th17) across liver sinusoidal endothelium is mediated by the chemokines CXCL9-11 as well as CXCL16 (NK and NKT). Biliary epithelial cells expressing CCL28 recruit CCR10-expressing regulatory T cells; CCL20 attract CCR6-expressing Th17 and CXCL16 attracts Th1, CD8, and NKT cells. In chronic hepatitis C and primary biliary cirrhosis, there is neovessel formation within the portal tracts, which has characteristics of lymphoid tissue, which is termed portal-associated lymphoid tissue (PALT) and has been shown to be associated with the chemokines CCL19 and CCL21 which are ligands for CCR7

a transmembrane form (Heydtmann et al. 2005). CXCL16 is upregulated on inflamed bile ducts and hepatocytes and is also expressed by sinusoidal endothelium where it mediates the patrolling of NK and NKT cells in the sinusoids (von Andrian and Mempel 2003; Geissmann et al. 2005). The engagement of CXCR6 on T cells by CXCL16 on epithelial cells promotes β1 integrin-dependent adhesion, which is important for the positioning, retention, and survival of effector cells in the inflamed liver (Germanov et al. 2008) (Table 3). A unique subset of HCV-specific $CXCR6^+$ liver-infiltrating CD8 T cells express the C-type lectin CD161 and secrete IL-17 and IFN-γ. These cells may represent an important liver-specific subset of effector cells (Billerbeck et al. 2010).

Other chemokines may also be involved in retaining T cells within the liver. These include CXCL12 (Terada et al. 2003) and the other transmembrane chemokine CX3CL1 (fractalkine), both of which are expressed on inflamed bile ducts (Isse et al. 2005). The fractalkine receptor CX3CR1 is expressed by Th1 cells and may help to retain these cells at sites of epithelial inflammation. The epithelial chemokine CCL28 is increased on cholangiocytes in a variety of liver diseases associated with T cells expressing the CCL28 receptor, CCR10 (Eksteen et al. 2006), a proportion of which are $FOXP3^+$ regulatory CD4 T cells. However, most liver-infiltrating Tregs express CXCR3 and CCR4, the latter allowing them to interact with chemokines secreted by hepatic dendritic cells.

Th17 and Tc17 cells express high levels of another chemokine receptor CCR6 and CCL20; the chemokine ligand for CCR6 is secreted by epithelial cells including cholangiocytes, providing a signal to localize Th17 cells at bile ducts at the epithelial surface and interface with the environment (Table 3).

Homeostatic Chemokines and Lymphocyte Egress From the Liver

Homeostatic chemokines can be upregulated at sites of inflammation where they play important roles in regulating leukocyte trafficking, particularly through the formation of tertiary neolymphoid structures (Grant et al. 2002) which are a feature of many chronic inflammatory liver diseases, particularly PBC, PSC, and HCV infection (Heydtmann et al. 2006). The CCR7 receptor is expressed on naive T cells and, a subset of central memory cells to promote their recirculation through secondary lymphoid tissues. CCR7 is also expressed on effector cells and is important for egressing out of inflamed tissue via the lymphatics (Debes et al. 2005). $CCR7^+$ effector T cells are present in inflamed human liver and because the CCR7 ligands CCL19 and CCL21 are expressed on hepatic sinusoids and lymphatic vessels (Grant et al. 2002), they may use CCR7 to migrate out of the liver via afferent lymphatics to draining lymph nodes where they are either removed during the resolution of infection or restimulated to maintain chronic hepatitis (Bromley et al. 2005).

T Lymphocytes Lineages in the Liver

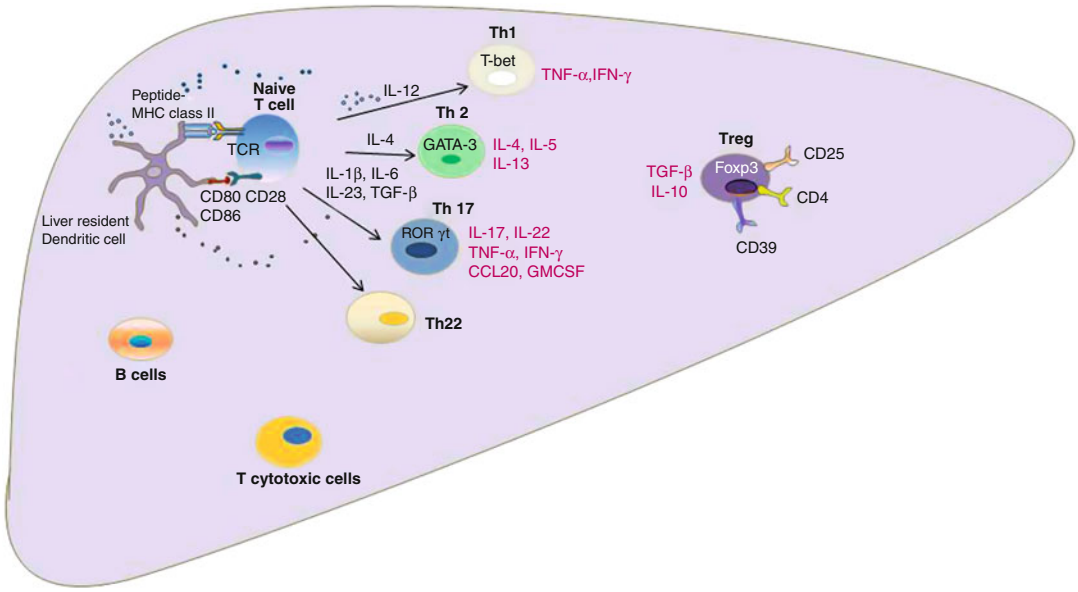
The normal human liver contains both CD4 and CD8 T cells with twice as many CD8 compared with CD4 T cells. Most conventional T cells in the non-inflamed liver are memory or effector phenotype and may be present as part of a circulating population of tissue-homing cells that provide immune surveillance against specific pathogens. The liver can act as a reservoir for antigen-specific T cells, and normal human liver contains memory cells with specificity for persistent viruses including CMV and EBV. In addition to conventional alpha beta T cells, the liver contains populations of *innate lymphoid cells* that include NK and NKT cells which play a role in immune surveillance against infection, epithelial injury, or malignant transformation (Mjosberg et al. 2012; Bernink et al. 2013). NKT cells are a subset of lymphocytes that express both the T cell receptor (TCR), specifically having an invariant VαJα-chain, and NK cell associated markers including NK1.1. NKT cells recognize glycolipid antigens presented by the non-polymorphic MHC class I-like protein CD1 in contrast to conventional $CD8^+$ and $CD4^+$ T cells that recognize peptide antigens presented by MHC. NKT cells are enriched in the human liver where they comprise nearly up to 20–30 % of hepatic lymphocytes whereas they make up less than 1 % of cells in other tissues. NKT cells are activated by glycolipid antigens presented by APCs or by cytokines such as IL-12, which is produced by dendritic cells and Kupffer cells. Subsequently, NKT cells secrete a large number of cytokines (IFN γ, TNFα, IL-4, IL-10, IL-13) and chemokines, allowing them to interact with the adaptive immune system and help determine the nature of the immune response.

Mucosal-associated invariant T (MAIT) cells are another subset of nonconventional αβ T cells whose T cell receptor (TCR) consists of an invariant Vα chain (iVα7.2-Jα33) combined with limited conserved Vβ chains that are restricted by a conserved MHC-related molecule MR1 (Gapin 2009). MAIT cells are present in human blood but use CCR6 and CXCR6 to preferentially locate to the lamina propria and liver (Gapin 2009). MAIT cells display active antimicrobial functions in vivo (Gold et al. 2010) and react with MR1-expressing cells infected or co-cultured with selective bacteria and yeasts, but not viruses (Gapin 2009). The activation of MAIT cells triggers secretion of IFN-γ, TNF-α, and IL-17 and again, they may have an important role in shaping immune responses in the liver.

In chronic hepatitis, both effector lymphocyte subsets and regulatory lymphocytes are present at the site of inflammation. The naive CD4 T cell is a multipotential precursor with defined antigen specificity, which can differentiate into distinct effector lineages, contingent upon signals from cells of the innate immune system. Th1 cells are crucial for bacterial and viral infection, Th2 for parasitic infection, and Th17 for fungal infection. Anti-inflammatory regulatory T cells (Treg) police these effector T cells and promote resolution of immune responses once infection has been cleared and help to maintain self-tolerance in the liver (Oo and Adams 2012). The balance of the cells recruited and their local differentiation and activation will determine the nature of hepatitis and liver disease (Fig. 2).

T cytotoxic Cells

Cytotoxic CD8 T cells are critical for antiviral and antitumor immunity. They kill target cells via activation of TNF receptors such as Fas and TRAIL and secretion of perforin and granzymes and also secrete proinflammatory cytokines including IFN-γ, TNF-α. They are present in normal human liver but increase in frequency in response to infection and are present in immune-mediated liver diseases where they may be associated with target structures such as bile ducts in PBC and hepatocytes in autoimmune hepatitis. Persistence of hepatitis B virus is associated with a failed CD8 T cells response which is a consequence of a combination of intrinsic T cell defects, particularly BIM-mediated apoptosis as a consequence of



Adaptive Immune Cells in the Liver, Fig. 2 T cell lineages in the liver. Once antigens are presented via MHC class II molecules and co-stimulatory molecule CD80/CD86, naive T cells differentiate into distinct CD4 helper T cell subsets, depending on the cytokine milieu, which drives a program of differentiation that includes the induction of key transcription factors, cytokine productions. Cytotoxic CD8 T cells and Th1 cells expressed inflammatory type chemokine receptors, CCR5& CXCR3; Th2 cells express CCR4 and CCR8; recently discovered Th17 cells express CCR4, CCR6, and CXCR3. Th22 subset was demonstrated in the liver, but chemokine receptors are still under investigation. Thymic derived regulatory T cells maintain the immune tolerance and prevent the excessive damage during infection and inflammation by controlling these T effectors cells. B cells are present in the liver and involved in humoral immunity by producing antibodies

activation by hepatic APCs, and a hepatic environment that favors apoptosis rather than survival of effector cells (Lopes et al. 2008). Liver-infiltrating CD8 cells express high levels of CXCR3 and CCR5, promoting their recruitment via endothelium, and also high levels of CXCR6 which allows them to be localized at and bind to epithelial targets that express the CXCR6 ligand CXCL16 (Berke 1995). In chronic liver inflammation, an exhausted phenotype similar to that seen in chronic HBV is suggested by downregulation of IFN-γ production along with upregulation of PD-1 on CD8 cells (Latchman et al. 2001).

Th1 and the Liver

Th1 immune responses are involved in cell-mediated immunity and the clearance of intracellular pathogens including viruses. They are also implicated in autoimmune and inflammatory liver diseases although in human liver disease, Th1, Th17, and even Th2 type cells can often be found together in the liver. Th1 cells differentiate when T cells are activated in the presence of dominant signaling through interleukin (IL)-12 and activation of signal transduction and activator of transcription (STAT)-4. They are characterized by expression of the transcription factor T-bet which promotes secretion of their signature cytokine IFN-γ. A critical factor in regulating the involvement of specific subsets at sites of inflammation is the differential expression of chemokine receptors between these different subsets of T cells. Liver-infiltrating CD8 T cells and Th1 both express high levels of CXCR3, CCR5, and CXCR6, promoting their recruitment to the inflamed liver (Curbishley et al. 2005; Heydtmann et al. 2006).

Th2 and the Liver

The differentiation of Th2 cells is driven by IL-4, STAT-6 and characterized by expression of the transcription factor Gata-3. They secrete Il-4, IL-5, IL-10, Il-13, and IL-21 and are involved in humoral immunity and the clearance of extracellular organisms and parasites including schistosomiasis (Cheever et al. 1995); (Wynn et al. 1998). IL-13 is a profibrotic cytokine implicated in Th2-dominated inflammatory response and subsequent liver fibrosis (Chiaramonte et al. 1999; Chiaramonte et al. 2001). IL-21 activates alternative macrophages and Kupffer cells and augments Th2 function and may have a role in hepatic fibrosis (Pesce et al. 2006).

Th17 and the Liver

Interleukin (IL)-17-producing Th17 cells have emerged as an independent T cell subset, whose differentiation requires IL-1, IL-6, and TGF-β, all of which are abundant in inflamed liver, activation of STAT3, and expression of the nuclear receptor, ROR-γt (Mosmann et al. 1986; Sakaguchi et al. 1995; Bettelli et al. 2006; Veldhoen et al. 2006; Annunziato et al. 2007). They are characterized by the secretion of IL-17 and IL-22 and can also secrete IFN-γ, GMCSF, and CCL20. They have been implicated in autoimmune diseases such as EAE and collagen-induced arthritis in mice (Mosmann et al. 1986; Sakaguchi et al. 1995; Bettelli et al. 2006; Veldhoen et al. 2006; Annunziato et al. 2007) and in the liver in steatohepatitis and autoimmune and viral liver disease (Lan et al. 2009; Lemmers et al. 2009; Tang et al. 2011; Zhao et al. 2011). Th17 cells link innate and adaptive immunity. The functional role of Th17 cells in the liver may be regenerative rather than pathogenic because their product IL-22 can promote epithelial repair and regeneration (Zenewicz et al. 2007). Th17 cells are present around peritumoral stroma of hepatocellular carcinoma (Kuang et al. 2010). Interleukin-17 signaling in murine models also promotes liver fibrosis (Gao and Waisman 2012; Meng et al. 2012).

Th22 and the Liver

Th22 cells mainly secrete IL-22, which is hepatoprotective in murine models (Xing et al. 2011). Il-22-secreting T cells can be detected in the inflamed human liver (Billerbeck et al. 2010; Kang et al. 2012), and some also express IL-17. The role of these cells is unclear, but they may be involved in repair and liver regeneration.

The recently reported Th9 cells that secrete IL-9 and develop from Th2 cells stimulated with IL-4 and TGF-β have not been reported in the liver.

Regulatory T Cells and the Liver

The efficient functioning of the immune system requires that effector responses against pathogens are tightly regulated to maintain homeostasis. Thymic derived naturally occurring $CD4^{+}CD25^{high}CD127^{low}$ regulatory T cells (T_{reg}) (Sakaguchi et al. 2008) are present and maintain tolerance in the liver. Hepatic regulatory T cells include natural Treg and induced Treg that develop in the TGF-β-rich intrahepatic cytokine milieu. Regulatory T cells are present in acute and chronic viral, autoimmune liver diseases and also in hepatocellular carcinoma (Longhi et al. 2005; Fu et al. 2007; Stross et al. 2012). Treg suppress immune response against self-antigens and also damp down effector responses to allow resolution and the restoration of immune homeostasis, thereby preventing autoimmunity and uncontrolled inflammation and tissue injury. Their function depends on activation of STAT-5 via IL-2 signaling. Liver-infiltrating Treg express patterns of homing receptors that overlap with T effector cells, Th1 cells (CXCR3, CCR5 and CXCR6), Th2 cells (CCR4 and CCR8), and Th-17 cells (CCR4, CCR6, CXCR3), allowing Treg cells to co-localize together with diverse effector T cells to suppress a wide range of inflammatory conditions (Curbishley et al. 2005). Treg in the inflamed human liver use CXCR3 to migrate through sinusoidal endothelium under with other receptors localizing them at epithelial surfaces (CCR10) or close to DCs (CCR4) (Eksteen et al. 2006).

The function of hepatic Treg may be impaired by the local inflamed microenvironment, as demonstrated by impaired phosphorylation of STAT5 (Oo et al. 2010). Recent studies implicated Treg surface markers CTLA-4, CD39 and Galactin-9 may play a role in liver diseases (Deaglio et al. 2007; Qureshi et al. 2011; Liberal et al. 2012).

B Lymphocytes in the Liver

B cells are present in chronically inflamed liver and use a combination of VCAM-1, ICAM-1, and two atypical adhesion receptors, VAP-1 and CLEVER-1, to enter the liver (Shetty et al. 2012). Hepatic lymphoid follicles with clear B and T cell areas develop in many chronic inflammatory diseases, usually close to portal tracts, leading to them being termed portal-associated lymphoid tissues (PALT). Activated B cells are surrounded by a follicular dendritic cells network and the distribution of IgM, IgD, IgG B cells and of bcl-2 and bcl-6 resembles that seen in lymph nodes (Racanelli et al. 2001). B cells also play their part in hepatic fibrosis as attenuated liver fibrosis was noted in the absence of B cells (Novobrantseva et al. 2005).

Utilizing the Adaptive Immune Cells in Liver Disease

Increasing understanding of the role played by specific chemokines and adhesion molecules in regulating adaptive immune cell recruitment to the liver opens up the chance of manipulating these pathways to prevent the recruitment of damaging effector cells or promote recruitment of anti-inflammatory regulatory cells. Potential therapeutic targets include CXCR3 and CXCR6 in inflammatory liver disease. Augmenting the immunoregulatory arm by supplementing autologous regulatory T cells to suppress unwanted inflammation is attractive in autoimmune disease and has been achieved in part by treating patients with IL-2 to activate Tregs. Another approach is to expand Treg ex vivo and re-infuse them into patients. In the context of liver cancer, Tregs suppress beneficial antitumor immunity and here Treg depletion is the aim. This can be achieved in part by judicious use of drugs such as cyclophosphamide but specific Treg-depleting therapy is missing. However, such approaches are complex, because it is difficult to specifically target either the regulatory or effector arm with current therapies. Further preclinical studies and better animal models are necessary to allow the development of safe and effective clinical therapies.

Synonyms

Non-scarring hair loss; Patchy alopecia; Patchy hair loss

Alopecia areata (AA) is a disease which causes hair loss commonly on the scalp and much less frequently over other hair-bearing areas of the body (e.g., eyebrows, beard). AA has a prevalence of 0.1–0.2 % with a lifetime risk of 1.7 % in the general population (Safavi 1992). It affects individuals of all ages, gender, and ethnicity.

It is a cutaneous disease which may have nail changes. However, other organ systems are not affected. Even in the most severe sequelae of entire scalp and body hair loss, this disease does not portend a serious medical problem; however, the psychological and social impact can be immense.

There is increased incidence of AA among patients with genetically related persons having this disease (10–20 %) (Freyschmidt-Paul et al. 2010).

This condition has been associated with a personal history of atopy and has been found to occur with other autoimmune diseases such as lupus erythematosus, vitiligo, type I diabetes mellitus (Wang et al. 1994), and autoimmune thyroid disorders (Kurtev and Iliev 2005).

Pathogenesis

The exact etiopathogenesis of AA is not fully known. There is overwhelming evidence

supporting the major role of the immune system in the pathogenesis of this disease. At present, AA is considered an autoimmune disease based on substantial research data though some crucial findings to establish true autoimmunity (e.g., identification of primary target self-hair-follicle-derived antigen/s; reactivity to self-follicular antigens leading to AA in humans) are still lacking (Freyschmidt-Paul et al. 2010).

In AA, inflammatory infiltrates are found mainly over the peribulbar region of the terminal anagen hair follicle (Whiting 2003; Dy 2011; Alkalifah et al. 2010).

The inflammatory attack does not occur over the region of the epithelial follicular stem cells (bulge area); thus, permanent damage is not seen in this disease and hair regrowth is possible.

Research findings indicate that cellular-mediated immune system plays a significant role in the pathogenesis of AA. The inflammatory infiltrate in AA consists of T cells mainly CD4 and CD8. CD4+ T lymphocytes are mainly found surrounding hair follicles, while CD8+ cells are located intrafollicularly (Freyschmidt-Paul et al. 2010; Carroll et al. 2002; McElwee et al. 2002). The activated CD8+ infiltrating inside hair follicles causes cytotoxic reaction, resulting in follicular damage. Molecules produced by cytotoxic T cells include tumor necrosis factor (TNF), granzymes, and Fas ligand (FasL) (Carroll et al. 2002; McElwee et al. 2002). Fas are highly expressed in dystrophic AA hair follicles (Bodemer et al. 2000; McElwee and Hoffman 2002). Interferon gamma (IFN gamma) produced by follicular antigen-presenting cells and mediated by CD4 T helper cells has been shown to be elevated in AA patients especially in alopecia areata totalis or universalis. This cytokine has been found to precipitate hair loss in AA (Freyschmidt-Paul et al. 2006; Arca et al. 2004).

The pathogenic role of T lymphocytes (mainly CD8 and CD4) is further supported by the induction of AA in animal models through the transfer of particular cells and grafting from AA mice to normal mice, leading to the development of patchy hair loss (McElwee et al. 2005; Freyschmidt-Paul et al. 2008). In murine models, transferred CD8+ induced localized disease, whereas CD4+/CD25-injection resulted in minimal local hair loss but induced a systemic reaction resulting in multiple extensive patches (McElwee et al. 2005). Immunoregulatory CD4+/CD25+ cells (immunosuppressive to CD4+/CD25- and CD8+ function) were found to decrease in active AA and prior to AA onset (Zoller et al. 2002).

AA has findings which extend beyond the affected sites. There is elevation of autoantibodies in serum, in addition to those found on lesional skin of patients with AA (Tobin 2003); however, the transfer of serum or autoantibodies has failed to induce alopecic patches (Gilhar et al. 1992); thus, these antibodies do not seem to have a primary role in the pathogenesis of AA.

The normal hair follicle is considered a relatively immune-privileged site through the downregulation of major histocompatibility complex (MHC) molecules (needed for autoantigen presentation to CD8+ T cells) and expression of immunosuppressive cytokines. In AA, an aberration in immune privilege in susceptible individuals may contribute to its pathogenesis. In the follicular epithelium of AA patients, there is an increase in MHC I and II expression and lower levels of immunosuppressive cytokines in contrast to non-AA hair follicles (Gilhar 2010; Gilhar et al. 2012). The immune-inhibitory molecules produced by anagen hair follicles which were found to be decreased in AA were alpha-melanocyte-stimulating hormone (alpha-MSH), transforming growth factor beta (TGF beta), indoleamine 2,3 dioxygenase (IDO), and Red/IK (Gilhar 2010). The decreased Red/IK cytokine in the outer root sheath of the hair follicle and hair matrix functions to suppress MHC II antigen (expression of which is triggered by IFN gamma) associated with autoimmune disease (Kang et al. 2012). There are elevated numbers of NKG2D+NK cells around lesional hair follicles in AA, and an agonist of NKG2D, MHC I polypeptide sequence A (MICA), is expressed in AA (Ito et al. 2008).

Many patients have positive history of the disease in genetically related family members.

Support for AA genetic susceptibility is being provided by study findings of genes relating to the immune system and regulation of the hair follicle.

A genome-wide association study (n = 1,054 AA cases; n = 3,278 controls) done in North America looking into the genetic component of alopecia areata has identified genes involved in autoimmunity and cell-mediated immunity specifically susceptibility loci on chromosomes 2q33.2(CTLA4), 4q27(IL2/IL21), 6P21.32(HLA), 6q25.1 (ULBP6/ULBP3), 9q31.1 (STX17), 10p15.1(IL2RA), 11q13 (PRDX5), and 12q13 (Eos/ERBB3) (Petukhova et al. 2010).

Of the aforementioned genes, the cytotoxic T-lymphocyte-associated antigen (CTLA4), interleukin (IL)2/IL21, and IL2 receptor A (IL2RA) have T cell proliferation function. Human leukocyte antigen (HLA) is involved with antigen presentation. Cytomegalovirus UL16-binding protein consisting of ULBP6/ULBP3 genes encoding activating ligands of the natural killer cell receptor NKG2D is being expressed in the hair follicle particularly in the dermal sheath of patients with AA. Lymphocytes around hair follicles composed of CD8+ can be activated by NKG2D-activating ligand. Two hair follicle genes were identified: syntaxin (STX17) and peroxiredoxin (PRDX5) (Petukhova et al. 2010).

A follow-up genome-wide association study in Europe (n = 1,702 cases; n = 1,723 controls) confirmed the significant association with the susceptibility loci for ULBP6/ULBP3, STX17, IL2/IL21, PRDX5, and ERBB3. In addition, two other susceptibility loci were identified: IL-13 produced by T helper cells with inflammatory cell recruitment role and KIA0359/CLEC16A expressed by immune cells but whose function is not yet known (Jagielska et al. 2012).

Some of the identified susceptibility alleles have also been found in other autoimmune diseases such as rheumatoid arthritis, type 1 diabetes mellitus, celiac disease, Crohn's disease, systemic lupus erythematosus, multiple sclerosis, and psoriasis signifying common autoimmune pathways (Petukhova et al. 2010).

Clinical Manifestations

Clinically, AA presents as non-scarring, well-defined alopecic patches mainly found over the scalp in majority of cases. Other sites which may be affected include the eyebrows, eyelashes, beard, and body hair. The lesions typically start as discrete, solitary, or multiple patches (Fig. 1) which may remain limited in size or may expand to involve larger areas. The cutaneous surface of the affected patches are normal and smooth in appearance, with skin colored or pinkish hue. Upon closer examination, there is note of intact follicular ostia. Typically this condition occurs rapidly and there is variability in terms of disease severity. In severe progression of the disease, there may be hair loss of the entire scalp (AA totalis/AT) (Fig. 2) or body hair (AA universalis/AU) (Freyschmidt-Paul et al. 2008, 2010; Shapiro 2002).

Clinical variants based on pattern distribution include patchy, ophiasis, and diffuse type of AA. Patchy AA is the most common type affecting majority of cases. The ophiasis type is a band-like pattern which commonly starts at the occipital hairline area and extends towards the lateral temporoparietal hair margins. In diffuse AA, there are no well-circumscribed alopecic lesions but rather diffuse thinning areas over the scalp. This type is difficult to diagnose clinically and may need a biopsy for confirmation (Shapiro 2002).

AA may preferentially attack pigmented hairs leaving white hairs intact, resulting in the appearance of scalp hair suddenly turning white.

Alopecia Areata, Fig. 1 Patchy alopecia areata (Courtesy of the University of British Columbia Hair Clinic)

Alopecia Areata, Fig. 2 Alopecia areata totalis (Courtesy of the University of British Columbia Hair Clinic)

Positive pull test over the peripheral hair margins indicates active disease. Some lesions may have exclamation point hairs which appear as short broken hair fibers tapered proximally compared to its distal end.

Nails may also be affected with development of changes such as pitting, red lunulae, and longitudinal ridging. In some cases, nail signs may precede the appearance of the alopecic patches (Freyschmidt-Paul et al. 2010; Shapiro 2002).

Pathobiology and Histopathology

In the early stage of AA, there is a dense inflammatory infiltrate over the peribulbar region of the terminal anagen hair follicle (swarm of bees). Some infiltration may occur intrafollicularly as well (Whiting 2003; Dy and Whiting 2011).

Predominant T cells mainly CD4 and CD8 cause destruction (apoptosis and necrosis) to the follicular epithelium. This active inflammation leads to a dystrophic anagen condition wherein the affected hair follicle's caliber/quality becomes compromised. Upon progression of the disease with increased inflammatory cell infiltrates attacking the hair follicle, these affected follicles undergo a miniaturization process with shortened rapid cycling of the anagen and telogen phases (nanogen hair follicles) (Wang and McElwee 2011).

Inflammation causes disruption of the hair follicle, leading to disease activity. The inflammatory infiltrates are found mainly over the lower part of the hair follicle (hair matrix and dermal papilla), not the bulge area. Damage to the hair shaft results in trichorrhexis nodosa-like fractures seen clinically as exclamation point hairs. There may be injury to melanocytes, leading to pigment incontinence. Repeated inflammation leads to development of miniaturized hair follicles. Terminal hairs become less and catagen/telogen hair follicles rise in number, leading to the subsequent decrease of the anagen to telogen ratio (Whiting 2003; Dy 2011).

Chronic AA has hair follicles in prolonged telogen without reentry into the anagen phase. At this stage any inflammation present would be found surrounding miniaturized hairs. There is significant increase of miniaturized hairs and decrease to absence of terminal hairs. The telogen to vellus ratio may drop to 1:3 compared to the usual normal of 7:1 (Dy and Whiting 2011).

Treatment

To date, there is no standard curative and preventive treatment for AA. There is a high rate of spontaneous hair regrowth for localized patchy scalp disease; thus, not instituting any medical intervention is one management option.

Evaluating medications according to the evidence-based medicine criteria shows that few medications show effectivity in the treatment of AA. Among the immunosuppressive agents, potent topical and intralesional corticosteroids are reasonable first-line therapies for patients with limited patchy disease. Based on study results, the most effective topical corticosteroid

seems to be the superpotent clobetasol propionate foam for patchy AA and the 0.05 % ointment under occlusion for more extensive disease (Tosti et al. 2003, 2006).

Various clinical studies have shown efficacy of intralesional glucocorticoid ranging from 63 to 97 % (Alkhalifa 2011).

The dosage used for injections such as triamcinolone acetonide ranges from 2.5 to 10 mg/cc every 4–6 weeks.

Uncontrolled clinical trials on the pulsed administration of systemic corticosteroids have shown some efficacy; however, hair regrowth was mostly temporary with hair loss ensuing after discontinuation of treatment (Freyschmidt-Paul et al. 2010).

Many institutions consider topical immunotherapy as first-line treatment for more extensive lesions of AT and AU. The agents utilized for this treatment are Diphenylcyclopropenone (DPCP) and squaric acid dibutylester (SADBE). Various clinical trials including well-designed controlled studies on the effectivity of DPCP and SADBE showed response to treatment ranging from 29 to 78 % with a median of 49 % (Freyschmidt-Paul et al. 2010; Shapiro 2002).

The use of biologics (i.e., TNF alpha inhibitor (etanercept); LFA 3 inhibitor (alefacept)) so far has proven ineffective, and in some studies, TNF alpha inhibitors have even worsened the condition (Freyschmidt-Paul et al. 2010; Strober et al. 2009).

Other therapies such as topical minoxidil, anthralin, and phototherapy have not been proven effective in various clinical trials (Freyschmidt-Paul et al. 2010; Strober et al. 2009). Minoxidil, if used, is more of an adjunctive medication in addition to other treatments such as topical and intralesional corticosteroids.

Course and Prognosis

The lesions of AA are non-scarring with hair regrowth being possible. The course is characterized as unpredictable with disease recurrence occurring at any given time.

Within a year, there may be spontaneous hair regrowth seen in about half of the patients with localized patchy type of AA. There is however a high rate of recurrence within 5 years (Freyschmidt-Paul et al. 2010; Shapiro 2002).

Severe cases usually follow a chronic course. Factors associated with poor prognosis include severe type of AA (AT and AU), early age of onset, long-standing disease, presence of nail changes, and positive family history of AA and personal medical history of atopy and other autoimmune diseases (Shapiro 2002).

Synonyms

Autoimmune disease and hair loss

Definition

Hair loss that is directly associated with autoimmune disease involves immune mechanisms in its pathogenesis targeting the hair follicles. They may be localized or generalized, as well as scarring and non-scarring in type. Secondary factors may also play a role in hair growth, including the medications used to treat the primary disease.

Lupus

Hair loss is one of the most common cutaneous signs of systemic lupus erythematosus (SLE)

and is present in more than half the patients at some time during the course of their illness (Moghadam-Kia and Franks 2013). Alopecia can be the presenting manifestation of SLE and may affect the scalp, eyebrows, eyelashes, beard hair, or body hair (McCauliffe and Sontheimer 1996). Alopecia may be associated with active disease and can also occur due to immunosuppressive medications used to treat lupus. Lupus alopecia can be scarring associated with discoid lupus or non-scarring. The Systemic Lupus International Collaborating Clinics (SLICC) has recently revised the American College of Rheumatology (ACR) SLE classification criteria (Petri et al. 2012). Discoid lupus has been always included in the most widely used classification criteria for SLE, including the new SLICC classification criteria. Non-scarring alopecia is also included in the new criteria as an individual criterion for SLE, as it was in the original ARA criteria.

Non-scarring Alopecia

Non-scarring alopecia in lupus often develops during flares of systemic disease and can occur under two scenarios. One is "telogen effluvium" that is a reactive process characterized by a diffuse thinning of the scalp and hair shedding caused by a metabolic or hormonal stress, like pregnancy, or the use of glucocorticoids. Generally, the normal hair usually grows back within 6 months when the antecedent etiology resolves. In diffuse patterned hair loss in general, up to 20 % of the hair can be lost before it is cosmetically visible. Therefore, complaints of hair loss should not be discredited in individuals who still have a full head of hair. Other scenario is "lupus hair," which is characterized by dry, course hair prominently over the frontal hairline that is very brittle and easily damaged. This condition is almost always observed during exacerbations of SLE and resolves when the disease activity abates (Alarcon-Segovia and Cetina 1974). Considerable overlap occurs between lupus hair and telogen effluvium. As in alopecia areata, non-scarring alopecia in lupus can occur as a wavy band-like area of hair loss extending across the peripheral temporal and occipital scalp (ophiasis pattern). Ophiasis gets its name from the Greek word "ophis," meaning snake.

Differential Diagnosis

Non-scarring alopecia in lupus must be distinguished from many other non-scarring alopecias. The differential diagnosis includes alopecia areata, telogen effluvium, traumatic alopecia, traction alopecia, female pattern hair loss, and male pattern alopecia (Table 2).

Alopecia Areata: Alopecia areata is a chronic inflammatory disease that causes recurrent non-scarring alopecia. It is thought to be an autoimmune condition caused by T cell-mediated immune dysfunction. There is an increased incidence of alopecia areata in patients with other autoimmune conditions such as lupus and DLE (Werth et al. 1992). It usually affects the scalp and presents with discrete circular well-delineated smooth patches of complete hair loss with no or little inflammation. The scalp lesions may be associated with burning sensation and slight erythema. Dermoscopy or 7x loupe magnification can aid in diagnosis and can reveal yellow dots and exclamation-point hairs with a tapering base and a ragged proximal portion that are diagnostic of the disease. Hairs that grow back are temporarily or permanently hypopigmented. This is another characteristic feature of alopecia areata. Scalp biopsy is useful is equivocal cases (Alkhalifah et al. 2010a, b).

Telogen Effluvium: Telogen effluvium is a non-scarring alopecia in which a physiologic stressor causes an increased number of hairs to go into resting phase (telogen phase). The hair loss in telogen effluvium occurs in a diffuse pattern. A hair-pull test can result in many hairs (more than 2 hairs on a group of 50 hairs) coming out easily from their roots with an elongated hair bulb. The scalp appears non-erythematous and unremarkable. Metabolic testing, including complete blood count, iron studies, thyroid function tests, serum chemistries, and liver enzymes, should be considered in the search for systemic causes of telogen effluvium. A drug history should be obtained as well. Scalp biopsy is usually not necessary (Tosti and Pazzaglia 2007).

Alopecia in Systemic Autoimmune Disease, Table 1 Comparative features of alopecia in lupus, dermatomyositis, and scleroderma

	Lupus	Dermatomyositis	Scleroderma
Frequency of scalp lesions	Frequently seen	Frequently seen	Occasionally seen
Frequency of alopecia	Frequently seen	Occasionally seen	Occasionally seen
Color of scalp lesions	Red, pink	Violaceous	Shiny, hypo- or hyperpigmented
Distinctive features of skin involvement	Involvement of the malar eminence, oral mucosa, dorsal fingers; hyperkeratosis	Involvement of the eyelids, periorbital areas, knuckles; pruritus	Systemic sclerosis (SSc): involvement of the fingers, hands, and face; edema and pruritus in the early stages; variable skin thickening; paucity of facial wrinkles; sclerodactyly; digital ulcers, calcinosis cutis; pitting at the finger tips; Raynaud's phenomenon
			Localized scleroderma: no Raynaud's phenomenon, no systemic involvement, no sclerodactyly; plaques tend to progress for 3–5 years and then arrest
Lab findings	Anti-DS DNA, Anti Smith	Autoantibodies directed against cytoplasmic RNA synthetases (Anti-Jo-1, Anti-PL-7, Anti-PL-12, Anti-OJ, Anti-EJ)	Limited cutaneous SSc: anticentromere antibody; diffuse cutaneous SSc: anti-Scl-70 (anti-topoisomerase I)
			Morphea: anti-histone antibodies
Pathology	Scalp DLE: intense mononuclear cell infiltrate, fibrosis, follicular hyperkeratosis, epidermal atrophy, thickened basement membrane, and basal vacuolar degeneration	Sparse perivascular lymphoid infiltrate, epidermal atrophy, basement membrane degeneration, and vacuolar changes in the basal keratinocyte layer	Intense inflammatory infiltrate at the margin at early stages and waning inflammatory infiltrate at later stages with infiltration of lymphocytes and plasma cells at the border and central fibrosis in the lower two-thirds of the dermis and upper subcutaneous tissue and eventually disappearance of pilosebaceous units and eccrine sweat glands and effacement of the rete ridges
Immunopathology	Dermal-epidermal junction granular deposits of immunoglobulin (IgG [less commonly IgM]) and complement (C3)	Dermal microvessel complement (C5 to C9) deposits (in DM, immunoglobulin deposition as opposed to complement is less common than in lupus)	Diffuse vascular deposits of immunoglobulins (predominantly IgM) and/or complement (predominantly Clq)
Associated comorbidities	SLE affects multiple organ systems	Up to 40 % of cases may be associated with occult malignancy	Epileptic seizures have been reported with en coup de sabre

Alopecia in Systemic Autoimmune Disease, Table 2 Differential diagnosis of non-scarring alopecia in lupus

Alopecia areata	Look for discrete circular well-delineated smooth patches of complete hair loss. Hairs that grow back are temporarily or permanently hypopigmented. Exclamation-point hairs with a tapering base and a ragged proximal portion that can be seen under dermoscopy are diagnostic of the disease
Telogen effluvium	Look for the history of a stressor or new medication, diffuse pattern of hair loss, and unremarkable examination of the scalp. A positive hair test with elongated hair bulbs is suggestive
Traction alopecia	Look for the history of long-term friction. The location of the hair loss at the temporal and frontal margins of the scalp, with broken fine vellus hairs at different stages, is suggestive
Traumatic alopecia (other than traction alopecia)	Trichotillomania: look for patches of alopecia with angulated and irregular borders and hairs that are broken off at varying lengths
Female pattern hair loss (FPHL)	Look for progressive thinning of hair in the central portion of the scalp with hairs of various lengths and diameter and retention of the frontal hair line. The loss is gradual. A family history is suggestive
Male pattern alopecia (MPA)	Look for progressive thinning of hair in an M-shaped pattern in the frontal hairline with bitemporal recession. The hair loss is gradual. A family history is suggestive

Traction Alopecia: Traction alopecia is a form of traumatic alopecia that occurs as a result of chronic and excessive tension on the hair follicles. Severe cases of traction alopecia due to chronic long-term friction can be associated with follicular atrophy and permanent non-scarring alopecia. Obtaining thorough history including the exact styling techniques and products used is necessary. The location of the hair loss at the temporal and frontal margins of the scalp, with broken fine vellus hairs at different stages, is a distinctive clinical feature of traction alopecia. The scalp appears normal without evidence of scarring. Scalp biopsy can be helpful in some cases that are hard to differentiate clinically (Borovicka et al. 2009).

Traumatic Alopecia (Other Than Traction Alopecia): These types of hair loss include trichotillomania and alopecia secondary to physical abuse. Trichotillomania usually occurs in adolescents during times of psychosocial stress. It usually presents with patches of alopecia with angulated and irregular borders and with broken hairs of different lengths, usually located on the frontotemporal or frontoparietal scalp opposite the dominant hand. Affected areas are not completely bald. Localized perifollicular erythema or hemorrhage may occur. Scalp biopsy can be helpful in complicated cases. Alopecia due to physical abuse can be difficult to differentiate from other types of alopecia. If there is concern for abuse, look for historical inconsistencies, signs of trauma such as scalp hematoma or tenderness, and psychosocial risk factors. Signs of inflammation are absent in all types of traumatic alopecia.

Female Pattern Hair Loss (FPHL): FPHL, also referred to as female androgenetic alopecia, is the most common type of hair loss in adult women. FPHL usually presents with diffuse thinning of the central portion of the scalp with retention of the frontal hair line. The affected area is usually widened and more obvious. Bitemporal recession is rare. The hair loss in FPHL is gradual with conversion of pigmented thick terminal hairs to shorter indeterminate hairs and finally nonpigmented miniaturized vellus hairs. These hairs of various lengths and diameter are classic signs of androgenetic alopecia. A family history of similar hair loss is suggestive of FPHL. A hair-pull test may be helpful (3 or fewer hairs on a

group of 20 hairs indicating normal shedding). Follicles are intact. Scalp biopsy may help rule out autoimmune or inflammatory disorders (Olsen et al. 2005).

Male Pattern Alopecia (MPA): MPA, or androgenetic alopecia, is the most common type of alopecia in adult men. It often affects men prior to the age of 40. MPA usually presents with progressive thinning of hair in an M-shaped pattern in the frontal hairline with bitemporal recession that moves posteriorly as the alopecia progresses. Similar to FPHL, the hair loss in MPA is gradual with hairs undergoing a transition from terminal hairs to indeterminate hairs to vellus hairs. Follicles are intact without evidence of scarring. Taking a family history can be helpful (Olsen et al. 2005; Sinclair 1998).

Scarring Alopecia

Introduction

Scarring alopecia or cicatricial alopecia associated with discoid lupus is categorized as an LE-specific skin disease on the Gilliam's classification (Gilliam and Sontheimer 1981, 1982).

Epidemiology and Pathogenesis

Scarring alopecia is a frequent complication of discoid lupus erythematosus (DLE, a form of chronic cutaneous lupus erythematosus according to the Gilliam's classification (Ross et al. 2005)) and has been reported in more than half (34–56 %) of the patients with DLE. Scalp DLE is present in 4–14 % of patients with SLE (Yell et al. 1996). Scalp DLE can be the presenting manifestation of lupus in more than half of affected individuals and can remain the only manifestation of disease in 11–20 %. It has been shown to correlate with disease chronicity. Scalp DLE affects females more often than male (Whiting 2001; Tan et al. 2004). Onset of disease is usually between 20 and 30 years of age (Tan et al. 2004 p. 30). Onset of disease has been reported to occur less frequently in children and particularly those under age 10 (Moises-Alfaro et al. 2003).

The action of genetic, environmental, immunoregulatory, hormonal, and epigenetic factors involved in the pathogenesis of lupus results in the generation of inflammatory T cells, inflammatory cytokines, autoantibodies, and immune complexes that may cause damage to various target organs. Progressive replacement of the follicular epithelium by connective tissue and varying degree of permanent injury to the pluripotent hair follicle stem cell region in the bulge of hair follicles (where the arrector pili muscle connects to the outer root sheath) is similar to other forms of scarring alopecia. Like other variants of cicatricial alopecia, permanent destruction of hair follicles in DLE is frequently associated with a loss of sebaceous gland (Sellheyer and Bergfeld 2006). In scalp DLE, the localization of inflammation around the upper, permanent portion of the hair follicle appears to result from antigenic stimulation of the Langerhans cells that are positioned in the follicular epithelium below the entry of sebaceous glands into the follicle. These Langerhans cells may then trigger a first-line T cell- or immune complex-mediated inflammatory response (Dutz and Sontheimer 2002). This pattern of follicular inflammation is similar to scarring folliculitides of lichen planopilaris, allogeneic graft-versus-host reaction, and atopy. In scalp DLE, the antigenic stimulus affecting the Langerhans cells appears to be ultraviolet light (Ross et al. 2005); however, its role on hair-bearing scalp, a relatively sun-protected site, needs further study. A study showed that patients with coexisting androgenetic alopecia do not preferentially develop DLE in bald areas. The Koebner phenomenon is associated with DLE. Constant rubbing and scratching can lead to new lesions in affected patients. The proinflammatory cytokines interleukin-17 (IL-17), interleukin-23 (IL-23), and IL-17-producing cells have been shown to be important in the pathogenesis of lupus and lupus nephritis (Crispín et al. 2008; Zhang et al. 2009). A recent study of 89 patients with systemic and cutaneous lupus showed that IL17 isoforms (IL-17A and IL-17 F) are implicated not only in SLE but also in DLE immunopathogenesis (Tanasescu et al. 2010). Another recent study on 15 subjects with lupus suggested that T helper 17 lymphocytes and IL-17 are involved in the immunopathogenesis of both SLE and DLE.

As previously mentioned, DLE scarring alopecia is considered a primary scarring alopecia as the target of inflammation seems to be the hair follicle. For primary cicatricial alopecia, several classification systems exist in the literature; however, it is still controversial. In 2001, the North American Hair Research Society (NAHRS) developed a provisional classification for primary cicatricial alopecia. This classification scheme is a mechanistic classification system based on pathologic interpretation of dominant inflammatory cell type existing in and around affected hair follicles in scalp biopsy taken from clinically active lesions. This scheme divides the entities into lymphocytic, neutrophilic, mixed, or unspecific. Alopecia due to DLE is considered to be the most common primary acquired lymphocytic scarring alopecia (Tan et al. 2004).

Clinical Manifestations

Early classic lesion presents as a quite well-circumscribed, erythematous, infiltrative patch with adherent follicular hyperkeratosis. Later, the lesion progresses centrifugally to form a coin-shaped ("discoid") white-ivory, atrophic, depressed, smooth plaque with follicular plugging and adherent scale. Telangiectasia might also be present (Whiting 2001; Shapiro 2002; Fabbri et al. 2004; Donnelly et al. 1995). They may have features of classic discoid lesions elsewhere. In darker-skinned individuals central hypopigmentation and peripheral hyperpigmentation may occur (Sontheimer and McCauliffe 2002). The scalp lesions may resemble alopecia areata, lichen planopilaris, or linear morphea. Discoid lesions of lupus in the scalp can commonly be pruritic or tender; however, the condition may be asymptomatic. The patients might report that UV exposure worsens their symptoms.

Diagnosis

The initial approach to the patient with scalp DLE should include examination of the entire scalp, assessing the location and pattern of hair loss and also the presence of extracranial cutaneous and systemic features. Scalp biopsy with adjunctive use of direct immunofluorescence is helpful in establishing the diagnosis and evaluating the degree of inflammation and differentiation of scalp DLE from other primary lymphocytic cicatricial alopecias, respectively. Scalp biopsy specimens should be from early clinically active disease, at least 4 mm in diameter, and extend into the fat. Ideally, two biopsy specimens, one for standard horizontal sections and one for longitudinal section, should be obtained for transverse and vertical suctioning (Shapiro 2002). The major histopathologic features include fibrosis, follicular hyperkeratosis, epidermal atrophy, lymphocytic infiltrate, thickened basement membrane, and basal vacuolar degeneration. Granular deposits of C3 and IgG (less commonly IgM) at the dermal-epidermal junction and/or the junction of the follicular epithelium and dermis are typical. These histopathologic aspects can resemble those found in lichen planopilaris, an inflammatory scarring alopecia (Fabbri et al. 2004).

Differential Diagnosis

DLE scarring alopecia must be distinguished from other conditions that cause alopecia. The differential diagnosis of scalp DLE includes lichen planopilaris, radiation-induced alopecia, central centrifugal cicatricial alopecia, sarcoidosis, psoriasis, burn scar, and squamous cell carcinoma. In addition, a variety of other scalp conditions such as tinea capitis can be very inflammatory and must also be considered. Less commonly, non-scarring alopecia can be confused for scalp DLE (Table 3).

Lichen Planopilaris (LPP): LPP, also known as follicular lichen plan, can cause scarring alopecia over time. As in lichen planus, LPP is an autoimmune condition that is most likely caused by cell-mediated immune dysfunction. Similar to the pattern of follicular inflammation in scalp DLE, T lymphocytes targeted at follicular antigens are involved. LPP occurs more frequently in women than men. Patient with lighter skin are more commonly affected than dark-skinned individuals. There are three variants of LPP: classic LPP, frontal fibrosing alopecia, and Graham-Little syndrome. Classic LPP is characterized by perifollicular erythema and patches of alopecia

Alopecia in Systemic Autoimmune Disease, Table 3 Differential diagnosis of scarring alopecia associated with discoid lupus

Lichen planopilaris (LPP)	Look for erythema that is confined to perifollicular areas (in contrast to scalp DLE) and keratotic plugs surrounding the patches of alopecia. Loss of follicular orifices can be viewed under dermoscopy. Dyspigmentation, in comparison with scalp DLE, is less common
Central centrifugal cicatricial alopecia (CCCA)	Look for shiny scarring alopecia usually seen from the vertex forward. The presence of burning sensation or pruritus in the area of hair loss can help. Premature desquamation of the inner root sheath in scalp biopsy is suggestive
Radiation-induced alopecia	Look for the history of radiation exposure and regular and sharp borders. Decreased number of follicular units with fibrosis of adjacent collagen in scalp biopsy is suggestive
Squamous cell carcinoma	Look for long-standing hyperkeratotic or ulcerated lesions and scars. Biopsy is needed to confirm the diagnosis
Tinea capitis	Look for signs of inflammation in the scalp including erythema and scaling. Positive fungal culture and examination of plucked hairs with KOH are diagnostic

with surrounding keratotic plugs. Frontal fibrosing alopecia presents with band-like scarring alopecia of the frontal hairline that commonly affects women. Graham-Little syndrome is characterized by scarring alopecia of the scalp, non-scarring alopecia of the pubic and axillary areas, and a lichenoid follicular eruption. In contrast to scalp DLE, erythema is confined to perifollicular areas in LPP. Also, dyspigmentation is less commonly seen. Dermoscopy or 7x loupe magnification can aid in revealing the perifollicular erythema and loss of follicular orifices. A hair-pull test may reveal an increased number of anagen hairs. Scalp biopsy performed at the margin of alopecia from the most active area of disease is the most useful test for the diagnosis. Histologic features of LPP include a lichenoid interface inflammation around the infundibulum and isthmus, sparing the hair bulb. Hyperkeratosis, acanthosis, and hypergranulosis can also be seen. In advanced disease, significant perifollicular lamellar fibrosis can be seen. Direct immunofluorescence is nonspecific and may show colloid body staining with IgM. These histopathologic features can resemble those found in scalp DLE.

Central Centrifugal Cicatricial Alopecia: Formerly known as follicular degeneration syndrome, central centrifugal cicatricial alopecia (CCCA) is a slowly progressive scarring alopecia that usually occurs in black women. CCCA usually presents with increased follicular spacing and circle-shaped, shiny flesh-colored, smooth scarring alopecia. In contrast to scalp DLE, CCCA usually involves the crown or vertex and expands centrifugally. The presence of burning sensation or pruritus in the area of hair loss can also help to distinguish CCCA from other types of scarring alopecia. A characteristic histologic feature of CCCA on scalp biopsy is premature desquamation of the inner root sheath (Borovicka et al. 2009).

Radiation-Induced Alopecia: Radiation-induced alopecia commonly occurs after therapeutic radiation for head and neck cancers or inadvertent overdose. Low radiation dose will lead to reversible alopecia. Higher doses can result in severe erythema weeks after the radiation exposure followed by poikilodermatous changes and irreversible scarring alopecia. In contrast to scalp DLE, radiation-induced alopecia often has regular and sharp borders. Radiation-induced alopecia is localized to the treatment zone and the shape and pattern of the alopecia in relevant to the radiation delivery window. Histopathologic features of radiation-induced alopecia include decreased number of follicular units with fibrosis or hyalinization of adjacent collagen.

Squamous Cell Carcinoma: DLE lesions and particularly long-standing hyperkeratotic lesions and scars of chronic DLE are thought to be a predisposing factor for squamous cell carcinoma, with a high rate of local recurrence and metastasis. Close observation of every alopecic area is mandatory to determine ulcerated or hyperkeratotic lesions, all of which should be biopsied (Ross et al. 2005).

Tinea Capitis: Tinea capitis, a *Trichophyton tonsurans* infection of the scalp, is usually associated with signs of inflammation including erythema and scaling. Cervical adenopathy can be present. Positive fungal culture and examination of plucked hairs with KOH are diagnostic for tinea capitis.

Therapy and Prognosis

DLE scarring alopecia is usually irreversible and the inflammation affects the upper portion of the hair follicle including critical elements within the mid-follicle required for follicular reconstruction, as opposed to non-scarring alopecias such as alopecia areata that affect the lower portion of the hair follicle and wherein the follicle has the potential to regrow hair (Tan et al. 2004). DLE scarring alopecia can lead to considerable societal costs and reduced quality of life. A recent study by Ferraz et al. showed that lupus patients with alopecia had lower quality of life (Ferraz et al. 2006). In contrast, diffuse non-scarring alopecia in lupus is usually responsive to treatment of the lupus; however, it can be occasionally persistent, particularly in individuals with persistent active systemic disease (Moghadam-Kia and Franks 2013).

Dermatomyositis

Dermatomyositis (DM) is a systemic autoimmune connective tissue disease that is classified as an idiopathic inflammatory myopathy (Dalakas & Hohlfeld 2003). DM most frequently occurs between the age of 40 and 50, but it can affect any age group. There is a female predominance (female: male, 2:1) (Tymms and Webb 1985). DM is associated with hallmark skin findings including distinctive rashes (Gottron's sign and heliotrope rash) and poikiloderma (hypo- and hyperpigmentation, telangiectasis, and epidermal atrophy). Involvement of scalp, manifested as diffuse, confluent, atrophic, violaceous, scaly plaques, can be commonly seen in DM and can be the presenting manifestation of DM; however, alopecia is only occasionally seen. In a case series of 17 patients with DM, scalp involvement was noted in 14, with alopecia present in 6 of the 14 patients (Kasteler and Callen 1994). Adult-onset classic DM and clinically amyopathic DM can be associated with scaly scalp and non-scarring diffuse alopecia that often follows a flare of the systemic disease (Euwer and Sonthheimer 1996; Callen and Wortmann 2006; Callen 2000; Santmyire-Rosenberger and Dugan 2003). This diffuse violaceous scaly alopecia is one of the characteristic cutaneous features of DM, despite not being pathognomonic (Euwer and Sonthheimer 1996; Callen and Wortmann 2006). Non-scarring alopecia has also been reported in juvenile-onset DM. Also, DM may rarely cause cicatricial alopecia. DM may overlap with features of other connective tissue disease, particularly scleroderma and lupus (Dawkins et al. 1998). The clinical features that can help to distinguish DM from lupus include the violaceous color of the poikiloderma (in contrast to the red poikiloderma in lupus, similar to the violaceous hue in lichen planus) and localization of lesions around the eyes and on the extensor surfaces and severe pruritus in DM. Also, the scale in DM skin lesions is usually less prominent than in lupus. The histopathologic features include epidermal atrophy, basement membrane degeneration, vacuolar changes in the basal keratinocyte layer, and a sparse perivascular lymphoid infiltrate; the changes may be difficult to distinguish from those seen in lupus on light microscopy. Like in lupus, the dermis is often pale due to the accumulation of mucin and edema. Immunofluorescence microscopy reveals an interface dermatitis (deposition of complements and immunoglobulin

at the dermal-epidermal junction) (in DM, immunoglobulin deposition as opposed to complement is less common than in lupus) (Dourmishev and Wollina 2006). Muscle biopsy can be also performed. A combination of type 2 muscle fiber atrophy and lymphocytic infiltrate in both a perifascicular and a perivascular distribution is classic.

Scleroderma

Scleroderma is a systemic autoimmune connective tissue disease. It is more common in women and the peak age of onset is between 30 and 50 years. The disease involves the autoantibodies to characteristic cellular antigens and characteristic sclerotic changes of skin. Scleroderma is different from other autoimmune diseases involving skin (lupus, dermatomyositis) because epithelial injury does not occur (Gilliam 2008). The sclerotic changes can affect the connective tissue on any organ. When the disease is associated with internal organ involvement, it is named systemic sclerosis (SSc). There are two major subsets of SSc based on the degree of cutaneous involvement: limited cutaneous SSc and diffuse cutaneous SSc. SSc is characterized by typical cutaneous changes, including variable extent and severity of skin thickening, shiny and wrinkleless skin, diffuse hyperpigmentation, and depigmentation with sparing of perifollicular skin, leading to a salt-and-pepper appearance and flat telangiectasis. SSc usually affects the fingers, hands, and face. Autoantibodies including antinuclear antibodies (ANA) with a discrete speckled or nucleolar pattern, anti-Scl-70, and anti-RNP antibodies assist in the diagnosis (Gilliam 2008; Chung et al. 2006). Cyclophosphamide, the prototypic alkylating and immunosuppressant agent that has been used to treat systemic scleroderma, is associated with alopecia (3 %).

Localized form of scleroderma, also known as morphea, is a self-limited inflammatory disorder. Morphea is a relatively uncommon disorder that may occur at any age, but most frequently affects young adults and children. There is a female to male predominance of about 3:1, and the condition is uncommon in blacks. Like SSc, morphea is also characterized by spontaneous sclerosis of the skin but lacks internal organ involvement, Raynaud's phenomenon, and sclerodactyly. It involves transition from an early inflammatory stage to sclerosis and subsequent atrophy after 2–3 years. It usually presents with shiny, oval, 10 cm or greater in diameter, firm, indurated plaques with surrounding erythema. The surrounding red or violaceous rim may fade and transition into hypo- or hyperpigmentation with time. Hair follicles and sweat glands are absent in well-developed lesions. The lesions usually affect the trunk and extremities. The most common forms of morphea are plaque, generalized, and linear variants. A form of linear morphea that affects the face or scalp, usually the midline or paramedian forehead, is known as en coup de sabre because the lesion is reminiscent of a cut of a sword. It usually presents as a unilateral, shiny, hypo- or hyperpigmented, atrophic, linear plaque. It can present with more than one lesion, typically following Blashcko's lines, extend onto the scalp, and cause permanent cicatricial alopecia secondary to loss of hair follicles. The diagnosis is usually made clinically but can be confirmed with a skin biopsy. Biopsies at early stages reveal an intense inflammatory infiltrate at the margin, and biopsies at later stages reveal waning inflammatory infiltrate with infiltration of lymphocytes and plasma cells at the border and central fibrosis in the lower two-thirds of the dermis and upper subcutaneous tissue and eventually disappearance of pilosebaceous units and eccrine sweat glands and effacement of the rete ridges, similar to the changes seen in SSC. Ultrasound can be used to assess skin thickness which correlates with disease severity. Table 1 summarizes the comparative features of alopecia in lupus, dermatomyositis, and scleroderma.

Fibromyalgia

Fibromyalgia is thought to be a functional somatic syndrome caused by alterations in central nervous system's pain processing. It is characterized by chronic generalized musculoskeletal pain, fatigue, and multiple tender points at

Alopecia in Systemic Autoimmune Disease, Table 4 Alopecia due to medications used to treat systemic autoimmune disease and fibromyalgia[a]

Associated medications
Citalopram
Cyclophosphamide
Danazol
Fluoxetine
Fluvoxamine
Gold
IFN alpha
IVIG
Leflunomide
Methotrexate
Mycophenolate mofetil
Phenytoin
Tacrolimus
Venlafaxine

[a]Many drugs that are currently used to treat systemic autoimmune disease have been reported to cause alopecia. The medication-induced hair loss is usually diffuse and non-scarring. The hair loss is usually limited to the scalp. Women are more commonly affected than men

specific soft tissue locations. There is typically no evidence of joint or muscle inflammation on physical examination or laboratory testing. Fibromyalgia is currently considered to be the most common cause of widespread musculoskeletal pain in women between 20 and 55 years of age. The prevalence is approximately 2 % and increases with age. Fibromyalgia may coexist with other inflammatory rheumatic diseases, such as SLE which can cause non-scarring or scarring alopecia. The medications that are used in the treatment of fibromyalgia can also cause alopecia. Tricyclic antidepressants including amitriptyline and desipramine can be associated with alopecia. Serotonin reuptake inhibitors, particularly fluoxetine and citalopram, can rarely (<1 %) cause alopecia (Table 4).

Inflammatory arthritis animal model

Definition

Rheumatoid arthritis is the most common form of inflammatory joint disease and is characterized by synovial hyperplasia, immune cell infiltration, pannus formation, cartilage destruction, and bone erosion. A variety of animal models of arthritis have been established, including those that involve the injection of TNF-alpha, proteoglycan, adjuvant, antibody, or collagen. These animal models demonstrate synovitis, pannus formation, bone and cartilage destruction, as well as other features observed in human rheumatoid arthritis. They provide a useful platform to investigate the pathogenesis and determine the effects of novel therapies for rheumatoid arthritis.

Rheumatoid Arthritis

Rheumatoid arthritis is the most common form of inflammatory arthritis and is characterized by synovial hyperplasia, immune cell infiltration, pannus formation, cartilage destruction, and bone erosion (Feldmann and Maini 2003). In the inflamed synovial membrane, highly prevalent cells include T cells and macrophages, while fibroblasts, plasma cells, endothelium cells, and

dendritic cells are present in lesser numbers. In the synovial fluid, the predominant cell is the neutrophil. Bone destruction is a remarkable feature and caused by bone resorption increasing more than bone formation.

Although the etiology and pathogenesis of rheumatoid arthritis are not yet fully understood, cytokines such as TNF-alpha, interleukin (IL)-1, IL-6, and receptor activator of NF-KB ligand (RANKL) are known to be involved in disease progression. Evidence demonstrates that TNF-alpha plays a crucial role in the pathogenesis of rheumatoid arthritis. TNF-alpha can stimulate osteoclastogenesis (Deng et al. 2005) and osteoclasts are crucial cells in bone destruction. In animal models of RA, intra-articular injection of TNF-alpha can induce arthritis directly (1), TNF-alpha transgenic mice spontaneously develop arthritis in multiple joints, and anti-TNF treatment inhibits development of arthritis. Meanwhile, TNF-alpha-deficient mice are resistant to the development of arthritis. Thus, TNF-alpha is an important therapeutic target in rheumatoid arthritis. Currently, a number of anti-TNF medications are highly effective in the treatment of rheumatoid arthritis (Feldmann and Maini 2003).

To gain insight into the etiology, pathogenesis, and response to therapy, a variety of animal models of rheumatoid arthritis have been established.

Animal Models in Rheumatoid Arthritis

Collagen-Induced Arthritis

Collagen-induced arthritis (CIA) is the most commonly used animal model of rheumatoid arthritis (Deng et al. 2005). Arthritis is induced by immunization of mice, rats, and monkeys with various cartilage proteins after tolerance is broken and an immune/inflammatory response is directed against the joints. The most commonly used immunogen is type II collagen which is injected in DBA/1J mouse. Chicken collagen type II emulsified with an equal volume of complete Freund's adjuvant with 0.1 ml of emulsion containing 100 μg of type II collagen is intradermally injected at the base of the tail of male DBA/1J mouse. A booster injection of 100 μg of type II collagen emulsified with an equal volume of incomplete Freund's adjuvant is administered to the mouse 21 days after the first immunization. The extent of arthritis is determined by evaluating clinical and histological scores. CIA is a well-controlled and reproducible model for RA.

Clinical Evaluation of Arthritis: Joint swelling is determined by measuring the thickness of the paws with a caliper. Clinical arthritis is assessed using the following scale: grade 0, no swelling; grade 1, slight swelling and erythema; grade 2, pronounced swelling; and grade 3, joint rigidity. Each limb is graded with a score of 0–3, with a maximum possible score of 12 for each mouse.

Histological Examination of Arthritis: After routine fixation with 10 % formalin, decalcification, and paraffin embedding of the joint tissue, joint sections are cut and stained with hematoxylin and eosin. The extent of synovitis, pannus formation, or bone and cartilage destruction is evaluated. A scale is used as follows: grade 0 (no signs of inflammation), grade 1 (mild inflammation with minimal hyperplasia of the synovial lining layer without cartilage destruction), and grades 2 through 4 (increasing degrees of inflammatory cell infiltrate or cartilage and bone destruction).

Adjuvant-Induced Arthritis

Adjuvant-induced arthritis (AIA) was the first animal model for RA (Conway et al. 1995). Male Lewis rats are injected with Freund's complete adjuvant which is prepared by adding 100 mg *Mycobacterium tuberculosis* to 15.6 ml heavy paraffin oil followed by addition of 1 ml saline. The mixture is then emulsified by pulsing for 5 min with a polytron. Each rat is injected intradermally at the tail base with 300 μg of *Mycobacterium* in a 0.05-ml volume. Paw inflammation is quantified by measuring paw diameter with calipers. The AIA model is useful in preclinical studies to evaluate drug efficacy, particularly for drugs that interfere with T cell function.

Antibody-Induced Arthritis

K/BxN mice express a transgene-encoded T cell receptor (TCR) that is reactive to a self-peptide derived from the ubiquitously expressed enzyme glucose-6-phosphate isomerase (GPI), presented by the MHC class II molecule. K/BxN mice spontaneously develop arthritis with many features similar to RA (Ji et al. 2001). Transfer of serum from arthritic K/BxN mice into healthy non-transgenic animals induces arthritis in a highly reproducible fashion. K/BxN serum pools are prepared from arthritic mice at 60 days of age. Arthritis is induced in diverse recipients by intraperitoneal injection of 7.5 µl serum per g weight diluted in 200 µl total volume at days 0 and 2. A major attraction of this model is to focus on the inflammatory effector phase of disease, without the complicating influences of the autoimmune initiation phase.

Proteoglycan-Induced Arthritis

Proteoglycan (PG)is isolated from cartilage of osteoarthritic patients undergoing joint replacement surgery (Glant et al. 2011). Mice are immunized with PG, 100 µg PG core protein emulsified with 2 mg dimethyl-dioctadecyl ammonium bromide (DDA) adjuvant in phosphate-buffered saline. Mice are immunized intraperitoneally on days 0, 21, and 42 with human cartilage PG emulsified in the synthetic adjuvant DDA. Arthritis severity is determined using a visual scoring system and histological examination. In the mice, such as C57BL/6J and BALB/c, female mice are more susceptible than male mice.

TNF-Induced Arthritis

Intra-articular injection of TNF-alpha induces arthritis (Deng et al. 2005). TNF-induced arthritis is useful for testing the effects of TNF inhibiting biologics. Prior to intra-articular injection, mice and rats are anesthetized with mixture of Hypnorm, Dormicum, and distilled water (1:1:2) and placed on a clean table. After disinfection of the injection area, TNF in 20 µl of PBS is injected intra-articularly into the knee joint. The mice are sacrificed and joints are removed for histopathological examination 3 days after intra-articular injection.

Human TNF-Alpha Transgenic Mice

Transgenic mice overexpressing the human TNF-alpha gene spontaneously develop arthritis (Keffer et al. 1991). A transgenic (Tg) mouse overexpressing human TNF-alpha has been generated. The TNF-Tg mouse develops an erosive polyarthritis with many characteristics of rheumatoid arthritis patients. The TNF-Tg mice are useful tools for dissecting the molecular mechanisms of the pathogenic process and evaluating the efficacy of novel therapeutic strategies for rheumatoid arthritis.

Definition

Human autoimmune hepatitis (AIH) is characterized by specific autoantibodies, elevation of serum aminotransaminases and gamma globulins, liver histopathology suggestive of AIH, and exclusion of other chronic liver diseases. The disease requires lifelong immunosuppression in most cases. Due to limited knowledge about the onset and course of disease, because of the late diagnosis, the limited availability of liver tissue and the required chronic immunosuppression with potentially severe side effects, there is strong need for suitable animal models that reflect AIH.

Introduction

Autoimmune hepatitis (AIH) is a severe and chronic autoimmune inflammation of the liver. The disease is normally diagnosed during advanced stages of disease. Therefore, knowledge about the onset and development of disease is very limited. Therapeutic intervention involves the restricted use of steroids that causes significant side effects. For this reason, there is an urgent to develop a suitable animal model that mirrors the main diagnostic criteria and course of AIH. The diagnostic criteria for AIH can be grouped into clinical, histological, and laboratory evidences.

Disease manifests more often in younger patients with an additional genetic prevalence for females in AIH. In addition to sex and age, some genetic factors predispose to AIH. These include MHC (Czaja et al. 1993), CTLA-4 (Djilali-Saiah et al. 2001), and TNF-α (Cookson et al. 1999) polymorphisms.

Environmental factors have also been suggested to be critical for the initiation of AIH. But due to the time lag between onset and diagnosis, it is difficult to conclude that infections preceding the diagnosis of AIH started liver autoimmunity. In the majority of patients, the induction of AIH has not been linked to a single environmental agent. The course of AIH is chronic and requires therapeutic intervention. 80–90 % of the patients can be treated with a life-long standard treatment regime using steroids, often in combination with azathioprine.

Diagnosis of AIH requires excluding other liver diseases such as PBC, PSC, and viral hepatitis. Histological features suggestive for AIH include lymphoplasmacellular portal infiltrates with interface hepatitis as well as intralobular inflammation.

Diagnosis of AIH is generally confirmed by histopathology and by testing the serum for elevated serum aminotransferases, increased IgG, and autoantibodies that allow differentiation into two clinical subtypes (AIH type I or type II).

An ideal mouse model of AIH should reflect these disease-specific criteria. Unfortunately, most mouse models of AIH display some aspects of liver-specific immunity without developing chronic autoimmune hepatitis.

Acute Liver Damage Induced by Cytokines

Treatment of mice with the ConA lectin leads to polyclonal antigen-independent activation and proliferation of T cells associated with a hepatic

cytokine storm that resulted in severe liver damage with transient elevated aminotransaminases (Tiegs et al. 1992). The inflammatory cytokines IFN-γ and TNF-α have been shown to be critical in ConA-induced liver damage. Neutralizing antibodies against IFN-γ or TNF-α prevented hepatic injury. In this model, $CD8^+$ T cells triggered severe inflammation that led to apoptosis of hepatocytes and fulminant hepatic failure (Tiegs 1997). Intrahepatic $CD4^+$ T cells and macrophages were responsible for the release of T_H1 cytokines (Gantner et al. 1996).

The ConA model explains the role of adaptive and innate immune cells in the liver such as LSEC and NKT cells. LSEC bind ConA preferentially and become targets of $CD4^+$ T cells resulting in their destruction (Knolle et al. 1996). There is strong evidence that FasL-expressing NKT cells are crucial for ConA-induced liver damage. Mice lacking CD1 showed a severe reduction of NKT cells due to the loss of the invariant NKT subpopulation. ConA-mediated hepatic injury was not observed in CD1-deficient mice (Takeda et al. 2000) but could be restored following adoptive transfer of intrahepatic NKT cells.

Thus, the ConA hepatitis model is a model of acute liver injury mediated by a cytokine storm associated with a strong T_H1 response but is not a model of chronic and progressive AIH.

Breaking Liver Tolerance by Immunization

Immunization of mice with liver extracts provided the first evidence that liver tolerance could be broken in mice. Many important and seminal studies with various immunization strategies and antigens were conducted in different mouse strains and have been discussed in detail elsewhere (Jaeckel 2002).

In a series of studies, Mori et al. (Mori et al. 1984) showed that C57BL/6 mice immunized with a syngeneic supernatant of liver homogenate centrifuged at 100 kg were more susceptible to experimental hepatitis than other mouse strains suggesting an important role of the genetic background. Adoptive transfer of LPS-treated activated splenocytes from these recipients to naive recipient mice transferred autoimmunity. This effect was only observed when splenocytes contained T cells, demonstrating the critical role of T cells in the development of AIH.

Lohse et al. used a modified protocol to confirm that the C57BL/6 strain was more susceptible to develop experimental AIH than other strains (Lohse et al. 1990, 1992). In addition, these authors observed a slight increase in serum aminotransferases. The disease could also be adoptively transferred to new recipients by activated splenocytes. But autoantibodies in the serum of recipient animals displayed different specificities than those described in the serum of AIH patients. The group confirmed also the paramount role of T cells in disease histology and pathology and showed that some T cells recognized hepatocyte-expressed antigens. In addition, they demonstrated that splenocytes isolated from mice developing experimental AIH developed some antigen-dependent and independent regulatory properties.

The immunization-induced AIH models brought new insights into the role of the genetic background in disease susceptibility and the critical role of T cells in the onset of hepatitis. Additionally, these studies revealed for the first time the regulatory function of leukocytes in hepatic tolerance and suggested that this regulation is critical to explain the chronic relapsing course of human AIH.

Transgenic Animals in Autoimmune Hepatitis Research

Transgenic models have been used to model AIH. In most models, transgenic mice expressing well-defined neoantigens in the liver were crossed with transgenic mice expressing a T cell receptor specific for the liver-expressed antigen. These models have several advantages over the models described above: (i) liver injury is mediated by T cells rather than cytokines, (ii) the T cell subset responsible for hepatitis is monoclonal rather than polyclonal, and (iii) the

autoantigen is known. However, a key problem in this type of models is that most of liver-specific neoantigens are also expressed in thymus thereby leading to negative selection of antigen-specific transgenic T cells (Klein and Kyewski 2000).

Jones-Youngblood et al. expressed a transgenic MHC I-like molecule Q10 in the liver (Jones-Youngblood et al. 1990). Transgenic mice did not develop spontaneous hepatitis, and liver damage could not even be observed by priming these mice with APCs expressing the Q10/H-2L^{d} fusion protein. Although cross-reactive CD8^{+} T cells recognizing the fusion protein were detected in transgenic mice, their proliferative capacity was reduced compared to CD8^{+} T cells from wild-type mice. T cells isolated from naive, non-transgenic mice caused periportal infiltrates after activation and adoptive transfer into Q10/H-2L^{d}-transgenic recipient mice. Although these results suggest that Q10/H-2L^{d} neoantigen expressing hepatocytes induced tolerance to antigen-specific T cells (Jones-Youngblood et al. 1990), anergy and thymic tolerance could not be excluded.

Similar results were obtained in transgenic mice expressing the allo-MHC molecule H-2K^{b} in hepatocytes (Morahan et al. 1989). Transgenic mice irradiated and reconstituted with non-transgenic bone marrow did not develop hepatitis (Morahan et al. 1989). However, adoptive transfer of non-transgenic lymphocytes into transgenic recipients resulted in severe hepatitis that lasted for up to three months, suggesting that neoantigens could act as alloantigens (Morahan et al. 1989).

Chisari and colleagues obtained similar results in transgenic mice expressing the surface antigen of the hepatitis B virus in hepatocytes (Moriyama et al. 1990). While transgenic mice did not develop hepatitis spontaneously, the transfer of primed non-transgenic T cells into HBV-transgenic mice expressing the neoantigen on hepatocytes caused elevation of serum amino-transferases, antigen-specific autoantibodies, and lymphatic liver infiltrates. Interestingly, the transfer of serum alone induced a mild hepatitis flair. Although this model allows to study the pathogenesis of CD8^{+} T cell-mediated liver damage, it is not a spontaneous model of AIH. Furthermore it remains unclear which mechanisms induce and maintain tolerance to the neoantigen. As circulating neoantigens were detectable in this model, it is not clear whether tolerance was only mediated by hepatocytes (Moriyama et al. 1990; Wirth et al. 1995) or whether tolerance was induced at other sites.

An interesting study used HLA-DRB1*0301 transgenic "humanized" mice immunized with SLA/LP (Mix et al. 2008), which developed SLA/LP-specific autoantibodies. T cells clones isolated from these mice recognized epitopes overlapping with the human autoantibody recognition site of SLA/LP. Although this model did not mimic human AIH, the results allowed the monitoring of autoreactive T cells in AIH patients using newly developed tetramers.

Bertolino and colleagues followed the fate of adoptively transferred H-2K^{b}-specific CD8 transgenic T cells activated intrahepatically in mice expressing the transgenic MHC I molecule H2-K^{b} in hepatocytes. Although hepatitis developed by recipient mice was short lived, they showed that activated CD8^{+} T cells were specifically retained and activated in the liver but underwent Bim-dependent apoptosis (Holz et al. 2008).

In another model TCR transgenic CD8^{+} T cells recognizing LCMVgp33 in the context of H-2D^{b} ignored the transgenic glycoprotein 33 (gp33) epitope of lymphocytic choriomeningitis virus (LCMV) expressed in hepatocytes under the control of the liver-specific albumin (alb) promoter (Voehringer et al. 2000). This ignorance might be due to ineffective cross-presentation of the gp33 antigen. Infection of mice with LCMV was required to break liver tolerance in this model, resulting in a mild and self-limited hepatitis characterized by elevated serum aminotransaminases.

In one of the most recent studies, ovalbumin (OVA) was expressed under the control of the albumin promoter (Buxbaum et al. 2008). These Alb-OVA mice were tolerant to ovalbumin as a result of intrathymic antigen expression and negative selection of anti-OVA T cells. As observed in other models, adoptive transfer of OVA-specific CD4^{+} (OT-II) and CD8+ (OT-I)

T cells into Alb-OVA mice resulted in self-limited liver inflammation. OT-I cells were required for the development of hepatic infiltrates, while OVA-specific $CD4^+$ T cells were dispensable, but enhancers of the $CD8^+$ T cell driven immune response. Other groups had obtained similar results using other liver-specific promoters (Derkow et al. 2007; Zierden et al. 2010).

The importance of LSECs for liver tolerance induction and maintenance was demonstrated in a series of studies by Knolle and coworkers that will be reviewed in the entry "▶ Liver Sinusoidal Endothelial Cells: Role in Immunity and Tolerance."

In summary, although neoantigen expressing transgenic mouse models pushed our knowledge of liver tolerance and hepatic immunology forward, it is not clear whether they model the response of T cells specific for naturally occurring autoantigens that are expressed to a much lower level than a transgene. In addition, autoreactive T cells have a much lower precursor frequency and a lower affinity to self-antigen than TCR transgenic T cells used in most models.

New Approaches to Develop Preclinical AIH Models

Chronic liver damage is a critical criteria for any AIH animal model. Most transgenic models described above are models of acute hepatitis that never evolved into chronic liver autoimmunity mimicking human AIH.

Most studies focused on T cell-hepatocyte or T cell-LSEC interaction but ignored other critical aspects of AIH such as the impact of genetic background and environmental factors for triggering onset of disease, the role of autoantibodies, regulatory mechanisms, and therapeutic interventions.

So far, only three models achieved a chronic autoimmune hepatitis in mice. Two used transgenically expressed neoantigens (Holdener et al. 2008; Zierden et al. 2010), while the third expressed transiently in the periphery a human alloantigen (Lapierre et al. 2004).

The transgenic neoantigen model described by Zierden et al. mentioned briefly before expressed HA under the control of the liver-specific albumin promoter in mice (Alb-HA). While adoptive transfer of naive HA-specific TCR transgenic $CD8^+$ T cells (Cl4-TCR) into Alb-HA recipients resulted only in transient hepatitis, double-transgenic Alb-HA/Cl4-TCR mice developed chronic hepatitis and hepatic fibrosis (Zierden et al. 2010). Christen and colleagues developed a transgenic model with the human autoantigen CYP2D6 under the control of its own promoter (CYP2D6-tg). While priming of these mice with adenovirus expressing CYP2D6 (Ad-CYP2D6) failed to induce hepatitis, wild-type FVB/N infected i.p. and i.v. with Ad-CYP2D6 develop a chronic form of severe, autoimmune liver damage with subcapsular fibrosis (Holdener et al. 2008). Alvarez and colleagues injected repeatedly intramuscular plasmids coding for CYP2D6-FTCD under a CMV promoter (CMV-CYP2D6-FTCD) and IL-12 in C57BL/6 mice that developed elevated levels of aminotransferases and showed chronic inflammatory infiltrates in the portal tracts, interface hepatitis and necrosis, but no fibrosis (Lapierre et al. 2004).

In addition to chronic liver damage, other clinical, histological, and laboratory criteria are important to reflect human disease. The prevalence of the disease in young individuals and females on one hand and the genetic predisposition for some MHC variants and polymorphisms of other factors on the other hand are two important criteria. While the Alb-HA/Cl4-TCR model results in hepatitis only in male individuals (Zierden et al. 2010), nothing is known about the causality between the genetic background and the Ad-CYP2D6 and the CMV-CYP2D6-FTCD models (Lapierre et al. 2004; Holdener et al. 2008).

The models described here share histologically the lymphoblastic infiltrates. Hepatitis in the Alb-HA/TCR-HA model was described to be fibrotic in the long term, while mice in the Ad-CYP2D6 model developed subcapsular and interlobular fibrosis. The livers of mice with CMV-CYP2D6-FTCD developed necrosis, but no fibrosis. The cellular populations detected in the Alb-HA/TCR-HA model are transgenic

$CD8^+$ T cells. This is in contrast to the polyspecific lymphocytes in the other models. Antigen-specific T cell responses from the polyspecific repertoire were demonstrated in the Ad-FTCD model as well as in the CMV-CYP2D6-FTCD model.

In the clinic, some laboratories use other criteria than pathology to diagnose of AIH. Disease-specific autoantibodies help to rule out other hepatic diseases and allow AIH subclassification. Furthermore, patients with AIH have elevated serum aminotransferases and hypergammaglobuminemia.

The model that used a self-limited adenovirus infection mimicked well the clinical situation (Holdener et al. 2008). Mice have hypergammaglobulinemia, and among the elevated gamma globulins are antigen-specific autoantibodies that recognize the antigen that was used to trigger the disease. None of the models have serum ALT of more than 100U/l after the acute phase during the chronic course of the disease raising the question whether aminotransferases are an adequate readout for chronic mouse models.

AIH mouse models need to be evaluated upon their ability to mirror human disease, to explain mechanisms that are observed in patients and, ideally, to enable preclinical trials that use new therapeutic drugs. The models described in this session fulfill some of these criteria. They will be important to understand the pathophysiology of AIH and might allow the development of AIH-specific therapies.

Definition

Infection by the hepatitis B virus (HBV) and hepatitis C virus (HCV) is limited to humans and chimpanzees. Considerable information about the mechanisms that cause viral clearance, viral persistence, and disease pathogenesis has been obtained in the last few decades using chimpanzees infected with HBV and HCV, smaller animal species (woodchuck, duck, Tupaia) infected with related viruses, as well as transgenic or humanized/chimeric mouse models that replicate the viral life cycles to varying degrees.

Introduction

Hepatitis B virus (HBV) and hepatitis C virus (HCV) are prototypic members of the Hepadnaviridae and Flaviviridae families, respectively, which are unique in their capacity to cause persistent infection, cirrhosis, and liver cancer in humans (Guidotti and Chisari 2006). HBV and HCV are considered noncytopathic viruses, and therefore, immune-mediated events play an important role in the pathogenesis and outcome of these infections. The experimental approaches to HBV and HCV pathogenesis have

been difficult because the host range of these viruses is limited to humans and chimpanzees and because of the lack of small animal models that are readily susceptible to infection. Nonetheless, a great deal of information pertaining to the mechanisms that cause viral clearance, viral persistence, and disease pathogenesis has been obtained in the last few decades, especially thanks to the analyses of the natural history and immunobiology of HBV and HCV in chimpanzees and infection studies with related viruses (such as the woodchuck hepatitis virus, WHV, and the duck hepatitis virus, DHBV) in susceptible species. Additional insight has been gained from multidisciplinary studies in transgenic or humanized/chimeric mouse models that replicate the viral life cycles to varying degrees. A concise summary of the contributions that animal models have given to our understanding of HBV and HCV immunobiology and pathogenesis is provided below.

The Chimpanzee Model

Chimpanzees experimentally infected with HBV or HCV develop transient or persistent necroinflammatory liver diseases that are similar to those observed in humans, although usually less severe and seldom evolving toward cirrhotic or cancerous phenotypes (Guidotti and Chisari 2006; Jo et al. 2011). These animals have been instrumental to dissect intrahepatic events that occur early after virus exposure, events that likely determine the outcome of infection (viral clearance versus viral persistence). Owing to these studies, it is clear that both HBV and HCV replicate and spread throughout the liver noncytopathically and that innate immune responses do not significantly contribute to the control of viremia or to the pathogenesis of liver disease (Guidotti and Chisari 2006). Notably, HBV and HCV are sensed very differently by innate defense mechanisms. HBV acts like a stealth virus remaining virtually undetected until the onset of adaptive immune responses, while HCV readily induces interferons and interferon-responsive genes but appears to be resistant to their antiviral effects (Wieland and Chisari 2005).

Perhaps the most important results obtained in chimpanzees infected by HBV or HCV relate to the pathogenic and antiviral roles that adaptive immune responses play during these infections. Indeed, the beginning of liver injury coincides with the entry of virus-specific $CD8^+$ T cells into the liver of chimpanzees infected by HBV or HCV (Guidotti et al. 1999), and depletion of these cells at the peak of viremia delays the onset of biochemical, histological, and clinical evidence of viral hepatitis (Thimme et al. 2003). Although associated with temporary control of viremia, these $CD8^+$ T-cell responses are usually transient in nature suggesting that, when it occurs, the initial priming and expansion of virus-specific $CD8^+$ T cells does not automatically guarantee sustained viral clearance. Rather, permanent virus control appears to require functional $CD4^+$ T-cell responses that are sustained over relatively long periods of time (Shoukry et al. 2004), indicating that virus-specific $CD4^+$ T cells contribute to disease outcome particularly at the level of $CD8^+$ T-cell induction and the establishment or maintenance of a memory cell pool.

Interestingly, humoral immunity is not kinetically associated with the early phases of HBV clearance in chimpanzees, as HBV-specific antibodies (Abs) emerge in these animals several weeks after resolution of a self-limited infection. The protective function of such Ab response is underlined by the notion that chimpanzees that resolved an acute HBV infection are completely protected from rechallenge (Guidotti and Chisari 2006). The observation that complete viral clearance (viral sterilization) following clinical recovery from HBV infection may never occur in humans (Rehermann et al. 1996) suggests that a sustained and protective Ab response prevents the reemergence of HBV in patients that resolved the infection. In contrast to HBV, studies in HCV reinfected chimpanzees have revealed that Abs are quite ineffective at protecting from reinfection, presumably because the viruses that

originally elicited them were counter selected, and such Abs are no longer protective for concurrent quasispecies. Protective immunity during HCV infection does emerge, however, and it is thought to be a T-cell-mediated process, as indicated by studies in chimpanzees that previously resolved an acute HCV infection. Indeed, it was shown in these animals that preexisting HCV-specific memory $CD4^+$ and $CD8^+$ T-cell responses are essential to protection from persistent HCV infection upon rechallenge (Shoukry et al. 2004).

Altogether, the use of chimpanzees experimentally infected with HBV or HCV has demonstrated that the adaptive immune response to these viruses plays a crucial role in viral clearance and liver disease. It is therefore reasonable to assume that viral persistence following these infections requires that immune responses must be either not induced or deficient or, if present, they must be overwhelmed, counteracted, or evaded.

Surrogate Animal Models of Infection with Related Viruses

As mentioned earlier, the availability of animal species that can be experimentally manipulated and represent natural hosts of HBV-related hepadnaviruses has created opportunity for investigation throughout the years. As a general rule these models are not ideal to study immunological phenomena pertaining to viral pathogenesis, mostly because they are outbred species whose immune system is far from being fully characterized. Nevertheless, relevant information has been produced, and it is briefly summarized below.

The Woodchuck model. Woodchucks are rodents that belong to the group of marmots (Marmota) and are susceptible of infection with the woodchuck hepatitis virus (WHV). Like chimps experimentally infected with HBV, woodchucks experimentally infected with WHV develop transient or persistent liver diseases resembling those observed in HBV-infected humans (Menne and Cote 2007). Moreover, persistent liver disease in these animals is tightly linked to the onset of primary liver cancer (hepatocellular carcinoma, HCC) (Menne and Cote 2007). Because of such similarities, WHV-infected woodchucks have been extensively used to uncover the natural history of virologic responses associated with neonatal or adult infection and to study safety and efficacy of vaccines and antiviral therapies (Menne and Cote 2007). We also owe to WHV-infected woodchucks various basic principles by which hepadnaviruses express their genome, replicate within susceptible cells, and promote hepatocellular transformation (Menne and Cote 2007). Notably, immunological tools determining a number of parameters related to T-cell responses in WHV infection have been introduced in recent years. These reagents allowed confirming results obtained in chimps and eased the evaluation of therapeutic vaccines against chronic hepadnaviral infections (Roggendorf et al. 2010).

The Duck model. The fact that DHBV shares fundamental features with HBV has allowed investigators to take advantage of DHBV-based infection systems to extend our comprehension of the molecular biology of HBV and its infectious cycle. Indeed, a variety of the principles of hepadnavirus replication have been established using DHBV, thanks to the experimental infections of ducks with wild-type and mutant viruses in vivo and in cultured primary hepatocytes, and the development of in vitro systems to study biochemically the intricate mechanism of hepadnaviral replication (Schultz et al. 2004). Although DHBV causes both acute and chronic infections in ducks, this virus does not appear to induce severe liver diseases in its host (Jilbert and Kotlarski 2000), thus limiting somehow the relevance of performing studies related to HBV pathogenesis. As per the woodchuck case, the advent of immunological tools detecting immune responses in DHBV-infected ducks has allowed relevant work pertaining to the evaluation of

preventive and therapeutic vaccines against chronic hepadnaviral infection (Jilbert and Kotlarski 2000).

Other models. Tree shrews (Tupaia belangeri) are non-rodent, primate-like, small animals whose hepatocytes are susceptible to infection with HBV and HCV (Cao et al. 2003). The notion that the extent of viral replication in vivo is usually very low coupled with the poor availability of species-specific immune reagents has limited thus far the use of these animals in studies of HBV or HCV pathogenesis. It is also of note that members of the Flaviviridae family such as the bovine viral diarrhea virus (BVDV) or the classical swine fever virus (CSFV) share a similar structural organization with HCV and cause chronic long-term infections in their respective hosts. Although BVDV and CSFV are not generally utilized to infect cattle or pigs experimentally, the manipulation of these viruses in vitro has helped the dissection of various molecular aspects of the HCV life cycle, and it has been used for the evaluation of antiviral agents (Buckwold et al. 2003).

Altogether, the use of surrogate animal models has certainly contributed to clarify and confirm mechanistically several aspects of viral pathogenesis (particularly HBV pathogenesis) and disease outcome. Future utilization of such models for immunological and immunopathological studies will mostly depend on the capacity/will of the scientific community to better characterize their immune system.

Transgenic, Humanized, or Chimeric Mouse Models

Definitive analyses of the immunological mechanisms involved in HBV or HCV pathogenesis required the development of easy-to-manipulate mouse models with a well-defined immune system. Thus far, a large amount of the cellular/molecular pathogenic or antiviral mechanisms that may occur during viral hepatitis in man has been obtained in transgenic mice replicating HBV at high levels in their liver (Guidotti et al. 1995). Up until recently, the absence of immunocompetent mice replicating HCV has hindered similar analyses in the HCV field. However, the very recent establishment of an immunocompetent humanized mouse model capable of sustaining HCV infection and replication in mouse hepatocytes (Dorner et al. 2011) has the potential to rapidly change this scenario, allowing to confirm/dispute whether pathogenic and antiviral mechanisms relevant to HBV (see below) are also operative during HCV infection. Additional pathogenic insight has emerged from the study of mice whose liver expresses structural and nonstructural HBV or HCV genes individually and from chimeric mice in which human hepatocytes repopulate the liver and support HBV or HCV infection/replication. Results that emerged from the models abovementioned are summarized below.

HBV and HCV transgenic mice. Possibly, the most relevant results obtained in HBV-replication-competent transgenic mice relate to the dissection of highly complex but coordinated processes that regulate the host immune response to this virus. Starting with the fundamental role that effector virus-specific $CD8^+$ T cells play in the pathogenesis of viral clearance and liver disease, it was shown that the adoptive transfer of these cells into HBV-replication-competent transgenic mice triggers a necroinflammatory liver disease which results in the inhibition of HBV replication and shares the same histologic features of acute viral hepatitis in man (Guidotti and Chisari 2006). These studies in mice have also taught us that the antiviral potential of virus-specific $CD8^+$ T cells is largely mediated by noncytolytic mechanisms involving the local production of IFN-gamma by these cells. Indeed, it has been reported that IFN-gamma (mostly via its capacity to induce nitric oxide in the liver) prevents the assembly of replication-competent HBV RNA-containing capsids in the hepatocyte in a proteasome- and kinase-dependent manner (Guidotti and Chisari 2006). During this process, the viral nucleocapsids

disappear from the cytoplasm of the hepatocytes, and the viral RNAs are destabilized by a SSB/La-dependent mechanism in the nucleus, yet the hepatocytes remain perfectly healthy. The notion that IFN-gamma produced by activated $CD8^+$ T cells plays a direct role in viral clearance is corroborated by studies in chimpanzees acutely infected with HBV (Guidotti and Chisari 2006).

As virus-specific $CD8^+$ T cells reach the liver parenchyma, the first step in the disease process is antigen recognition by these cells, which rapidly induces hepatocellular apoptosis. The initial apoptotic process, however, involves a relatively small number of hepatocytes. As time progresses, many antigen nonspecific polymorphonuclear and mononuclear inflammatory cells are recruited into the liver, and they contribute to worsen disease severity (Kakimi et al. 2001). While the recruitment of antigen nonspecific mononuclear cells is mostly a chemokine-dependent event, the recruitment of antigen nonspecific polymorphonuclear cells largely relies on the recognition of hepatocellular damage. Studies have indeed shown that high-mobility group box 1 (HMGB1) protein, an abundant nuclear protein acting as an architectural chromatin-binding factor, can be passively released by necrotic (but not apoptotic) hepatocytes and chemoattract polymorphonuclear cells (Sitia et al. 2011). Notably, the recruitment process of virus-specific $CD8^+$ T cells into the liver is quite different from that of antigen nonspecific inflammatory cells, and it largely depends on platelets capable of becoming activated within the liver microvasculature (Iannacone et al. 2005).

Studies in HBV transgenic mice also helped us in characterizing the immune-mediated basis of hepatocellular transformation during chronic hepatitis. It was shown that the maintenance of low-level liver cell destruction caused by a dysfunctional and detrimental virus-specific $CD8^+$ T-cell response (unable to completely clear HBV antigens from the liver) is sufficient to cause HCC development (Nakamoto et al. 1998). According to these results, chronic viral hepatitis could be viewed as T-cell-dependent premalignant state promoting processes, like hepatocellular regeneration (i.e., cellular DNA synthesis) and inflammation (i.e., production of mutagens) that are oncogenic and result in the random and multiple genetic/chromosomal alterations responsible for HCC development.

Finally, it is worth mentioning that additional information related to how specific HBV or HCV gene products may influence the pathogenesis of these infections has been developed in transgenic mice that hepatocellularly express structural and nonstructural HBV or HCV genes individually. A variety of phenotypes have been reported, and they include mice that spontaneously develop chronic hepatitis, fibrosis, steatosis, cirrhosis, or HCC (Guidotti and Chisari 2006). It must be noted, however, that most of the studies have been obtained in animals that express viral products at levels that are much higher than those detected during natural infection in humans and, therefore, further work needs to be performed in order to understand the relevance of these observations.

Humanized and chimeric mice. As stated above, the absence of immunocompetent mice replicating HCV has held back studies on HCV immunobiology and pathogenesis for a number of years. Interestingly, however, it has been recently shown that the in vivo hepatocellular expression of the HCV coreceptors CD81 and occludin renders fully immunocompetent inbred mice permissive to HCV infection (Dorner et al. 2011). It is expected that this important breakthrough will open important opportunities for studying HCV pathogenesis and immunobiology in the future. As also stated above, different investigators have used chimeric mice in which human hepatocytes repopulate the liver and support HBV or HCV infection/replication (Meuleman and Leroux-Roels 2008). Besides limitations that include high costs, low throughput, and significant individual variability in viral replication levels, the fact that these chimeric mice must be maintained under strict immunocompromised conditions renders them not particularly suited for immunological and immunopathological studies. Whether this model will significantly improve thanks to the simultaneous implantation of a fully functional immune system of human origin remains to be determined.

Concluding Remarks

Our comprehension of the pathogenesis of HBV and HCV infection has significantly advanced in recent years, particularly because of the experimental use of animal models. In spite of these accomplishments, however, many mechanistic issues pertaining to the immunopathogenesis of chronic HBV or HCV infection remain unresolved, especially those that are linked to the development of cirrhosis, steatosis, or cancer. Addressing such issues in animal models will be challenging but certainly important for the design of novel approaches to treat these life-threatening diseases.

Anti-glomerular Basement Membrane Disease

Stephen P. McAdoo and Charles D. Pusey
Department of Medicine, Imperial College Renal and Transplant Centre, London, UK

Synonyms

Goodpasture's disease

Definition

Anti-glomerular basement membrane (anti-GBM) disease, also known as Goodpasture's disease, is a rare but life-threatening condition that is characterized by circulating and deposited antibody directed against the GBM, which presents with features of crescentic glomerulonephritis, with or without concomitant pulmonary hemorrhage.

History

The eponymous term "Goodpasture's Syndrome" was first used by Australians Stanton and Tange (Stanton and Tange 1958) in their 1958 article describing 9 cases of glomerulonephritis in association with pulmonary hemorrhage, in which they acknowledge the American pathologist Ernest Goodpasture with the first description of the syndrome in his 1919 paper on the etiology of influenza (Goodpasture 1919). However, it is not known whether any of these cases had anti-GBM antibodies, as it was not until the development of immunofluorescence techniques in the 1960s that Sheer and Grossman first described the typical linear staining pattern for immunoglobulins in renal tissue seen in this disease. In 1967, Lerner and colleagues showed that these antibodies, eluted from the kidneys of patients, were reactive with normal kidney tissue, and subsequently demonstrated their pathogenic potential by administration to nonhuman primates (Lerner et al. 1967). The first comprehensive clinical report of "anti-GBM disease" was by Wilson and Dixon in 1973 (Wilson and Dixon 1973).

The term "Goodpasture's disease" is now generally reserved for those patients with detectable anti-GBM antibodies in association with renal or pulmonary disease.

Epidemiology and Associations

Goodpasture's disease is a rare disorder, with an approximate incidence of 1 per million population per year. There is a slight male preponderance and bimodal age distribution, with peak incidence in the third and sixth decades. The disease is more common in Caucasian populations, is well represented in Asians, and thought to be rare in those of African origin. Some series have suggested a higher disease incidence in spring and early summer.

Reported environmental associations include cigarette smoking (Donaghy and Rees 1983) and exposure to hydrocarbons and industrial solvents. Associations with other diseases include membranous nephropathy, ANCA-associated vasculitis, and renal stone disease treated with lithotripsy.

In common with other autoimmune diseases, genetic predisposition is believed to be an important determinant of disease development (Zhou et al. 2010), and there is a strong association with human leucocyte antigen (HLA) genes in particular, with approximately 80 % of patients inheriting an HLA-DR2 haplotype. Genotyping studies have revealed a hierarchy of associations with particular DRB1 alleles: DRB1*1501, DRB1*03, and DRB1*04 are positivity associated with disease, whereas there is a negative association with DRB1*01 and DRB1*07 (Fisher et al. 1997). The molecular basis of these HLA associations is not defined, although the observation that the DRB1*01 and DRB1*07 alleles appear to confer a dominant negative effect and that these protective alleles bind peptides from the Goodpasture autoantigen with greater affinity than the positively associated alleles suggests that they might compete for peptide epitopes with the susceptibility alleles.

A link to major histocompatibility complex (MHC) Class II genes has also been reported in murine strains susceptible to experimental disease, although non-MHC genes are also involved since both resistant and susceptible rat strains have been shown to share the same MHC type. In addition, the susceptibility alleles in humans are common in the general population, yet the disease remains exceedingly rare. These observations demonstrate the importance of other, as yet undefined, genetic and environmental factors in the development of disease.

Pathogenesis

Lerner's classic transfer experiments (since repeated in a number of different species) were the first demonstration that autoantibodies could directly cause disease, and the role of humoral immunity and the nature of the target autoantigen have been the predominant focus of historical research interest in this condition. More recent observations, and in particular studies of animal models that manifest a similar pathology, also confirm an important role for cellular immunity, both as orchestrator of the autoimmune response and direct effector of tissue injury.

The Goodpasture Autoantigen

The Goodpasture autoantigen (Pedchenko et al. 2010; Saus et al. 1988; Turner et al. 1992) was first identified as a 27 kDa protein from collagenase-digested GBM preparations, and the key autoantibody target was subsequently defined as the non-collagenous (NC1) domain of the alpha-3 chain of type IV collagen (α3(IV)NC1) found in the basement membrane of the glomerulus and lung (and also retina, choroid plexus, and cochlea). Immunization with either collagenase-solubilized or recombinant forms of the protein from various species induces disease in a number of animal models, confirming the universal antigenicity of this protein.

In its native form, the collagen IV network in the GBM consists of triple-helical protomers of α3, α4, and α5 chains. The carboxy-terminal domains of these α3α4α5 protomers form a trimeric "cap," end-to-end association of which results in the formation of the hexameric NC1 domain (Fig. 1). The quaternary structure of this hexamer is stabilized by hydrophobic and hydrophilic interactions across the planar surfaces of opposing trimers and reinforced by sulfilimine bonds cross-linking opposing NC1 domains. Two key autoantibody epitopes within α3(IV)NC1 have been described, designated E_A (incorporating residues 17–31 towards the amino-terminus) and E_B (residues 127–141 towards the carboxy-terminus), which in the native form are sequestered at the junction with α4 and α5 chains within the triple-helical structure.

Humoral Immunity

Sera from all patients with anti-GBM disease recognize α3(IV)NC1, although sera from a proportion of patients may also recognize other collagen chains. Approximately 70 %, for example, will have both circulating and deposited antibodies to the α5(IV)NC1 domain, suggested to arise through a process of "epitope spreading" following primary disease initiation by autoantibodies to α3(IV)NC1. Circulating and deposited antibodies to α3(IC)NC1 recognize both epitopes E_A and E_B, with one study suggesting that antibodies to E_A are more strongly associated with disease outcome.

In addition to the passive transfer models of Lerner and others, several clinical observations support a directly pathogenic role for these autoantibodies in anti-GBM disease. Antibody titer, immunoglobulin subclass, and in at least one study, antibody avidity have been correlated with disease outcome in patient cohorts. In addition, the rapid removal of circulating antibodies by plasmapheresis is associated with better clinical outcomes, and disease recurs rapidly in renal allografts if circulating antibodies are present at the time of transplantation.

The function of other components of the humoral immune system, such as the Fc receptor

and the complement cascade, has also been implicated in the pathogenesis of this disease. Copy number variation of activatory FcγIIIA genes is found at higher frequency in patients compared with healthy controls, and certain FcγIIB receptor polymorphisms are also present at higher frequency in diseased patients. Similarly, copy number variation of the orthologous FcγRIII genes is a determinant of disease susceptibility in the rat (Aitman et al. 2006). Mice deficient in activatory FcγR are protected from a variety of autoimmune diseases, including glomerulonephritis, and FcγIIB (an inhibitory FcR)-deficient mice are also more susceptible to experimental disease. Classical activation of the complement pathway by immune complexes formed by antigen and antibody has also been shown to contribute to murine models of disease, and mice deficient in C3 and C4 components are resistant to nephrotoxic nephritis.

The presence of low-titer "natural" autoantibodies to GBM has been reported in normal populations (Cui et al. 2010). These antibodies recognize the same epitopes as antibodies from patients, although their presence does not result in disease. This may be due to differences in the titer or predominant subclasses of these natural autoantibodies (IgG2 and IgG4 versus IgG1 and IgG3 in disease) or the role of other regulatory factors. The presence of circulating antibody has

been reported to predate the onset of clinical disease by several years (Olson et al. 2011) (although antibody subclass and epitope specificity was not reported in this study), an observation that suggests the involvement of other factors in the development of disease.

Cellular Immunity

Several clinical observations support a role for cell-mediated immunity. CD4+ and CD8+ T cells can be demonstrated in diseased glomeruli in humans, and the presence of class-switched, high-affinity autoantibody, along with a strong HLA-association, implies a requisite for T cell-mediated help. Mononuclear cells from patients have also been shown to proliferate in response to α3(IV)NC1 (as do cells from healthy individuals, though at much lower frequency), and the frequency of autoreactive CD4+ T cells has been shown to correlate with disease activity. The pathogenic T cell epitopes in humans, however, have not been consistently defined.

Studies in various experimental animal models, particularly in rodents, also implicate cellular immune responses in disease pathogenesis. Resistant mouse strains, for example, may develop circulating antibody following immunization with the autoantigen, yet fail to develop glomerulonephritis, suggesting the need for other factors for the full expression of disease. In certain susceptible mouse strains, passive transfer of autoantibody does not result in disease in T cell receptor deficient animals. Likewise, CD4 and CD8 deficient mice are protected from experimental disease, and in rat models a variety of anti-T cell approaches have ameliorated disease – such as the use of cyclosporine A, monoclonal antibodies against CD4 and CD8, and co-stimulation blockade targeted at CD40-CD40L or B7-CD28 interactions (Reynolds et al. 2000).

Studies in animal models also suggest that cell-mediated immunity may have a significant role as a direct effector of tissue injury, in addition to directing the humoral response. In early avian models, mononuclear cells could transfer disease to bursectomized birds. More recently, B cell (μ-chain) deficient mice have been shown to develop glomerular injury following immunization with α3(IV)NC1 (Dean et al. 2005), and experimental disease in rats has been transferred by CD4+ T cells from nephritic rats expanded in vitro by stimulation with α3(IV)NC1 (Wu et al. 2002). In these experiments, animals developed glomerulonephritis in the absence of detectable antibody, suggesting a directly injurious response by cellular immune effectors. However, there is no direct evidence yet of a similar process in human disease.

Tolerance and Autoimmunity to α3(IV)NC1

α3(IV)NC1 is expressed in human thymus, although the finding of natural autoantibodies and T cells reactive to α3(IV)NC1 in normal individuals suggests some failure to achieve central tolerance to this antigen during immunological development. It has been suggested that certain autoreactive T cell peptides are sensitive to rapid enzymatic degradation during antigen processing, limiting the exposure of autoreactive cells to their corresponding antigens and thus allowing them to escape negative selection (Zou et al. 2007). The additional factors that result in further breakdown of tolerance and development of clinical disease are not clear, though may include the need to expose sequestered epitopes within the Goodpasture antigen.

Notably, the cross-linked native hexameric NC1 domain does not bind antibody, and it is thought that disruption of its quaternary structure, with rupture of the sulfilimine cross-links and dissociation of the hexamer, is required to expose the pathogenic epitopes required for autoantibody binding. Both cross-linked and non-cross-linked forms of the hexamer exist in humans and other primates, but only the cross-linked form in mice, perhaps explaining the resistance of some mice strains to passive transfer models of disease. This requirement for "conformational transition" of the autoantigen may also explain the association of anti-GBM disease with other processes

that may damage the basement membrane in the kidney (such as membranous nephropathy, ANCA-associated disease, or lithotripsy) or the lung (such as smoking and inhalation of hydrocarbons), resulting in exposure of usually sequestered epitopes.

The recovery phase of this condition is associated with a progressive fall in autoantibody titer (even in the absence of immunosuppressant treatment) and a lower frequency of CD4+ T cells reactive to α3(IV)NC1, along with development of a regulatory CD25+ T cell subset that may suppress responses to α3(IV)NC1 (Salama et al. 2003). This suggests the re-emergence of immunological tolerance, which may be reflected by the rarity of clinical relapses in this condition.

Clinical Considerations

The great majority of patients will present with features of rapidly progressive glomerulonephritis, which is characterized by an abrupt decline in renal function with an active urinary sediment containing protein and red cell casts. There are a small number of reported cases, however, with only mild renal impairment. Approximately 50 % of patients will have coexistent pulmonary hemorrhage, which may present with hemoptysis and be seen as alveolar shadowing on chest radiography or detected by the finding of an increased carbon monoxide transfer factor. A small number of patients may present with isolated lung disease in the absence of overt renal pathology.

Strictly, the diagnosis of anti-GBM disease rests on the demonstration of:

(a) Circulating anti-GBM antibodies – these are detectable in the majority of patients by conventional techniques such as enzyme-linked immunosorbent assay (ELISA) and Western blotting using purified human or animal GBM preparations. In the small proportion of patients who do not have detectable antibodies using these methods, more sensitive techniques such as biosensor assay using recombinant antigen have been reported to detect circulating antibody.

(b) Deposited anti-GBM antibodies – seen as linear deposits of IgG along the GBM by immunofluorescence techniques (Fig. 2a). The majority of patients will also demonstrate linear staining for complement C3 and some for other antibody isotypes, such as IgA and IgM.

(c) Crescentic glomerulonephritis – seen on standard light microscopy of renal tissue (Fig. 2b). Fibrinoid necrosis may be present. The finding of monophasic injury, where all glomeruli show lesions of similar acuity, is typical.

Standard treatment for anti-GBM disease, first introduced in the 1970s (Lockwood et al. 1976), consists of plasmapheresis, to rapidly remove the pathogenic antibody (and possibly other proinflammatory mediators) from the circulation, and immunosuppression with cyclophosphamide and corticosteroids, which inhibit the production of further autoantibody and reduce end-organ tissue inflammation and damage. Retrospective series suggest this combination of treatment is effective in most patients with serum creatinine <500 micromol/l at presentation, and one large study showed it can be successful even in patients who present with severe renal injury (creatinine >500 micromol/l) but not yet on dialysis (Levy et al. 2001). In the same study, lung hemorrhage responded to treatment in 90 % of patients. One small trial suggested better recovery of renal function when plasmapheresis was used in addition to drug therapy (Johnson et al. 1985); however, given its rarity (and the efficacy of accepted treatments), there are no large randomized controlled trials in this disease. The use of alternative immunosuppressant agents (such as cyclosporine, mycophenolate mofetil, or rituximab) has been reported in small series and individual cases, although there is insufficient evidence to support their use as first-line treatment at present. Poor prognostic features include dialysis dependency at diagnosis and 100 % crescents on renal biopsy, which suggest the patient will not recover independent renal function.

Alport Syndrome and Transplantation

The Alport syndrome of progressive renal disease and deafness has been attributed to mutations in any of the three genes which encode the α3, α4, or α5 chains, resulting in a failure to produce the normal type IV collagen network present in the GBM. The most common mutation is in the COL4A5 gene located on the X chromosome, giving the typical X-linked disease. These patients may develop end-stage renal failure requiring renal transplantation. Of these, approximately 5–10 % will develop anti-GBM antibodies post-transplant, due to the development of an alloimmune response to "normal" α3 or α5 chains within the renal graft, seen as a neo-antigen to the recipient immune system. These antibodies do not recognize the individual E_A and E_B epitopes recognized by sera from Goodpasture patients, but rather a composite epitope that is not sequestered within the native hexamer. The development of Goodpasture's disease in this context often results in loss of the renal allograft, and repeated transplantation will invariably lead to disease recurrence and graft loss.

Antioxidants

David A. Lawrence
Laboratory of Immunology, Wadsworth Center, New York State Department of Health, Albany, NY, USA

Synonyms

Electron donors; Molecules capable of blocking or reversing the oxidation of other molecules; Reducing agents; Thiols, such as glutathione and cysteine

Definition

Antioxidants are molecules that inhibit the formation of oxidative products and prevent or reverse the actions of oxidants. Antioxidants can be exogenous or endogenous small molecules such as N-acetylcysteine and glutathione, respectively, that can neutralize the presence or block the production of oxidants; enzymes that modify the levels of oxidants such as superoxide dismutase, glutathione peroxidase, and catalase; and enzymes that synthesize or regenerate reducing agents, such as γ-glutamylcysteine ligase and glutathione synthase and glutathione reductase, respectively.

Introduction of Reduction-Oxidation (Redox) and Immunity

Although lymphocytes have been known to be more sensitive to oxidative stress than many other cell types, the subcellular mechanisms responsible for their sensitivity and for the differential oxidative sensitivities among the lymphoid and myeloid subsets have not been fully elucidated. There is an extensive amount of literature that documents a decline in the immune capacity of older individuals (>65 years), especially with regard to a loss or dysregulation of T cell functions (Murasko and Goonewardene 1990; Ben-Yehuda and Weksler 1992). Likewise, there have been numerous theories and reports that link aging with oxidative stress (Sohal and Orr 1992; Harman 2006). Oxidative stress is a consequence of an excess of oxidants, such as reactive oxygen species (ROS), and/or a deficit of antioxidants. However, oxidative stress does not equally affect all antioxidants at equivalent rates, e.g., the most abundant antioxidants in plasma are cysteine and glutathione (GSH), and both are converted to their oxidized partners (cystine and glutathione disulfide, GSSG) by the increase in oxidative stress that occurs with age, but the loss of cysteine and GSH occurs at different rates. Oxidative stress can modify DNA/RNA, protein, carbohydrate, and lipid structure and function, and reduction-oxidation (redox) processes play important regulatory roles in cellular signaling, proliferation, and apoptosis. Aging and the concomitant immunosenescence are likely due to genetic and environmental causes. However,

oxidative stress and inflammatory processes, which are closely connected, are associated with disorders that accompany aging, including immunopathologies. Thus, the prevalence of immunopathologies, such as rheumatoid arthritis, multiple sclerosis, and leukemias, is a posited consequence of age-related redox changes.

Depletion of cellular thiols can result in immunomodulation due to a restructuring of plasma membrane (PM) lipids and proteins (surface receptors and their signal transduction circuits) of lymphocytes and antigen-presenting cells (APC), which may alter early signal transduction events (Go to G1) associated with APC-T cell interactions and subsequent events, including proliferation and the production of different types of cytokines. Depletion of cellular thiols (changes of the thiol-reactive proteins and nonproteins, such as cysteine and GSH) results in immunomodulation with lowered antigen-specific lymphocyte responses, but with an elevated level of some innate immune responses causing inflammation with elevations of inflammatory cytokines (interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)α), as a result of signaling changes that occur with age. Cellular thiol proteins can influence membrane lipid domains (Bergman et al. 1984), membrane lipids can influence the number of cellular thiols (Schacter et al. 1983), and oxidative stress can directly alter the lipid composition of the PM via lipid peroxidation (Hu and Tappel 1992; McIntyre and Hazen 2010). All of these actions are directly or indirectly related to inflammatory processes. Endogenous antioxidant melatonin and dietary antioxidants, including vitamin E (tocopherols) and lipids, such as eicosapentaenoic acid, docosahexaenoic acid, and γ-linolenic acid have modulatory effects on the generation of lipid peroxides due, in part, to their lipophilic nature. The differential compartmentalization of endogeneous and dietary antioxidants, cellular thiols, and the enzymes (Go and Jones 2008), including thioredoxins (Trx1 and Trx2), glutaredoxin, and peroxiredoxins, that influence ROS and protein and nonprotein thiols and the dependent and independent relationships between these redox modifiers (molecules that regulate reduction-oxidation reactions) are the complexities that delay understanding of antioxidant influences on immunity. However, it is clear that redox pathways (thiol/disulfide exchange reactions) play a key role in immune cell activities and survival (Perl et al. 2002), e.g., signaling molecules apoptosis signal-regulating factor-1 (Ask-1), nuclear factor-2 (Nrf2), and nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) are regulated differentially by Trx1 and GSH (Go and Jones 2008).

Thiol Levels Differentially Affect T Cell Subset Activation

The topographical distribution of surface molecules, such as the T cell antigen-specific receptor (TCR), the CD3 complex, and CD4 and their association with the lipid domains of the PM have been suggested to influence signal transduction events such as the activation of phospholipase Cγ1 (PLCγ1), which has a thiol-sensitive membrane association (Kanner et al. 1992). The heterogeneous complex which has received much attention in T cell activation has been that of the TCR molecule (α/β chains) and the CD3 complex, which consists of multiple polypeptide chains (γ/δ/ε/ζ). Surface expression of the disulfide-linked homodimer of CD3ζ (CD247) is especially sensitive to oxidative stress, and it is the main signaling peptide of the CD3 complex via the tyrosine kinase ZAP-70. CD4 (monomer or disulfide homodimer) or CD8 (a disulfide heterodimer) also is closely associated with this complex within a "lipid raft" (a plasma membrane region with a higher concentration of cholesterol, sphingolipids, and saturated lipids), in that anti-CD4 or anti-CD8 have been shown to provide substantial proliferative signals only when cross-linked with antibodies to the TCR/CD3 complex. The conformation of the protein transmembrane domains of the TCR/CD3/CD4 or CD3 complex affects their association with intramembrane enzymes and the lipid-lipid domains. CD4 and CD3, which during activation are intimately associated with

TCR, usually undergo phosphorylation and internalization after T cell activation, due to their proximity to specific transmembranal and/or cytoplasmic kinases. These topographical changes with T cell activation are dependent on cellular thiols.

Protein functions can be altered by interconversions of their sulfhydryls (−SH), intra-, or interchain disulfides (−S-S-) with each other. A good example is the surface expression of CD4, in that the disulfide-linked CD4 homodimer signals better than the monomer (Maekawa et al. 2006). It also has been suggested that lck, another tyrosine kinase involved in T cell activation, is associated with thiols on the cytoplasmic C-terminal end of CD4. Thus, T cell activation involves numerous protein-protein interactions that can be influenced by redox modifications of cellular thiols. Domain effects dependent on the structure and location of costimulatory molecules, such as CD4 and CD3ζ, may influence the preferential activation of a T cell subset, in that there have been reports that Th1 and Th2 cells require the expression of distinct costimulatory signals from molecules in addition to class II-bound peptide on APCs (Weaver et al. 1988). CD30 expression by T cells was thought to be a specific marker of Th2 cells, but recent evidence suggests it is expressed by Th1 and Th2 cells but is expressed longer by Th2 cells. When released as soluble (s)CD30 during inflammation/oxidative stress, sCD30 affects the Th1/Th2 balance by binding to CD30, which is a receptor for Trx1. CD30 interaction with CD30L (CD154) leads to enhancement of Th1 cell activity. However, sCD30 blocks CD30/CD154 and affects the oxidoreductase activity of Trx1, which can affect the level of IL-12 (a disulfide-linked heterodimer of p40 and p35), the promoter of Th1 development, and p40, which blocks IL-12 activity. Thus, sCD30 can promote Th2 activity indirectly via redox effects on cytokine expression (Contasta et al. 2010). Th1 and Th2 cells also differ with regard to galectin-9 binding, which preferentially causes apoptosis of Th1 cells and enhances Th2 chemotaxis. These differences also relate to redox effects, in that galectin-9 binds to cell surface protein disulfide isomerase (PDI), a protein that promotes sulfhydryl-disulfide interchanges (Bi et al. 2011). It is surface expression of PDI that aids HIV infection of CD4 T cells. As with antioxidant changes during oxidative stress, not all immune activities uniformly undergo changes with age, in that $CD8^+$ T cells decline more rapidly than $CD4^+$ T cells, and Th2 cells become hyperactive in some older individuals. It is interesting to note that HIV-seropositive individuals progress to acquired immunodeficiency syndrome (AIDS) more readily when IL-4 levels (produced by Th2 cells) predominate over IL-2 (produced by Th1 cells). Within the mouse (M) AIDS model system, upregulation of Th2 activity also occurs. Interestingly, the activity and survival of regulatory T (Treg) cells are less sensitive to oxidative stress than effector T cell subsets due to their expression of Trx1 (Mougiakakos et al. 2011). The described differences in T cell subset sensitivities highlight the fact that many aspects of redox processes remain unresolved and many of the redox processes at the cell surface and intracellular affect immunity and involve protein and nonprotein antioxidants.

Oxidant/Antioxidant Effects on APC Modulation of the Th1/Th2 Balance

Oxidative stress on APC (macrophages (Mp) and possibly dendritic cells (DC)) allows Th2 development to predominate. This outcome may involve Trx1 effects on the level of IL-12 and p40, as discussed earlier, as well as a differential stimulation potential by APC dependent on their amounts of GSH. APC that preferentially activate Th1 and Th2 cells have been referred to as classically activate Mp, M1 cells, or redMp (Mp with a higher reductive capacity than oxMp) and alternatively activated Mp, M2, or oxMp, respectively. The differential redox capacities of redMp and oxMp are related to the higher amount of GSH in the redMp (Murata et al. 2002). IL-4, a cytokine promoting Th2 activities, can lower the GSH level of Mp, thus enhancing the number of oxMp. These GSH influences on Mp further implicate thiol chemistry in

immunomodulation. It is not unexpected that Mp would be more resistant to oxidative stress than lymphocytes since they produce oxidants. Many accessory characteristics of monocytes (production of IL-1, IL-6, and TNFα and expression of ICAM-1, LFA-3, and MHC class II) from healthy older humans do not change with age although the T cells from the elderly respond less well to PHA and the monocytes from the elderly provided less help to young T cells in response to PHA. Thus, the lack of monocyte aid may relate more to redox than cytokine assistance. Th2 cells seem to be more dependent on factors such as IL-1, which appears to be in agreement with inflammatory Mp having less GSH and being better able to activate Th2 cells. Similar to the influence of GSH on the Th1/Th2 balance controlled by Mp, the GSH levels of DC affect Th1 versus Th2 activation; however, with DC, the balance is affected by IL-27 (Kamide et al. 2011). IL-27 preferentially promotes development of Th1 cells, and like IL-12, IL-27 is a disulfide-linked heterodimer of Epstein-Barr virus (EBV)-induced gene-3 (EBI-3) and p28 (IL-30), which resemble p40 and p35 of IL-12, respectively. IL-23 is another disulfide-linked heterodimer composed of p40 (IL-23 and IL-12 share the same molecule) and p19, which resembles the p35 of IL-12. IL-23 affects development of a third $CD4^+$ effector T cell (Th17). As for IL-12, IL-23 activity is inhibited by p40. Thus, redox modifications can directly affect immune cells or indirectly affect immune cell development and function by altering the structure of regulatory cytokines.

Thiols and Aging: Early Signal Transduction Events

As mentioned earlier, antioxidants function differently in different cellular compartments. Furthermore, even at a particular location, not all antioxidants may function similarly. Even when the GSH level is lowered with the inhibition of γ-glutamylcysteine synthesis by L-buthionine-S,R-sulfoximine (BSO, a specific γ-glutamylcysteine ligase inhibitor), 2-mercaptoethanol (2ME, a potent reducing agent) is unable to support concanavalin A (ConA)- or phytohemagglutinin (PHA)-induced proliferation of human T cells. Under atmospheric oxygen conditions, 2ME is required for proliferation of mouse, but not human, lymphocytes. Mouse lymphocytes have less GSH than human lymphocytes, and mouse and human lymphocytes have other known thiol-related differences, e.g., mouse cells contain 50 % of the γ-glutamyl transpeptidase activity of human lymphocytes. In addition, ConA stimulation of human lymphocytes increases the transpeptidase activity, while the activity within mouse lymphocytes further declines.

The loss of proliferative ability with aging does not always correlate with a loss in the ability to produce IL-2. Although in vitro activation of T cells from the elderly generally results in less IL-2 production in comparison to T cells from young individuals, this deficit can be overcome by pre-culture of the peripheral blood mononuclear cells (PBMC), boosting with a vaccine, or hormone treatment. However, overall activation as measured by proliferation (DNA synthesis) usually remains depressed with PBMC from the elderly. It is interesting to note that as posited for the depressed lymphoproliferative response of PBMC from older donors, the lymphocytes from human immunodeficiency virus (HIV)-infected individuals have an elevated level of oxidative stress, in terms of lower amounts of GSH and other antioxidants. The additive oxidative effects of aging and HIV infection could be an explanation for why the onset of AIDS in older individuals appears to be more rapid. Non-HIV-infected "young" T lymphocytes depleted (90 %) of GSH by BSO also are unable to synthesize DNA (progress through S-phase) after ConA stimulation; however, cellular activation events are not inhibited in these GSH-deficient cells, in that these cells can express IL-2, IL-2R, and transferring receptor. The growth-promoting factor originally derived from adult thymic leukemic cells referred to as ADF is able to induce formation of the high-affinity IL-2 receptor (α/β/γ, CD25/CD122/CD132), and ADF is Trx1.

Hence, T cell proliferation is intimately dependent on GSH and Trx1, which likely relates to the cellular compartmentalization differences among oxidant and antioxidant processes. Oxidative stress (or aging) may modify early signal transduction events as well as later events required for proliferation. Several enzymes with immunomodulatory potential are thiol-regulated, including adenylate cyclase, 5-nucleotidase, insulin receptor, and Na^+/K^+-ATPase. Changes in the transport functions start early in G1 (Na^+, K^+, and Ca^{++} changes occur within 1 min; glucose by 10 min; amino acids and nucleosides by 1 h). Since cell transport mechanisms directly utilize thiol-sensitive proteins, thiol modulation is suggested to have regulatory influence on multiple early events involved in lymphocyte activation. As might be anticipated, many of the above activities are altered with aging. Na^+/K^+-ATPase activity decreases in lymphocytes from the elderly; membrane potential changes are less responsive with aged cells; and nucleotide pools, kinase activity, protein phosphorylation patterns, and G protein involvements have been reported to be modified with age. Many of these processes are interconnected in the activation of T cells.

GSH and Lymphocyte Activation

GSH is critical in maintaining a viable cellular redox state, which becomes modified during lymphocyte activation and proliferation. GSH (and total thiol levels) have been shown to rise significantly following lymphocyte activation by mitogens. Human lymphocytes significantly increase their GSH concentration within 4 h of activation. By 8 h after activation, there is a significant increase in surface thiols (Lawrence et al. 1996). Interestingly, when GSH production is blocked, lymphocytes can progress to G1b but cannot synthesize DNA. DNA synthesis was previously shown to be sensitive to thiol modulation. Some possible explanations for the block in DNA synthesis include interference in the glutaredoxin/thioredoxin-mediated conversion of ribonucleotide reductase, inactivation of DNA polymerase I, which is thiol-sensitive, or alteration of PCNA activity or mitosis-promoting factor. It is important to note that lymphocyte treatment with maleimides (or benzoquinone), which alkylate thiols, prevents IL-2 synthesis; however, GSH depletion does not inhibit IL-2 production, but the cells cannot proliferate due to inhibition of DNA synthesis. Cellular redox status controls production and activity of cellular transcription factors. Intracellular cysteine is required for synthesis of GSH. DNA synthesis and cell proliferation in mitogenically stimulated T lymphocytes have been shown to be upregulated with increases in extracellular cysteine and downregulated with increases in extracellular glutamate. Lymphocytes are incapable of synthesizing cysteine, because they lack a cystathionine pathway; therefore, they rely on intracellular transport of cysteine or cystine. Intracellularly, cystine must be converted to cysteine. Cysteine transport occurs via the well-characterized Na^+-dependent ASC system, whose activity increases in mitogen-stimulated lymphocytes. The less understood membrane active transport system xc is involved in cystine uptake, in which intracellular glutamate is exchanged for extracellular cystine. Surprisingly, dehydroascorbate (DHA), the oxidized product of the antioxidant vitamin C (ascorbic acid), is a more potent inducer of GSH than N-acetylcysteine, which apparently involves the pentose phosphate pathway (Perl et al. 2002).

Membranes, Aging, ROS, and Antioxidants

In addition to a direct thiol influence on surface protein conformation, modulation of surface proteins could be influenced by the lipid architecture of the membrane, including the mitochondrial membrane. Lipid domains exist within biological membranes, and aggregates of lipids may diffuse as units of compartmentalized lipid only domains or together with protein constituents with which they are specifically associated. Modification of

membrane lipid components is well known to produce alterations in cellular functions. It has been established that the inflammatory process can generate ROS by both neutrophils and monocytes/macrophages. The formation of ROS (O_2^-, H_2O_2 and $^{\cdot}OH$) can induce lipid peroxidation of the cell membrane. In addition, the superoxide anion (O_2^-) can be converted by superoxide dismutase or spontaneous dismutation to hydrogen peroxide (H_2O_2), which freely diffuses into cell membranes. H_2O_2 can oxidize (enzymatically and nonenzymatically) cellular thiols (e.g., GSH) and lead to disulfide exchange reactions between oxidized glutathione (GSSG) and protein thiols. In addition, H_2O_2 can undergo further reduction to $^{\cdot}OH$, a Fe^{++}- or Cu^{+}-dependent process. The $^{\cdot}OH$ is extremely reactive and oxidizes the nearest protein, carbohydrate, or lipid. If the reaction occurs with proteins or carbohydrates, the "damage" is limited to the particular molecule with which the $^{\cdot}OH$ reacts. However, if $^{\cdot}OH$ oxidizes a lipid molecule, a process referred to as lipid peroxidation, an autocatalytic reaction, may ensue and lead to extensive membrane alterations. The question arises as to whether this increase in ROS preferentially affects lymphocyte subsets resulting in an imbalance in "normal" immunoregulation. Intracellular endogenous oxidants such as malondialdehyde also are generated during prostaglandin synthesis from transiently produced prostaglandins PGG_2/PGH_2 and, if unregulated, may oxidize protein amino groups directly or GSH indirectly. In the presence of exogenous oxidants such as O_2^- and $^{\cdot}OH$, autocatalytic lipid peroxidation through prostaglandin endoperoxides and/or oxidation of polyunsaturated lipids can lead to PM failure or disruption of the lipid structure surrounding regulatory proteins. When lymphocytes are activated, there is generally an increase in the concentration of polyunsaturated lipids within the membrane, which accounts in part for the increase in membrane fluidity. The increase in membrane fluidity is only transient likely due to the breakdown (peroxidation) of the polyunsaturated lipids. If the basal level of oxidative stress increases (as posited in the aging process), the polyunsaturated lipid content of the membrane will decline leading to a lower state of membrane fluidity. Membrane fluidity is known to decrease with loss of unsaturated lipids. This appears to occur with aging, which may be due to loss of desaturase activities. Based on numerous criteria – electron spin resonance (ESR), fluorescence polarization, and lipid insertion studies – the membranes of cells from older individuals have less axial rotation of phospholipids and higher packing/stacking of lipids, which are indices of less fluidity.

The mitochondrial membrane and mitochondria functions are of special importance, because in the process of producing adenosine triphosphate (ATP), the electron transport chain (ETC.) of five complexes utilized to produce ATP from adenosine diphosphate (ADP) generates superoxide anion. Mitochondria efficiency is assessed as the amount of protons needed to produce ATP by ATP synthase. Since ETC. activities generate superoxide anion, mitochondrial structures are vulnerable to oxidation, which is why they contain their own superoxide dismutase (MnSOD). However, generation of H_2O_2 by MnSOD or cytoplasmic Cu/ZnSOD can be dangerous to the mitochondria, in that they contain a high content of iron, which can convert H_2O_2 to the highly reactive hydroxyl radical. Mitochondria have Trx2 and peroxiredoxins to assist in controlling the level of H_2O_2. Mitochondria are highly compartmentalized with a double membrane normally restricting influx and efflux of factors, especially oxidants generated by the oxidative phosphorylation processes and molecules associated with apoptosis. Mitochondrial DNA would be especially vulnerable to the loss of control over the level of oxidants and antioxidants. The role of mitochondria in oxidative processes, aging, and cell survival are intimately associated (Wallace 2005).

Conclusion

The ability of antioxidants to control lymphocyte activation processes and the excesses of oxidants that can arise during inflammation are critical for

maintenance of a healthy state. It is often difficult to know whether the malfunctioning of antioxidants induces an immunopathology or whether an immunopathology causes a loss in the redox balance. In either case, it is clear that the extracellular and intracellular activities of antioxidants regulate immune functions and that an imbalance of redox activities occurs with loss of lymphocytes as HIV infection progresses to AIDS and with a loss of immunoregulation as oxidative stress leads to tissue damage with type 1 diabetes, lupus, and rheumatoid arthritis. The compartmentalized redox reactions evolved to allow for the differential subcellular organelle functions needed for cell activation, cell division, and cell function. The differential immune cell sensitivities to oxidants and antioxidant modulations exist as a means for controlling the type and duration of an immune response.

Autoimmune thrombosis

Definition

Anti-phospholipid antibodies (aPL) induce a prothrombotic diathesis, ultimately leading to clotting events through three main mechanisms: interference with coagulation proteins in the fluid phase, interaction with the cell types involved in the haemostatic balance, and complement activation. Placental thrombosis contributes to the pathogenesis of aPL-induced pregnancy complications together with defective placentation, decidual inflammation, and complement activation.

Introduction

Anti-phospholipid antibody syndrome (APS) is characterized by recurrent arterial and/or venous thrombosis and/or pregnancy morbidity associated with aPL detectable by anti-cardiolipin (aCL) and/or anti-β2 glycoprotein I (β2GPI) and/or lupus anticoagulant (LA) assays (Miyakis et al. 2006).

aPL are not only diagnostic autoantibodies but are believed to play a pathogenic role mediating several clinical manifestations of the syndrome. The persistent presence of aPL is a risk factor for developing the syndrome but an additional second hit is thought to be required for triggering the clinical manifestations (*two hit theory*) (Meroni et al. 2011).

Although APS is currently considered as a single disease, the clinical and the biological characteristics of the vascular involvement are different from those associated with the obstetrical problems. aPL-induced thrombophilic state plays a key role in the vascular events, but it cannot explain some clinical manifestations and most of the pregnancy complications. Additional aPL-mediated pathogenic mechanisms have been suggested (Meroni et al. 2011; Shoenfeld et al. 2009; Ruiz-Irastorza et al. 2010).

Pathogenesis of the Vascular Manifestations

The association between aPL and both venous and arterial thrombosis is supported by several epidemiological studies, and clot formation is the key event for vascular manifestations (Meroni et al. 2011). The thrombophilic state is supported by the aPL interference with both soluble components and different cell types involved in the coagulation cascade (Meroni et al. 2011). Table 1A and Fig. 1 report the main aPL-mediated pathogenic mechanisms that have been related to thrombosis in APS.

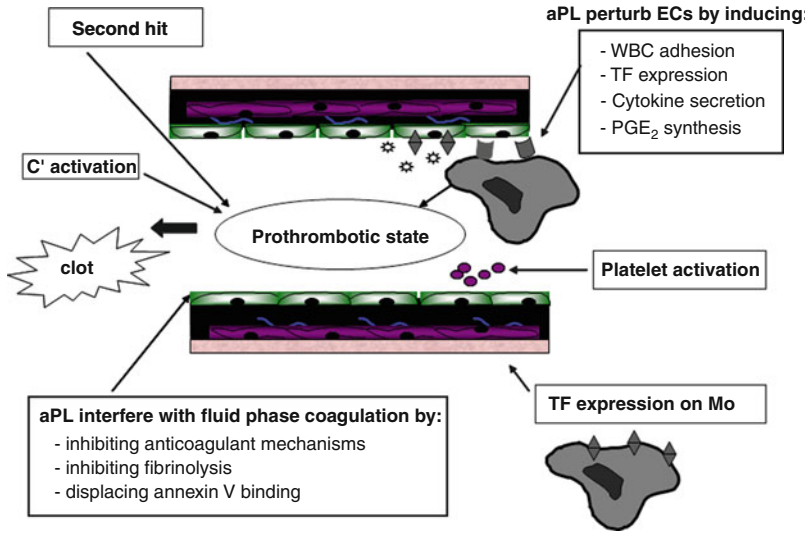
Most of the pathogenic mechanisms potentially responsible for thrombus formation have been demonstrated using in vitro models. However, three different in vivo models of thrombosis induced respectively by mechanical, chemical, or photochemical trauma have confirmed that aPL are able to increase venous and/or arterial thrombus formation in vivo (Meroni et al. 2011). Two of these experimental models demonstrated the ability of aPL to increase the thrombus size already triggered respectively by the mechanical or the chemical stimulus and to slow down its dissolution. On the other hand, the third model showed that the passive infusion of human aPL IgG together with a small amount of lipopolysaccharide (LPS) is able by itself to start clotting in the rat mesenteric arterial microcirculation (Fischetti et al. 2005).

The evidence of aPL interference with fluid phase components of coagulation has been

Anti-phospholipid Antibody Mechanisms of Thrombosis, Table 1 Anti-phospholipid antibody–mediated pathogenic mechanisms for thrombosis (A) and fetal loss (B)

(A) Thrombosis	(B) Fetal loss
Interference with fluid phase coagulation components:	Placental thrombosis
Inhibition of natural anticoagulants	Inflammatory villitis
Inhibition of Protein C activation	Inhibition of syncytium-trophoblast differentiation
Disruption of the Annexin V shield	Induction of decidual cells inflammatory phenotype
Inhibition of fibrinolysis	Embryo and/or placental apoptosis
Interference with cells of the coagulation cascade:	Complement activation
Endothelial cell perturbation	
Monocyte activation (TF expression)	
Platelet activation	
Complement activation	

provided mostly by in vitro models and by few ex vivo experiments (Giannakopoulos et al. 2007; Pierangeli et al. 2008; Meroni et al. 2011). aPL have been found to bind to some members of the serine protease (SP) family, which enlists proteins involved in hemostasis (pro-coagulant factors as thrombin, prothrombin [PT], FVIIa, FIXa, and FXa, and anticoagulants as protein C) as well as fibrinolysis (plasmin and tissue plasminogen activator [tPA]). aPL interaction with these proteins may be explained by the evidence that β2GPI and SP enzymatic domains share conformational epitopes. Most importantly, aPL interact with thrombin and FXa, interfering with the formation of thrombin-antithrombin (AT) and FXa-AT complexes, thus hindering the AT inactivation of thrombin and FXa. Moreover, a disruption of protein C and protein S pathways has been described. Indeed, aPL are reported to decrease activated protein C (APC) activity through competition



Anti-phospholipid Antibody Mechanisms of Thrombosis, Fig. 1 aPL interfere with: (A) the fluid phase coagulation factors, (B) potentiate platelet aggregation induced by other agonists, (C) induce monocytes (Mo) activation with the upregulation of Tissue Factor (TF ⧫) expression, and (D) endothelial cell (EC) perturbation with the induction of a pro-adhesive phenotype for white blood cells (WBC), TF upregulation, cytokine (✲) release and prostacyclin PGE_2 metabolism changes

with APC for PL binding. Accordingly, an increased APC resistance has been demonstrated in APS patients.

Several groups have also found decreased levels of both proteins C and S and aPL with affinity for either protein S or C in APS subjects. In addition, some aPL were shown to inhibit plasmin-mediated fibrinolysis, consistent with the evidence that IgGs from APS patients lead to an impairment of fibrin dissolution by plasmin. Moreover, some aPL subpopulations were found to bind to tPA, inhibiting tPA-mediated conversion of plasminogen to plasmin. Concordantly, antibodies against tPA have been described in APS patients, with an inverse correlation with plasma tPA activity.

Besides the inhibitory effects on anticoagulants, aPL may increase the enzymatic activity of pro-coagulants. There is evidence that some aPL subpopulations induce a gain of function of PT, leading to increased fibrin production. In addition, aPL have been demonstrated to disrupt the crystallization on endothelial cell (EC) monolayer of Annexin A5, a potent anticoagulant that prevents PL bioavailability for coagulation enzymes (Giannakopoulos et al. 2007; Pierangeli et al. 2008; Meroni et al. 2011).

More recently, research has focused on aPL interaction with cells involved in the haemostatic balance including platelets, monocytes, and ECs (Meroni et al. 2011).

Platelet Involvement

The first hint of platelet involvement in aPL-mediated thrombus formation comes from the frequent clinical finding of a mild thrombocytopenia among APS patients.

It is well described that aPL induce aggregation and activation of platelets. To note, prestimulation by agonists such as thrombin or collagen is necessary for aPL to potentiate platelet activation, as it leads to the exposure of phosphatidylserine (PS) on the cell outer membrane. Being a negatively charged PL, PS favors the adhesion of the cationic β2GPI on the platelet membrane, eventually offering the right antigenic target for aPL. aPL have been shown to neutralize β2GPI interaction with von Willebrand factor (vWF). β2GPI acts as a biologically relevant inhibitor of VWF function, thus interfering with vWF-dependent platelet adhesion. This action could contribute to aPL-induced thrombosis and may explain the consumptive thrombocytopenia frequently observed in aPL carriers. Moreover, aPL have been shown to enhance the expression of platelet membrane glycoproteins (GPs) IIb/IIIa and IIIa. GPs are fibrinogen receptors that mediate platelet aggregation, whose role in APS pathogenesis is further supported by in vivo findings. In fact, aPL did not affect thrombus formation in GPIIb/IIIa-deficient mice and pretreatment with a monoclonal anti-GPIIb/IIIa antibody inhibited aPL-mediated reduced thrombus formation. In vivo evidence of platelet activation by aPL has been gained in other models: (i) aPL produced a platelet-rich thrombus in rats, after treatment with low concentration of adenosine diphosphate (ADP), and (ii) platelet involvement was reported in the thrombus formation by photochemical injury in the rat.

Concordant findings regarding platelet activation by aPL have been provided by ex vivo studies. Elevated levels of platelet-derived thromboxane (the major eicosanoid produced by platelets, [TX]) metabolic breakdown products have been found in the urine of APS patients.

aPL interaction with platelets and the consequent activation is mediated by cell membrane receptors. To date, β2GPI has been demonstrated to bind two surface receptors on platelets. Apolipoprotein E Receptor 2′ (ApoER2′) is the only member of Low-Density Lipoprotein (LDL) receptor family expressed by platelets; its LDL-binding domain I has been shown to recognize positively charged patch of lysine residues in domain V of β2GPI. An inhibitor of LDL receptors was shown to block platelet activation and TX synthesis induced by aPL. Lastly, β2GPI has been shown to bind directly GPIba, a subunit of the GPIb-IX-V platelet receptor.

Involvement of Monocytes

The upregulation of tissue factor (TF), the major initiator of the clotting cascade, has also been advocated as an important mechanism to explain the prothrombotic aPL effects. aPL significantly increase TF expression in ECs and monocytes, IgGs from APS patients are stronger TF inducers than IgGs from aPL asymptomatic carriers.

In particular, TF expression on monocytes is increased in patients with APS and correlates with the expression of β2GPI. Accordingly, cell-surface expression of TF on monocytes is higher in APS patients than in subjects without thrombotic events. Interestingly, vascular endothelial growth factor (VEGF) stimulates TF expression in monocytes through its tyrosine-kinase receptor Flt-1 and expression of both VEGF and Flt-1 is increased in monocytes from APS patients. On monocytes, aPL have been suggested to interact with β2GPI in association with Annexin A2 and Toll-like Receptor (TLR) 4 within lipid rafts. Other authors provided indirect evidence of TLR2 involvement in mediating aPL-induced monocyte activation (Boles and Mackman 2010; Meroni et al. 2011).

Involvement of Endothelial Cells

The endothelium is a key player in the pathogenesis of APS. The vascular perturbation induced by aPL drives a pro-inflammatory and pro-coagulant endothelial phenotype, ultimately leading to clotting events.

aPL have been shown to induce a significant upregulation of cellular adhesion molecules (CAMs) such as ICAM-1, VCAM-1, and E-selectin in EC in vitro cultures. The increased expression of CAMs on the vascular surface is in turn responsible for the increased leukocyte adhesion to the endothelium, hence favoring the prothrombotic diathesis of the syndrome. Moreover, aPL promote the in vitro synthesis of pro-inflammatory cytokines such as interleukin (IL)-1β, IL-6, and IL-8 in ECs. Lastly, aPL modulate the vascular tone by inhibiting endothelial nitric oxide synthase and altering prostaglandin metabolism. Accordingly, in vivo studies have shown that passive infusion of aPL induced an increase in the rate of leukocytes adhering to the endothelium.

Ex vivo studies in APS subjects reported raised levels of soluble CAMs such as s-ICAM-1, VCAM-1, P-selectin although with contrasting results among the different groups. More importantly, APS patients were found to display endothelial perturbation, as suggested by the impaired brachial artery flow–mediated vasodilation responses and the significant increase in the numbers of circulating ECs and in t-PA and vWF titers (Meroni et al. 2011).

aPL-induced effects on the endothelium are mainly mediated by the reactivity of the autoantibodies with β2GPI expressed on the endothelial cell membrane. Since the evidence for an endothelial synthesis of the molecule is lacking, it has been suggested that β2GPI is adhering to EC membrane. The adhesion is apparently mediated by several different receptors whose nature remains uncertain. Annexin A2, a receptor for tPA and plasminogen, has been demonstrated to directly bind β2GPI. As Annexin A2 lacks an intracytoplasmatic tail, a co-receptor is required to trigger signaling cascade. TLR 2 and 4, Heparan sulfate, and ApoER2′ have all been indirectly shown to bind β2GPI on endothelial surface. TLRs 2 and 4 have been found to mediate also intracellular aPL signaling in ECs; to note, TLR2 is expressed by ECs only upon cell activation while TLR4 is constitutively expressed. More recently, it has been suggested that a multiprotein complex including TLR4 and Annexin A2 is involved in aPL-induced EC activation (Allen et al. 2012). Annexin A2, TLR4, and ApoER2′ have also been investigated in vivo. Animals deficient in any one of these molecules are only partially protected against aPL thrombogenic effects, suggesting redundancy in the signaling cascade (Meroni et al. 2011).

With regard to the downstream signaling pathways engaged by aPL, there is general agreement that nuclear factor κB (NFκB) and p38 mitogen-activated protein kinase (MAPK) are involved both in EC and monocyte activation (Meroni et al. 2011).

Pathogenic Antibodies

aPL are generally thought to be heterogeneous but there is evidence that only the antibodies

reacting with PL-binding proteins – in particular β2GPI and PT – can be pathogenic.

For example, aPL reacting with human β2GPI and cross-reacting with the murine, rat, and hamster molecule were shown to be pathogenic in all the in vivo models. In particular, the effect was reproduced by affinity purified anti-β2GPI IgG and specific absorption of the anti-β2GPI activity inhibited the thrombotic effect (Meroni et al. 2012). In view of these experimental findings, β2GPI-dependent aPL should be considered the main antibody subpopulation responsible for the thrombotic manifestations in the syndrome.

The analysis of the fine specificity of β2GPI-dependent aPL is still a matter of investigation. Preliminary studies showed heterogeneous activity of anti-β2GPI autoantibodies in APS patients, which are directed, often concurrently, against various (mostly linear) epitopes located in β2GPI-domain(D)1, D4, and D5. More recently, antibodies that recognize a cryptic epitope (Gly40-Arg43) in DI of β2GPI were closely associated with LA activity and strongly correlated with thrombosis and obstetrical complications. The ability of soluble DI to protect mice from the thrombogenic effect of aPL was considered a proof of concept for the key pathogenic role of anti-DI antibodies (Mahler et al. 2012). Interestingly, IgG reacting with β2GPI in sera from asymptomatic patients, individuals with leprosy, or children with atopic dermatitis have been reported to preferentially recognize epitopes on D4/5. Moreover, the ratio between anti-β2GPI-D1 and anti-β_2GPI-D4/5 IgG antibody reactivities was suggested to provide important information to discriminate between APS patients and individuals with other pathologies (Mahler et al. 2012). The D1 of β2GPI is usually hidden as a result of its linkage with D5 in the circular form of the molecule and is presented to the afferent limb of the immune system when the molecule is opened after binding to anionic PL monolayers or scavenging LPS (Agˇar et al. 2006).

Besides β2GPI, aPL are also known to react with other PL-binding proteins, in particular PT. The way anti-PT antibodies exert their procoagulant effect is unknown. In vitro studies suggested that anti-PT may perturb ECs by reacting with the molecule on the cell surface. However, there is no clear evidence for anti-PT pathogenic activity in animal models and their pathogenic role is mainly supported by the epidemiological association with thrombosis (Meroni et al. 2011). The best link was reported for antibodies detected by the PS-PT assay, suggesting that the pathogenic antibodies may recognize a conformational epitope(s) expressed by PT when complexed with anionic PL in the presence of calcium ions (Bertolaccini 2012).

The pro-coagulant mechanisms of aPL are mainly related to their ability to react with PL-binding proteins expressed on the cell membrane of different cell types. It is still not clear whether aPL react in a significant manner with the PL-binding proteins (in particular β2GPI and PT) in fluid phase. In this regard, all aPL are low-avidity antibodies, suggesting that complex formation in the fluid phase requires stoichiometric antigen-antibody ratios that are uncommon in patients (Tincani et al. 1996). This point further supports the notion that aPL reactivity with the target molecules expressed on the cell membranes plays a major role in APS pathogenesis. In particular, β2GPI is expressed on the cell membranes at high antigenic density and so more easily recognized by low-avidity autoantibodies. In addition, it has been reported that circulating β2GPI is usually present in the circular-closed form while it is opened only after binding to negative PL or after complexing with LPS. Since the autoantibodies were reported to react mainly with the opened form (i.e., reacting with the exposed cryptic epitope of D1), this finding may further explain the reason for the limited reactivity with the circulating form.

Is Clotting Also Involved in the Pathogenesis of the Pregnancy Complications?

The persistent presence of aPL represents the most frequent acquired risk factor for a treatable cause of recurrent pregnancy loss and for pregnancy complications (early and severe

pre-eclampsia) (Miyakis et al. 2006). Such an association is clearly supported by epidemiological studies and by experimental models showing that passive transfer of aPL IgG induces fetal loss and growth retardation in pregnant naive mice (Meroni et al. 2011).

Intraplacental thrombosis with impairment of maternal–fetal blood exchange was initially suggested to be the main pathogenic mechanism. Accordingly, in vitro studies showed that aPL may induce a pro-coagulant state at the placental level through different mechanisms including the ability of the aPL/anti-β2GPI to disrupt the anti-coagulant Annexin A5 shield on trophoblast and EC monolayers. The reduced distribution of Annexin A5 covering the intervillous surfaces found in placentas of aPL-positive women was thought to represent the in vivo demonstration of such a mechanism (Rand et al. 2010). These observations were not confirmed by other studies which failed to show intravascular or intervillous blood clots; histopathological findings suggestive of thrombosis cannot be detected in the majority of APS miscarriage samples and placentas (Meroni et al. 2010).

There is evidence from experimental animal models that repeated intraperitoneal injections of large amounts of human IgG with aPL activity to pregnant naive mice after embryo implantation induce marked placental inflammatory damage that results in fetal resorption and growth retardation. Immunohistochemical and histological examination of decidua showed deposition of human IgG and murine complement, neutrophil infiltration, and local tumor necrosis factor (TNF) α secretion, associated with a transient but significant increase in blood TNFα levels. Several lines of evidence support the role played by the complement system in this model, as suggested by the protection of animals deficient in complement components or following in vivo complement inhibition (Meroni et al. 2011).

In another experimental fetal loss model, mice deficient in D6 (a placental receptor which recognizes and targets to degradation most inflammatory chemokines of the CC subfamily) were more susceptible to fetal loss when passively infused with small amounts of human aPL IgG than pregnant wild-type mice or mice infused with normal IgG (Martinez de la Torre et al. 2007).

Altogether these findings strongly suggest that additional pathogenic mechanisms are present.

Such experimental data stand in contrast with the lack of evidence of: (i) acute local inflammatory events and complement deposition in abortive material or term placentae from APS women and (ii) the efficacy of corticosteroid treatment for preventing aPL-associated fetal loss (Meroni et al. 2011). Finally, an inflammatory process does not seem to be involved in another model of fetal resorption and growth retardation obtained by i.v. injection of small amount of human aPL IgG into mice before implantation, as indicated by the histological analysis of the placentae which failed to show clear signs of inflammation (Martinez de la Torre et al. 2012).

Evidence has been collected from in vitro experimental models for alternative pathogenic mechanisms supporting the ability of aPL to directly target the maternal decidua and the invading trophoblast. Table 1B reports all the pathogenic mechanisms that have been described to explain the aPL-mediated pregnancy complications.

As a whole, these findings suggest that APS-associated pregnancy complications can be mediated by different and not alternative pathogenic events which are not necessarily related to the aPL pro-coagulant effect or to inflammation. On the other hand, data from in vivo animal models as well as histological examination of human term placentae can be biased by the fact that findings are restricted to a given period of the pregnancy when the investigation was performed or at the time of autoantibody passive infusion. So, it is possible that different mechanisms can take place at different times during the pregnancy.

The expression of β2GPI on the trophoblast cell membranes is the pre-requisite to explain the aPL/anti-β2GPI placental tropism. β2GPI binds to PS exposed on the external cell membranes of trophoblast undergoing syncytium formation, but additional receptors may also be involved. Hence, β2GPI-dependent aPL appear to represent the main pathogenic autoantibodies in obstetrical APS. It has been hypothesized that most of these

potential pathogenic autoantibodies can be absorbed at the placental level (where β2GPI is expressed) and not transferred to the fetus. This would explain why thrombotic events are rarely reported in babies born to aPL-positive mothers in spite of the high thrombophilic profile of neonates (Meroni et al. 2011).

Unsolved Issues Regarding Anti-phospholipid Antibody-Induced Thrombosis

A *two hit hypothesis* has been suggested to explain the clinical observation that the thrombotic events occur only occasionally in spite of the persistent presence of aPL. The antibody (*first hit*) induces a thrombophilic condition but clotting takes place in the presence of another thrombophilic condition (*second hit*) (Meroni et al. 2011). Accordingly, the administration of small amount of LPS was required for human β2GPI-specific aPL IgG to display their thrombogenic effect in the rat mesenteric microcirculation (Fischetti et al. 2005). In line with this observation, it has been suggested that infectious processes may be the *second hit* since they frequently precede the full-blown picture of the syndrome and may be the initiator of the catastrophic subtype (Shoenfeld et al. 2006). This hypothesis fits well with the potential involvement of Pattern Recognition Receptors (i.e., TLRs) in sensing microbes and triggering an inflammatory response. Since TLR 2 and 4 have been reported to contribute to EC and/or monocyte activation by β2GPI-dependent aPL, one can speculate that the combination of the infection plus the TLR perturbation mediated by the autoantibodies overcome the threshold for triggering thrombosis (Meroni et al. 2011). Alternatively, infection/inflammation may increase the expression of the target antigen for aPL or the expression of antigenic epitopes that are hidden in resting conditions. In line with this hypothesis, preliminary data showed that LPS is able to upregulate the β2GPI expression in murine tissues (Agostinis et al. 2011).

The two hit hypothesis does not fit well with the APS obstetrical manifestations. In fact, passive infusion of IgG fractions with aPL activity induces fetal loss in naive pregnant mice without necessarily requiring a second hit. β2GPI is largely expressed in placental tissues even in physiological conditions and binding of labeled exogenous β2GPI infused into naive pregnant mice to trophoblast and EC in the labyrinth was recently documented in vivo by eXplore Optix™ imager (Agostinis et al. 2011). So, the large availability of the target antigen for potentially pathogenic aPL at the placental level is in strong contrast with the lack of a comparable expression in other tissues of naïve mice and even in highly vascularized human tissues such as kidney. It is possible to speculate that a high expression of β2GPI at the placental level together with the hormonal and blood flow modification linked to the pregnancy is sufficient to favor the pathogenic activity of the autoantibodies without any additional factor (Meroni et al. 2012).

Complement activation has been demonstrated as a necessary step in both aPL-mediated thrombosis and fetal loss. Sera from the majority of APS patients were found to fix complement in vitro. However, the strongest evidence of the role of complement in mediating aPL thrombotic events came from in vivo models. Animals deficient in complement components or complement receptors or treated with inhibitors of complement activation were protected from the aPL thrombogenic effects. However, a clear decrease of complement levels has not been described in patients, with only two studies reporting mild hypocomplementemia in primary APS (Meroni et al. 2011).

Similarly, the complement role in mediating aPL-induced pregnancy complications is supported mainly by in vivo experimental models. Pregnant mice deficient in complement C3 or C5, or C5a anaphylatoxin chemotactic receptor, or treated with an inhibitor of C3 convertase, did not experience aPL-induced fetal loss. In humans, a retrospective study found complement deposition in placenta tissues from aPL-positive women. However, a case study reported no complement deposition in fetuses miscarried by women with primary APS, whereas a more recent prospective study on full-term placentas and abortive specimens showed

only mild complement deposition but without any relationship with pregnancy outcome or therapy.

So, definite conclusions about the involvement of complement in APS-associated thrombosis and miscarriages cannot currently be drawn; however, the potential role of complement in aPL-mediated clinical manifestations should not be discounted.

Hughes Syndrome

Definition

Antiphospholipid syndrome (APS) is an autoimmune disease characterized by recurrent thrombotic events and pregnancy morbidity, in the presence of distinct autoantibodies. The treatment of APS should be directed to subgroups based on clinical manifestations, immunological findings, and whether accompanied by other autoimmune disease. The treatment includes anticoagulants and/or aspirin.

Treatment for Thrombosis

Recently updated criteria for APS in 2006 define the syndrome as the combination of a clinical event (including at least one thromboembolic event, pregnancy morbidity, or both) and an abnormal test result (including the presence of antibodies to cardiolipin (aCL) or beta-2-glycoprotein I (anti-b2GPI) or the presence of the lupus anticoagulant (LAC) detectable at least twice over an interval of 12 weeks or more) (Miyakis et al. 2006). Thromboses are usually recurrent and frequently involve the same territory in subsequent thrombotic events (Cervera et al. 2002). Updated treatment options are presented according to clinical and antibody status (Erkan and Pierangeli; Galli et al. 2003; Prandoni et al. 2009; Cosmi et al. 2010; Ramires de Jesus et al. 2012; Heilman et al. 2011; Bramham et al. 2010; Ruiz-Irastorza et al. 2010; Danza et al. 2012; Cohen et al. 2010; Branch 2011; Ruiz-Irastorza et al. 2011; Scoble et al. 2011).

1. *Antibodies and risk of thrombosis*: The risk of developing APS and thrombotic events is directly related to the number and titers of antiphospholipid antibodies (aCL, anti-b2-GPI, and LAC). LAC is linked most strongly with thrombotic events (Erkan and Pierangeli; Galli et al. 2003). LAC increases the risk for stroke by a factor of 46, and for myocardial infarct by a factor of 11. This risk is far less for individuals with elevated anti-b2GPI titers b2-GPI which is only associated with stroke. In SLE, triple positivity (aCL, anti-b2GPI, LAC) confers an increased risk of thrombotic events. In addition, SLE patients with persistently elevated titers of aCL are at increased risk for thrombosis. APS patients with conventional cardiovascular risk factors (smoking, hypertension, high cholesterol levels, and use of oral contraceptives) are at increased risk for thrombosis. A lower risk of thrombosis is observed among individuals with intermittent low–medium titers of aCL or anti-b2-GPI. The presence of multiple positive antiphospholipid antibodies may also be associated with pregnancy morbidity.
2. *Treatment for the first venous thromboembolic event (VTE)*: Effective standard anticoagulation for VTE with vitamin K antagonists for venous thromboembolism (VTE) is recommended with a goal INR of 2 to 3. Higher intensity therapy may be associated with bleeding or paradoxical thrombotic events in APS patients. For the first event, treatment should be for 3–6 months if there was a provoked VTE (such as surgery or trauma), single positivity with aCL or anti-b2GPI, and primary APS. Before discontinuation of therapy, repeated

ultrasound-Doppler and D-dimer levels are recommended to assess residual thrombosis (Prandoni et al. 2009; Cosmi et al. 2010).

Long-term therapy after a first event may be appropriate for patients with unprovoked VTE, triple positivity, the development of pulmonary embolus, those with concomitant thrombophilia, and patients with associated autoimmune diseases (Erkan and Pierangeli).

3. *Treatment for recurrent VTE*: Indefinite antithrombotic treatment is warranted for individuals with APS and recurrent VTE. Strict control of cardiovascular risk factors is recommended for high-risk aPL profile individuals to reduce the risk of an event. Patients with definite APS and recurrent events despite warfarin with a target intensity of INR 2.0–3.0 should receive indefinite therapy with warfarin with a target intensity of INR 3.0–4.0 or an extended therapeutic dose of low molecular weight heparin (LMWH) (Erkan and Pierangeli).
4. *Treatment for first arterial thromboembolic event (ATE)*: Although VTE is usually the presenting event, patients have numerically more arterial embolic events. Patients should receive intensive anticoagulant therapy with an aim of INR 3.0–4.0 or combined anticoagulant (INR: 2.0–3.0) and antiplatelet therapy (e.g., low-dose aspirin) following a bleeding risk assessment. Non-SLE patients with a first non-cardioembolic cerebral stroke, a low-risk aPL antibody status, and reversible precipitating factors may receive antiplatelet therapy alone. Patients with definite APS and recurrent events despite warfarin with a target intensity of INR 2.0–3.0 should receive indefinite therapy with warfarin with a target intensity of INR 3.0–4.0 or extended therapeutic dose of LMWH (Erkan and Pierangeli).
5. *Treatment for antibody carriers without clinical disease*: Although not based on strong evidence, it is suggested that non-SLE patients that are high-risk aPL carriers should receive primary prevention with indefinite low-dose aspirin (Ruiz-Irastorza et al. 2011). There is good evidence that carriers of antiphospholipid antibodies (without clinical disease) should have thromboembolic prophylaxis for high-risk situations such as surgery, immobilization, and puerperium (Ruiz-Irastorza et al. 2011). The preferred treatment is LMWH. Strict control of cardiovascular risk factors is recommended for high-risk aPL profile individuals to reduce the risk of thrombosis (Erkan and Pierangeli).
6. *Treatment for antibody carriers with SLE but without APS clinical disease*: It is suggested that SLE patients that are carriers of LAC or persistent medium–high titers of aCL receive prophylaxis with hydroxychloroquine (Plaquenil) and low-dose aspirin (Ruiz-Irastorza et al. 2011).

Treatment for Obstetric APS

In obstetric APS, there are maternal and fetal morbidities. The most common maternal complications are preeclampsia, eclampsia, and placental insufficiency. Fetal morbidities are fetal compromise (first and second trimester) and premature birth. Both miscarriage and maternal thrombosis may occur simultaneously in 2.5–5 % of cases.

Recurrent miscarriage occurs in approximately 1 % of women of the reproductive age. In APS, some 10–15 % of women will experience recurrent miscarriages. Antiphospholipid antibodies are encountered in 5–20 % of women with recurrent miscarriages. About one third of untreated women with APS will develop preeclampsia during pregnancy, and more than 10 % will deliver infants that are small for gestational age.

All pregnant women with SLE or other autoimmune diseases should be tested for antiphospholipid antibodies and LAC (Ramires de Jesus et al. 2012; Heilman et al. 2011; Bramham et al. 2010; Ruiz-Irastorza et al. 2010; Danza et al. 2012).

7. *APS and pregnancy*: Pregnant women with APS have the likelihood of live births of up to 80 % if treated, but only 15 % if untreated. Pregnant women with APS should attend a high-risk pregnancy clinic every 4 weeks until mid-pregnancy, then every 1–2 weeks

until delivery. At these visits, blood pressure, urine spot checks, or a 24-h urine collection for proteinuria should be performed. Physical exam for thrombosis and obstetric ultrasound and Doppler every 4 weeks starting at 18–20 weeks are warranted. Patients should be aware of symptoms of preeclampsia (Ramires de Jesus et al. 2012; Heilman et al. 2011). Anticoagulation should be initiated when a live embryo is detected by ultrasound (Ramires de Jesus et al. 2012).

8. *Antibodies and risk of fetal morbidity*: The risk of developing APS and fetal morbidity is directly related to the type of aPL antibodies (aCl, anti-b2-GPI, and LAC). LAC is strongly correlated with recurrent fetal losses before the 24th week of gestation. Its effect on recurrent early miscarriages (REMs) is not clear. LAC most strongly influences pregnancy outcome (Danza et al. 2012). In addition, patients with persistently elevated titers of aCL IGG or IGM are at increased risk for recurrent fetal losses before the 24th week of gestation. aCL IGG is also associated with REM, but anti-b2-GPI is not. Elevated titers of aCL IgM are associated with late recurrent fetal losses. Triple positivity is associated with poor pregnancy and fetal outcomes. Newborns of APS mothers with triple positivity have a higher rate of complications including respiratory distress, infections, and bronchopulmonary dysplasia. Women with pregnancy morbidity only (without a history of thrombosis) and given conventional therapy tend to have better neonatal outcomes (Cohen et al. 2010; Branch 2011).
9. *Recurrent early miscarriage (REM)*: According to the Cochrane systematic review, treatment to reduce the risk of REM should include unfractionated heparin (5,000 U twice daily). However, expert opinion suggests treatment with 5,000–7,500 U of heparin or LMWH twice daily with low-dose aspirin (Cohen et al. 2010; Branch 2011).
10. *Fetal death*: To reduce the risk of fetal death, treatment with aspirin and unfractionated heparin 5,000 U twice daily or LMWH in prophylactic doses are the recommendations (Cohen et al. 2010; Branch 2011).
11. *Severe preeclampsia or placental insufficiency (delivery < 34 weeks)*: Treatment with aspirin and unfractionated heparin in a prophylactic or intermediate dose is suggested to reduce the risk of preeclampsia or placental insufficiency (Cohen et al. 2010; Branch 2011).
12. *Postpartum care*: The main recommendation is to continue the same medication protocol given during pregnancy. Most experts agree that treatment should continue for about 6 weeks postpartum. The therapeutic options are low-dose aspirin, heparin, or LMWH.

    Of note, low-dose aspirin, heparin, warfarin, and hydroxychloroquine are considered acceptably safe during lactation (Cohen et al. 2010; Branch 2011).
13. *Long-term implications in obstetric APS only*: Treatment with aspirin and LMWH during pregnancy will improve gestational outcomes, but not all obstetric morbidities will be reduced. If the patient had pregnancy issues only, long-term low-dose aspirin is recommended (Cohen et al. 2010; Branch 2011).
14. *Long-term implications in obstetric and thrombotic APS*: Pregnant women with APS who have experienced thrombosis have worse outcomes. They have more preterm deliveries and eclampsia and deliver more babies that are small for gestational age as compared with otherwise similar women with APS who do not have a history of thrombosis (Ramires de Jesus et al. 2012). Treatment consists of low-dose aspirin and full anticoagulant doses of heparin. Warfarin may be used after 6–12 weeks of pregnancy. Heparin can be switched to warfarin from 14 to 36 weeks pregnancy (INR 2–3 for first events; 3–4 for recurrent events). Warfarin can be reinstituted following pregnancy. Heparin can be discontinued and renewed 12 h before and after a procedure such as epidural

anesthesia. Low-dose aspirin can be continued through labor though some experts recommend discontinuing it 1 week prior to labor. If the patient had previous thrombosis, especially an arterial event such as stroke and pregnancy complications, anticoagulation for life is necessary (Bramham et al. 2010; Cohen et al. 2010; Branch 2011; Ruiz-Irastorza et al. 2011).

General Statements

15. *Primary prophylaxis*: In non-SLE patients with a high-risk aPL profile and concomitant thrombotic risk factors but no prior thrombosis, long-term thromboprophylaxis with low-dose aspirin is recommended (Ruiz-Irastorza et al. 2011).
16. *Secondary prophylaxis*: Patients with undetermined APS (arterial or thrombotic event and aPL) that do not fulfill laboratory criteria for APS should receive thromboprophylaxis in the same manner as APL-negative patients. Patients with definite APS and an unprovoked first venous event should receive anticoagulation for life with a target INR 2.0–3.0 (Ruiz-Irastorza et al. 2011).
17. *Caveats*: Some issues regarding the management of APS are yet to be determined. There is no consensus regarding the proper treatment for arterial events in definite APS. Should the patient receive anticoagulation with an INR target >3 or combination therapy with an anti-aggregant? Should the treatment of a low-risk APL-positive patient with a first provoked thrombosis be limited to 3–6 months? What is the treatment for patients in whom conventional anticoagulation is contraindicated? What is the best therapy for patients with refractory APS?
18. *Alternative treatments*: Yet to be determined are the roles of alternative treatments such as hydroxychloroquine, low molecular weight heparin, and statins especially in refractory cases (Branch 2011; Ruiz-Irastorza et al. 2011). Ongoing and future research may establish a role for rituximab, factor Xa inhibitors (dabigatran and rivoroxaban), or other novel agents for refractory thrombosis in APS patients (Scoble et al. 2011).

Conclusions

APS is an autoimmune disease characterized by recurrent thrombotic events and/or pregnancy morbidity in the presence of distinct autoantibodies. The risk for thrombotic events is dependent on the APL profile and includes the type, level, persistence, and number of antibodies involved; the presence of other risk factors; and the presence of SLE or other autoimmune diseases. The treatment of APS should be directed to subgroups based on clinical manifestations (thromboembolic events and/or pregnancy morbidity), immunological findings (which type of antibody, the titer and persistence, and the coexistence of triple positivity), and the presence of other autoimmune disease (primary or secondary APS).

APS – clinical manifestations

Definition

Antiphospholipid syndrome is a systemic autoimmune disease characterized by various clinical manifestations (the most characteristic are thromboses and pregnancy morbidity) in the presence of elevated levels of antiphospholipid antibodies.

Antiphospholipid syndrome (APS) is a systemic disorder characterized by the presence of elevated levels of antiphospholipid antibodies (aPLs) and either thrombosis or pregnancy morbidity. As the latter 2 groups of clinical manifestations define the criteria for the diagnosis of APS, many other clinical manifestations are also prevalent in APS.

The major groups of clinical manifestations in APS are (Cervera et al. 2002, 2011a, b; Ramos-Casals et al. 2004; Rodrigues et al. 2010; Sherer and Shoenfeld 1998; Shoenfeld et al. 2008):

1. Thromboembolic manifestations
   (a) *Deep venous thrombosis and pulmonary emboli*: Thrombosis is one of the most common features of APS, and deep venous thrombosis (usually of the lower extremities) is the most common manifestation of thrombosis is APS. About one-third of the cases of deep venous thrombosis are associated with pulmonary emboli. Depending on their size, the pulmonary emboli may sufficiently impair

perfusion to reduce oxygenation. The clinical manifestations of pulmonary emboli include chest pain, dyspnea, tachypnea, decreased blood oxygen saturation, cardiac dysfunction, and sudden death.

(b) *Coronary artery disease* (*CAD*): Although this disease is found in many patients in the general population and is the leading cause of death in the Western world, the risk of CAD is even higher among patients with APS. Myocardial infarction occurs in about 7 % of APS patients, although some studies have reported a prevalence of up to 30 %. Objective evidence of coronary artery disease is found in 10 % of APS patients who also have SLE. In addition to aPLs, several risk factors contribute to cardiovascular diseases in these patients (smoking, hypertension, hypercholesterolemia, and diabetes mellitus), and therefore, interventions for these risk factors are of a great importance.

2. Recurrent miscarriage, pregnancy, and fetal morbidity
   (a) *Infertility*: The cause of infertility in some patients remains unexplained, and some investigators have suggested a possible involvement of aPLs. However, aPLs are normally associated only with recurrent miscarriages and obstetric complications.
   (b) *Recurrent miscarriage*: 2–5 % of women of reproductive age experience two or more miscarriages. Pregnancy loss during any stage of pregnancy may be the first and occasionally the only sign of APS. The characteristics of pregnancy losses vary in different research studies, but aPLs are generally associated both with early and late pregnancy loss. Most cases of miscarriage in women with and without APS occur during the early stages of pregnancy. Since APS is also associated with late pregnancy loss, the percent of women with APS and this type of miscarriage is relatively high. The presence of aPLs is important for the diagnosis, but it also has therapeutic and prognostic significance: A high rate of successful pregnancy can be anticipated while properly treated with anticoagulants. The subsequent miscarriage rate in women positive for aPLs is as high as 90 %, significantly higher than in women without aPLs.
   (c) *Pregnancy morbidity*: Preeclampsia is not a rare manifestation during pregnancy, but its frequency is higher among APS patients. In APS patients, preeclampsia usually occurs at an earlier stage of pregnancy and is more severe than in women without APS. Preterm delivery is also more frequent in women with APS (approximately 20 % of cases) and is usually the result of childbirth induced by the physician due to preeclampsia and fetal growth retardation. This latter complication of APS is usually the result of placental dysfunction, and it has been reported in 10–30 % of pregnancies in women with APS.
3. Heart and respiratory manifestations
   (a) aPLs have an important role in heart valve damage both in primary APS and in lupus; they are found in 90 % of lupus patients who have heart valve injury and in only 40 % of lupus patients without heart valve disease. The most frequent manifestation of heart valve disease, both in APS and in lupus (SLE), is heart valve thickening. The valve most frequently involved is the mitral valve, followed by the aortic valve. Thickened heart valves have impaired function. About one-quarter of patients with APS and lupus have mitral valve disease, which results in mitral regurgitation. This disease is significant in 5 % of the patients and results in heart failure. Another relatively common manifestation of valve disease in APS is the development of heart valve vegetations. Another interesting manifestation in APS is pseudo-infective endocarditis, which imitates the clinical manifestation of infective endocarditis with signs and symptoms of fever, heart valve vegetations, heart murmur, and

splinter hemorrhages. However, no infective agent can be detected by blood cultures, but moderate to high titers of aPLs can be found (similar to "marantic endocarditis").

(b) *Cardiac thrombosis*: APS is characterized by hypercoagulability, which can also manifest as a thrombus within the cardiac chambers. A thrombus in this location can cause severe heart dysfunction as well as producing emboli that could cause occlusion of vessels that supply the brain, kidneys, and other vital organs.

(c) *Pulmonary arterial thrombosis*: This is a rare manifestation of APS. However, as thrombosis can occur in every vessel in the human body, it can also occur in one of the major arteries of the lung. Thrombosis can also affect smaller lung vessels.

(d) *Pulmonary hypertension*: Pulmonary hypertension occurs in 2–3 % of APS patients and is usually the result of recurrent pulmonary emboli.

(e) *Pulmonary hemorrhage*: Pulmonary hemorrhage is characterized by cough, fever, dyspnea, and hemoptysis.

4. Skin involvement in APS

(a) *Livedo reticularis*: This rash is characterized by a netlike reddish-blue discoloration beneath the skin. Occasionally, similar phenomenon can be found in healthy subjects following cold exposure. Livedo reticularis can be found in about one-fourth of APS patients, more frequently in women than in men, and more frequently in patients having secondary APS associated with lupus.

(b) *Skin ulcers*: These occur in 55 % of APS patients. These usually manifest as small and painful lesions with a diameter of 0.5–3 cm, with a round- or star-shaped border circled by brown-purple border and intradermal hemorrhage.

(c) *Digital necrosis*: This occurs in approximately 3 % of patients with APS. The risk factors for digital necrosis in APS are smoking, hypertension, and oral contraceptive use.

5. Central nervous system and APS

(a) *Stroke*: Strokes in APS can be the result of intracerebral thrombosis, thrombosis in the large vessels supplying the brain (the carotid arteries in the neck or the vertebral arteries in the spinal column), or due to emboli of thromboses originating in the aorta or heart. The presence of aPLs is associated with a 2–7 times increased risk for stroke compared with patients without aPLs. Strokes in individuals with APS also occur earlier, several decades prior to their occurrence in the general population.

(b) *Venous sinus thrombosis*: Thromboses of the venous sinuses can be severe and lead to brain infarcts.

(c) *Sneddon's syndrome*: This is defined as recurrent strokes and livedo reticularis. The prevalence of aPLs in Sneddon's syndrome is 50–85 %.

(d) *Epilepsy*: The presence of aPLs is associated with epilepsy in patients with lupus. A possible pathogenic mechanism of epilepsy in APS is thrombosis followed by brain infarct and scar formation. aPLs could also promote epilepsy by having a direct effect on the brain, such as decreasing the activity of the neurotransmitter GABA.

6. Hematological manifestation of APS

(a) *Thrombocytopenia*: Thrombocytopenia occurs in 20–40 % of individuals with APS, but usually in a mild form with platelet counts above 50,000 per mL. Severe thrombocytopenia is found in the minority (5–10 %) of patients. Severe bleeding rarely accompanies the low platelet counts.

(b) *Anemia*: In some cases of autoimmune hemolytic anemia, aPLs (usually anticardiolipin antibodies) can be detected. A minority of patients have both thrombocytopenia and anemia (Evan's syndrome), which can be detected in about 5 % of lupus and 10 % of the patients with primary APS.

7. Other clinical manifestations in APS

(a) *Renal injury*: The kidneys are a target affected in many systemic diseases such

as diabetes mellitus, hypertension, and SLE. In APS, renal artery thrombosis can also occur, with arterial stenosis or emboli blocking the renal artery. Disruption of renal blood flow for any reason leads to hypertension and, occasionally, to severe and life-threatening hypertension. Renal vein thrombosis can also be part of APS; these thrombi occur mainly in the presence of nephrotic syndrome. Thrombosis can also occur within the small vessels of the kidneys, including arterioles, venules, and even in the glomerular vessels.

(b) *Intestinal manifestations*: Thrombosis of the intestinal arteries can result in intestinal necrosis. An early manifestation of intestinal thrombosis is abdominal angina resulting from narrowing and incomplete occlusion of the intestinal arteries.

(c) *Budd-Chiari syndrome*: In APS, Budd-Chiari syndrome is caused by interference of hepatic venous drainage. Liver venous thrombosis can be accompanied by thrombosis of larger veins such as the inferior vena cava. Budd-Chiari syndrome can be acute or chronic, can completely resolve, or can lead to death due to hepatic failure. aPLs have been found in many patients with liver cirrhosis, portal vein hypertension, and hepatitis C virus infection.

(d) *Hearing impairment in APS*: Hearing loss can result from impairment of the blood supply to the cochlear nerve. aPLs have been detected in patients with sudden hearing loss, with different studies reporting frequencies varying from very low to approximately one-fourth of these patients.

(e) *APS and the eyes*: Central nervous system involvement may affect vision in both eyes. However, single eye involvement also occurs in APS, and the underlying mechanism is decreased blood supply to the eye or an inflammatory reaction specific to that eye. Another pattern of visual injury is the result of injury to the cranial nerves that supply eyeball muscles or injury to the optic nerve itself. The symptoms presented by patients having ocular manifestations of APS are diverse and can include double vision, ocular pain, headache, visual fields impairment, and transient visual loss is one or both eyes.

(f) *Bones and joints in APS*: Bones, muscles, and joints are not usually affected in patients having APS. However, as APS is frequently secondary to other autoimmune diseases, including lupus, these primary diseases can have joint manifestations, such as arthritis. Whereas primary APS is not characterized by arthritis, arthralgias are relatively common in APS. In addition, bone marrow necrosis has also been reported in some patients with APS. The main injury to the bones in APS is avascular necrosis, which results from blood supply impairment.

In conclusion, APS is a multisystem autoimmune disease that is characterized mainly by thrombosis and pregnancy morbidity. However, many other clinical manifestations are common among patients with APS, and therefore clinical suspicion of APS should be high in the presence of typical clinical presentations, especially among patients with other autoimmune diseases.

Atherosclerosis and Cytokines

Harald Loppnow
Internal Medicine III, Research Laboratory (FG6-E01), Medical Faculty, Martin-Luther-University Halle-Wittenberg, Halle (Saale), Germany

Synonyms

Atherosclerosis – Arteriosclerosis; atheroma establishment; blood vessel narrowing; vessel wall hardening; ischemic heart disease; coronary artery disease; inflammatory disease

Inflammation – *Dolor*; *rubor*; *calor*; *tumor*; *functio laesa*; pain; redness; temperature; swelling; impaired function; cell recruitment; cytokine production; secondary mediators; secondary functions; cytokine-mediated

Cytokines – Hormone-like mediators; growth factors; proinflammatory cytokines; anti-inflammatory cytokines; monokines; lymphokines; intercellular communication mediators; LMW (low molecular weight) proteins; immune cell-released; inflammatory cell-released; stimulated proteins; primary inflammatory mediators

Definition

Atherosclerosis is a life-threatening thickening of the vessel wall, resulting in a reduction or failure of oxygen nourishment of heart or brain tissues. It is the leading cause of infarction and stroke in the industrial countries. The development of atherosclerosis, a process termed atherogenesis, is crucially controlled by inflammatory processes. Cytokines are central regulators of inflammation, thus, they are essential for atherogenesis. The role of cytokines for atherogenesis has been indicated by measurement of cytokines in blood samples and by in vitro cell-culture experiments and has finally been proven using cytokine-gene-deficient animals.

Historical Background

It is probably not possible to determine unequivocally the first mentioning of atherosclerosis in ancient history, may it be of Asian or European origin. More recently, it has been Leonardo da Vinci in the sixteenth century who investigated the anatomy of vessels and discussed the phenomenon of vessel narrowing. The terms arteriosclerosis and atherosclerosis have then been introduced in the nineteenth century. Already at this time, inflammation was linked to atherosclerosis by a number of scientists including Joseph Hodgson and Rudolf Virchow. However, it took more than a century that this idea was seized again and investigated in more detail. Due to the discovery of the inflammatory mediators in the twentieth century, the contribution of inflammation (i.e., its mediators) to atherogenesis is now well established (for further historical reading see Nieto (2012)).

Atherosclerosis

Cardiovascular diseases are a major cause of morbidity and mortality in the industrial countries. Atherosclerotic alterations in the vessel wall are the underlying cause of many of these diseases. Atherosclerosis has been associated clinically with risk factors such as hypercholesteremia, diabetes, diet, obesity, metabolic syndrome, hypertension, smoking, and shortcomings in physical activity, gender

(man > woman), and age (older > younger). On the other hand, it is now well accepted that inflammatory pathways are involved in the development and progression of atherosclerosis (Hansson and Libby 2006; Ross 1999). Exogenous or endogenous compounds or conditions, representing the risk factors, can be determined, and cells of the immune system or the vessel wall, by responding to these challenges, may initiate the inflammatory response in or on the vessel wall (Loppnow et al. 2011). The exogenous activation pathways may include bacterial components, such as endotoxin (LPS, lipopolysaccharide) or other bacterial products. The endogenous activators of inflammation may include dietary or metabolic products, stress, or even inflammatory mediators, such as cytokines themselves. Activation of inflammation results in leucocyte invasion into the vessel wall, as well as migration and proliferation of local smooth muscle cells. These cellular processes are influenced by fluctuations in cytokine production and reactivity, by altered responses to blood flow, or by the "inflammatory burden" caused by the exogenous or endogenous triggers, representing the risk factors. The putative steps in atherogenesis (compare Libby 2012) are summarized in Table 1.

Atherosclerosis and Cytokines, Table 1 Inflammatory steps in atherosclerosis[a]

Activation of adhesion molecules on the endothelium (presumably by exogenous or endogenous inflammatory triggers related to the risk factors, which activate cytokine production)
Adhesion and penetration of monocytes and, subsequently, other cells, into the intima and activation of the intravascular inflammation process by cytokines
Accumulation and further attraction of cells by chemokines
Transformation of monocytes to foam cells in response to cytokines and cholesterol uptake
Migration, proliferation, as well as death, of vascular smooth muscle cells, in response to invading-cell-derived cytokines or autocrine cytokines
Alteration of plaque stability by cytokine-mediated enzyme production
Modification of the fibrous cap and, in the worst case, rupture of the plaque
Thrombosis, resulting in stroke or myocardial infarction

[a]Modified after Libby (2012)

In early atherosclerosis, innate mechanisms, such as enhanced cytokine (i.e., IL-1 (interleukin-1) or TNF (tumor necrosis factor)) production, as well as monocyte or granulocyte invasion, may lead to endothelial dysfunction, enhanced coagulation, or enhanced plasma protein leakage. Enhanced adhesion to the endothelium or increased numbers of "patrolling" monocytes may increase accumulation of leukocytes in the vessel wall and promote the local inflammatory response. The later phases of plaque development are characterized by an immense accumulation of various cell types in the vessel wall, as well as by accumulation of extracellular matrix compounds and cholesterol. In the wall, monocytes eventually become foam cells, which form a core region in the plaque. Besides these cells, which represent the numerical largest part of the invading cells, T cells and other cells have been detected in the plaque. Among the cells involved in atherogenesis are also mast cells. They may contribute to plaque vulnerability in late atherosclerosis by production of cytokines and, subsequently, by production of enzymes, such as matrix metalloproteases, cathepsins, chymases, or other proatherogenic proteases. These processes may reach a time point where they become irreversible and vessel wall architecture is destroyed. The ratio of migrating and emigrating cells appears to be important for progression of plaque development. The vulnerability of the plaque in the late phase of atherosclerosis is a very critical element in the fatal outcome of atherosclerosis in many cases. Inflammation and the resulting activation of proteolytic enzymes has been suggested to be an important determinant of plaque stability.

Thus, formerly regarded as a lipid disease, more recently, inflammation is supposed to be an important factor in atherogenesis. Based on the "response to injury" proposal by Russel Ross (Ross 1999), vascular inflammation may be initiated by one or more of various pathways (including activation by lipids). Extending this suggestion, the risk factors, previously determined in clinical research, may be epitomized

by biochemical or cell-biological compounds or functions, which regulate the extent of inflammation in the vessel wall. Although the past decades have taught researchers immensely about the biology of atherosclerosis, many important questions remain open. Among them is the question of the location of the atherosclerotic lesion, that is, why are particular types of vessels and particular regions in these vessels preferentially haunted by atherosclerosis? Another question is the importance of the sequence and intensity of the activation of inflammation in the early steps of atherogenesis by the various "risk factor-related" compounds or situations. Also of importance is the question at what time the "point of no return" in the lesion is trespassed, where cellular repair mechanisms keeping inflammation in check are no longer effective.

Inflammation

The term inflammation is derived from the Latin *inflammo, inflammatio* (i.e., to enkindle, to inflame; inflammation). The phenotype of inflammation has been described since the first and second century AD (Celsus; Galenus) by pain, redness, temperature, swelling, impaired function (i.e., *dolor*, *rubor*, *calor*, *tumor*, and *functio laesa*). These symptoms are caused by a variety of assaults, including infections, injury, or cell damage. Inflammation is a more generalized, that is, less specific, response of the body, in order to initiate repair or defense mechanisms. Thus, it is related to the innate immune pathways. Although inflammation is essential for healing processes, a dysregulated, in particular an enhanced inflammation, may cause chronic inflammatory diseases. In the inflammatory process, many different systems of the body are involved. Thus, prostaglandins, leukotrienes, histamines, bradykinins, complement factors, as well as coagulation and fibrinolysis factors play a role in inflammation. In this inflammatory reaction of the body, the cytokines have a central regulatory role. The cytokines cause the production and/or regulation of the above mediators, that is, many of these mediators are secondary to the cytokines. In turn, some of the mentioned substances may interfere with cytokine production. Since the cytokines have such a central and complex role in inflammation, and inflammation is so importantly involved in atherosclerosis, this overview concentrates on the cytokines and their relationship to atherosclerosis.

Usually, an inflammatory response is induced upon an insult, kept active until the insult is managed, and downregulated as soon as it is no longer required. This is due in part to the short half-life of the involved mediators. On the other hand, there are regulatory processes at various levels, which keep the inflammation in check. These regulatory levels are discussed below in the cytokine paragraphs. If the cause of the insult cannot be resolved or the inflammatory processes are dysregulated, chronic inflammatory diseases may develop.

The insults causing the inflammatory response do that by activating a cellular response. The cells involved in this response are, in the first line, monocytes and granulocytes. They are the basis of the so-called innate immune response in inflammation. Only later, their response will attract and activate cells of the adaptive immune system, which react much more specific to the insult(s). In the innate immune response, the cells are activated by the compounds causing the insult via pattern-recognition receptors (PRR). These receptors do not react very specifically to particular activators, as it is the case in the adaptive immune system, which is antigen specific. The PRRs can be activated by a variety of activators, although these activators must be of a comparable structure, type, or "pattern." These receptors react with substances containing a so-called "pathogen-associated molecular pattern" (PAMP) or a "damage/danger-associated molecular pattern" (DAMP). A variety of such receptors has been identified (e.g., TLR (*toll*-like receptor), NLR (NOD (nucleotide-binding oligomerization domain containing)-like receptor), CLR (C-type lectin receptor), etc.) and their activators described (compare (Loppnow et al. 2011)). Due to the broad specificity of these receptors and their

location in high concentrations on monocytes and granulocytes, the PAMPs or DAMPs quickly and potently activate the cytokine production and the production of subsequent inflammatory compounds.

Cytokines

The term cytokine is derived from the Greek *kýtos* (vessel, jar, cell) and *kinein* (movement), meaning as much as "interacting between cells." These hormone-like mediators regulate a variety of important cell functions, including cell differentiation, tissue repair, immune response, inflammation, contraction, or cell death. More than 150 different cytokines have been described in the past. In the beginning, cytokine terminology has been related to the function of the cytokine (e.g., "endogenous pyrogen" causes fever, it is now termed interleukin-1 (IL-1); "T cell growth factor" stimulates T cell proliferation, it is now termed IL-2). However, some cytokines have been discovered in parallel in different assay systems, because each cytokine may exert different functions. For example, IL-1 was isolated as the inducer of fever. In this situation, it was called endogenous pyrogen (EP). In addition, IL-1 was also isolated as the protein inducing the stimulation of IL-2 production of T cells and was termed lymphocyte-activating factor (LAF). Later, upon isolation of the respective cDNAs, it turned out that these and many other proteins, described for other functions, are identical and, finally, were called IL-1. Just to give one example, others exist for other cytokines.

Also, other previous specifications have taken the cellular source into account. The first interleukin, that is, IL-1, was identified originally in monocytes, thus, the terminus "monokine" was coined for such monocyte-derived cytokines. On the other hand, IL-2 was described in lymphocytes and, therefore, called a "lymphokine." This turned out to be not practical, since it became clear afterwards that many different cells, not only monocytes or lymphocytes, but also tissue cells, can produce a particular cytokine.

On the other hand, the designation pro- and anti-inflammatory has been used to show the function of cytokines in reactions of the body. This brings together many different types of cytokines, however, is not applicable to all cytokines, since some cytokines are not primarily involved in inflammation. Still, this terminology is useful, since it refers to biological or medical functions.

Since the discovery of the first cytokines, a variety of cytokine groups have been determined. Starting from the functional description, the molecular characteristics and the relation to the corresponding receptors have been integrated in the establishment of these groups (summarized in (Loppnow 2001)). Although some editors have put some efforts into a comprehensive description of the cytokine groups (Thomson and Lotze 2003), no current handbooks or summary on this topic are available. This is probably due to the myriad of information available regarding the cytokine topic. Indeed, at the day of writing this text, a PubMed search with the keyword "cytokine" resulted in 580,265 titles. The cytokine groups include the interferons (IFN), the interleukins (IL), the tumor necrosis factors (TNF), the colony-stimulating factors (CSF), the chemokines, various growth factors, and the virokines. The virokines, as well as the viroceptors, are cytokine-related products, such as IL-10 homlogous or caspase-1 inhibiting proteins, as well as IL-1 receptor-like or TNF receptor-like proteins, respectively. The microorganisms, in particular viruses, may thwart the immune response against themselves by causing the infected cell to produce these substances, thereby reducing inflammation. The original activities, as well as additional activities of the respective cytokine groups, are mentioned in a very general way in Table 2. This table does not make any claim of being complete; rather, it shall enunciate the capacity of given cytokines, or cytokine groups, to fulfill various functions in parallel, functions which may be very different from each other. This – pleiotropy – is a central feature of cytokines, always to be considered in research involving cytokines. The table also

Atherosclerosis and Cytokines, Table 2 Cytokine groups

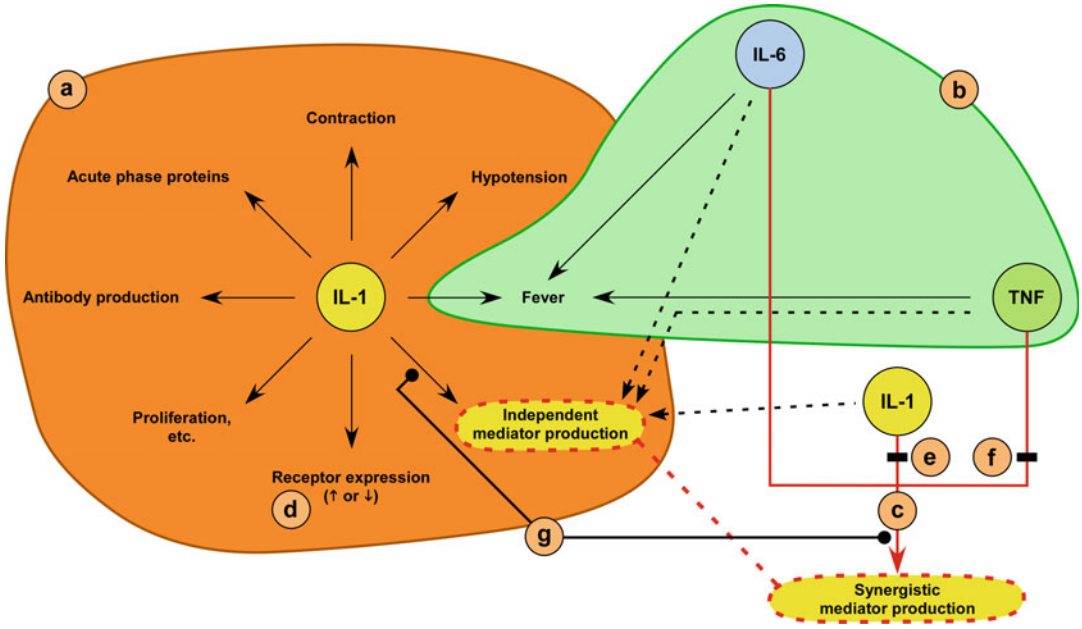
Group	Original description	Additional functions
Interferon	Antiviral	Immunoregulation
		Macrophage activation
		MHC-class I induction
Interleukin	Immunoregulation	Regulation of inflammation
		Regulation of other mediators
		Regulation of enzyme production
		Chemotaxis
Tumor necrosis factor	Tumor necrosis	Immunoregulation
		Regulation of apoptosis
Colony-stimulating factor	Hematopoiesis (i.e., cell differentiation of precursor cells)	Immunoregulation
Chemokine	Chemotaxis	Immunoregulation
		Adhesion
Growth factor	Proliferation	Immunoregulation
Virokine/viroceptor	Cytokine/cytokine receptor mimetic	

Abbreviations: *MHC* major histocompatibility complex

gives an allusion to another central feature of cytokines, the – redundancy – of the cytokine system. Redundancy means that various different cytokines, or cytokine groups, may have the same function, for example, interleukins, TNFs, and CSFs have immunoregulatory functions (compare also Fig. 1).

Many of the cytokines have been characterized at the molecular level. As it turned out, defined molecular characteristics do exist. Although the classification of the various cytokine groups with respect to their 3-dimensional structure is not completely uniform in the literature, some well-defined groups have been suggested (Nicola 1994). These groups are differentiated basically by protein-biochemical criteria. These groups and some examples are summarized in Table 3. One group is characterized by the presence of a set of beta sheets (long chain β-sheet cytokines). Some contain four (long or short) alpha helices (4-α-helical bundle cytokines) in their structure, and two other groups contain various elements (short-chain α-β-cytokines; mosaic cytokines).

The functions of cytokines are mediated by binding of the cytokines to the respective receptor. As in the case of the cytokines, the receptors also share some particular structural characteristics. There are three groups of cytokine receptors (in the broader sense of the word): (1) the cytokine receptor group in the narrow sense of the word, including four families (C1–C4 in Table 3); (2) the receptor kinase group with several subfamilies (K in Table 3); and (3) the chemokine receptor group (7-M in Table 3). (1) The receptors of the cytokine receptor group in the narrow sense are classified by their extracellular molecular characteristics. This group contains four families. The first is determined the "cytokine receptor family I" or "hemopoietin receptor family" (C1 in Table 3). The "cytokine receptor family II" or "interferon receptor family" (C2 in Table 3) utilizes similar signaling pathways, although it has different extracellular characteristics. The third family (C3) is the "TNF/NGF receptor family," which is connected to caspase or NF-kB (nuclear factor "kappa-light-chain-enhancer" in B cells) signaling. The "immunoglobulin receptor family," including the IL-1 receptor, also utilizes NF-kB, as well as MAP (mitogen-activated protein) kinase pathways. (2) The "kinase receptor groups" (K in Table 3) are classified by their intracellular kinase domains. They contain various types of tyrosine or serine/threonine kinases. The signaling pathways are in general different from those of the cytokine receptor group; they include Ras (rat sarcoma)/Raf



Atherosclerosis and Cytokines, Fig. 1 *Cytokine regulatory and interaction pathways:* The different parts (**a**-**g**) of the figure explain by representative examples the particular characteristics and/or pathways schematically. (**a**) **Pleiotropy**: one cytokine has a number of different functions; in this part of the figure (orange area), some IL-1 functions are mentioned; many other functions are not included but only referred to by the "*etc*." in "proliferation, *etc*." (**b**) **Redundancy**: one function can be induced by more than one cytokine; the green area of the figure indicates that IL-1, IL-6, and TNF can induce fever and replace each other inducing this symptom. (**c**) **Synergism**: here, mediator production is used as an example; the *red lines* and *red arrow* indicate that the mediator production in the simultaneous presence of IL-1, IL-6, and TNF is synergistic. The broken red line and the yellow fields surrounded by the broken red frame indicate the comparison of the "mediator production" by each of the three cytokines independently (broken black lines; black arrow), as compared to the production following parallel stimulation (red lines; red arrow). A synergism is present if the "synergistic mediator production" is much higher (overadditive) than the sum of the three "independent mediator productions" (e.g., 5,000 % vs. 100 + 100 + 100 %). (**d**) **Receptor expression**: cytokines can only cause a function if their respective receptor is expressed. Cytokines themselves can regulate the expression of their receptors. Thus, they may cause the expression (upregulation) or the disappearance (downregulation) of their own or other cytokine receptors, thereby making the cells responsive or irresponsive to themselves or the other cytokine, respectively. As an example, IL-1 may downregulate its own receptor, whereas other cytokines, such as IL-4, may upregulate the IL-1 receptor. (**e**) **Competitive inhibitors**: if a protein can bind to the receptor, without causing a signal, thereby preventing the binding of the substrate, competitive inhibition may take place. In the cytokine universe, the IL-1 receptor antagonist and the IL-36 receptor antagonist, also an IL-1 family member, are examples. They circumvent binding of the IL-1 or IL-36, respectively, thereby preventing activation of the cell. (**f**) **Soluble receptors**: the extracellular portion of a receptor may be released from the cell by enzymatic digestion. In some cases, this soluble form of the receptor (e.g., IL-1-, IL-6-, or TNF-soluble receptor) can still bind the substrate; this prevents the respective cytokine from binding to membrane-associated receptors, thereby preventing the activation of the cell. (**g**) **Anti-inflammatory cytokines**: particular cytokines can reduce the production or function of other cytokines. As an example, IL-10 may downregulate cytokine production by TH1 cells or monocytes. Such an inhibition is indicated in the figure by the *round-headed arrows*

(rapidly growing fibrosarcoma), phospholipase, Smad (Sma- and MAD-related proteins), or TAK (transforming growth factor-β–activated kinase) pathways, to mention only a few. (3) The chemokine receptors are particular, since they are seven-membrane-spanning-G-protein-coupled receptors, like the thrombin or the endothelin receptor.

In its schematic overview, Table 3 also points out that there is a functional relationship between

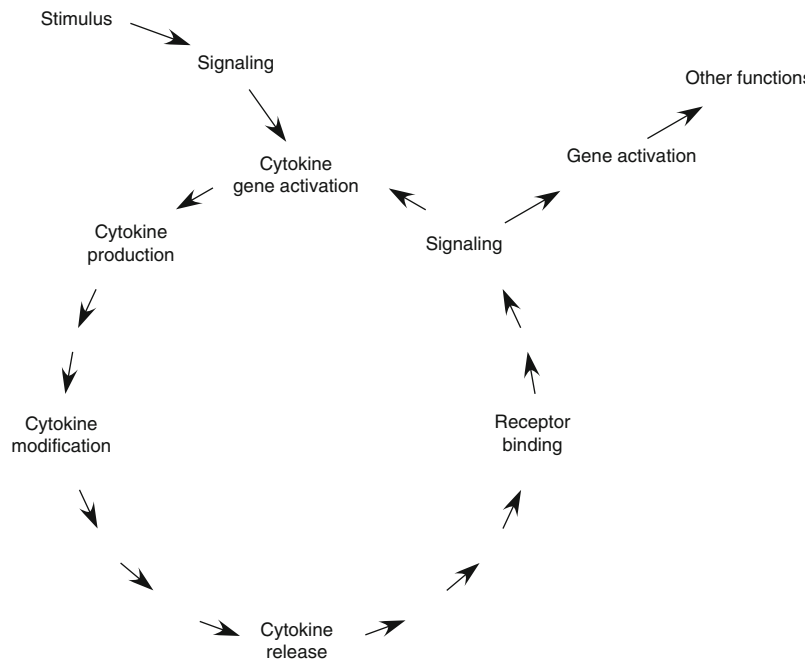
Atherosclerosis and Cytokines, Table 3 Cytokine groups and their relation to the respective cytokine receptor groups

Group	Family	Structural characteristic	Examples	Related receptor families[a]
Long chain β-sheet cytokines	IL-1 family	β-trefoil	IL-1[b]	C4
			FGF	K
	Cystein-knot family	-s-s-groups; β-sheets	PDGF, TGF-β, NGF	K
			LT	C3
	TNF family	β-jelly roll	TNF	C3
4-α-Helical cytokines	Short chain	< 25 aa / helix	IL-2, IL-3, IL-4	C1
			IFN-γ	C2
			M-CSF	K
	Long chain	> 25 aa / helix	IL-6, IL-11, G-CSF	C1
			IL-10, IFN-β	C2
Short chain α-β-cytokines		-s-s-groups; β-sheets	EGF, TGF-α, IGF	K
			IL-8, MCP, Rantes	7-M
Mosaic cytokines		Various	HRG, HGF	K

[a]C1–C4 are the four families of the cytokine receptor group; K are receptors of the receptor kinase group (yellow), 7-M is the chemokine receptor group (orange), Modified after Nicola (1994)
[b]Abbreviations: *CSF* colony-stimulating factor, *EGF* epidermal growth factor, *FGF* fibroblast growth factor, *HGF* hepatocyte growth factor, *HRG* heregulin, *IFN* interferon, *IGF* insulin-like growth factor, *IL* interleukin, *LT* lymphotoxin, *MCP* monocyte chemoattractant protein, *NGF* nerve growth factor, *PDGF* platelet-derived growth factor, Rantes regulated on activation, normal T expressed and secreted, *TGF* transforming growth factor, *TNF* tumor necrosis factor

the cytokines and their respective receptors: cytokines more prominently related to immunoregulation or inflammation are preferentially substrates of the receptors of the cytokine receptor group (C1–C4), whereas growth factors bind preferentially to receptor kinase family receptors (marked in yellow). The chemokines are interacting with the seven membrane spanning chemokine receptors (marked in orange). Thus, finally it turns out that the cytokine function is related (one even may say caused) by the subsequent signal-transduction mechanisms. However, for reasons of space limitation, this topic is not discussed here in more detail (for more information compare Fig. 2 in (Loppnow 2001)).

For the comprehension of the role of cytokines in pathogenesis, knowledge of some particularities of cytokines and their pathways is important. Two important characteristics of the cytokines have already been mentioned above. These were the pleiotropy and the redundancy in the cytokine system. Simply spoken, pleiotropy means that most cytokines do not only exert one particular function but can activate a variety of functions. IL-1 is a good example for a pleiotropic cytokine, since it is involved in a great number of biological functions (Fig. 1a, orange area) important for pathogenesis of many diseases (Dinarello 1996). In Fig. 1, redundancy (b) is depicted by the capacity of three different cytokines to induce fever (green area), that is, one particular function can be activated by different cytokines. This is a problem, if a therapy is based on blocking of a cytokine, since a failure of blocking may appear, due to the capacity of another cytokine to perform that particular function also, thereby replacing the original one. In the body, not only one cytokine will be present. Thus, the cytokines may interact in a synergistic fashion, that is, the effect induced by (c) three cytokines (red lines) in combination may be much higher (overadditive, synergistic) than the separate effects induced by the single cytokines (dashed black lines) summed up (indicated by yellow areas with red dashed lines). Another important regulatory pathway of cytokines is that they can regulate the receptor expression (d) of their own or other cytokine receptors. Upregulation of a certain cytokine receptor will make a cell responsive for a cytokine, whereas downregulation will make the cell irresponsive. This means that not only the concentration of a given cytokine is important



Atherosclerosis and Cytokines, Fig. 2 *Stimulation, production, and response to cytokines.* Activation of cytokine production, the subsequent modification and release pathways, and the following binding to receptors may lead to further production of atherosclerosis-related cytokines or to other functions relevant for atherogenesis. At many positions in this cascade of reactions, approaches for therapeutic attempts appear possible.

for its activity, but also the presence of a functioning receptor, indicating the complex regulation pathways involved in regulation of cytokine function. Other negative regulators of cytokine functions (in addition to receptor downregulation) are competitive inhibitors, such as receptor antagonists (e) which are described for some IL-1 family members. Furthermore, soluble extracellular portions of the respective receptors (f), for example, the soluble TNF receptor (soluble TNF R), which may bind and, thereby, inactivate the particular cytokine, are also proposed negative regulators. Finally, anti-inflammatory cytokines (g) may either block the cytokine production or the function of certain cytokines in various ways.

The above paragraph indicates the complex interactions of cytokines. However, these interactions are only a part of the cytokine regulatory system. In this paragraph, an attempt is made to bring the different levels of regulation together in an overview (Fig. 2). Cytokines are in general produced after stimulation. In the case of atherogenesis, it may be assumed that risk factor-related compounds, such as cholesterol, stress, infectious agents, or cytokines themselves, may activate cells of the blood or the vessel wall. They will do so by binding to the respective receptors, initiating intracellular signaling, which finally activates cytokine genes. In the activation of the production of some cytokines, for example, of IL-1, NF-kB plays a central role. Upon cytokine gene activation, the respective cytokine is produced in the cell. Some cytokines are modified then, for example, by glycosylation (e.g., IL-6 or IFN); others are produced as precursors (e.g., IL-1) and require further enzymatic processing in order to become active. In the case of IL-1β, this "processing" is regulated by activation of caspase-1, the enzyme responsible for IL-1β maturation. This step is regulated by a multiprotein complex termed "inflammasome," which has a central position in many inflammatory processes (Tschopp and Schroder 2010). Thus, IL-1β can only mature if both, the genes of itself and caspase-1 are active. Most cytokines contain a signal peptide, which makes them applicable for the classical release through the endoplasmic reticulum – Golgi release pathway. In case of IL-1, other pathways, such as vesicles, membrane transporters, or cell lysis, are proposed (Eder 2009). Upon release of the cytokine, it may bind to its specific receptor in an autocrine, paracrine, or endocrine fashion,

Atherosclerosis and Cytokines, Table 4 Examples of cytokines linked to atherogenesis[a]

Cytokine	Inflammatory		Producers	Putative functions in atherosclerosis
	Pro	Anti		
Interleukin-1	+		M[b] S E T	Potent EC and SMC activator; activates SMC migration and proliferation; activates enzyme production; increase fatty streak formation; decrease lesion size upon knockout; alter cholesterol and HDL levels; alter cell composition of the plaque
Interleukin-6	+	+	M S E	Activates SMC proliferation; activates enzyme production; activates acute phase protein production; alter lesion size; biphasic effects discussed
Interleukin-10		+	M T B	Anti-inflammatory activities; increase lesion formation upon knockout; risk factor
Interleukin-18	+		M S E	Proinflammatory activities; alter lesion size; T cell differentiation
Tumor necrosis factor	+		M S	Causes SMC apoptosis; regulates scavenger receptors; cell activator; decrease lesion size upon knockout; risk factor
Fractalkine	+		M S E	Monocyte attraction
M-CSF	+		M S E	Cell activator; chemotaxis

[a]This table summarizes a few cytokines suggested to be involved in atherogenesis. A more complete summary can be found in the excellent work of (Tedgui and Mallat 2006) and (Kleemann et al. 2008)
[b]Abbreviations: *B* B cells, *E* endothelial cells, *M* monocytes/macrophages, *M-CSF* macrophage-colony-stimulating factor, *S* smooth muscle cells, *T* T cells

meaning, it binds to the same cell, to another cell, or to a cell at another location. This activates intracellular signaling, which on the one hand may keep the cytokine gene activation active for another cycle of production. However, on the other hand, other genes may also be activated, resulting in other inflammatory functions. Many of these regulatory steps appear to be candidates for therapeutics targeting reduction of inflammation.

Evidence for the Role of Cytokines in Atherosclerosis

The role of cytokines in inflammation is apparent from the above paragraphs. What then indicates that cytokines are indeed involved in atherosclerosis? Research has focused at various levels of investigation in order to answer this question: (1) if cytokines are important for cardiovascular diseases, they may be present in the plasma of patients. Thus, a great number of clinical studies have been performed. Cytokines have been found in patients suffering from cardiovascular diseases, and some treatments have altered the cytokine levels (compare (Loppnow et al. 2008; Tedgui and Mallat 2006) for further reading). (2) A role of cytokines in cardiovascular diseases, such as atherosclerosis, would be further supported if the cells involved in plaque development, such as monocytes, granulocytes, endothelial cells, and smooth muscle cells, would be able to produce cytokines and interact by means of these mediators. This has been shown in an overwhelming wealth of publications. These data indicate that the cited cells can produce inflammatory mediators, such as IL-6 or IL-1, can respond to these substances, and can interact by cytokines (Chen et al. 2009; Loppnow and Libby 1990; Loppnow et al. 1998; Loppnow et al. 2008). (3) Since the patient and the in vitro cell-culture data indicated the importance of cytokines, efforts to prove the importance directly were performed in animals. Mice containing genetic deficiencies of the LDL (low-density lipoprotein) receptor or ApoE (apolipoprotein E) develop atherosclerosis upon cholesterol-rich chows. Crossing such animals with animals lacking cytokine genes (e.g., lacking the IL-1 receptor gene or the IL-1β gene) resulted in reduced atherosclerosis (Kleemann et al. 2008; Chi et al. 2004; Kirii et al. 2003). These data provided final evidence for the essential role of

cytokines in atherosclerosis. Cytokine research in this field has now reached a point where cytokine compounds are used in patients in clinical trials (Ridker et al. 2011).

Conclusion

There is now undisputed evidence that cytokines, the most prominent mediators of inflammation, are importantly involved in development of atherosclerosis (compare Table 4). The many regulatory steps in the cytokine interaction network offer a wealth of targets for therapeutic intervention.

Autoantibodies in Rheumatoid Arthritis

Robert H. Shmerling
Division of Rheumatology, Beth Israel Deaconess Medical Center; Department of Medicine, Harvard Medical School, Boston, MA, USA

Synonyms

Autoimmunity; Autoimmune disease; Polyarthritis

Definition

Rheumatoid arthritis (RA) is a chronic disease of unknown cause marked by chronic joint inflammation. While RA is associated with a number of autoantibodies, the role of these antibodies in disease pathogenesis remains uncertain. Measures of RA-associated autoantibodies may be a source of diagnostic and prognostic information for individuals with suspected or established joint inflammation. Rheumatoid factor (RF) has long been the primary biomarker used by researchers and clinicians. However, recent studies confirm that anti-cyclic citrullinated peptide (anti-CCP) has higher specificity for rheumatoid arthritis than RF. In the future, it seems likely that additional autoantibodies will be discovered among individuals with RA. These could provide new insights into disease development and prove useful in the evaluation and treatment of individuals with rheumatoid arthritis or related disorders.

Introduction

In 1940, Waaler and Rose discovered the rheumatoid factor (RF) (Waaler 1940) and soon its association with rheumatoid arthritis (RA) provided compelling evidence of the autoimmune nature of RA. In addition, the RF became a common diagnostic test for patients with suspected rheumatoid arthritis or other rheumatic conditions. There was hope that determining the origin of RF production would unravel the pathogenic events leading to disease development.

Yet, many patients with RA lack significant quantities of RF in their blood. And, over time, other autoantibodies have been detected in patients with RA. The search for autoantibodies in RA continues in the hopes of advancing our understanding of disease pathogenesis, discovering preventive strategies, and improving our diagnostic and prognostic acumen. In the current era of early, aggressive treatment, the value of a highly sensitive and specific biomarker has never been higher.

At the current time, the presence of a single autoantibody cannot establish the diagnosis of RA or accurately predict its future development in an individual. Similarly, the absence of an autoantibody cannot rule out a current diagnosis of RA and a negative RF does not preclude its development in the future. Still, the presence or absence of autoantibodies in a person with polyarthritis can be helpful to the researcher, the clinician, and the patient.

Rheumatoid Factor (RF)

The RF is an antibody targeting the Fc portion of IgG. While a number of different RF immunoglobulin types (including IgM, IgA and IgG) can be detected in people with RA, it is the IgM subtype that is commonly called “RF” and that is usually measured in clinical practice. The strong association between RF and RA is clear and has been well established for decades. However, the reason some individuals produce RF, its physiologic function, and its role in disease pathogenesis remain unclear. RF does not appear to have a primary pathogenic role; that is, RF is not the cause of RA. However, it is associated with more severe disease. For example, RF-positive RA patients are more likely to have erosive and extra-articular disease than RF-negative RA patients.

While testing for RF is quite common in clinical practice, interpreting its results can be challenging because:

- The test is not standardized – There are many methods for measuring RF and different laboratories may provide different results on the same patient.
- A sizeable subset of patients with RA do not produce RF; estimates of "sero-negative" RA range from 10 % to 70 % (Shmerling and Delbanco 1991).
- The test is not specific for RA – Other conditions associated with chronic antigenic stimulation may be associated with RF. Examples include viral infections and subacute bacterial endocarditis (McInnes and Schett 2011).
- Genetic factors may drive RF production – As a result, people without RA but who have family members with RA may be more likely to be RF positive.
- RF may be present in rheumatic diseases other than RA, including most patients with Sjogren's syndrome and mixed connective tissue disease.

The 1958, 1987, and 2010 revised criteria for the classification of RA include the RF along with other clinical findings. Interestingly, the RF can be present years before clinical evidence of RA develops (Nielen et al. 2004).

Anti-Cyclic Citrullinated Peptide (Anti-CCP) Antibodies

Over the last decade, the high specificity of anti-CCP antibodies for RA has become clear (Nishimura et al. 2007; Whiting et al. 2010) and, as a result, testing patients with possible RA has become common. In fact, anti-CCP antibodies are the first highly specific markers for RA that are also sensitive enough to be clinically useful.

Anti-CCP antibodies target citrulline, an arginine molecule that has been posttranslationally modified by the action of peptidyl-arginine-deaminase. Two recent meta-analyses described the sensitivity and specificity of the anti-CCP antibody for RA as 57 % to 67 % and 96 % to 98 %, respectively (Nishimura et al. 2007; Whiting et al. 2010). Despite the high specificity of the test and the finding of citrullinated antigens in synovial tissue (De Rycke et al. 2005; Chang et al. 2005), there is no compelling evidence that anti-CCP antibodies are actually pathogenic. The absence of detectable anti-CCP antibody in the serum of a third or more of RA patients also suggests that the antibody is not pathogenic (or that RA is actually more than one disease). The observation that smoking and HLA-DR shared epitope genes are associated with anti-CCP positivity could be a clue to an interaction of environmental and genetic factors in the pathogenesis of seropositive RA (Klareskog et al. 2006; MacGregor et al. 2000).

Variations in anti-CCP antibody titer (and RF) may correlate with disease activity in some patients, but monitoring antibody levels is not routine or considered useful. However, the test does have prognostic significance: As with RF, anti-CCP-positive RA patients tend to have more active and erosive disease and tend to require more aggressive therapy (De Rycke et al. 2004).

In addition, anti-CCP-positivity may be predictive of response to specific treatments. For example, one study found that RA patients who are anti-CCP-positive are more likely to respond to anti-TNF therapy or rituximab than RA patients who are anti-CCP-negative (Braun-Moscovici et al. 2006; Lal et al. 2011).

The most common use of anti-CCP in clinical practice is for the diagnosis of RA; given the test's high specificity, it has high positive predictive value in settings of moderate to high pretest probability of RA (e.g., in setting of otherwise unexplained chronic, symmetric polyarthritis). As is true with RF, the anti-CCP antibody is included among the newly revised criteria for RA and the antibody can often be detected years before the clinical onset of disease (Aletaha et al. 2010).

Other Autoantibodies in RA

A number of other autoantibodies are detectable in patients with RA, including some that are more

Autoantibodies in Rheumatoid Arthritis, Table 1 Autoantibodies associated with rheumatoid arthritis other than RF and anti-CCP

Antibodies to citrullinated peptides other than anti-CCP		Sensitivity	Specificity	Comments
	Anti-mutated citrullinated vimentin	0.6 to 0.85	0.8 to 0.95	May correlate with radiographic erosions
	Anti-perinuclear factor and anti-keratin antibodies	0.49 to 0.85	0.7 to 0.99	May correlate with radiographic erosions and treatment-resistant disease; may precede symptoms
	Anti-Sa	0.45 to 0.7	0.8 to 0.96	May correlate with radiographic damage
	Anti-citrullinated fibrinogen	0.55 to 0.6	0.9 to 0.99	Similar operating characteristics to anti-CCP but not entirely overlapping
	Anti-citrullinated synthetic type I or type II collagen telopeptides	0.8	0.9	May increase risk of RA synergistically with anti-CCP antibodies
Anti-alpha-enolase		.25	Uncertain	May predict which patients with undifferentiated, early arthritis will eventually develop RA
Anti-p68 (BiP) antibodies		0.7	0.95	The p68 autoantigen could play a role in RA pathogenesis
p-ANCA		Uncertain	Uncertain	Occasional; perinuclear ANCA without anti-MPO specificity; possible correlation with joint damage
Antibodies to glucose phosphate isomerase (GPI)		Uncertain	Uncertain	May correlate with extra-articular manifestations of disease, including Felty's syndrome and rheumatoid vasculitis
Antibodies to PADI4		0.45	0.85 to 1.0	PADI4 is involved in the production of citrulline, another potential autoantigen

highly associated with another rheumatic disease. For example, up to 40% of patients with RA have a positive anti-nuclear antibody (ANA).

In general, their significance with respect to disease pathogenesis, diagnostic and prognostic utility, and implications for treatment is limited or uncertain. None of these are commonly used by clinicians outside of research settings for patients with suspected or established RA.

A few of these are listed in the Table 1.

Other Disease Associations

It is important to emphasize that the autoantibodies described in association with RA have variable specificity and so are found in other conditions. For example, up to a third of patients with SLE may be RF positive. False-positive RF results are usually found in low titer but exceptions do occur.

Despite the high specificity of the anti-CCP antibody, non-selective testing in settings of a low likelihood of RA will inevitably produce false-positive results. A number of studies have documented the presence of anti-CCP antibodies conditions other than RA, including infectious diseases (e.g., tuberculosis) and other rheumatic diseases (e.g., SLE, Sjogren's Syndrome, and psoriatic arthritis) (Elkayam et al. 2006; Maejima et al. 2010; Atzeni et al. 2008; Kakumanu et al. 2009).

Conclusions

It has become clear that RF is not the only autoantibody associated with RA. Some are likely "epiphenomena," perhaps, an indication of dysfunctional immune function. However,

others may be intimately involved in disease pathogenesis and may even be useful targets for treatment. Currently, no single antibody has been identified with perfect sensitivity and specificity for RA; however, combinations of autoantibodies may prove more useful than any one alone.

It is likely that in the future, new autoantibodies will be discovered among individuals with RA and that we will have a better understanding of how these antibodies can be helpful to providing insights into disease development and for the clinical evaluation and treatment of affected patients.

Autoantibodies to Endothelial Cells

Gemma D. Banham, Matthew D. Morgan and Caroline O. S. Savage
Renal Immunobiology, School of Immunity and Infection, College of Medical Sciences, University of Birmingham, Birmingham, West Midlands, UK

Synonyms

AECAs; Anti-endothelial cell antibodies

Definition

Endothelial cells form a single cell layer lining of the luminal wall of blood vessels. They are critical for the integrity of the vessel wall and in a prime location to interact with components circulating in the blood. Endothelial cells are capable of modulating the immune response by secretion of cytokines and by regulation of adhesion and transmigration of leukocytes. Antibodies targeted to endothelial cells are known as anti-endothelial cell antibodies (AECAs). AECAs were first described over 40 years ago and have since been detected in serum from patients with a wide range of medical conditions. AECAs represent a heterogeneous group of antibodies directed against a range of endothelial cell antigens. The characterization of antigenic targets of AECAs is incomplete, but known targets include membrane antigens, ligand-receptor complexes, and planted molecules which are circulating proteins that have become adhered to the endothelium. AECAs can also be found in healthy people. These "natural endothelial cell antibodies" have physiological functions increasing the anti-inflammatory effects of endothelial cells.

Detection of AECAs

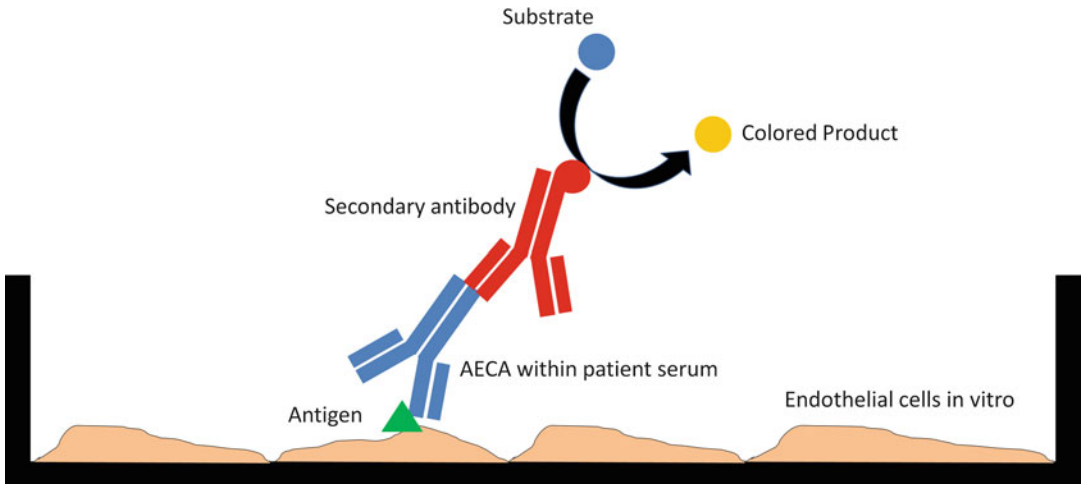
The reported incidence and prevalence of AECAs varies widely, partly due to differences in assays used to quantify them and a lack of gold standard method of detection (Youinou et al. 1995). The majority of studies have relied on cell-based enzyme-linked immunosorbent assays (ELISA) with human umbilical vein endothelial cells (HUVEC) as a detection system (Fig. 1).

The fixation process utilized in cell-based ELISA results in permeabilization of the endothelial cells, exposing intracellular antigens as well as surface membrane antigens to the test antibody leading to false-positive results. Flow cytometry analysis of unfixed endothelial cells detects more specifically AECAs directed against surface antigens (Westphal et al. 1994). Other techniques including indirect immunofluorescence, immunoprecipitation in conjunction with Western blotting, fluorescence-activated cell sorting (FACS), and radioimmunoassay have also been utilized to detect AECAs. Each technique has its own limitations.

AECAs can be distinguished on the basis of their reactivity to the endothelium of capillaries and large vessels (Praprotnik et al. 2001). Further, the binding affinity of AECAs varies depending on the endothelial cell target used, with differences between cell donors and cell line localization. Granulomatosis with polyangiitis (Wegener's) is associated with organ-specific AECAs. In a study by Holmen et al., the reactivity of AECA to endothelial cells depended on the origin of the endothelial cell line; there was a high incidence of AECAs reactive with human kidney microvascular endothelial cells (71 %) but lower reactivity to nasal endothelial cells (61 %), pulmonary microvascular endothelial cells (25 %), and HUVEC (7 %) (Holmen et al. 2004).

Incidence of AECAs

AECAs have been associated with a wide range of diseases. The most evidence exists for an association with antiphospholipid syndrome (discussed in detail later) and the systemic vasculitides, a group of disorders characterized by inflammation within the vascular wall. AECAs have been described in large-, medium-, and small-vessel vasculitides including giant cell



Autoantibodies to Endothelial Cells, Fig. 1 Indirect ELISA. Endothelial cells are grown in vitro until confluent. Patient serum is added. AECA present within the serum binds to an unidentified antigenic target present on the endothelial cells. A secondary antibody is applied which binds to bound AECA. Unbound antibody is washed away. This secondary antibody has an enzyme conjugated to it. Added substrate changes color in the presence of the conjugated enzyme. The higher the concentration of AECA within the sample, the greater the concentration of bound enzyme and the stronger the color change. This can be measured using a spectrometer, thereby quantifying the concentration of AECA within the original sample

arteritis, Takayasu arteritis, polyarteritis nodosum, Kawasaki disease, Henoch-Schonlein purpura, and the antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides, namely, granulomatosis with polyangiitis (Wegener's) and microscopic polyangiitis. In granulomatosis with polyangiitis (Wegener's), AECAs are found in 19–71 % of people (reviewed in Savage and Williams (2007)). The wide-ranging estimates of prevalence are likely in part to be due to differences in the detection system used.

AECAs are also reported in association with other systemic autoimmune and connective tissue disorders. Estimates of prevalence are widespread. They have been reported in up to 90 % of those with systemic lupus erythematosus (SLE) and up to 68 % of those with rheumatoid arthritis, with increased prevalence in the setting of rheumatoid arthritis in association with vasculitis. In addition, AECAs are associated with Behcet's syndrome, Sjogren's syndrome, and systemic sclerosis.

Vascular injury has also been implicated in diseases not classically thought of as vasculitides. AECA levels are elevated in inflammatory bowel disease in some studies. In ulcerative colitis, AECA levels are correlated with circulating levels of von Willebrand factor, a marker of vascular injury. AECA levels are also increased in a series of miscellaneous disorders including chronic obstructive pulmonary disease, insulin-dependent diabetes mellitus, multiple sclerosis, masked hypertension, previous myocardial infarction, peripheral arterial disease, preeclampsia, thrombotic thrombocytopenic purpura, heparin-induced thrombocytopenia, and kidney allograft rejection.

AECA Targets

Given the wide range of diseases associated with AECAs, it is likely that the targets for AECAs are diverse. Antigenic targets may be constitutively expressed or modulated by cytokines in the context of inflammation or infection, for example, CMV infection. Planted molecules which bind to the surface of endothelial cells can also act as targets for AECAs, for example, DNA in SLE, myeloperoxidase and proteinase 3 in

ANCA-associated vasculitis, and β2 glycoprotein I in antiphospholipid syndrome. In many cases, the specific antigenic target for AECAs is unknown. Recent hypothesized targets include heat shock protein 60 (hsp60), peroxiredoxin 2 in systemic vasculitis, topoisomerase I and CENP-B in systemic sclerosis, alpha-enolase in Behcet's syndrome, and tropomyosin and T-plastin in Kawasaki disease. Heparin sulfate proteoglycans or heparin-like molecules have been suggested as a target for AECAs. The antibodies from patients with heparin-induced thrombocytopenia recognize platelet factor 4 bound to heparin, stimulating endothelial cells to produce tissue factor and bind platelets.

Although the presence of AECAs have been detected in a number of conditions, the clinical relevance is less clear. Are AECAs pathogenic or are they formed secondary to endothelial damage? Do they have a role in promoting a proinflammatory environment, or do they exhibit more direct cytotoxic effects? In vitro studies give useful insight into potential mechanisms of pathogenicity of AECAs; clinical studies provide evidence for the role of AECAs in causing disease.

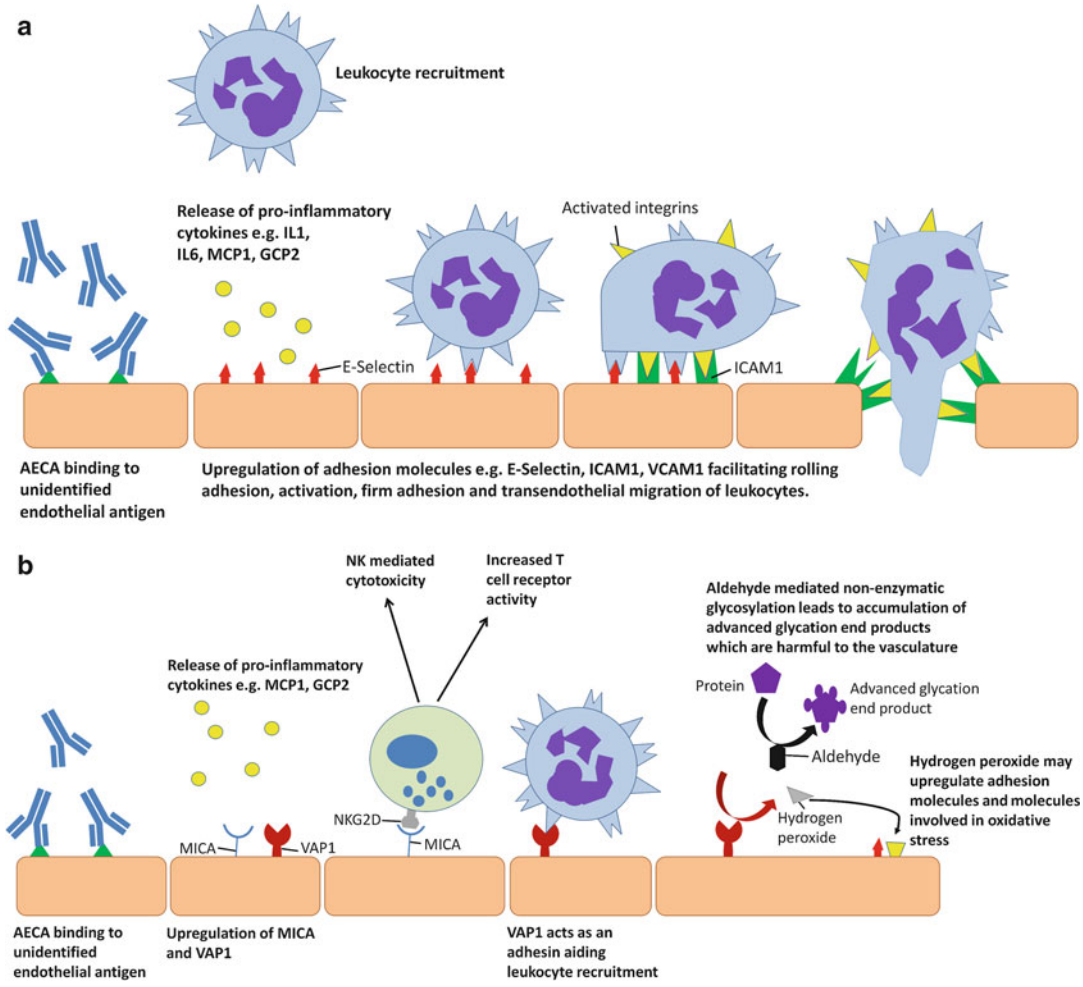
Potential Mechanisms of Pathogenicity

AECAs may act via direct antigen-specific mechanisms, for example, through activation of cell signaling cascades resulting in leukocyte activation and recruitment, or via non-antigen-specific pathways, for example, triggering antibody-dependent cellular cytotoxicity (ADCC) and apoptosis.

Effects of AECAs

AECAs may have direct functional effects, triggering cell signaling cascades on binding to endothelial cell antigens resulting in upregulation of adhesion molecules, recruitment of leukocytes, and secretion of proinflammatory cytokines, with potential to further potentiate the process via autocrine effects (Papa et al. 1999) (Fig. 2a). Immunoglobulin G from patients with SLE and systemic vasculitis upregulates adhesion molecule expression (intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), E-selectin) and leukocyte adhesion in vitro, mediated via interleukin-1 and an unidentified cytokine released from endothelial cells (Carvalho et al. 1999). Binding of AECA from granulomatosis with polyangiitis (Wegener's) patients to human kidney microvascular endothelial cells (HKMEC) elicited a calcium flux associated with secretion of monocyte chemotactic protein-1 (MCP-1) and granulocyte chemotactic protein-2 (GCP-2) (Fig. 2b). MCP-1 and GCP-2 are cytokines that mediate monocyte, T cell, and neutrophil infiltration and upregulation of the ligands MHC class I-related antigen A (MICA) and vascular adhesion protein-1 (VAP-1). MICA is a ligand for the co-stimulatory receptor NKG2D which is expressed on natural killer (NK) cells, CD8 T cells, and $\gamma\delta^+$ T cells and is involved in increasing T cell receptor activity and cell-mediated toxicity of NK cells. VAP-1 has roles in chemotaxis and oxidative stress through mediating production of hydrogen peroxide, aldehydes, and ammonium. Renal biopsy specimens from patients with active granulomatosis with polyangiitis (Wegener's) had strong expression of MICA and VAP-1 as well as evidence of infiltrating cytotoxic $CD8^+$ and $\gamma\delta^+$ T cells and cells expressing the MICA ligand NKG2D, suggesting a role for AECAs in initiating leukocyte recruitment in ANCA-associated vasculitis (Holmen et al. 2007).

AECAs may act in this direct way at concentrations below the limit of detection by conventional immunohistochemistry, offering a possible mechanism of pathogenesis in pauci-immune conditions. Monoclonal AECA IgG generated by hybridoma formation with human SLE cells induces a proadhesive and proinflammatory endothelial phenotype through nuclear factor kappa B (NF-κB) activation, with involvement of an autocrine loop of interleukin-1β secretion. Endothelial cell activation was found to be dose dependent. E-selectin was upregulated at lower concentrations of AECA than ICAM-1 or interleukin-6, perhaps facilitated by the autocrine effects of cytokines produced by endothelial cells (Yazici et al. 2001). Absence of AECAs on



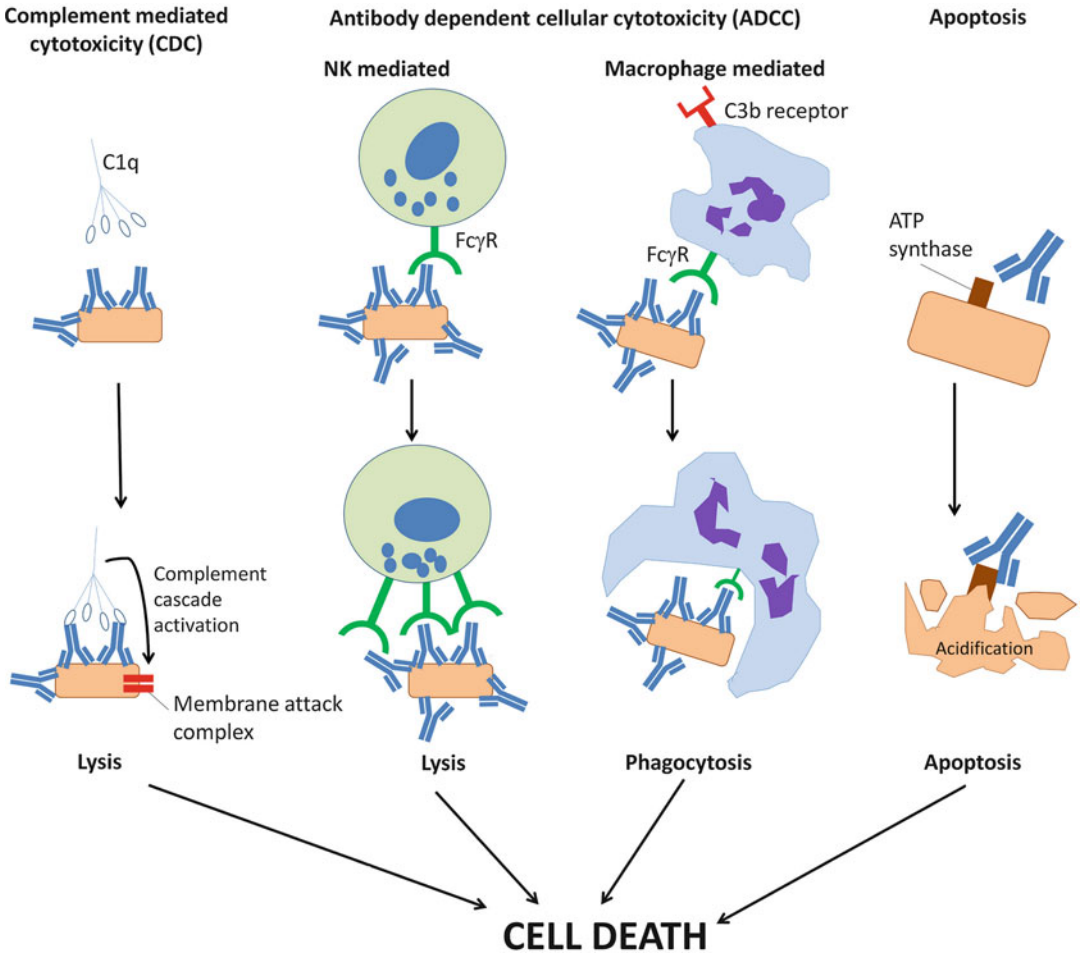
Autoantibodies to Endothelial Cells, Fig. 2 Direct effects of AECAs. (**a**) AECA binding to endothelial cells causes release of proinflammatory cytokines and upregulation of adhesion molecules. As a result, leukocytes are recruited and able to progress through the leukocyte adhesion cascade, resulting in transendothelial migration and accumulation at the site of inflammation. (**b**) Direct effects of AECAs. The cytokines MCP1 and GCP2 cause upregulation of MHC class I-related antigen A (*MICA*) and vascular adhesion protein-1 (*VAP1*). MICA is a ligand for NKG2D, a co-stimulatory receptor expressed by NK cells, CD8 T cells, and γδ T cells. Engagement leads to NK-mediated cytotoxicity and increased T cell receptor activity. VAP1 is both an adhesin and an enzyme involved in producing potent inflammatory mediators, for example, hydrogen peroxide, aldehyde, and ammonium

immunochemistry can also be explained by low avidity binding via the $F(Ab)_2$ portion of the immunoglobulin.

Indirect effects of AECAs

Complement-Mediated Lysis and Antibody-Dependent Cellular Cytotoxicity

AECAs can also cause damage via complement-mediated lysis or antibody-dependent cellular cytotoxicity in vitro (Fig. 3). However, there are questions over the in vivo relevance given the high effector/target cell ratios required. In SLE, complement-fixing AECAs are capable of mediating platelet adhesion and stimulating the release of tissue factor from endothelial cells, promoting thrombus formation (Cines et al. 1984). Recent evidence suggests that complement activation is important even in the absence of



Autoantibodies to Endothelial Cells, Fig. 3 Indirect effects of AECAs. Opsonization of cells by AECA marks them as a target for phagocytosis, NK-mediated antibody-dependent cellular cytotoxicity (*ADCC*), and complement-mediated cytotoxicity. AECAs can cause apoptosis directly via an interaction with surface ATP synthase

demonstrable immune complex deposition in pauci-immune vasculitis. The neutrophil C5a receptor may even prove to be a useful therapeutic target in ANCA-associated vasculitis.

Induction of Apoptosis

AECAs are capable of inducing endothelial cell apoptosis. Binding of AECA to endothelial cell surface ATP synthase, the endogenous receptor for heat shock protein 60 (hsp60), induced intracellular acidification which is known to induce endothelial cell death and trigger inflammation (Jamin et al. 2005). Normally apoptotic cells are cleared by macrophages in a noninflammatory manner. AECA opsonization of apoptotic cells may increase macrophage phagocytosis and trigger a further inflammatory response from macrophages through engagement of Fc receptors.

Do AECAs Have a Role in Disease Pathogenesis?

Association studies do not prove that AECAs are pathogenic and that they cause disease. AECAs may merely be associated with disease, an irrelevant epiphenomenon related to

endothelial damage. AECAs may potentiate endothelial damage even if they are not the primary cause of it, for example, by amplifying endothelial injury initiated by proteolytic enzymes released from neutrophils following activation by antineutrophil antibodies in ANCA-associated vasculitis.

Animal models provide some evidence for pathogenicity. Three out of ten mice injected with ANCA-depleted IgG derived from a granulomatosis with polyangiitis (Wegener's) patient developed mouse antihuman AECAs and subsequently perivascular lymphoid cell infiltrates as well as deposition of IgG at the outer part of blood vessel walls within kidney and lung. The lungs and kidneys from AECA-negative mice were free of any inflammatory cell infiltration (Damianovich et al. 1996).

Clinical human studies also support a role in disease pathogenesis. Several studies have correlated the presence and levels of AECAs with markers of disease activity and organ damage. AECAs may be an independent risk factor for disease relapse in ANCA-associated vasculitis. However, this correlation is not universal; the largest study to date looking at 173 granulomatosis with polyangiitis (Wegener's) patients enrolled in a clinic therapeutic trial found no correlation between the presence of AECAs measured using HUVEC in a baseline serum sample with markers of disease activity (Sebastian et al. 2007). AECAs have been isolated from patients with ANCA-negative pauci-immune glomerulonephritis, suggesting perhaps a role for AECAs in the absence of ANCA. Furthermore in this patient group, different AECAs were associated with different clinical presentations of disease.

In some cases, presence of AECAs appears to correlate with a particular phenotype of disease. For example, in Behcet's syndrome, AECAs are associated with previous CNS involvement. In sarcoidosis, AECAs are associated with multiple lesions and requirement for corticosteroid therapy. In SLE, AECAs are associated with lupus nephritis and pulmonary hypertension. In systemic sclerosis, they are associated with severe digital ischemia and pulmonary arterial hypertension; prevalence rates are higher in those with diffuse compared to those with limited scleroderma.

Antiphospholipid Antibodies

Antiphospholipid antibodies (aPL) are a well-characterized form of AECA. Antiphospholipid syndrome is a condition characterized by a prothrombotic state causing venous and arterial thrombosis in the presence of aPL. It is often diagnosed following ischemic stroke or thromboembolic disease affecting the young or following recurrent miscarriage. Antiphospholipid syndrome can be described as primary in the absence of another autoimmune disease or secondary to a preexisting autoimmune disease, most commonly SLE.

The main antigenic target for aPL is β2 glycoprotein I (β2GPI), a protein planted on endothelial cells. β2GPI is a cationic protein that displays high binding affinity to endothelial cells via electrical interactions with cell membrane structures such as heparin sulfate, via interactions with the annexin-2 receptor, and potentially also via cell membrane receptors for lipoproteins, given β2GPI's role in lipid transport. Affinity-purified antibody against β2GPI isolated from patients with aPL syndrome binds to endothelial cells. Binding is reduced by removal of β2GPI in vitro and restored in a dose-dependent manner by exogenous human β2GPI.

Treatment with aPL induces endothelial cell activation, with increased expression of adhesion molecules (VCAM-1 and E-selectin); increased tissue factor transcription, expression, and function; and increased interleukin-6 production. Tissue factor acts as a receptor for activated factor VII (VIIa), increasing its activity within the coagulation cascade. Under normal circumstances, circulating factor VII is not exposed to tissue factor and has low activity. Vascular injury and inflammatory mediators, for example, tumor necrosis factor alpha (TNF-α) and bacterial lipopolysaccharide, can induce expression of tissue factor, converting the endothelium into a procoagulant state. Tissue factor expression on

the endothelium has also been described in association with sepsis and malignancy. Inappropriate expression of tissue factor therefore may underpin the thrombotic process seen in antiphospholipid syndrome and other conditions.

Thus, aPL – defined as antibodies are capable of activating endothelial cells in vitro and in vivo and appear to be implicated in the thrombogenic state of antiphospholipid syndrome. Experimental animal models have supported the in vivo pathogenic role of anti-β2GPI antibodies in both thrombosis and fetal loss. Anti-β2GPI antibodies therefore represent a class of AECAs where the target, potential signaling pathways, and pathogenic mechanisms are well defined (Fig. 4).

Alternative AECA targets may also play a role in the pathogenesis of antiphospholipid syndrome. Autoantibodies to heparin sulfate inhibit formation of antithrombin III-thrombin complexes, a natural anticoagulant, thus favoring a thrombophilic state. AECAs also interfere in apoptotic cell clearance (Graham et al. 2009). Clearance of procoagulant apoptotic cells by healthy endothelial cells is inhibited, while opsonization by AECA enhances Fc-mediated uptake by professional phagocytes. This change results in increased thrombin generation and a proinflammatory, procoagulant state.

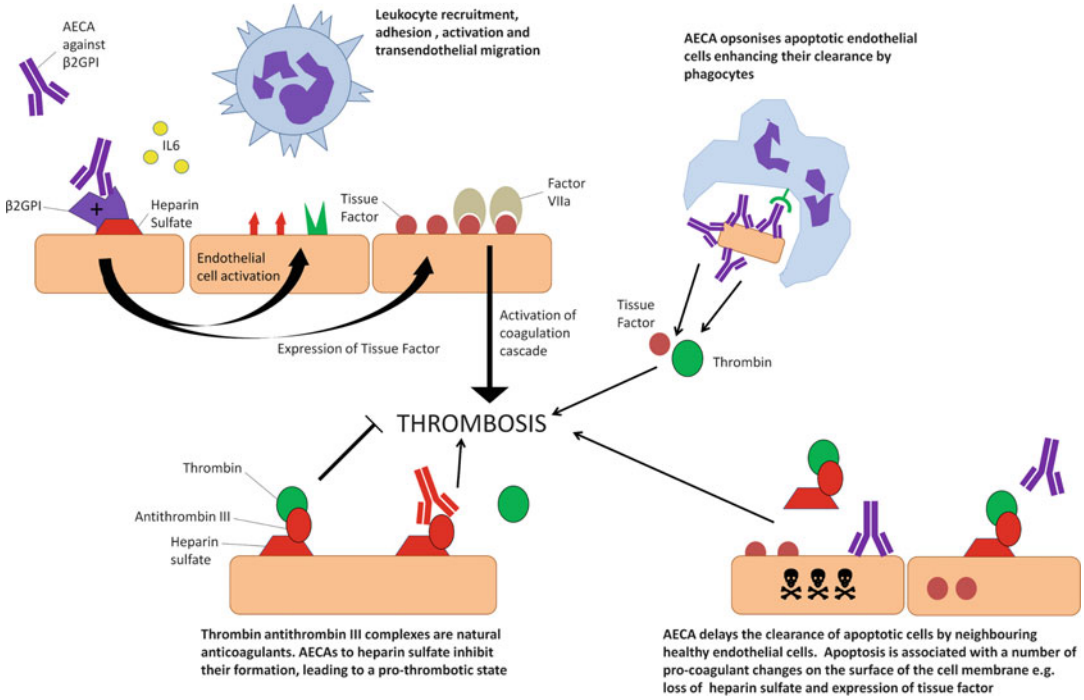
AECAs and Cardiovascular Impact

Patients with autoimmune disease such as rheumatoid arthritis, SLE, and systemic vasculitis have increased risk of cardiovascular disease. Cardiovascular disease is the leading cause of mortality in these conditions. Chronic inflammation is thought to be a risk factor for accelerated atherosclerosis by promoting vascular endothelial dysfunction. Classical risk factors for atherosclerosis precipitate endothelial dysfunction; hypertension is associated with increased shear stress; cigarette smoking is associated with free radical damage. AECAs may contribute by causing endothelial injury, promoting a proinflammatory, proadhesive endothelial cell phenotype and altering the metabolism of lipoproteins involved in atherogenesis (reviewed in Narshi et al. (2011)). The resultant endothelial dysfunction may lead to atherosclerotic plaque formation and subsequent cardiovascular events. The importance of adhesion molecule expression is shown by a reduction of plaque lesions in atherosclerosis-prone apolipoprotein E-deficient mice that are also deficient in E-selectin (Dong et al. 1998). Elevated levels of soluble VCAM-1 in the systemic circulation have been identified in humans with coronary artery disease.

Antiphospholipid antibodies have been particularly studied in relation to accelerated atherosclerosis. ß2GPI is present in human atherosclerotic plaques, and adoptive transfer of ß2GPI reactive lymphocytes enhances early atherosclerosis in LDL receptor-deficient mice. Antiphospholipid antibodies may enhance atherosclerosis via oxidative modification of lipoproteins, for example, low-density lipoprotein, and by promoting the uptake of lipoproteins by macrophage scavenger receptors. In clinical studies, the relevance of aPL antibodies in atherosclerotic disease is hotly debated. In a prospective study of 182 SLE patients, presence of aPL, elevated markers of endothelial activation (von Willebrand factor (vWf), soluble vascular cellular adhesion molecule-1 (sVCAM-1)), and fibrinogen were found to be predictors for first cardiovascular event in age-adjusted Cox regression analysis. The association with positive aPL was maintained in a multivariable Cox model (Gustafsson et al. 2009).

AECAs have been shown to be associated with ischemic heart disease in the absence of autoimmune disease, with increased prevalence of AECA positivity in those undergoing coronary angiography for ischemic heart disease compared to controls, where those with clinical and/or laboratory features of SLE, systemic sclerosis, or vasculitis were excluded. There was also an association with severity of symptoms and restenosis rates.

Statins inhibit anti-β2GPI antibody-mediated endothelial cell activation, downregulating the expression of adhesion molecules. These drugs, proven to be beneficial in cardiovascular disease, may be acting in part through modulation of AECA pathogenicity.



Autoantibodies to Endothelial Cells, Fig. 4 AECAs in antiphospholipid syndrome. AECAs are pathogenic in antiphospholipid syndrome. β2GPI is a cationic protein that is planted on the endothelial surface and bound to endothelial proteins, for example, heparin sulfate, via electrical interactions. AECAs against β2GPI activate endothelial cells, leading to increased leukocyte recruitment. AECAs promote a prothrombotic environment through upregulation of tissue factor expression, inhibition of the natural anticoagulant action of thrombin-antithrombin III, impaired clearance of apoptotic cells, and increased phagocyte activity. This prothrombotic state underpins the clinical features of antiphospholipid syndrome

AECA in Transplantation

Accelerated cardiovascular disease is also a problem following transplantation. AECAs have been associated with coronary artery disease following cardiac transplantation. Chronic allograft rejection has histological findings of narrowing of muscular arteries or obliterative arteriopathy. The vascular endothelium of transplanted organs represents an important target of allograft-directed immune responses, and endothelial cell injury is paramount in chronic allograft rejection. Both cellular and humoral arms of the immune system have been implicated. AECAs have been associated with acute rejection, chronic rejection, and decreased allograft survival in renal transplantation.

The role of AECAs directed against antigens other than human leukocyte antigen (HLA) in kidney allograft rejection is being increasingly studied. Sun et al. used HUVEC as a substrate for a cell-based ELISA detecting non-HLA antibodies pre- and posttransplantation. The presence of preexisting AECAs was not associated with either an increased risk of rejection or a detrimental impact on recipient/graft survival. However, de novo AECAs appearing posttransplantation in patients who did not have AECAs pretransplantation were associated with a higher risk of early rejection, which tended to be more severe. There were histological similarities to classic antibody-mediated rejection despite the absence of C4d deposition (Sun et al. 2011). However, critics claim that the study did not prove that AECA reactivity was not due to HLA antibodies reactive with the nonspecific HUVEC assay used. XM-ONE is a method of flow cytometry crossmatch using donor precursor endothelial

cells as target cells. Using this technique, Xavier P et al. showed an association of AECAs with early acute rejection following renal transplantation. In addition, they identified a subgroup of patients experiencing rejection (19/43) who had AECAs but not HLA antibodies. A positive AECA result in the setting of rejection was significantly associated with a poor prognosis, with 20/31 going on to develop progressive graft dysfunction (Xavier et al. 2011). The majority of AECA-positive patients (51 %) did not experience rejection, perhaps due to the absence of target antigens on the renal vascular endothelium.

Infectious Agents and AECAs

AECAs may be driven by the presence of microorganisms, for example, cytomegalovirus (CMV). Most viral infections can induce polyclonal B cell activation, triggering autoantibody production as well as a viral-specific antibody response. CMV infection upregulates adhesion and major histocompatibility complex (MHC) molecule expression on CMV-infected endothelial and immune cells and increases their cytokine secretion. CMV infection also modifies the peptides expressed on HLA class I and II molecules; some CMV peptides display molecular mimicry with alloantigens; additionally, neoantigens are produced during CMV infection and may be expressed on endothelial cells.

Increased levels of AECAs have been reported in a small group of cardiac and renal transplant recipients during and after CMV infection. CMV infection is known to be associated with both acute and chronic allograft rejection. CMV infection has been implicated more widely in the atherosclerotic process, with studies associating levels of CMV antibodies with patients with vascular disease and isolation of CMV antigens from atherosclerotic plaques. Could this be in part due to CMVs role in AECA formation?

There are also associations between AECAs and other infectious diseases. In dengue fever, the host immune response contributes to endothelial cell damage in addition to direct viral damage. Antibodies against dengue virus nonstructural protein 1 (NS1) cross-react with endothelial cells, inducing endothelial cell apoptosis and cell lysis in the presence of complement. The resulting vascular leak, endothelial dysfunction, and hemorrhagic diathesis may contribute to the life-threatening complications of dengue hemorrhagic fever and dengue shock syndrome (Lin et al. 2003).

Conclusion

There is growing evidence to suggest an association between AECAs and a wide range of diseases. The difficulties in measuring AECAs, lack of gold standard technique, and incomplete identification of targets have complicated this area of research, making it difficult to draw firm conclusions.

In vitro models have enabled identification of some of the downstream effects of AECAs. Endothelial cell activation and subsequent upregulation of adhesion molecules, tissue factor, and secretion of proinflammatory cytokines provide a mechanism by which AECAs could mediate their effects in autoimmune disease and cardiovascular disease.

It remains unclear if antibodies occur prior or secondary to endothelial cell damage. Perhaps this distinction is somewhat academic if the antibodies contribute by amplifying the disease process. There is a pressing need to identify the antigenic targets of AECAs. Until they are identified and antigen-specific ELISAs are developed, it will not be possible to determine the true incidence of AECAs in disease states and health. As more specific antigen targets are identified, the study of direct antibody effects will become possible and the role in pathogenesis will become more clear opening up opportunities for therapeutic intervention.

Autoimmune Bullous Disease Introduction

The bullous skin diseases, although uncommon, may have substantial morbidity. Coupled

Autoimmune Blistering Diseases, Table 1 Autoimmune Bullous diseases

Disease	Direct IF	Isotype	Target antigens	Location
Subcorneal				
Pemphigus foliaceus	Intercellular	IgG	Desmoglein-1	Desmosome
	Greater in upper epidermis		Desmocollins	
	C3 may be present		Other plakins	
Pemphigus erythematosus	Intercellular	IgG	Desmoglein-1	Desmosome
	Greater in upper epidermis			
	C3 is present			
	Granular deposition in BMZ			
Intraepidermal				
Pemphigus vulgaris	Intercellular	IgG	Desmoglein-3	Desmosome
	Greater in lower epidermis	Rarely, few IgA	Desmoglein-1	
	C3 often present	Rarely, few IgM	Desmocollins	
			Desmoplakin	
			E-cadherin	
			Other non-cadherin targets	
Pemphigus vegetans	Intercellular	IgG	Desmoglein-3	Desmosome
			Other non-Desmocollins 1	
			Other non-Desmocollins 2	
Paraneoplastic pemphigus	Intercellular	IgG	Envoplakin	Desmosome
	Other non-May have subepidermal component		Periplakin	
	Other non-C3 may be present		Desmoplakin 1	
			Desmoplakin 2	
			Plectin	
			BP230	Hemidesmosome
Subepidermal				
Bullous pemphigoid	BMZ, linear	IgG	BP 230	Hemidesmosome
	C3 present, may see only C3	Rarely, few IgA	BP 180	
		Rarely, few IgM		
Mucous membrane pemphigoid	BMZ, linear	IgG	BP 180	Hemidesmosome
	C3 present	Rarely, few IgA	Laminin 5	
			α6β4 integrin	
			BP 230	
			Collagen VII	
Linear IgA disease	BMZ, linear	IgA	BP180	Hemidesmosome
	C3 may be present	Rarely, few IgG	(Shed ectodomain)	
		Rarely, few IgA	LAD285	
			BP230	
			Collagen VII	

with the clinical presentation, these autoimmune disorders are characterized by their immunopathology and histopathology. Pathogenic autoantibodies bind to antigens with adhesion functions within the epidermis or dermis. The level of split within the skin or mucous membranes dictates the specific morphology. The target antigens are components of intercellular desmosomes or the adhesion complex, which is the basement membrane zone (BMZ) functional unit. However, target antigens and specific epitopes may be found with more than one disorder. The overlap between blistering disorders can make a definitive diagnosis challenging. Even when the specific target antigen is known, the exact pathogenesis for many bullous diseases is not fully understood.

Immunofluorescence (IF), along with the histopathologic features, has become the mainstay of diagnosis and has helped determine the specific pathogenic antigens for many of the autoimmune bullous disorders. Direct IF displays the deposition site of immunoglobulins, complement, and fibrinogen, whereas indirect IF of the serum detects circulating antibodies.

Depending on the target antigen, the level of split may be subcorneal (beneath the stratum corneum), intraepidermal (within the stratum spinosum), or subepidermal (at the dermal-epidermal junction). Subcorneal and intraepidermal blisters rupture easily and are classically described as "flaccid," as opposed to "tense" subepidermal blisters.

The autoimmune blistering disorders will be presented here sequentially by blister depth in the skin, from more superficial to deep (Table 1).

Autoimmune Heart Disease: Animal Models

Urs Eriksson
Department of Internal Medicine, GZO – Zurich Regional Health Center, Wetzikon, Switzerland
Division of Cardioimmunology, Department of Cardiovascular Research, Institute of Physiology, University of Zurich, Zurich, Switzerland

Definition

Autoimmune heart disease defines any structural or functional alteration of heart tissue due to aberrant immune responses against cardiac self-antigens, which impairs the capacity of the heart to maintain sufficient cardiac output to meet metabolic demands of the body. The term autoimmune myocarditis specifies cardiac inflammation due to an autoimmune response. Of note, autoimmune heart disease can also be part of a general self-reactive process involving other organ systems as well. This entry, however, focuses exclusively on animal models, which (1) mirror heart-specific autoimmunity only, and (2) on animal models in which self-antigen exposure but not infection trigger autoimmunity.

Introduction

During the past several years, autoimmune mechanisms had been increasingly recognized to be involved in the development of almost all cardiac diseases, such as dilated or structural cardiomyopathy, valvular heart disease, coronary arterial disease, hypertensive heart failure, and even conduction disturbances. In the following entry, however, I focus specifically on animal models of autoimmune myocarditis and postinflammatory cardiomyopathy.

Despite the fact that myocarditis can be observed in many species, such as anthropoid apes, rabbits, dogs, cats, and guinea pigs, current

animal research activities rely mostly on mouse and rat models. This, however, was not the case in the past: one of the first landmark papers describing a "filter-passing agent" isolated from the chest cavity of a male gibbon who died from myocarditis reported myocarditis-inducing transmission experiments on mice, guinea pigs, and rabbits (Helwig and Schmidt 1945). Research in the 1960s, 1970s, and 1980s of the past century developed myocarditis models in mice, rats, pigs, and rabbits as well. In 1963, Kaplan and Craig studied cardiac lesions in rabbit hearts caused by immunization with heterologous heart tissue (Kaplan and Craig 1963). Further studies successively refined immunization strategies and led to the first experimental autoimmune myocarditis models in mice, based on the injection of a mixture of whole mouse heart-specific alpha myosin together with Complete Freund adjuvant (CFA) (Neu et al. 1987). Ethical, logistical, statistical, and economic reasons, the availability of genetically altered mice and an acceptable level of relevance in mirroring human disease mechanisms all explain why mouse and – to a lesser extent – rat models currently dominate autoimmune myocarditis research.

Autoimmunity in Inflammatory Dilated Cardiomyopathy

Inflammatory dilated cardiomyopathy (iDCM) represents an important cause of heart failure in humans and often evolves from progressive myocarditis (Pauschinger et al 1999; Schultheiss et al. 2011). The protozoan Trypanosoma cruzi (Chagas disease) represents a leading cause of myocarditis in South America, but viral infections are the most common triggers in developed countries. The most important cardiotropic viruses are parvovirus B19, HHV-7-viruses, and entero- and adenoviruses (Badorff et al. 1999; Pauschinger et al 1999; Schultheiss et al. 2011). Importantly, infections not only infer direct damage to the heart (Badorff et al. 1999) but may also promote autoimmunity. Autoimmunity develops if the extent of autoreactive T cell activation is sufficient to overcome counter-regulatory tolerance mechanisms in genetically susceptible individuals. Accordingly, many patients with viral myocarditis develop heart-specific autoantibody responses on follow-up (Frustaci et al 2009; Schultheiss et al. 2011). In addition, viral genomes were found in biopsies of patients with dilated cardiomyopathy in the presence or absence of heart-specific autoantibodies. These observational findings suggest that viral infections indeed trigger heart-specific autoimmunity. The finding that immunosuppressive therapy improves heart function in patients without persistence of viral genomes in heart biopsies (Frustaci et al 2009; Schultheiss et al. 2011) further supports the concept that autoimmunity plays a central role in iDCM.

Strong evidence for autoimmunity in inflammatory heart disease, however, results from mouse and rat models. Mice infected with the human pathogen Coxsackie type B3 (CVB3) virus develop myocarditis. In susceptible strains, inflammation progresses even after clearance of the virus (Smith and Allen 1991; Fairweather et al. 2001) and adoptive transfer of T cells, but not serum from diseased mice transfers myocarditis in Severe Combined Immune Deficient (SCID) mice genetically lacking B and T cells. This observation, together with the fact that depletion of $CD4^+$ T cells markedly reduces disease severity, argues for autoimmunity and suggests that T cells contribute to myocarditis progression (Smith and Allen 1991; Pummerer et al. 1996; Fairweather et al. 2001).

Transgenic Models of Autoimmune Heart Disease

Several transgenic myocarditis models have been developed so far. Epidemiologic data suggest an association between dilated cardiomyopathy and specific HLA alleles, such as HLA D6. Consequently, Bachmaier et al. generated double CD4- and CD8-deficient transgenic humanized

mice expressing the human CD4 molecule and HLA antigen. These mice developed autoimmune myocarditis upon immunization with heart-specific peptides and therefore strongly argue for the autoimmunity hypothesis of inflammatory dilated cardiomyopathy in humans (Bachmaier et al. 1999).

NOD mice, on the other hand, contain many genetic susceptibility loci, which cause spontaneous T cell-dependent autoimmune diabetes. Replacement of a specific allele of the MHC class II complex (I-Ag7) with the human DQ8 allele ($DQ8^+$NOD mice) led to protection from NOD autoimmune diabetes but gave rise to spontaneous myocarditis, autoantibodies, and heart failure instead (Lv et al. 2011). Myocarditis in these mice, however, did not result from cardiac autoantibodies, but was clearly the result of autoimmune $CD4^+$ T cell responses. Mechanistically, a defect in thymic negative selection (i.e., the deletion of autoreactive T cells during their development) was underlying autoreactive T cell expansion and cardiac inflammation in the $DQ8^+$NOD mice.

Another recently developed model is based on the generation of mouse heart myosin epitope-specific, T cell receptor (TCR) transgenic mice on a BALB/c background. These mice develop spontaneous myocarditis and die from heart failure (Nindl et al. 2012).

CD4 T cells are critical for Experimental Autoimmune Myocarditis in most mouse strains. In humans, however, viral infections are the most common triggers of postinflammatory cardiomyopathy, at least in developed countries. From this point of view, CD8 T cells cannot be excluded as disease-promoting T cell subsets in the human system. Accordingly, a transgenic mouse model had been developed, which allows us to specifically address the immunopathogenesis of CD8 T cell-mediated cytotoxicity in the absence of viral infections (Grabie et al. 2003). These mice express ovalbumin peptide specifically on cardiac myocytes and develop severe CD8-mediated myocarditis upon OVA immunization. Taking advantage of these mice, as well as of the experimental autoimmune myocarditis model, Tarrio et al. described on the genetic level the potentially important role of PD-1 in myocarditis development. PD-1, a member of the CD28 family of immune regulatory molecules expressed on activated T cells, interacts with its ligands, PD-L1/B7-H1 and PD-L2/B7-DC, on other cells and, thus, delivers inhibitory signals to the T cell. The absence of PD-1 signaling resulted in enhanced cardiac inflammation, mainly due to less limited expansion of autoreactive CD8 and CD4 T cells (Tarrio et al. 2012).

Given the complexity and the myriads of potential inflammatory triggers of heart-specific autoimmune responses, further transgenic models of myocarditis will be developed in the future. Nevertheless, transgenic mice are a quite artificial system. They are helpful to answer specific mechanistic questions, but their relevance in mirroring the transition from infection to autoimmunity remains questionable. One of the most innovative strategies to study mechanisms of human autoimmunity in vivo will certainly include the reconstitution of complete immunodeficient mice (such as the $Rag2^{-/-}gammac^{-/-}$ mice) with a selected complete adaptive human immune system.

Experimental Autoimmune Myocarditis (EAM)

Immunization models offer the advantage to study autoimmune disease mechanisms in vivo without using infective agents. The concept is based on the idea that activation of antigen-presenting cells (APC), taking up and processing self-antigen, is a prerequisite for priming of autoimmune T cell responses. In the absence of appropriate APC activation, however, autoreactive T cell expansion is neither sustainable nor capable to overcome immuno-tolerance in non-transgenic mice and rats. Accordingly, delivery of self-antigen by itself is not sufficient to induce an autoimmune disease phenotype in naïve mice and rats. Therefore, autoantigen has to be applied together with a nonspecific strong adjuvant, such as Complete Freund adjuvant (CFA), containing heat-killed *M. tuberculosis* (Mtb^{hk}) as an active component,

for example. Whole alpha-myosin heavy-chain protein is heart specific and represents the best characterized self-protein for autoimmune myocarditis induction in mice and rats (Neu et al. 1987; Kodama et al. 1990). Unfortunately, the isolation of heart myosin from mice is a cumbersome and time-consuming procedure. Furthermore, whole alpha myosin exerts toxic effects in cell cultures limiting its use in T cell proliferation assays and related immunological in vitro studies. These drawbacks of whole heart myosin immunization can be overcome by using commercially available cross-reactive porcine heart myosin for rat immunization or by using short synthetic peptides representing the most self-pathogenic epitope of either mouse or rat heart myosin (Wegmann et al. 1994; Pummerer et al. 1996) or recombinant mouse cardiac troponin I (Kaya et al. 2008).

Not all mouse and rat strains are equally susceptible to EAM induction. The model works best with female Lewis rats (Kodama et al. 1990). In mice, highest disease scores are observed in A/J, A.CA, and A.SW strains. BALB/c mice are only moderately susceptible, but using specific alpha-myosin peptides rather than whole mouse heart myosin significantly increases disease severity. C57BL/6 and C57BL10 mice are completely resistant (Neu et al. 1987).

Despite highly reproducible and severe inflammation scores in A/J mice after alpha-myosin/CFA immunization, BALB/c mice and myosin peptides are usually preferred as self-antigens. This preference relies on the potential technical difficulties with mouse myosin isolation and purification, the availability of several transgenic models and knockouts on this background, and the facts that synthetic peptides are more practical in cell cultures and proliferation assays. Nevertheless, some of the pathogenic myosin-heavy-chain self-peptides are very hydrophobic and barely soluble in biological fluids and media. Introducing two Arginine residues at the H_2N- and the –COOH terminus of the hydrophobic peptide greatly increases solubility without affecting efficacy and specificity of the immune response. For an immunization of an 8–10-week-old BALB/c mouse, 100–150 μg peptide are required. Hydrophobic peptides can be dissolved in the oily CFA before creating a 1:1 emulsion with phosphate buffered saline. The emulsion is injected subcutaneously into both flanks of the mouse. Mice are boosted after 7 days and first cardiac infiltrates are visible as early as 14 days after the first immunization. Intraperitoneal injection of pertussis toxin on days 0 and 3 additionally enhances myocarditis incidence. Depending on the goal of the experiment, mice will be sacrificed at day 21 (peak of myocarditis) or between days 40 and 60 (if inflammatory dilated cardiomyopathy is the desired phenotype). Of note, disease incidence is rarely >80 % with BALB/c mice. Several nonspecific factors, such as commercial source of the mice, housing conditions, food, and experience of the person doing the immunization, influence disease severity and incidence. This must be taken into account while planning experiments, and performing pilot studies prior to start expensive and time-consuming projects is strongly recommended.

Lewis rat immunization follows a similar protocol. Instead of the standard CFA, however, reliable myocarditis induction requires the use of supplemented (i.e., containing 10 mg/ml heat-killed *Mycobacterium tuberculosis* strain H37Ra) adjuvant. A great advantage of the Lewis rats is the fact that disease incidence and severity are usually reliably high (>90 %). The use of strong adjuvant, however, shifts the histological phenotype to a picture similar to human giant cell myocarditis (Kodama et al. 1990; Wegmann et al. 1994).

Using short self-peptides, EAM can also be induced in BALB/c mice by injection of in vitro-activated α-myosin-peptide-loaded dendritic cells (Eriksson et al. 2003). Dendritic cells are sentinels of the immune system scavenging foreign pathogens as well as cell debris and necrotic tissues. Nonspecific activation of dendritic cells through Toll-like receptors (TLR) is critical for autoreactive T cell priming and can be achieved in vitro with a short (no longer than 2 h!) exposition to 1 μg/ml of lipopolysaccharide (LPS) or other TLR stimulants. Once activated, CD40-ligand-expressing autoreactive T cells

further increase the priming efficacy of the dendritic cells by a positive feedback loop that promotes production of proinflammatory cytokines and survival of activated dendritic cells via CD40-CD40L interaction. Disease induction by vaccination with self-antigen-loaded dendritic cells offers theoretically alternative approach to study APC-effector-cell interactions and priming mechanisms of autoimmune T cells in vivo in the absence of adjuvant. The concept that innate activation of self-antigen-loaded dendritic cells is sufficient to induce autoreactive T cells does not exclude a role for antigenic mimicry or failure of self-tolerance mechanisms in putting the heart at risk for autoimmune attack; it is conceivable that an immune system that was formerly exposed to any microorganisms mimicking self-antigen is more susceptible to boost autoreactive T cells after a second hit releasing self-antigen in the presence of a strong inflammatory response. Clinical and experimental observations strongly support this concept: it explains heart-specific autoimmunity after noninfectious tissue damage, such as cardiac surgery or myocardial infarction (Maisel et al. 1998; Rose 2001). Any tissue damage results in uptake of self-antigens by dendritic cells. If such self-antigen-loaded dendritic cells become activated, they might initiate autoimmune responses depending on the genetic susceptibility of the host.

Adoptive transfer of heart-specific T cells offers another approach to induce autoimmune myocarditis in both rats and mice. Unfortunately, injection of in vitro-restimulated $CD4^+$ T cells isolated from spleens/lymph nodes of mice with EAM results in mild myocarditis in SCID mice or lipopolysaccharide (LPS)-pretreated wild-type animals only (Smith and Allen 1991; Eriksson et al. 2003). The efficacy of adoptive transfer, however, can be greatly improved if heart-specific $CD4^+$ T cells are either isolated from T cell receptor (TCR) transgenic mice (Nindl et al. 2012) or specifically enriched over several cycles of in vitro restimulation/expansion (Valaperti et al. 2008).

It must be emphasized, however, that all immunization strategies are to a certain extent artificial and there is no model, which mirrors exactly the complexity of natural autoimmune disease development in an organism.

Analysis of Cardiac Infiltrates

At the peak of disease, inflammatory infiltrates mainly consist of myelo-derived mononuclear cells, neutrophils, and some T cells. Giant cells are occasionally observed in A/J mice and on a regular basis in Lewis rats, suggesting that the latter two models somehow mirror human giant cell myocarditis. To grade disease severity at this time point, we recommend to follow a well-established semiquantitative scoring system, which allows comparisons between different studies (Neu et al. 1987; Smith and Allen 1991; Wegmann et al. 1994). Importantly, EAM is a patchy disease. From this point of view, we recommend to cut several step sections throughout the heart. Standard hematoxylin-eosin staining is sufficient for analysis. To enhance reproducibility and specificity, mainly in the presence of mild inflammation, two independent and blinded scientists (experienced pathologists preferred) are required for scoring.

Alternatively, inflammatory cells can be quantified with Fluorescence Activated Cell Sorting (FACS) analysis. This technique offers the advantage to reliably specify different cell subsets but is technically difficult to establish and requires profound experience (Afanasyeva et al. 2004; Kania et al. 2008). Nevertheless, flow cytometry and cell sorting allowed a better characterization of heart-infiltrating cells and helped to elucidate their role in pathological remodeling and disease progression (Kania et al. 2008; Cihakova et al. 2008; Barin et al. 2012). FACS analysis confirmed that the majority of heart-infiltrating cells express a monocyte/macrophage phenotype. A substantial proportion of these monocyte-like cells, however, express a pattern of surface markers, which labels them as immature myelo-derived precursors with the capacity to differentiate either in mature monocytes/macrophages into granulocytes or TGF-β dependently into fibroblasts (Kania et al. 2008;

Kania et al. 2009; Blyszczuk et al. 2009). Thus, the major cell subset among cardiac infiltrates not only provides a precursor pool for inflammation-promoting macrophages (Kania et al. 2009; Barin et al. 2012) but also represents the cellular source of subsequent tissue fibrosis (Kania et al. 2009).

Models of Postinflammatory Dilated Cardiomyopathy

Inflammatory dilated cardiomyopathy (iDCM) represents the end-stage heart failure phenotype of progressive myocarditis in humans (Schultheiss et al. 2011). The EAM models provided important insights in the pathomechanisms of immune-mediated cardiac inflammation. Nevertheless, the relevance of these models for human inflammatory dilated cardiomyopathy had been questioned for a long time. This was mainly due to the fact that the readout for disease severity is the extent of cardiac infiltrates after 21 days. Because physical findings in animals at the peak of disease are directly related to histological severity, mice with mild or moderate myocarditis are only minimal symptomatic at this time point. In fact, mortality rates are usually <1 % within 3 weeks after the first immunization. Only A/J mice and Lewis rats develop consistently high disease severity with signs of overt heart failure. Accordingly, pericardial and pleural effusions and ascites can often be seen at autopsy in these animals.

Over the past several years, more long-term follow-up data of mice with EAM became available. In fact, inflammatory infiltrates slowly resolve after day 21 and get successively replaced by fibrotic tissue. In parallel, hearts enlarge and develop a typical end-stage heart failure phenotype with wall thinning, interstitial fibrosis, and excentric hypertrophy. This process of pathological remodeling can be monitored in vivo using echocardiography or cardiac magnetic resonance imaging (MRI) (Eriksson et al. 2003; Blyszczuk et al. 2009; Moon et al. 2012; Nindl et al. 2012). Accordingly, the EAM model also provided valuable insights into disease mechanisms during the late phase of inflammatory heart diseases and allowed conclusions regarding iDCM development in humans (Afanasyeva et al. 2005; Blyszczuk et al. 2009). Thus, it was possible to define novel roles for several key cytokines in iDCM progression, which go beyond their well-known significance in mediating autoreactive T cell responses. The absence of Interleukin-17A (IL-17A), for example, did not prevent acute myocarditis, but almost completely protected from progression to cardiomyopathy by inhibiting pathological remodeling and cardiac fibrosis (Baldeviano et al. 2010). Similar protective effects are observed in anti-TGF-β-treated, myosin/CFA-immunized mice (Kania et al. 2009) or in animals lacking the IL-1 receptor-linked, downstream adaptor molecule MyD88 (Blyszczuk et al. 2009). Both TGF and IL-1 are closely linked to IL-17. In fact, increasing evidence suggests a critical role for IL-17 in chronic progressive inflammatory responses and fibrogenesis that go beyond its role as key cytokine of a distinct helper cell subset. Despite the not yet clarified role for IL-17 in EAM induction, IL-17 therefore appears as promising target for the prevention of heart failure progression.

The optimal time schedule to study mechanisms of iDCM development has not been defined yet. Forty to sixty days after the first immunization are sufficient for most experiments to get micro- and macroscopic evidence of pathological remodeling and reproducible changes in systolic or diastolic echocardiographic parameters, without reaching an ethically problematic level of symptomatic disease burden in mice.

Outlook

EAM models became helpful in vivo tools to study the pathogenesis of human inflammatory heart diseases. On one hand, they illustrate the cooperation between innate and adaptive immunity as the critical event triggering autoimmunity. On the other hand, they help to understand immunological mechanisms underlying disease development and progression to end-stage heart failure. Nevertheless, it is not known exactly yet to what extent these observations can be

transferred to the human system. Additional studies are clearly needed. Meanwhile, however, autoimmune myocarditis models already offer attractive tools to support the development of innovative and novel treatment strategies.

Summary

Several lines of evidence indicate that autoimmune mechanisms contribute to the pathogenesis of iDCM, which represents an end-stage phenotype of progressive, mostly virus-triggered, myocarditis. Several models of myocarditis – mostly on rats and mice – have been developed. Transgenic mice can answer specific questions on potential disease mechanisms. Most insights into the immune mechanisms of iDCM development, however, result from the EAM model in mice and rats. EAM is based on the observation that susceptible animals injected with heart-specific, self-antigen-loaded dendritic cells or immunized with self-antigen together with a strong adjuvant develop cardiac inflammation peaking 21 days after the first immunization. Later on, myocarditis progresses to an end-stage heart failure phenotype, which resembles in many aspects of iDCM in humans. Despite the simple immunization procedure, however, reliable results depend critically on careful protocols, appropriate strain, sex, and age selection, and on careful interpretation of histology or imaging studies. Nevertheless, the EAM models provided important hints to relevant mechanisms and potential novel treatment strategies in human iDCM.

Synonyms

Autoimmune chronic active hepatitis; Autoimmune hepatitis (AIH); Lupoid hepatitis

Definition

Autoimmune hepatitis (AIH) is an inflammatory liver disorder that affects mainly females and characterized by elevated transaminase

levels, autoantibody positivity, immunoglobulin G (IgG) elevation, and the histological picture of interface hepatitis (Krawitt 2006; Mieli-Vergani and Vergani 2011a). Immune reactions against liver antigens are likely to be the major pathogenic mechanism (Vergani and Mieli-Vergani 2012).

Clinical and Systemic Manifestations

Historical Background – The first full description of AIH was given by Waldeström in 1950 when he reported six patients, five female, with hepatitis and marked elevation of gamma globulins in whom ACTH, administered to investigate concomitant amenorrhea, resulted in clinical and biochemical improvement. In 1956, Mackay reported the presence of lupus erythematosus (LE) cells in patients with a similar clinical picture and proposed the term "lupoid hepatitis." Later, when it became clear that liver disease is rare in systemic lupus erythematosus and that LE cells reflect the presence of antinuclear antibody, Mackay suggested the name of "autoimmune hepatitis," which was universally accepted in the 1990s (Vergani and Mieli-Vergani 2007).

The diagnosis of AIH is based on positive findings and exclusion of other causes of liver disease. Diagnostic criteria have been defined and revised by the International Autoimmune Hepatitis Group (Johnson and McFarlane 1993; Alvarez et al. 1999; Hennes et al. 2008). Positive criteria are elevation of transaminase and IgG levels, presence of diagnostic autoantibodies, and interface hepatitis on liver biopsy (i.e., a dense portal tract inflammatory infiltrate composed of lymphocytes, monocytes, and plasma cells, which crosses the limiting plate and invades the surrounding parenchyma). The liver biopsy is important not only for diagnostic purposes but also for the evaluation of the severity of liver injury, as the degree of biochemical and immunological abnormalities does not reflect the extent of the histological damage. Other hepatic disorders, such as viral hepatitis B and C, Wilson disease, and alcohol- or drug-induced liver disease, which may share clinical and biochemical features of AIH, must be excluded.

AIH Subtypes – AIH is divided in two main forms according to the type of autoantibody present: smooth muscle antibody (SMA) and/or antinuclear antibody (ANA) define AIH type 1, while liver/kidney microsomal type 1 antibody (anti-LKM-1) and liver cytosol type 1 antibody (anti-LC-1) define AIH type 2 (Vergani et al. 2004). As anti-LKM-1 positive disease is infrequent in adults, the distinction in type 1 and type 2 AIH is particularly relevant in pediatric age, where anti-LKM-1 positive AIH represents one-third of all cases. Type 1 and type 2 AIH have a similar clinical course, though anti-LKM-1 positive children present at a younger age, more often with an acute onset, including fulminant hepatitis, and have associated IgA deficiency (Mieli-Vergani and Vergani 2011b).

Other autoantibodies that support the diagnosis of AIH are anti-soluble liver antigen (anti-SLA) and perinuclear antineutrophil cytoplasmic antibodies (pANCA). The former is highly specific, though not very sensitive, for the diagnosis of AIH and can be present in the absence of conventional diagnostic autoantibodies. The latter is frequent in AIH/sclerosing cholangitis overlap syndrome and in primary sclerosing cholangitis (Vergani and Mieli-Vergani 2006).

Prevalence and Systemic Manifestations – AIH affects 2–20/100,000 people and is more frequent in females, who represent 75 % of the cases (Mieli-Vergani and Vergani 2011a). Some 40 % of patients have a family history of autoimmune disease, and at least one-fifth of the patients suffer from other autoimmune disorders either at diagnosis or during follow-up, including thyroiditis, ulcerative colitis, insulin-dependent diabetes, systemic lupus erythematosus, vitiligo, nephrotic syndrome, hypoparathyroidism, and Addison disease. The latter two endocrinological disorders are observed mainly in anti-LKM-1 positive patients or in patients with autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), an autosomal recessive monogenic disorder with a variable phenotype that includes AIH in about 20 % of cases (Mieli-Vergani and Vergani 2011b).

Presentation – There are three main patterns of disease presentation: (1) an acute onset, characterized by nonspecific symptoms of malaise, nausea/vomiting, anorexia, and abdominal pain, followed by jaundice, dark urine, and pale stools (30–40 % of cases); (2) an insidious onset, with an illness characterized by progressive fatigue, relapsing jaundice, headache, anorexia, amenorrhea, and weight loss (50–60 % of cases); and (3) a presentation with complications of portal hypertension, such as hematemesis from esophageal varices, bleeding diathesis, chronic diarrhea, weight loss, and vomiting (5–10 % of cases). Since the mode of presentation is so variable, AIH should be suspected in all patients presenting with symptoms and signs of prolonged or severe liver disease. Occasional patients, however, are asymptomatic and diagnosed after incidental discovery of abnormal liver function tests.

Treatment

AIH responds well to immunosuppressive treatment, which should be instituted immediately after diagnosis (Vergani and Mieli-Vergani 2011).

The aim of treatment is to achieve early complete remission to prevent disease progression and to maintain remission long term on the lowest possible drug dose (Manns et al. 2010). Remission is obtained in about 80 % of cases, whatever the disease presentation, apart from those rare patients with fulminant hepatitis, in whom disease is usually too advanced for medical treatment to be effective and who usually require liver transplantation.

Standard Treatment – A combination of predniso(lo)ne and azathioprine is the basis of treatment for AIH. The old suggestion of waiting for 6 months before starting treatment is now obsolete, as early treatment has been shown to halt disease progression, which can be otherwise very rapid (Manns et al. 2010). Most AIH patients who respond to immunosuppressive treatment have an excellent prognosis and lead a normal life on low-dose medication.

The 2010 American Association for the Study of Liver Diseases (AASLD) practice guidelines (Manns et al. 2010) recommend starting treatment in adult patients with either a combination of predniso(lo)ne (30 mg) and azathioprine (1–2 mg/kg) daily or with prednisone monotherapy at a starting dose of 40–60 mg daily. For children up to 18 years of age, a dose of 1–2 mg/kg predniso(lo)ne (maximum daily dose 60 mg) is recommended in combination with azathioprine (1–2 mg/kg/daily) or 6-mercaptopurine (1.5 mg/kg). However, as azathioprine can be hepatotoxic, especially in the presence of jaundice, it is advisable to add it in icteric patients only when partial disease control is achieved and jaundice has subsided. The most common side effects of steroids are cushingoid changes; less common adverse events include osteoporosis, vertebral collapse, diabetes, cataract, hypertension, and psychosis. However, only about 13 % of patients necessitate dose reduction or premature steroid withdrawal because of side effects (Vergani and Mieli-Vergani 2007). Side effects of azathioprine, including cholestatic hepatitis, venoocclusive disease, pancreatitis, nausea and vomiting, rash, and bone marrow suppression, affect less than 10 % of patients and usually settle after drug withdrawal. As myelosuppression during treatment has been reported only in patients with near-zero erythrocyte concentrations of thiopurine methyltransferase activity, its measurement is only warranted in the presence of pretreatment or intra-treatment cytopenia or when higher than conventional doses of azathioprine are needed to maintain remission (Mieli-Vergani and Vergani 2011a).

Complete remission is defined as disappearance of clinical symptoms, normalization of transaminase and IgG levels, and negativization or reduction to a very low titer of the autoantibodies (Manns et al. 2010; Mieli-Vergani and Vergani 2011a). Histological resolution of inflammation occurs months after biochemical improvement. As AIH responds swiftly to immunosuppressive treatment, lack of improvement on steroids suggests other causes of liver disease.

Relapse, characterized by an increase of transaminase levels, occurs in 40–80 % of patients, often during attempts of treatment withdrawal or as a result of nonadherence. Episodes of relapse usually respond to a temporary increase in the steroid dose. Nonadherence to treatment is a serious problem particularly in young adults and adolescents (Mieli-Vergani and Vergani 2011b).

Most patients, including those with cirrhosis, reach complete remission on treatment. In the presence of significant steroid side effects, remission can be maintained with azathioprine alone at a dose of 2 mg/kg daily. Treatment with both steroids and azathioprine is safe during pregnancy (Mieli-Vergani and Vergani 2011a), as neither drug has been reported to have teratogenic properties in humans. However, pregnant women anxious about the use of azathioprine can be switched to steroid monotherapy.

In asymptomatic or paucisymptomatic adult patients, the benefit of therapy should be weighed against corticosteroid side effects, particularly in postmenopausal women or elderly patients. The decision to treat depends on the severity of inflammation and liver damage.

Children have a more aggressive disease than adults, despite being often paucisymptomatic; hence, treatment should be started promptly in childhood, even if the diagnosis is made incidentally (Czaja et al. 2005).

Most authors recommend at least 3 years of continuous therapy, before considering drug withdrawal (Manns et al. 2010). Attempts to stop treatment should be made only if a liver biopsy shows resolution of the inflammatory changes. During treatment withdrawal the patient must be monitored closely, as relapse may be severe and even fatal.

The risk of developing primary hepatocellular carcinoma (HCC) in AIH is associated with the presence of cirrhosis, akin to other chronic liver diseases; hence, surveillance for HCC is advisable (Manns et al. 2010).

Alternative Treatments – Ciclosporin and tacrolimus have been used as steroid-sparing agents, but whether the use of these toxic and expensive drugs confers any advantage over standard treatment is unclear.

Budesonide, a corticosteroid with a high first pass liver metabolism, has been used to induce remission in AIH with a marginal benefit when compared to conventional corticosteroids (Mieli-Vergani and Vergani 2011a).

Difficult-to-treat cases respond to mycophenolate mofetil at a dose of 20 mg/kg twice daily in association with predniso(lo)ne, although this drug appears more effective in patients intolerant of but not in those unresponsive to azathioprine (Lohse and Mieli-Vergani 2011). For patients who do not respond to or who develop mycophenolate mofetil side effects (headache, diarrhea, nausea, dizziness, hair loss, and neutropenia), calcineurin inhibitors should be considered in combination with predniso(lo)ne (Manns et al. 2010). In particularly difficult to treat patients, anecdotally, the use of the anti-B-cell monoclonal antibody rituximab and of the antitumor necrosis factor alpha monoclonal antibody infliximab has been reported with variable outcomes (Vergani and Mieli-Vergani 2011). An important risk of these biological treatments is the occurrence of severe infections.

Liver Transplantation – Liver transplantation is the treatment of choice for those rare patients who present with fulminant hepatic failure (grade II–IV hepatic encephalopathy) or for the 10–20 % of cases that progress to end-stage liver disease despite immunosuppression. AIH recurrence, characterized by high transaminase levels, positive autoantibodies, interface hepatitis, and/or steroid dependence, occurs in some 20 % of transplanted patients (Liberal et al. 2012). Steroid treatment long term and at a dose higher than that generally used after liver transplantation for other conditions are recommended to try and avoid recurrence.

Future Treatments – Over the past 10 years, it has become apparent that loss of immunoregulation is central to the pathogenesis of AIH (Longhi et al. 2010), as in this condition there is a reduction in number and function of regulatory T cells (Tregs) especially during the active phases of the disease. Current research is focusing on restoring both number and function of Tregs in vitro to reinfuse them in patients in an attempt to halt/cure the disease by reinstating immune tolerance to self.

Autoimmune hepatitis

Definition

Autoimmune hepatitis (AIH) is a rare inflammatory liver disease that is clinically characterized by elevations of transaminases (ALT > AST), immunoglobulins, and certain autoantibodies (AAB) as well as exclusion of other relevant causes of hepatitis (e.g., infectious, toxic, vascular, metabolic). Histological hallmarks are the predominantly lymphocytic, mostly plasma cell-rich portal infiltrates with interface hepatitis, although histology alone is never used as diagnosis. A successful treatment with steroids can strengthen the diagnosis of AIH.

Immunopathogenesis

The presence of liver-specific autoantibodies against cytochromes (UDP-glucuronosyltransferases (UGTs) and formiminotransferase cyclodeaminase (FTCD)), the elevation of immunoglobulins, and the dense lymphocytic portal infiltrates suggested an autoaggressive cellular immune response. This was further supported by successful therapy with immunosuppressants (Kirk et al. 1980; Manns et al. 2010).

Break of Humoral Tolerance

The appearance of organ-specific (e.g., liver cytosol type 1 (LC1)) as well as non-organ-specific (e.g., antinuclear antibodies (ANA), anti smooth muscle antibodies (SMA), anti-liver kidney microsome (LKM) antibodies, soluble liver antigen/liver pancreas (SLA/LP)) AAB is one of the key features of AIH and is therefore used in diagnosis to distinguish AIH from other inflammatory liver diseases. These AAB also help to divide AIH into at least two subtypes (type I: ANA and/or SMA; type II: LKM and/or LC1; putative type III: SLA) (Strassburg and Manns 2002).

The discovery that hepatocytes from AIH patients were covered with immunoglobulins and were susceptible to antibody-mediated cytotoxicity first suggested that these AAB might have some pathophysiological relevance. Furthermore in AIH type II, the main target antigen, cytochrome P450 2D6 (CYP2D6), is recognized by AAB (LKM) as well as by T cell receptors (TCR). CYP2D6 is expressed at the surface of hepatocytes and thus directly accessible to AAB. In contrast, the epitopes of ANA, SLA, and SMA, AAB are not only expressed in the liver and are not present on the surface of hepatocytes. These autoantigens are probably accessible to the immune system after apoptotic cell death (Wachter et al. 1990; Longhi et al. 2010b; Lleo et al. 2011).

From a clinical point of view, various AAB are associated with markers of biochemical and histological disease activity (Longhi et al. 2010b), and anti-SLA positivity defines usually a more severe disease course (Czaja 2010). Furthermore, plasma cells, antibody-producing B cells, are mostly found in the expanded portal tract in AIH and may indicate an AAB production in the liver itself, although the specificity of the plasma cells is not known (Oo et al. 2010).

On the other hand, 10–20 % of AIH patients have no relevant AAB titers at diagnosis or of other specificities than the ones routinely tested (Oo et al. 2010). Furthermore, AAB are commonly found in other chronic liver diseases too, e.g., hepatitis C (Longhi et al. 2010b; Boberg et al. 2011). Most of the antibodies are not liver disease specific, and most target antigens are not specifically expressed in the liver. Why ubiquitously expressed antigens become a target of a liver-specific autoimmune response remains difficult to explain. The altered-self hypothesis postulates that common antigens are altered in the liver by substances generated during the detoxification process in the liver. It is remarkable in this context that many of the AAB recognize liver-specific antigens related to the hepatic detoxification machinery (cytochrome P450s, UGTs). T cells specific for these chemically altered neoantigens cannot be negatively selected in the thymus explaining the fulminant clinical presentation of the disease that is occasionally observed in pediatric patients.

Although these AAB are used to diagnose AIH, it is not clear whether they are involved in the pathophysiology leading to chronic immune-mediated destruction of hepatocytes. In this context, it is interesting to note that serum transfer did not lead to hepatitis in an animal model of AIH (Hardtke-Wolenski et al. 2013). On the other hand, experiments in other tissue-specific autoimmune diseases like type 1 diabetes have suggested a role of autoantibodies especially in the initiation of autoimmunity by enhanced antigen uptake and presentation (Greeley et al. 2002; Hardtke-Wolenski et al. 2011).

Break of Self-Tolerance

The peripheral blood of AIH patients contains mostly autoreactive T helper cells while the liver contains mostly autoreactive cytotoxic (► Cytotoxic T Lymphocytes) and γδ T cells.

Clonal analysis has revealed the presence of both CD4 and CD8 T cells reactive against various autoantigens in AIH (e.g., asialoglycoprotein receptor (ASGPR), alcohol dehydrogenase, CYP2D6 and SLA) (Mix et al. 2008). Further investigations have shown that the polyclonal T cell reactivity and T cell-derived cytokine production correlated with biochemical and histological disease activity. Autoreactive T cell clones could also stimulate AAB production by anti-ASGPR-specific B cells in vitro (Longhi et al. 2010b; Lleo et al. 2011). Altogether, numerous effector cell lineages of the adaptive immune system seem to be involved in the autoreactive liver damage in AIH. The reactivity of CD4, CD8 T cells, and B cells against the same or adjacent epitopes suggests a functional interplay of the adaptive immune system in AIH (Longhi et al. 2010b; Lleo et al. 2011).

In recent years, the role of regulatory T cells (Treg; ▶ Tregs in the Liver) in AIH has attracted more attention. Tregs, which constitute about 5 % of the peripheral CD4 T cell pool, play a major role in controlling immune activation in a cell-contact dependent as well as in a cell-contact independent manner by producing anti-inflammatory cytokines (Sakaguchi et al. 2010).

Several reports described a quantitative as well as a functional impairment of Treg in the peripheral blood of pediatric AIH patients that in part could be restored under therapy and during disease remission (Longhi et al. 2010b).

A major obstacle in the analysis of Tregs in human is the broad phenotypic similarity of activated conventional effector T cells (Teff) and Treg and the lack of markers expressed exclusively by Tregs. More markers have been used to characterize Tregs in the last years. These include FOXP3 expression, reduced CD127 expression, and DNA demethylation of a preserved promoter region of the FOXP3 gene locus in addition to CD4+CD25+ (Sakaguchi et al. 2010). As a consequence, the contamination of activated Teff in the population of analyzed Treg is variable and depends on the marker panel used to define Tregs. Using a more extended panel to characterize Tregs, a recent study showed that AIH patients did not display a deficiency in Treg number or function (Peiseler et al. 2012). Interestingly, IPEX (immune dysfunction, polyendocrinopathy, enteropathy, X-linked) patients, who lack completely Tregs or have a profound defect of Treg function, develop numerous autoimmune diseases, but rarely AIH (Gambineri et al. 2008). Thus, a general defect in Tregs is not the likely cause for AIH development.

Other mechanisms have been proposed to explain impaired immunoregulation in AIH. Downregulation of Tim3 expression on Teff cells might decrease their sensitivity to Treg regulation, while reduced Galectin-9 on Tregs might decrease their suppressive capacity (Liberal et al. 2012).

A defect in innate immunity has also been suggested to play an important role in the pathogenesis of AIH. As Monocytes from AIH patients are more activated than those from healthy individuals (Longhi et al. 2010a). In addition, the number and function of NKT cells in AIH patients is decreased, while the number of γδ T cells in the peripheral blood of AIH patients is increased in comparison to control individuals (Ferri et al. 2010; Liberal et al. 2011).

Although both innate and adaptive immune cells seem to be involved in the autoreactive liver inflammation, the events initiating this harmful interplay are not completely understood.

Genetic Associations

Genetic association studies are powerful tools to identify genes or molecules that have a potential pathophysiological contribution in human diseases. As in various other autoimmune diseases, the strongest genetic association in AIH affects genes that encode molecules related to T cell recognition and activation.

MHC Complex

Class II MHC Molecules

The strongest genetic predisposition in AIH has been linked to major histocompatibility complex (MHC) class II genes. These are located on the short arm of chromosome 6, more specifically in

Autoimmune Hepatitis: Pathogenesis, Association with Other Syndromes, Table 1 Genetic association of the HLA-DR haplotypes with AIH type I

	HLA-DR haplotype		
	Predisposition		Protection
Ethnic group	*Major association*	*Secondary association*	
White northern European background	DRB1 *0301 DRB1*0401 DRB3 *0101		
North Americans		DRB1 *13	
Japanese	DRB1*0405		
Latin America	DRB1 *1301	DRB1 *03	DRB1*1302
Mexicans	DRB1 *0404		

the human leukocyte antigen (HLA)-DR locus (Liberal et al. 2011; Oliveira et al. 2011). The class II MHC molecules present peptide sequences (epitopes) to T helper cells.

The genetic predisposition is different in AIH type I and II, most probably reflecting the different antigens, against which the autoimmune attack is targeted. While HLA-DRB1*0701 and/or DRB1*0301 confer the strongest risk for AIH type II, the set of predisposing and protective HLA haplotypes is shaped by the ethnic background in AIH type I (Table 1) (Liberal et al. 2011; Oliveira et al. 2011).

The association of AIH with HLA-DR3 (DRB1 *0301) and DR4 (DRB1 *0401) is considered strong enough, to be used as a criteria in the diagnosis of AIH type I in Caucasians in the diagnostic AIH scoring system (Liberal, Longhi et al. 2011). Both molecules share a homologous amino acid sequence at position 67–72 (LLEQKR). The haplotypes DRB1 *0404 and DRB1 *0405, predisposing to AIH in Japan as well as in Middle and South America (Table 1), exhibit a similar sequence at the same position (LLEQRR), implying a putative role for presentation of similar autoantigens in AIH. In other studies, particular sequences of HLA alleles (e.g., a histidine at position 13 of the DRB1 allele in Japan or a valine/glycine dimorphism at position 86 of the DR-beta polypeptide in South America) are associated with AIH (Liberal et al. 2011).

As mentioned above, the clinical course of AIH is variable and can depend on the types of AAB detected (e.g., more severe course with SLA positivity) (Czaja 2010). The HLA haplotype is also associated with the course and prognosis in AIH type II, suggesting that the course of the disease is influenced by the presented respectively recognized target antigen. While HLA-DR3 (DRB1*0301) is associated with anti-LKM1 and LC1 positivity, HLA-DR7 (DRB1*0701) is associated only with anti-LKM1 positivity, a more restricted anti-LKM1 immunoglobulin repertoire and even with a more severe AIH course (Liberal et al. 2011).

Non-MHC Genes

CTLA-4/CD152

CTLA-4 is a membrane-bound molecule expressed by T cells that act as a negative feedback loop of the T cell activation cascade by competing with CD28, a costimulatory molecule that binds to the same ligands as CTLA-4 (B7-1/CD80 and B7-2/CD86) expressed on antigen-presenting cells. Due to its regulatory role in T cell activation, CTLA-4 is thought to play a critical role in the maintenance of peripheral tolerance (► CTLA-4; ► B7 and CD28 Families). Although associations of polymorphisms of CTLA-4 have been reported in several populations (e.g., an A/G polymorphism at position 49 in exon 1 in Caucasian), they could not be confirmed in all populations (e.g., in Latin Americans or Japanese). Nonetheless, polymorphisms of the CTLA-4 gene have been associated with other autoimmune diseases like diabetes type 1 and multiple sclerosis (Tang, Zhou et al. 2012). The influence of the genetic variability of the CTLA-4 gene does not just affect negative costimulation on effector T cells. CTLA-4 is also constitutively expressed on Tregs and has important regulatory functions (Shevach 2009).

Fas Gene

The Fas receptor is thought to be involved in the maintenance of the peripheral tolerance by induction of receptor-mediated programmed cell death (apoptosis) of autoreactive T cells in the periphery (► Fas/Fas Ligand). Although a genetic link

of Fas polymorphisms with AIH and development of liver cirrhosis has been reported (Tang et al. 2012), there is no clear evidence that this molecule is a susceptibility gene for AIH.

Tumor Necrosis Factor (TNF)

The TNFA*2 gene is another example, in which a genetic link has been reported in some populations (e.g., European and North American Caucasian) but could not be confirmed in others (e.g., Latin American) (Tang et al. 2012). Nonetheless, this association is of interest from a clinical point of view as TNF inhibitors are widely used anti-inflammatory biological agents and have been successfully used to treat single AIH cases (Weiler-Normann et al. 2009).

Transforming Growth Factor (TGF)

A single report has linked polymorphism of the immunomodulatory molecule TGF-β1 to pediatric and adult AIH (Tang et al. 2012) (▶ TGF-β). However, more studies in other cohorts are required to confirm this association.

T-bet

T-bet is the key transcription factor for the Th1 cells lineage of T helper cells and is encoded by TBX21. A single report suggested a susceptibility of the TBX21 polymorphism for AIH in Chinese. Once again, further confirmation is necessary (Tang et al. 2012).

Vitamin D Receptor

Genetic associations of the receptor for 1, 25-dihydroxyvitamin D3, which is considered to act as an immunomodulator, have been found in several autoimmune diseases like multiple sclerosis, type 1 diabetes mellitus, and Graves' disease. A polymorphism at the beginning of exon 2 has been linked to AIH in European and Chinese patient cohorts (Vogel et al. 2002).

APECED

APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy) is a monogenetic autosomal recessive immune disorder, which is mostly caused by mutations in the transcription factor AIRE (autoimmune regulator). A deficiency in AIRE expression results in a fundamental impairment of central tolerance induction promoted by defective deletion of autoreactive T cells in the thymus. Furthermore, the number and function of Tregs are impaired in the peripheral blood of AIRE-deficient patients (Kisand and Peterson 2011). As the name implies, APECED patients suffer from multiple autoimmune diseases mostly of the endocrine glands, and about 20 % of the patients exhibit a hepatitis resembling AIH type 2 (Lankisch et al. 2009). As indicated by AAB specificity aromatic l-amino acid decarboxylase, cytochrome P450 1A2 and ~2A6 are putative target antigens in these type of AIH (Lankisch et al. 2009; Kisand and Peterson 2011). Although the wide variability of the symptoms in APECED with AIH being an infrequent event is not understood yet, a defective central tolerance induction is thought to be a potential factor in the pathogenesis of AIH. However, APECED is a very rare disease, and mutations in AIRE are rarely found in patients with classical AIH (Vogel et al. 2001).

Molecular Mimicry/Similarity and Environmental Influences

One of the main hypotheses to explain how self-tolerance is broken to initiate AIH proposes that there is molecular mimicry or molecular similarity between pathogens and self-antigens. Pathogens would express antigens that are similar or homologue to self-structures, and the immune defense against these pathogens can progress to autoimmunity via cross-reactivity in susceptible individuals.

Consistent with this hypothesis, break of humoral tolerance is a common phenomenon in chronic viral hepatitis (e.g., hepatitis B and C), where up to 50 % of the patients have circulating AAB (ANA, SMA, or LKM). Thereby, anti-LKM-1 AAB of patients with chronic hepatitis C can even recognize the major B cell epitope of AIH type II (CYP2D6 193–212) (Longhi et al. 2010b).

Besides classical molecular mimicry, it has been suggested that due to the degeneracy of the TCR/pMHC interaction, cross-reactive T cells

can also be generated by heterologous immunity. According to the heterologous immunity model, the same TCR can recognize two peptides with unrelated amino acid sequences. Thereby, a viral infection could break tolerance against tissue antigens (Selin et al. 2004).

Danger signals leading to immune activation and tissue damage (e.g., during viral infections) have also been proposed to play a role in breaking tolerance. A vigorous immune activation, initiated by external pathogens, can overcome the immune balancing factors and allows an immune attack against self-antigens that are subsequently released during the inflammatory process. Several reports have associated viruses such as hepatitis A, B, and C virus, Epstein-Barr virus, humane herpes virus 6, and herpes simplex virus to the initiation of AIH. Although this is an attractive model, the causative contribution of infections, often subclinical and that took place months, even years before the diagnosis of AIH, is hard to prove in rare disease like AIH (Beland et al. 2009). For this reason, to date, there is no single causative infectious agent for AIH.

The genetic predisposition of the HLA DRB1 *1301 haplotype both to pediatric AIH type I and to persistence of the endemic hepatitis A virus in South America may combine the concept of molecular mimicry, autoimmune initiation via danger signals, and the ability to present autoantigens in susceptible individuals (Liberal et al. 2011).

Beside infections, some case reports have shown an association between some drugs, e.g., minocycline or some statins (atorvastatin, simvastatin), with AIH initiation supporting the altered-self hypothesis mentioned above. Once again, this hypothesis is hard to validate especially when modes of action are highly speculative and other susceptibility factors like HLA types predisposing to AIH are potential confounders in some reports (Beland et al. 2009).

Sex and Age

As many other autoimmune diseases, the female sex is overrepresented in AIH (3:1 in AIH type I; 9:1 in AIH type II). The pathophysiological mechanisms leading to this discrepancy are unknown, but several reports shed light on differences that may contribute to this phenomenon (Beland et al. 2009).

The influence of sexual hormone on AIH is suggested by several examples. AIH has the highest incidence in pediatric patients (40 % of AIH type I and 80 % of AIH type II), and a second peak is reported in postmenopausal patients. The hormonal changes during pregnancy can lead to a new diagnosis of AIH in the beginning or shortly after gravidity. Furthermore, patients in AIH remission during pregnancy often experience a postpartum disease flare (Beland et al. 2009).

Potential explanations for this clinical observation could be related to sexual differences in basic immunological processes. Women are reported to have higher T helper cell numbers and higher cytokine levels of the Th1 type and show higher immune activation after vaccination. Furthermore, estrogen can increase the production of Th1 cytokines in vitro, while testosterone can stimulate the production of the anti-inflammatory cytokine IL-10 (Beland et al. 2009).

AIH After Liver Transplantation

As AIH is often diagnosed when the patient has developed cirrhosis, liver transplantation is an important treatment option for end-stage autoimmune liver damage. Even under continued immunosuppressive therapy after liver transplantation, up to 25 % of patients suffer from a disease recurrence that displays several of the histological and biochemical hallmarks of AIH (Oo et al. 2010).

The pathogenic mechanisms of recurrence are critically discussed as alloreactivity, e.g., reactivity between mismatched HLA types from host and donor cells, and autoreactivity is hard to distinguish in clinical routine tests (Oo et al. 2010; Czaja 2012). The recurrence of AIH in transplanted patients suggests the host immune system retains reactivity against the newly transplanted liver despite continuous exposure to multiple immunosuppressants.

There are some rare reports of newly diagnosed AIH after liver transplantation subsequent to other diseases than AIH. This "de novo AIH" or "plasma cell hepatitis" affects mostly children (prevalence in children <10 %). Additionally, several studies described an overlap between de novo AIH and late cellular rejection (Oo et al. 2010). An interesting pathophysiological hypothesis in this context is the immune response against glutathione-S-transferase T1 (GSTT1), suggested by GSTT1-specific AAB, in GSTT1-deficient hosts (about 20 % of Caucasian) with a GSTT1-positive graft (about 14 % of liver transplantations). In addition to GSTT1, there might be numerous other mismatched antigens between donor and recipient that are not linked to HLA. It could be envisioned that such neoantigens could be target of an autoimmune response in genetically predisposed individuals.

Animal Models

Animal models of autoimmune liver diseases are necessary to elucidate the gaps in the understanding of the pathophysiology of AIH and have already contributed substantial inside in to initiation of autoimmunity in the liver, e.g., in terms of unspecific T cell activation by concanavalin A, immunization strategies or genetic modification of lymphocyte signaling pathways, or TCR repertoires (Hardtke-Wolenski et al. 2011). This is reviewed in detail in a separate entry of this encyclopedia.

Association with Other Syndromes

Autoimmune Liver Diseases

Primary biliary cirrhosis (PBC; ▶ Primary Biliary Cirrhosis, Overview) and primary sclerosing cholangitis (PSC; ▶ Primary Sclerosing Cholangitis: Clinical and Systemic Manifestations and Treatment) are the major autoimmune liver syndromes affecting respectively the small and the large bile ducts. Although hepatocytes are the main target of autoimmunity during AIH, the distinction between hepatic and biliary autoimmune inflammation is not as stringent as the taxonomy may imply.

Overlap of AIH and PBC Characteristics

A quarter to one-third of patients with "classical AIH," without serologic or other evidence for PBC (negativity for anti mitochondrial antibodies (AMA)), can have biliary abnormalities in liver biopsies, including destructive as well as nondestructive cholangitis or ductopenia. Reciprocally, the same percentage of PBC patients can display severe lymphocytic interface hepatitis typically observed in AIH (Boberg et al. 2011).

Both diseases display also common AAB. While ANA, SMA, and SLA are detectable in more than 30 % of PBC patients, AMA specific for the E2 subunit of the pyruvate dehydrogenase complex (PDC-E2) that are highly specific AAB for PBC are rarely seen in AIH. In addition to anti-AMA, anti double-stranded DNA antibodies are more frequent in AIH-PBC than in PBC alone (Boberg et al. 2011).

The term "overlap syndrome" is commonly used, when patients fulfill the criteria for both disease entities.

As evidence-based criteria for the diagnosis of an overlap syndrome of AIH and PBC are missing, the percentage of AIH-PBC overlap in PBC patients varies between 5 % and 20 % depending on the diagnostic or scoring systems used. The characteristics of AIH in PBC and vice versa can develop at the same time or sequentially within months or years (Boberg et al. 2011).

Several scenarios might be proposed to explain the coexistence of interface hepatitis with PBC specific characteristics. Both portal and biliary inflammation may represent two facets of an autoimmune liver injury. An autonomous hepatocyte specific autoimmune damage in PBC beside the disease defining reactivity to PDC in the biliary epithelium seems not very likely, however. Interface hepatitis in PBC and biliary abnormalities in AIH could be caused by collateral damage. The damage of hepatocytes during PBC could release hepatocyte self-antigens, in the presence of inflammation. Similar to the danger signals caused by viral

infections, this may thus initiate a spreading of the autoimmunity to other target antigens. Why portal and not biliary inflammation responds better to immunosuppressive therapy is not completely understood (Oo et al. 2010).

Overlap of AIH and PSC Characteristics

Although portal tract inflammation associated with lymphocytic bile duct infiltration, ductular proliferation, and periductal fibrosis is a common histological characteristic of PSC, interface hepatitis can be found in up to one-third of PSC patients (Boberg et al. 2011).

The overlap of AAB profiles in AIH and PSC is substantial, as ANA, SMA, and SLA are detectable in up to 80 % of PSC patients, and perinuclear antineutrophil cytoplasmic antibodies (pANCA) can be found in 50–90 % of AIH patients (Boberg et al. 2011).

Once again, the degree of overlap depends on the scoring systems used. While PSC and PBC overlap with AIH similarly in adults (each 2–20 %), the degree of overlap in children is much higher and reaches up to 50 % of pediatric PSC patients. The majority of PSC patients (80 %) display inflammatory bowel disease (IBD) as well. Concomitant IBD in AIH is mostly diagnosed when AIH overlaps with PSC (Boberg et al. 2011).

Liver biopsies of patients displaying AIH-PSC-IBD symptoms contain a substantial infiltration (about 20 %) of T cells displaying a phenotype characteristic of gut-derived cells (α4β7+ and chemokine receptor 9+) that are rare in other liver diseases. Furthermore, in these patients, the liver endothelium expresses molecules normally displayed in the vascular bed of the small intestine (CCL25 and MADCAM-1). Thus, it is likely that other mechanisms than the ones discussed for AIH-PBC contribute to induce the AIH-PSC overlapping disease (Oo et al. 2010).

All three autoimmune liver diseases are genetically associated with the HLA locus on chromosome 6. But data regarding HLA haplotypes predisposing to overlap syndromes are inconsistent yet, because varying criteria for overlap syndromes were applied and the number of patients with overlapping syndromes is generally low (Boberg et al. 2011).

Extrahepatic Autoimmune Diseases

Several extrahepatic autoimmune diseases (EAID) are a common feature in AIH patients. In large patient cohorts, up to 40 % of AIH patients, including those that overlap with PSC and PBC, have at least one concomitant autoimmune disease mostly of the thyroid gland (Hashimoto and Graves' disease), skin (vitiligo and urticaria), joints (rheumatoid arthritis), lacrimal glands (Sjogren's syndrome), and the intestinum (e.g., celiac disease, gastritis, Crohn's disease) (Teufel et al. 2010). The cause for the disproportionate prevalence of EAID is so far unknown, but has been reported for other autoimmune diseases like type 1 diabetes. It has been shown that many patients developing autoimmune diseases share common predisposing genes. In addition to common predisposing genes, there are organ-specific genes (like insulin in type 1 diabetes). However, organ-specific predisposing genes for AIH are currently not known. There is no evidence so far that AIH patients with EAID display a more severe disease course (Teufel et al. 2010; Efe et al. 2012).

Summary

Although multiple aspects of AIH pathogenesis are scientifically accepted, the sequence of events responsible for breaking tolerance and initiating AIH is not fully understood. AIH seems to be initiated by external triggers in genetically susceptible individuals. As discussed above, immunologic susceptibility in this context is multifactorial. The ability to present relevant autoantigens is of central importance in this context as implied by the strong association with the MHC haplotypes. The association with MHC class II underlines the role of T helper in contrast to cytotoxic T cells in the immunoregulation in AIH. The role of AAB as cause or consequence of AIH remains ambiguous. In addition to these systemic factors, the exploration of the liver inflammatory local milieu will hopefully reveal further insight into the pathogenesis of AIH in the future. This might eventually lead to the development of more specific therapies for AIH patients.

Definition

A number of autoimmune kidney diseases, including systemic lupus erythematosus (SLE), systemic sclerosis, and atypical hemolytic-uremic syndrome, may be present during pregnancy. Pregnancy in patients with these conditions must be considered from three different perspectives: the effect of pregnancy on disease activity/progression, effects of disease/treatments on the fetus, and health of the mother during pregnancy and after delivery.

Introduction

The optimal management of patients with autoimmune kidney disease who become pregnant is crucially dependent on a multispecialty team consisting of a nephrologist, rheumatologist, and obstetrician. Adverse fetal outcomes (spontaneous abortion, prematurity, intrauterine growth restriction) as well as maternal outcomes (preeclampsia, renal disease flare) are common, particularly in patients with active renal disease at conception. Consequently, irrespective of the underlying etiology, remission of renal disease for $>$ 6 months prior to conception is recommended. The major goal of immunosuppressive therapy in pregnancy is control of disease activity with medications that are relatively safe for a growing fetus. While worsening proteinuria in the third trimester may occur in all proteinuric renal diseases, the differential diagnosis includes a renal disease flare and preeclampsia, a pregnancy-specific condition clinically characterized by hypertension and proteinuria. Due to the elevated risk for renal disease flares postpartum, the affected women need to be followed after delivery.

Systemic Lupus Erythematosus and Lupus Nephritis

The most common, hence the most studied, autoimmune disease in pregnancy is systemic lupus erythematosus (SLE), a multisystem autoimmune connective tissue disorder that predominantly affects women of childbearing age. SLE does not directly affect fertility; as such, pregnancy is a frequent occurrence. Although initial studies suggested an association between SLE and poor pregnancy outcomes, improved outcomes have been observed more recently, including live birth rates of up to 85 %. Similarly, the mortality associated with SLE has declined (Smyth and Garovic 2009). Consequently, a growing number of women with SLE are seeking to become pregnant.

Fertility

Data suggest that fertility is preserved in patients with SLE in the absence of advanced renal insufficiency, defined as a serum creatinine $\geq$3 mg/dL, or previous therapy with cytotoxic alkylating agents, including cyclophosphamide. As not all pregnancies in patients with SLE are planned, it is proposed that lupus does not affect fertility and that fertility rates are comparable to the general population (Smyth and Garovic 2009). In patients with advanced renal

insufficiency, renal transplantation may restore fertility; no significant differences in pregnancy outcomes have been reported when compared to non-SLE transplant recipients.

Pregnancy Outcomes

Pregnancy outcomes in women with SLE have improved significantly since the original reports. There has been a decrease in the rate of fetal loss from 40 %, in 1960–1965, to 17 %, in 2000–2003 (Smyth and Garovic 2009). Although outcomes have improved, reported rates of maternal and fetal morbidity vary widely. Postulated causes include variations in ethnicity, socioeconomic status, measures of SLE activity/diagnosis, and the heterogeneity of study designs (Petri 1997). A US study, including 13,555 pregnancies in patients with lupus nephritis (LN), showed a 20-fold increase in maternal mortality in those with LN compared to the general population, with odds ratios of 1.7 for caesarean section, 2.4 for preterm labor, and 3.0 for preeclampsia. Meta-analyses of pregnancy outcomes in patients with SLE and LN reported maternal (e.g., lupus flare in 25.6 %, preeclampsia in 7.6 %) and fetal complications (e.g., spontaneous abortion in 16.0 % and intrauterine growth retardation [IUGR] in 12.7 %). Regression analysis showed that active nephritis was associated with premature birth and hypertension. In addition, a previous history of nephritis was associated with hypertension. The presence of antiphospholipid antibodies was also associated with hypertension, premature birth, and induced abortion (Smyth et al. 2010).

Fetal Complications

Although the majority of patients with SLE sustain pregnancy with minimal complications, compared to the general population, the overall risk for fetal loss is increased (Smyth and Garovic 2009). Rates of 11.5–46 % are reported in those with inactive renal disease, but >50 % in the presence of active renal disease (Wagner et al. 2009) (Fig. 1). This risk is even higher if previous pregnancies were affected by complications, in particular, previous pregnancy loss (Smyth and Garovic 2009).

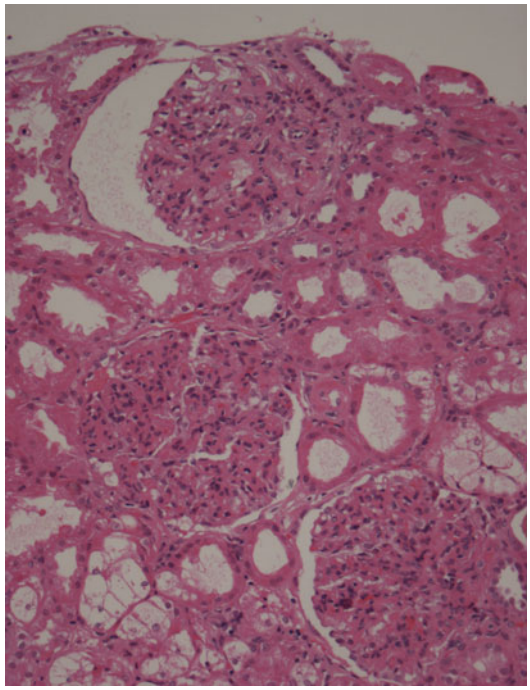
Spontaneous abortion, defined as the spontaneous loss of a fetus before 20 weeks of gestation, occurs more often in patients with SLE. When induced abortions are excluded, the rate of spontaneous abortion may be as high as 16.0 % (Smyth et al. 2010).

Preterm birth, defined as a live birth occurring before 37 weeks of gestation, occurs more frequently in patients with SLE. Rates of 34–50 % have been reported, consistent with a rate of 39.4 % from meta-analyses. Intrauterine growth restriction (IUGR), defined as an estimated birth weight less than the 10th percentile for gestational age, occurs in 12.7 % of SLE pregnancies (Smyth et al. 2010). Hypertension, particularly during early pregnancy, correlates strongly with lower birth weight. It is thought that the development of vascular necrotic lesions in the placentas of women with SLE contributes to the pathogenesis of spontaneous abortion and IUGR (Smyth and Garovic 2009).

Neonatal lupus is a passively acquired autoimmune disorder occurring in babies born to mothers with autoimmune conditions, including SLE, due to passage of maternal anti-Ro/SSA into the fetal circulation. It is associated with fetal congenital heart block, but has not been associated with any significant effects on other pregnancy outcomes. Congenital heart block carries a high mortality rate of 19 %, and up to 64 % of surviving infants will require a pacemaker. The incidence of neonatal lupus in the offspring of mothers who are anti-Ro/SSA positive is reported to be 1.5–2.0 % (Smyth and Garovic 2009).

Maternal Complications

Rates of maternal hypertension in pregnant lupus patients vary widely, with rates as high as 43 % reported; meta-analyses reported a rate of 16.3 % (Smyth et al. 2010). Hypertension in pregnancy is defined as a systolic blood pressure greater than 140 mmHg and/or a diastolic blood pressure greater than 90 mmHg, and is referred to as gestational hypertension when documented after 20 weeks of gestation. The diagnosis of preeclampsia is entertained when the onset of



Autoimmune Kidney Disease and Pregnancy, Fig. 1 A 19-year-old, gravida two, para one, presented with cough and hemoptysis at 8 weeks of gestation. Past medical history was significant for SLE diagnosed at age 12, and preeclampsia with her previous pregnancy, leading to labor induction at 8 months of gestation. Five months prior to pregnancy, due to worsening renal function and proteinuria, renal biopsy showed diffuse proliferative LN. Mycophenolate mofetil and prednisone were commenced, but when pregnancy was confirmed, mycophenolate mofetil was discontinued. The patient subsequently presented with shortness of breath, fever, hypoxia, and hemoptysis. Antinuclear antibody (ANA) was elevated to 9.1 U, creatinine increased from <1.0 to 1.6 mg/dL, and urine studies showed an active urine sediment, with dysmorphic red blood cells and proteinuria of 6 g in 24 h. As chest x-ray showed diffuse pulmonary infiltrates, bronchoscopy was performed and showed diffuse pulmonary hemorrhage. Treatment with prednisone, azathioprine, and plasma exchange was initiated. Unfortunately, the patient developed vaginal bleeding and subsequent pregnancy loss. Mycophenolate mofetil was restarted, with improvement in renal function and a follow-up creatinine of 0.8 mg/dL.
This case demonstrates poor pregnancy outcomes in patients with active LN. The necessity to modify and/or discontinue immunosuppressive agents (in this case, mycophenolate mofetil) may contribute to exacerbation of disease activity and, consequently, poor outcomes

hypertension after 20 weeks gestation is accompanied by de novo proteinuria > 300 mg/day.

Preeclampsia may affect up to 7.6 % of lupus pregnancies (Smyth et al. 2010) and may be difficult to distinguish from a lupus flare (Table 1). The diagnosis of preeclampsia is characterized by negative or unchanged lupus serologies, absence of extrarenal manifestations of SLE, proteinuria (in the absence of an active urine sediment), and elevated serum uric acid levels. Decreased urinary output, worsening renal function, low serum complement levels, and increased titers of anti-DNA antibodies are more characteristic of a lupus flare. Complement levels may not be helpful in differentiating a lupus flare from preeclampsia; instead, the CH50/Ba ratio may be more useful. In active lupus, CH50 levels remain normal, but elevations of complement split products, which include Ba, result in a high ratio of CH50/Ba (Smyth and Garovic 2009). Newer biomarkers, including antiangiogenic markers, such as soluble vascular endothelial receptor 1, sFlt-1 (Maynard et al. 2003), may help with this differentiation in the future. Preeclampsia is more common in patients with antiphospholipid antibodies, preexisting diabetes mellitus, or with previous histories of preeclampsia. Eclampsia, defined as generalized convulsions and/or coma occurring in the setting of preeclampsia, in the absence of other neurological conditions, is a rare but significant complication and affects <1 % of lupus pregnancies (Smyth et al. 2010).

Maternal mortality in SLE patients is a relatively rare complication in the developed world. Its true rate is difficult to assess. There may be a reporting bias favoring the publication of cases of maternal death, and the true number of lupus pregnancies (the denominator) is unknown. Meta-analyses have reported a rate of <1 % (Smyth et al. 2010). Importantly, a recent review of the literature identified seventeen cases of maternal mortality in pregnancies with LN. In all cases, death occurred in the setting of active renal disease, with infection and SLE complications being the two most common

causes, accounting for 41.2 % and 29.4 % of all deaths, respectively (Ritchie et al. 2012). This emphasizes the importance of planning pregnancy in patients with SLE, judicious use of immunosuppressive therapy, and the need for expert monitoring.

SLE and Renal Flares

During pregnancy, the maternal immune system adapts to facilitate the growth of the semi-allogeneic fetus. This includes the inhibition of cytokine production by type-1 helper cells (Th1) of the cellular immune system and enhanced cytokine production by type-2 helper cells (Th2) from the humoral immune system (Tower et al. 2011). This upregulation of Th2 cytokines may increase the risk of diseases mediated by Th2 cells, including SLE. In addition, delivery/termination of pregnancy may result in further changes in this immune state, toward a more stimulated state, which may also increase the risk of flare (Smyth and Garovic 2009).

Studies of the effects of pregnancy on SLE/LN disease activity have provided conflicting data when comparing flare rates between pregnant and nonpregnant patients (Smyth et al. 2010). In contrast, studies that have used a patient's own nonpregnant course for comparison have commonly demonstrated an increase in disease activity during pregnancy (Smyth and Garovic 2009). Another factor that may have contributed to the differing results with respect to the risk of SLE flare in pregnancy relates to the varying definitions of flare being used in published studies. Some features used to diagnose flare in the nonpregnant state may not be valid during pregnancy, as these may represent either normal physiologic changes or pregnancy-related complications other than lupus flare. One notable example is the worsening of proteinuria that commonly occurs toward the end of pregnancy in women with preexisting proteinuric renal diseases, which, in the case of LN, may be confused with LN flare and/or preeclampsia. To overcome this problem of misclassification, three scoring systems, which are used to measure ongoing SLE activity and flare, have been modified to take into account the physiological and clinical changes of pregnancy that can confound the evaluation of lupus activity (Ruiz-Irastorza et al. 2004).

In summary, significant differences in study designs and definitions of flare might have contributed to the conflicting data regarding the risk of SLE flare in pregnancy. As the risk for flare may be as high as 70 %, close monitoring of these patients, with monthly assessment of disease activity, is recommended (Petri 1998).

Lupus Nephritis

Up to 75 % of patients with SLE have clinically evident renal disease, which is one of the American College of Rheumatology criteria used for the classification of SLE. Active renal involvement is defined as the presence of an active urine sediment (greater than five red and white blood cells per high-power field and/or one or more cellular casts) and/or proteinuria > 0.5 g/day, with or without an elevation in serum creatinine. Pregnancies in patients with stable renal involvement generally have good outcomes, particularly if pregnancy is planned and conception occurs after a period of 12–18 months (Urowitz et al. 1993) (minimum of 6 months) of disease remission. In contrast, those with active disease at conception are associated with severe complications and deterioration in renal function (Hayslett and Lynn 1980).

The relationship between lupus nephritis and pregnancy outcome is complex. Pregnancy may have adverse short- and long-term effects on kidney function, including an increased risk for LN flare and progression to end-stage renal disease. Similar to other renal diseases in pregnancy, the risk for progression is determined in part by the severity of the underlying renal disease and is increased for patients with creatinine values greater than 1.4 mg/dL (Hou 1999). Underlying renal disease, in turn, places these pregnancies at higher risk for

maternal and fetal complications, including spontaneous abortion, premature delivery, intrauterine growth retardation, and superimposed preeclampsia.

Management of SLE and Pregnancy

Lupus pregnancies are high risk, and care should be provided by obstetricians and internal medicine specialists with an interest in SLE. Cornerstones of management include preconception counseling, close monitoring, and the provision of expert care throughout. Prior to pregnancy, it is advised that lupus be quiescent to achieve the best pregnancy outcomes. Accordingly, some patients will require maintenance immunosuppression during pregnancy. As many of these agents can cross the placenta and potentially cause fetal harm, the immunosuppressive regimen needs to be carefully reviewed and modified prior to pregnancy.

Once pregnancy is confirmed, the initial consultation should include a thorough physical examination, blood pressure monitoring, urinalysis, and 24-h urine protein collection. Investigations should include complete blood count (to rule out anemia, leukopenia, or thrombocytopenia) and serologies for autoantibodies, including anti-Ro/SSA and anti-La/SSB (due to risk of neonatal lupus), and antiphospholipid antibodies. Markers of disease activity should be reassessed monthly during the first two trimesters, with more frequent monitoring in the third trimester. Excluding antiphospholipid antibodies, those with increased serological activity in the absence of symptoms do not require the immediate initiation of treatment; instead, they are considered higher risk and should be followed up more closely.

If a renal flare occurs during pregnancy, it is important to differentiate LN from preeclampsia and its severe form, HELLP syndrome (Weinstein 1982), which is characterized by **h**emolysis, **e**levated **l**iver enzymes, and **l**ow **p**latelet count (Table 1). Superimposed preeclampsia may be particularly difficult to diagnose in a hypertensive patient with proteinuria predating pregnancy. This distinction is critical as a LN flare is managed with immunosuppression, whereas delivery, even remote from term, is indicated for severe and superimposed preeclampsia. In select cases, renal biopsy may be safely performed in patients with good blood pressure control and normal coagulation parameters (Smyth and Garovic 2009) to make a definitive diagnosis and to inform treatment decisions (Table 2). Typically, renal biopsy is not advisable after 32 weeks of gestation.

Autoimmune Kidney Disease and Pregnancy, Table 1 Differentiation of preeclampsia, HELLP syndrome, and lupus nephritis flare

	Preeclampsia	HELLP syndrome	LN flare
Timing in pregnancy	After 20 weeks	After 20 weeks	Any time during pregnancy
Complement (C3, C4)	Normal	Normal	Typically decreased
Thrombocytopenia	Absent	Present	Present
Neutropenia	Absent	Absent	Present
Active urine sediment (red blood cell casts)	Absent	Absent	Present
Other organ involvement	Absent	Absent	Present
Anti-double-stranded DNA antibodies Direct Coombs antiplatelet antibodies	Absent	Absent	Present
Anti C1q antibodies	Normal	Normal	May be high
Abnormal liver function tests	Absent	Present	Absent
Serum uric acid	Increased	Increased	Normal

Antiphospholipid Antibodies/Syndrome

Antiphospholipid antibodies, including lupus anticoagulant and anticardiolipin antibodies, are autoantibodies that bind to cardiolipin and/or β2 glycoprotein I bound to phospholipids. The presence of these antibodies, in association with clinical features such as venous or arterial thromboses, recurrent miscarriages, livedo reticularis, cutaneous ulcers, cardiac valvular disease, and thrombocytopenia, constitutes

Autoimmune Kidney Disease and Pregnancy, Table 2 Anti-inflammatory and immunosuppressive drugs in pregnancy

Drug name	Comments	FDA class[a]	Breast-feeding[b]
Corticosteroids	Risks of use often outweighed by risk of underlying disease Potential risks for orofacial clefts and premature birth	C	Usually compatible with breast-feeding
Hydroxychloroquine	Considered safe in pregnancy at 200–400 mg/day. Discontinuation during pregnancy associated with increased risk of lupus flare. May use for maintenance or mild flares	Not assigned	Usually compatible with breast-feeding
Nonsteroidal anti-inflammatory drugs (NSAID)	Avoidance after 30 weeks of gestation because of the effects of NSAID-related prostaglandin inhibition on the fetal cardiovascular system (closure of ductus arteriosus)	C	Usually compatible with breast-feeding
Cyclosporine	Can be maintained in pregnancy at lowest effective dose No significant increase in rate of congenital malformations	C	Not recommended
Tacrolimus	Can be maintained in pregnancy at lowest effective dose Potential risk of neonatal hyperkalemia and renal dysfunction	C	Not recommended
Rituximab	Limited safety data; may alter fetal and neonatal B-cell development	C	Not recommended
Azathioprine	May use for flare during pregnancy. Consider as alternative to mycophenolate. Avoid doses >1.5–2 mg/kg/day due to risk of suppressed neonatal hematopoiesis	D	Not recommended
Mycophenolate mofetil	Contraindicated during pregnancy due to teratogenicity (ocular, facial, and digits)	D	Not recommended
Cyclophosphamide	Useful when maternal disease is life-threatening High risk of fetal loss but less pronounced in more recent studies	D	Not recommended
Methotrexate	High risk of miscarriage and congenital abnormality Treatment should be withdrawn 3 months before pregnancy	X	Not recommended

[a]According to the Food and Drug Administration pregnancy ratings
[b]According to either the World Health Organization and/or Thomson lactation ratings

antiphospholipid syndrome (APS) (Rosove and Brewer 1992). Antiphospholipid antibodies can be seen in patients with SLE and other connective tissue diseases (CTD) (secondary APS), but may also occur in patients without other identifiable disease (primary APS).

Both the presence of antiphospholipid antibodies and antiphospholipid syndrome are frequently seen in association with SLE and are reported to occur in almost one in four of these pregnancies (Smyth et al. 2010). The main complication associated with these antibodies is fetal loss, which generally occurs after 10 weeks gestation (Smyth and Garovic 2009). As the risk of pregnancy loss has been correlated with the number of positive tests for different antiphospholipid antibodies (Ruffatti et al. 2009), screening for the presence of these antibodies during the initial evaluation of all lupus pregnancies is recommended. Several studies have demonstrated an increased relative risk of preeclampsia in patients with antiphospholipid antibodies or APS (do Prado et al. 2010).

The prevalence of renal involvement in patients with APS is unknown (D'Cruz 2009). Patients with antiphospholipid syndrome may develop thromboses in small diameter renal vessels leading to areas of cortical ischemia and/or necrosis and renal infarction. These patients may present with hypertension, variable degrees of proteinuria, and renal insufficiency. Renal biopsy typically demonstrates thrombotic microangiopathy. Patients with antiphospholipid antibodies are also at risk for the development of renal vein thrombosis, which frequently presents with sudden onset of severe, often nephrotic range, proteinuria. The thrombosis of the renal vein can often be confirmed by ultrasound studies. The risk of these

complications may be increased due to the hypercoagulable state of pregnancy.

The mainstay of management of antiphospholipid antibody/syndrome is anticoagulation, which appears to improve both maternal and fetal outcomes in patients with APS. In the nonpregnant state, patients are usually started on heparin and then transitioned to warfarin, with a target INR of 2.5–3.5. The use of warfarin is contraindicated during pregnancy, as it crosses the placenta resulting in teratogenicity and life-threatening hemorrhage in the infant during the perinatal period. Instead, most centers use aspirin and/or low-molecular-weight heparin. Immunosuppression is reserved for those who, in addition to APS, have active SLE, as glucocorticoids have been associated with increased prematurity without a reduction in pregnancy loss rate (Smyth and Garovic 2009).

Women with a history of antiphospholipid syndrome and arterial thrombotic events should be advised against pregnancy due to high risks, not only for pregnancy losses, but also for stroke and related maternal morbidity and mortality (Petri 1997). For these women, surrogacy can be considered as a means of achieving parenting goals without taking risks related to their own child bearing.

Systemic Sclerosis/Scleroderma

Scleroderma is up to five times more prevalent in women than in men, with a mean age of onset at age 40, and thus not commonly seen in women of childbearing age (Steen 1999). Up to 10 % of all scleroderma patients develop scleroderma renal crisis, a condition that presents with an abrupt onset of renin-mediated hypertension and renal failure in patients with diffuse sclerotic skin changes. It remains unclear as to whether the risk for scleroderma renal crisis is increased in pregnancy. Adequate treatment of this condition involves angiotensin-converting enzyme (ACE) inhibitors and thus poses a major challenge in pregnant patients, as these medications, along with angiotensin II receptor blockers (ARB), are contraindicated during pregnancy. However, their use in pregnancy may be justified as a life-saving treatment for severe hypertension in association with scleroderma renal crisis. As renal crisis is most common within 5 years of disease onset, women with scleroderma should be advised that delaying pregnancy may lessen the risk of renal crisis. Patients with the limited form of scleroderma, known as CREST (calcinosis, Raynaud's, esophageal dysmotility, sclerodactyly, telangiectasia) syndrome, usually do not have renal involvement and may do well in pregnancy, save for Mallory-Weiss tears that may occur in patients with esophageal disease who vomit during pregnancy.

Atypical Hemolytic-Uremic Syndrome (HUS)

Atypical hemolytic-uremic syndrome (HUS) is characterized by hemolytic anemia, thrombocytopenia, and renal impairment that occur as a consequence of uncontrolled activation of the complement system. In contrast, classical HUS occurs secondary to infection with bacteria that produce Shiga-like toxin (Noris and Remuzzi 2009). Complement abnormalities occur due to inactivating mutations of the factors that downregulate complement activation (factor H, factor I, or membrane cofactor protein), activating gain-of-function mutations in factor B or C3 leading to complement activation, and as a result of acquired anti-factor H antibodies. The pregnancy state may trigger abnormal complement activation leading to atypical HUS. In a recent series of 100 patients with atypical HUS, 21 women developed atypical HUS with pregnancy, with 79 % occurring postpartum (Fakhouri et al. 2010), with complement abnormalities present in 18 of the 21 patients. These patients were at an increased risk for fetal loss and preeclampsia, and 76 % reached end-stage renal disease by last follow-up. Recent work suggests that mutations in the genes coding for complement regulatory proteins may increase the risk for preeclampsia in other disease entities, such as SLE and/or APL antibodies (Salmon et al. 2011).

Membranous Nephropathy

Membranous nephropathy (MN) is one of the most common causes of nephrotic syndrome and is characterized by diffuse thickening of the glomerular basement membrane and subepithelial electron-dense deposits. The majority of cases are idiopathic, and the M-type phospholipase A2 receptor (PLA2R), expressed on glomerular podocytes, has recently been identified as a major antigen in human idiopathic MN (Beck et al. 2009). In young women of childbearing age, it is most commonly associated with SLE, with other etiologies including drug exposure (such as penicillamine, NSAIDs, and biologic agents), hepatitis B, hepatitis C, malignancy, and syphilis. In the nonpregnant state, treatments include ACE inhibitors, lipid-lowering therapy, anticoagulation, immunosuppression (including cyclophosphamide, glucocorticoids, or calcineurin inhibitors), and rituximab. ACE inhibitors during the first semester of pregnancy are associated with increased risks of cardiovascular or neurological malformations (Cooper et al. 2006), and during the second and third trimesters, may impair fetal renal function or result in poor pulmonary maturation and the development of limb contractures and skeletal malformations (Pryde et al. 1993). As such, ACE inhibitors are contraindicated during pregnancy.

Vasculitides

Takayasu's arteritis commonly affects women with age of onset of between 10 and 40 years. Subsequently, it is the second most common form of vasculitis in pregnancy, after lupus. It typically presents as a multisystem disease with renal involvement, hypertension, stroke, and heart failure. The risk of preeclampsia is increased in patients with abdominal aortic and renal artery involvement. In contrast to lupus and Takayasu's, other forms of vasculitides are more common in men than in women and typically present after the reproductive period. Subsequently, there are very few published studies, and those that are available present limited information. Briefly, ANCA vasculitides, including granulomatosis with polyangiitis (previously known as Wegener's granulomatosis) and microscopic polyangiitis, may present for the first time either during pregnancy or postpartum. In a few cases, cyclophosphamide has been used to treat flares during pregnancy with the subsequent successful deliveries of healthy babies. For the most part, patients with inactive disease at conception fare well, leading to the current recommendation that a stable remission of 6 months duration be obtained prior to conception. In addition, as steroid withdrawal can predispose to Churg-Strauss syndrome, high-dose steroids for fetal lung maturation should be used judiciously (Gordon 2004).

Conclusion

A number of autoimmune conditions are prevalent in women of childbearing age, and the occurrence of pregnancy in such patients is not infrequent. Both maternal and fetal complications may occur if the disease is active at conception. Although individual disease management is subspecialized, it is recommended that pregnancy in such patients be planned to occur when disease has been in remission for a minimum of 6 months prior to conception. Immunosuppressive agents should be optimized prior to conception, and should a flare occur during pregnancy, agents including corticosteroids, hydroxychloroquine, cyclosporine, tacrolimus, and azathioprine are safe for use. NSAIDs are best avoided after 30 weeks of gestation; rituximab and cyclophosphamide use is discouraged; methotrexate and mycophenolate mofetil are not safe for use.

Synonyms

CAR, coxsackievirus and adenovirus receptor; CD, cluster of differentiation; cMRI, cardiac magnetic resonance imaging; DCM, dilated cardiomyopathy; DNA, deoxyribonucleic acid; ECG, electrocardiography; EKG, echocardiography; EMB, endomyocardial biopsy; GCM, giant cell myocarditis; HLA, human leukocyte antigen; IFN, interferon; IgG, immunoglobulin G; IgM, immunoglobulin M; IL, interleukin; LV, left ventricle; PCR, polymerase chain reaction; RNA, ribonucleic acid; RV, right ventricle; Th1/Th2, T helper cell 1/2; TNF-α, tumor necrosis factor alpha; TnI, cardiac troponin I

Definition

Myocarditis: Myocarditis is an inflammatory disease of the heart muscle (myocardium) that can result from a variety of causes.

Pericarditis: Pericarditis is an inflammation of the two layers of the thin, saclike membrane that surrounds the heart and major blood vessels. This membrane is called the pericardium, so the term pericarditis means inflammation of the pericardium.

Myocarditis

Myocarditis is defined by the inflammation of the heart muscle composed of an inflammatory infiltrate and myocyte necrosis resulting in damage of the heart muscle with decrease in myocardial function. Because of inflammation and muscle damage, the heart is unable to respond to the increase in volume and impaired systolic function of one or both ventricles through an increase in contractility (Starling's law).

Myocarditis can be classified by etiology, histology, immunohistology, clinicopathological, and clinical criteria (Table 1). The diagnosis of myocarditis is still difficult given the vast scale of its clinical presentations ranging from almost asymptomatic to cardiac dysrhythmias and heart failure with the need of heart transplantation. As most cases are characterized by a subclinical course, many patients do not ever see a doctor while acutely suffering from myocarditis. In more than half of the patients, there is spontaneous healing and no symptoms remain. But, the destruction of the myocardium in conjunction with tissue remodelling can also lead to ventricular dysfunction and dilated cardiomyopathy in some patients, even when asymptomatic. Acute myocarditis has been shown to be the cause of sudden death in up to 12 % of cases in individuals less than 40 years old.

The Dallas criteria (presence of inflammatory cellular infiltrate with or without associated myocyte necrosis and damage not characteristic of ischemic tissue) were proposed in 1986 (Aretz et al. 1987; Cooper Jr 2009) to provide a histopathological classification for the diagnosis of myocarditis. Because of their limitation (low sensitivity that is part due to sampling error, variability in expert interpretation, lack of prognostic value, variance with treatment outcomes), newer histological criteria using cell-specific immunoperoxidase stains for surface antigens like CD-3, CD-4, CD-20, or CD-28 or human leukocyte antigen have been introduced (Blauwet and Cooper Jr 2010).

Acute myocarditis with viral etiology is the most common cause for myocarditis in Western Europe and North America (Cooper Jr 2009; Blauwet and Cooper Jr 2010; Sagar et al. 2011; Calabrese et al. 2010; Schultz et al. 2009; Yajima et al. 2009; Kühl and Schultheiss 2009). A study

Autoimmune Myocarditis and Pericarditis, Table 1 Proposed classification scheme for myocarditis (Modified from Sagar et al. 2011)

Classification scheme				
Cause	Histology	Immunohistology	Clinicopathological	Clinical
Viral	Eosinophilic	14 or more CD3+ or CD68+ cells/high power field	Fulminant	Acute heart failure
Enteroviruses (Coxsackie B)	Giant cell	Increased expression of leucocyte antigens (HLA-DR, etc.)	Acute	Syncope
	Granulomatous		Chronic active	Chest pain
Erythroviruses (Parvovirus B19)	Lymphocytic	Increased expression of adhesion molecules (ICAM1, etc.)	Chronic persistent	Myopericarditis
Adenoviruses				
Herpes viruses (Herpes simplex 6)				
Bacterial

on 172 cardiomyopathy patients (Kühl et al. 2005) in which polymerase chain reaction (PCR) had demonstrated viral genomes in the biopsy samples showed that the most common viruses were adenovirus, parvovirus B19 (although present in a large percentage of patients who do not have myocarditis (Yajima et al. 2009)), human herpesvirus 6, and enteroviruses like Coxsackie B. Other viruses often found to cause myocarditis are, for example, influenzavirus or Epstein-Barr virus.

The following model of viral infection of cardiac cells has been proposed: Both coxsackievirus and adenovirus use the same receptor, the coxsackievirus and adenovirus receptor (CAR), to infect a cardiac cell. In the absence of this receptor and co-receptor, the virus does not infect the cell. The high level of CAR expression in the heart at young ages might be one of the reasons for the apparently higher incidence of myocarditis in children. Viruses that overcome the innate immune system replicate and (in the mouse) lead to the production of viral proteins which can cause direct myocardial injury. Six to seven days after virus infection, the adaptive immune system is activated, triggering among others the infiltration of T lymphocytes in the heart (maximal infiltration 7–14 days after virus infection), leading to both the clearance of virus-infected myocytes and myocardial injury or necrosis (Blauwet and Cooper Jr 2010; Yajima et al. 2009; Kühl and Schultheiss 2009).

Besides viruses, other agents are known to cause myocarditis.

The spirochete *Borrelia burgdorferi*, trigger of Lyme disease, can cause acute and, rarely, chronic myocarditis, particularly in children (Cooper Jr 2009).

A protozoan agent to cause myocarditis is *Trypanosoma cruzi*, very common in Central

and South America. Here it may cause acute myocarditis or chronic myocardiopathy, supposedly through immune activation after infection (Aretz et al. 1987; Cooper Jr 2009; Sagar et al. 2011).

Other causes of myocarditis may be toxic chemicals such as hydrocarbons and arsenic. Many substances have reported to induce hypersensitivity reactions which lead to inflammation of the myocardium. Common medical agents to provoke similar reactions include ampicillin, clozapine, or sulfonamide drugs. Environmental agents implicated in myocarditis include lead, arsenic, or spider venom. Physical causes may be found in electrocution or radiation therapy. Immunological etiologies encompass a vast number of clinical syndromes, such as allergic reactions, rheumatoid arthritis, giant cell arteritis, rejection of graft after heart transplantation, and many more (Sagar et al. 2011).

An acute myocardial infarction-like syndrome with normal coronary arteries as well as heart failure, even with dilated left ventricle, have a good prognosis, while ventricular arrhythmias and high-degree heart block do not.

Symptoms

Various symptoms are associated with myocarditis, including fatigue, generalized body swelling, arthralgia, myalgia, orthopnea, tachypnea, and tachycardia – out of proportion to fever, palpitations, a "stabbing" pericardial chest pain which cannot be differentiated from acute coronary syndrome, cardiac dysrhythmias, circulatory impairment due to left ventricular failure, syncope, fulminant congestive heart failure, cardiogenic shock, sudden death, and many more. In the European Study of the Epidemiology and Treatment of Inflammatory Heart Disease (ESETCID), 3,055 patients with suspected myocarditis were screened for their various symptoms: 72 % showed dyspnea, 32 % had chest pain, and 18 % showed arrhythmias (Hufnagel et al. 2000). In pediatric patients the symptoms tend to be less specific, including poor appetite and sweating while feeding, fever, abdominal pain, respiratory distress, or chronic cough, which is often misinterpreted as asthma or pneumonia. In severe cases cyanosis may be noticed. In more than half of all cases, myocarditis follows a respiratory infection and patients report a history of fever, rash, joint pain, cough, or diarrhea, while symptoms specific for the heart usually arise during the subacute virus-clearing phase, approximately 2 weeks after viremia. Ventricular dysfunction due to a strong inflammation of the heart presents the classic symptoms, such as ascites and peripheral edema.

Auscultatory murmurs of mitral or tricuspid regurgitation may indicate ventricular dilation, while in advanced cases with an evolved dilated cardiomyopathy peripheral or pulmonary thromboembolism may be found. Lastly, the evolving inflammation may yield pericardial effusion of inflammatory infiltrate without tamponade and resulting pericardial and pleural friction rub (Schultz et al. 2009).

Pathophysiology

In fulminant myocarditis there is often evidence of viral RNA into patient's cells, suggesting cytotoxic necrosis without the formation of infiltrates. The progression in this case is exceptionally fast, and severe ventricular dysfunction may occur within 1 or 2 days. Macrophage activation and the resulting cytokine release lead to accumulation of a histologically visible interstitial infiltrate of mononucleated cells. Natural killer cells target damaged myocardial cells expressing viral proteins, helping to extend the process, which takes 4–14 days after viral infection, and prolonging the typical course of the disease (Cooper Jr 2009; Sagar et al. 2011; Schultz et al. 2009). Cytotoxic T lymphocytes will infiltrate the myocardium in later stages of the disease, triggering apoptotic cell death of such myocytes that present viral proteins on the cell surface. In many patients viral genomes are persistent in the myocardium. Overexpression of the cytokine tumor necrosis factor alpha (TNF-α) has been implicated in the progression of the disease and the development of irreversible heart failure (Calabrese et al. 2010; Schultz et al. 2009). When chronic myocarditis develops, the immune response itself leads to tissue destruction and remodelling, resulting in dilated

cardiomyopathy, in ventricular dysfunction, and ultimately in chronic heart failure. In case of acute myocarditis, the primary damage to the myocardium usually leads to myocardial cell death and thus liberation of a critical amount of cardiac self-antigens previously hidden to the immune system. In most patients with viral myocarditis, in fact, the pathogen is cleared and the immune system is downregulated with no further adverse effects. However, in a minority of patients, the virus is not cleared, resulting in persistent myocyte damage and myocardial inflammation due the immune response to cardiac autoantibodies (Blauwet and Cooper Jr 2010).

Diagnosis

Erythrocyte sedimentation rate, C-reactive protein concentration, or an increased level of antiviral antibody may help to diagnose acute myocarditis but they are nonspecific.

Sinus tachycardia, impairment of left ventricular systolic and diastolic function, compromised ejection fractions, conduction delays, and segmental wall motion abnormalities can be shown by electrocardiographic (ECG) examination. Changes include sinus tachycardia, ST-wave and T-wave abnormalities, and occasionally atrioventricular or bundle branch block. Associated with poor prognosis in acute myocarditis are widened QRS and Q waves (Cooper Jr 2009; Sagar et al. 2011; Kühl and Schultheiss 2009). Elevated rates of cardiac troponins or myosin are known markers for myocardial damage but are also unspecific.

Echocardiography helps to establish left ventricular (LV) and right ventricular (RV) function and to rule out other causes of heart failure. In myocarditis the usual findings are global hypokinesis with or without pericardial effusion (Cooper Jr 2009; Schultz et al. 2009).

A coronary catheterization will reveal normal coronary vessels and regional wall motion abnormalities with diminished ejection fraction and can help to exclude an ischemic origin of the patient's symptoms.

Diagnosis of myocardial viral infection and associated inflammatory process can only be confirmed by analysis of endomyocardial biopsies (EMB). This invasive procedure is performed in patients with unexplained acute-onset heart failure with hemodynamic compromise (Calabrese et al. 2010; Schultz et al. 2009; Kühl and Schultheiss 2009). Biopsies are examined histologically, often including immunostains for surface antigens such as anti-CD3, anti-CD4, anti-CD20, anti-CD28, anti-CD68, and antihuman leukocyte antigens. The interstitium may show abundant edema, focal destruction of myocytes, fibrosis, and infiltrates (Blauwet and Cooper Jr 2010; Schultz et al. 2009; Kühl and Schultheiss 2009). The introduction of amplification methods like PCR allows the detection of low copy viral genomes even from small biopsy samples. However, it is very important to use these molecular techniques in combination with other clinical and morphological techniques since the mere presence of viral nucleotide sequences does not imply a direct role of the virus in question in the pathogenesis of myocarditis. It must be remembered that only a positive PCR result is of diagnostic relevance, while a negative result for virus nucleotides does not exclude viral disease because the causative virus may not have been included in the analysis (Caforio et al. 2009; Schultz et al. 2009).

Noninvasive cardiac magnetic resonance imaging (MRI) may provide additional diagnostic value. With the unique potential for tissue characterization using T1- and T2-weighted images, cardiac MRI can evaluate three important markers of tissue injury: (i) intracellular and interstitial edema, (ii) hyperemia and capillary leakage, and (iii) necrosis and fibrosis (Sagar et al. 2011).

Treatment

Patients should receive standard heart failure care as outlined in the ACC/AHA/ESC and heart failure society guidelines.

Treatment trials of subpopulations of chronic viral-associated and nonviral myocarditis with biopsy-guided therapy are an area of active investigation. The finding of viral genomes on endomyocardial biopsy has been used to guide treatment in acute and chronic cardiomyopathy. In some but not all studies, the presence of viral

genomes was associated with subsequent worsening of heart function and the need for cardiac transplantation. Interferon beta (IFN-β) has been used successfully in patients with viral persistence in chronic, stable dilated cardiomyopathy. Viral clearance was achieved in all patients after antiviral treatment, with a significant increase in left ventricular function in the treatment group. Ongoing trials of antiviral treatment such as the use of IFN-β may lead to the use of specific antiviral treatment in the future. Conversely, patients with chronic dilated cardiomyopathy and no evidence of viral genome in the heart tissue may benefit from immunosuppressive therapy if preliminary results are confirmed in randomized, controlled trials. Immunosuppressive treatments might also prevent progression of some forms like the giant cell myocarditis by allowing control over the autoinflammatory process.

In patients whose condition deteriorates despite optimal medical management, mechanical circulatory support, such as ventricular assist devices or extracorporeal membrane oxygenation, as a bridge to transplantation or recovery, are suggested.

Autoimmune Myocarditis

Some autoimmune diseases, such as systemic lupus erythematosus, scleroderma, and vasculitides, may involve the myocardium. Interestingly, Frustaci (2002) state that serological detection of cardiac autoantibodies, HLA (human leukocyte antigen) profile, negative PCR studies for cardiotropic viruses, and responsiveness to a gluten-free diet and immunosuppressive therapy suggest the existence of an autoimmune disorder directed toward antigenic components of both the myocardium and small bowel celiac disease in their patients. Ventura et al. go even further in stating that the severity of associated autoimmune diseases in celiac disease patients can be influenced by a gluten-free diet (Ventura et al. 1999).

Autoimmunity is one of the main mechanisms in the pathogenesis linking myocarditis to dilated cardiomyopathy (DCM). Autoimmune myocarditis is thought to be precipitated by an initial infection with a pathogen, such as a virus. It may express surface epitopes which are highly similar to host epitopes found on the cell surface of cardiomyocytes, a process known as molecular mimicry. Some pathogens such as coxsackievirus B have epitopes immunologically similar to cardiac proteins. Animals developing autoimmune myocarditis after Coxsackievirus B3 infection show an abundance of antibodies to multiple cardiac antigens, for example, to epitopes of cardiac myosin. After having been activated by the virus, the immune system may attack these cardiac proteins.

In viral myocarditis the cardiomyocytes infected with a virus express HLA class I receptors with bound viral peptide antigens and effector CD8+ lymphocytes kill the infected cells inducing apoptosis. CD4+ helper T lymphocytes recognize antigens bound to HLA class II receptors on B cells. Upon activation they activate primed B cells to differentiate into memory B cells and effector plasma B cells which secrete antibodies. Virus-specific antibodies opsonize free virus particles which, once opsonized, form immune complexes which are then detected and destroyed by phagocytes.

Antibodies of both the IgM and IgG classes can activate the classical complement cascade leading to the destruction of uninfected cells and the release of large quantities of intracellular and hence immunologically protected antigens that are taken up by macrophages. These will present self-peptides to autoreactive CD4+ T helper cells. The result is a failure of tolerance. Antibodies directed against intracellular host antigens, including anti-nucleic acid, anti-myosin, anti-troponin I, and anti-actin antibodies are found in the bloodstream of patients suffering from autoimmune myocarditis.

Antibodies against cardiac troponin I (TnI) lead to severe inflammation and fibrosis in the myocardium in a murine model leading to cardiac dilatation and reduced survival (Kühl and Schultheiss 2011; Rose 2009; Kaya et al. 2010).

The removal of autoantibodies might positively influence the progression of the disease. In pilot studies various antibodies, including the

cardiodepressive autoantibodies of the IgG class, were removed from patient's blood by immunoadsorption and, in order to prevent infections, replaced by 0.5 mg/kg KG polyclonal IgG with promising results. About 60 % of the treated patients experienced improvement of their condition (Rose 2009), and later studies showed that even a single treatment could lead to a lasting positive effect (Kühl and Schultheiss 2011; Rose 2009).

A study conducted by Watanabe (2001) indicated that delivery of plasmid DNA expressing IL-10, an anti-inflammatory cytokine produced mainly by monocytes and lymphocytes, by electroporation provides marked cardioprotection in a rat model of autoimmune myocarditis. IL-10 downregulates the expression of Th1 cytokines and MHC class II antigens and costimulatory molecules on macrophages while it enhances B-cell proliferation, survival, and antibody production.

Idiopathic giant cell myocarditis (GCM) is an autoimmune form of myocarditis histologically defined by the presence of multinucleated giant cells, a lymphocytic inflammatory infiltrate, and myocyte necrosis. Often it is fatal except when mechanical support or heart transplantation is performed (Blauwet and Cooper Jr 2010). Immunosuppressive treatment proved to delay fatality of GCM and improve long-term survival, while in many other forms of myocarditis, this treatment had mainly disappointing results (Blauwet and Cooper Jr 2010), although it was hypothesized that GCM is a heterogeneous disease with one form that can recover without immunosuppression and other forms that respond to immunosuppressive therapy (Murashita et al. 2006). Immunosuppressive therapy is also indicated in refractory cardiac insufficiency, after GCM, granulomatous myocarditis, or eosinophilic necrotizing myocarditis has been histologically confirmed (Cooper Jr 2009; Kühl and Schultheiss 2011).

These are rare diseases (they make up only about 10 % of acute myocarditis cases), but they have been shown to be successfully treated by immunosuppressive measures, when therapy was started early. Untreated they are coupled with a high mortality rate.

Pericarditis

The pericardium is a double-layered sac of connective tissue covering the outer surface of the heart. It is filled with a small, physiological amount of fluid which prevents the two layers from rubbing directly on each other causing friction and which augments in case of inflammation. It anchors the heart in the chest wall and shields it from infection. It also prevents the heart from overexpanding when blood volume increases. Pericarditis is an inflammation of the pericardium, often characterized by chest pain.

Pericarditis can be classified according to the composition of the inflammatory exudate found between the layers of the pericardium (pericarditis exudativa) into serous pericarditis, fibrinous p., purulent p., hemorrhagic p., and tuberculous p. as forms of acute pericarditis and *concretio pericardii* (adhesive pericarditis), *accretio pericardii*, and *constrictio pericardii* (constrictive pericarditis) as forms of chronic pericarditis. In *concretio pericardii*, the epi- and pericardium become joined by a stringlike growth, while in *accretio pericardii* the pericardium becomes joined to the surrounding mediastinum, making adjustments of the heart's position in response to movement almost impossible. In *constrictio pericardii* the surface of the pericardial sac becomes obliterated by, for example, calcifications.

In pericarditis sicca there is no significant exudate detected. Pericarditis fibrinosa is the form usually present at the beginning with inflammatory infiltrates deposit between the two layers of the membrane. In p. exudativa there is typically less pain than in p. sicca and auscultation reveals diminished friction rub. In most cases pericarditis exudativa is caused by a viral or other infection or an immunological condition. The amount of exudate can limit the function of the heart to the point of cardiac tamponade and circulatory impairment and, in extreme cases, can lead to a shock. The heart may be compressed by the constrictive process, which may cause blood to back up into the lungs, abdomen, and legs causing edema.

Apart from pericardial effusion, later on the result is fibrosis and calcifications can be found, both of which significantly hinder the function of

the heart. If acute pericarditis lasts several months, it becomes a chronic form. Almost always the layers of myocardium under the inflamed tissue are influenced to some degree by the pericardial damage; in these cases a process called perimyocarditis is in effect. When endocardium is also involved, the process is called pancarditis. Pericarditis is likely to recur even after it was successfully treated.

Symptoms

Often pericarditis is characterized by intense substernal, retrosternal, or left precordial pleuritic chest pain which worsens in supine position or during cough, swallowing, or inspiration, while it does not worsen upon exertion and it eases up in sitting positions or when the patient leans forward. In this it differs from the pain experienced in angina pectoris. The pain may irradiate to the trapezius ridge and the left or both shoulders.

Cough, fever, fatigue, palpitations, tachypnea, diaphoresis, or syncope may be noticed, as well as mild dysrhythmias, pulsus paradoxus from a possible cardiac tamponade, distant heart sounds, jugular vein distention, and anxiety. Some of the symptoms are proportional to the amount of exudate present.

In chronic forms lethargy, cough, and respiratory distress may be noticed, as well as distant heart sounds upon auscultation and equilibration of all the diastolic blood pressures on cardiac catheterization due to the constriction of the pericardium. Other symptoms may be jugular vein distension and pulsus paradoxus. Chronic forms are usually characterized by absence of chest pain. Severe cases can lead to hypotension and hence water retention and edema of the lower extremities, liver, and stomach.

Diagnosis

Because of the similarity of the pain experienced by patients to the pain of a myocardial infarction, pericarditis can be misdiagnosed when solely based on clinical data.

Isolation of viruses causing pericarditis using PCR analysis is highly difficult due to the delay between the initial pericardial infection and the clinical manifestation of pericarditis, as well as the limited number of virus genomes which can be screened. PCR analysis allows for precise etiological characterization and reduces the number of cases of idiopathic pericarditis greatly; however PCR analysis is usually reserved to recurrent cases, as the disease resolves quite often spontaneously (Calabrese et al. 2010).

Often alterations of the ECG can be observed, such as repolarization troubles with ST-segment anomalies. By echocardiography even small amounts of exudate, pus, or pericardial thickening can be detected. Transesophageal or transthoracic echocardiography is often used to diagnose cardiac tamponade. Upon auscultation a rubbing friction sound can be distinguished; this sound usually diminishes or vanishes in pericarditis exudativa.

X-ray of the thorax may reveal only substantial effusions, cardiomegaly, and/or heart congestion of the lungs.

Pericardiocentesis, while relieving the heart of some of the pressure from the high amount of exudate, may also allow detecting bacterial infections or cancerous cells. Association of pain typical for pericarditis and a heightened amount of urea acid or creatinine in the bloodstream may suggest uremic pericarditis.

Cardiac MRI and CT scans may reveal excess fluid in the pericardium, evidence of inflammation, and pericardial thickening, while cardiac catheterization will provide hemodynamic information.

Causes

The causes of pericarditis can be separated into infectious and noninfectious although the most frequently reported cause of acute pericarditis is idiopathic. Presumably, the latter is mostly of viral origin. Viral pericarditis is mainly caused by the same viruses that cause myocarditis (see above), particularly enteroviruses, adenoviruses, and influenza viruses (Calabrese et al. 2010). Others causes of pericarditis include bacterial or fungal infections – *Mycobacterium tuberculosis* being a common cause in developing nations, a condition with almost 85 % mortality rate within the first 6 months (Calabrese et al. 2010). Uremic pericarditis, Dressler's or

post-infarct pericarditis epistenocardica, kidney failure, and autoimmune diseases like systemic lupus erythematosus, systemic sclerosis, rheumatoid fever, rheumatoid arthritis, sarcoidosis, or Sjogren syndrome also should be mentioned. Pericarditis may result from genetic diseases such as Familial Mediterranean fever, as well as from associated myocarditis, neoplasias, hypothyroidism, immune deficiencies, radiation therapy, traumas of the thorax, and surgery. Rarely, it results from allergic reactions or side effects of pharmaceuticals.

Treatment

The basic treatment for pericarditis is limited to bed rest under strict ECG control and nonsteroidal anti-inflammatory drugs. More specific treatments depend on the causes and symptoms. Antibiotics or antimycotics may be needed in case of other infectious causes. Corticosteroids are reserved for rare cases and are seldom required, except in the case of certain systemic autoimmune diseases. Diuretics may be used in constrictive pericarditis to control fluid retention. Severe cases may require pericardiocentesis or surgery. When pericardiocentesis is ineffective, a pericardial window may be performed. Pericarditis constrictiva calcarea can in many cases be treated by pericardectomy.

Autoimmune Pericarditis

For a long time researchers have been discussing whether recurrent episodes of pericarditis could be attributed to autoimmune processes. To correctly diagnose autoimmune pericarditis, Shabetai (2005) advises that antisarcolemmal antibodies should be searched for, PCR for cardiotropic viruses and other infectious agents should be proven to be negative, and IgM against these agents should not be detectable.

Circumstantial evidence for pericarditis to be an autoimmune process is divided into 6 subgroups by Rose (2010):

(I) An increased number of pro-inflammatory cells and cytokines in the pericardial tissues and fluid
(II) Antibodies against pericardial tissue in serum and pericardial fluid
(III) Exclusion of the presence of an infectious agent by PCR, and no antibodies to an infectious agent in the serum
(IV) Weak but discernable statistical association with a particular HLA haplotype
(V) A slight but consistent male bias
(VI) Pericarditis found in association with other autoimmune diseases

Rose underlines, however, that it is still uncertain whether autoimmunity has a causative role or is a consequence of the inflammatory process.

The similarities between idiopathic recurrent pericarditis and autoinflammatory diseases, together with the marked efficacy of anakinra, a drug developed to treat rheumatoid arthritis, in their patients, led Picco et al. to suppose that at least a subset of patients diagnosed as having idiopathic recurrent pericarditis could be affected by a autoinflammatory disease, possibly related to gene mutations leading to dysregulation of IL-1β production and secretion (Picco et al. 2009).

Dressler's Syndrome

Dressler's syndrome, also known as post-myocardial infarction syndrome, post-cardiac injury syndrome, or postpericardiotomy syndrome, develops between the second and tenth week after a myocardial infarction, traumatic injury, and heart surgery or rarely after percutaneous procedures like stent or pacemaker implantations. It is thought to be the result of an autoimmune response to myocardial neo-antigens following damage to the heart tissue. It is usually self-limiting and does only very seldomly lead to cardiac tamponade. Showing most of the symptoms of other forms of pericarditis, it may rarely lead to cardiac tamponade, pleuritis, pulmonary infiltration, or pericarditis. It tends to subside within a few weeks but may recur. It is possible to find pleuritis, sometimes with pleural effusions, in some patients. It needs to be distinguished from pulmonary embolism which also causes pleuritic chest pain and often occurs in hospitalized patients recovering from heart injury. The treatment of Dressler's syndrome is concurrent with that of other forms

of pericarditis. Treatment usually concentrates on medical agents which decrease the inflammatory response such as nonsteroidal anti-inflammatory drugs or with corticosteroids. However corticosteroids are reserved for rare cases and are seldom required. Inpatient care is usually necessary only in cases which indicate a possible tamponade. A rare but fatal complication of Dressler's syndrome is the occlusion of coronary artery bypass grafts.

Definition

This entry reviews current understanding of the contribution of autoimmunity and inflammation to the development and progression of diabetic kidney disease.

Introduction

Inflammatory autoimmune beta cell destruction in the pancreas (insulitis) is characteristic of type 1 diabetes, whereas type 2 diabetes is a complex, polygenic disease that involves combinations of insulin resistance and defects in insulin secretion. Although type 1 diabetes results from an immune-mediated inflammatory process, the pathogenesis of diabetic nephropathy, one of the chronic microvascular complications of diabetes, is generally considered to be multifactorial. Although associated with inflammation at various stages (see below), the genesis of the specific lesions of diabetic nephropathy is not thought to be via an autoimmune mechanism.

Glycemic control is strongly associated with development and progression of diabetic nephropathy. In the Diabetes Control and Complications Trial (DCCT) study, the risk of microalbuminuria increased geometrically with the increasing hemoglobin A_{1c} (A_{1c}) levels during the study (The Diabetes Control and Complications Trial Research Group 1993). Moreover, the DCCT (type 1 diabetes) and the United Kingdom Prospective Diabetes Study (UKPDS; type 2 diabetes) demonstrated the benefit of strict glycemic control on the development and progression of microalbuminuria and overt proteinuria, as predictors and indicators of diabetic nephropathy (The Diabetes Control and Complications Trial Research Group 1993; UK Prospective Diabetes Study (UKPDS) Group 1998). In type 1 diabetic patients who had a kidney transplant, diabetic nephropathy lesions, manifesting as increased glomerular basement membrane width (GBM) and mesangial and mesangial matrix fractional volumes, developed at rates similar to those seen in the native kidneys of type 1 diabetic patients. This occurred despite immunosuppressive therapy in the diabetic recipients beginning when the normal kidney was first placed into a diabetic environment (Chang et al. 2008). Furthermore, diabetic nephropathy lesions can be reversed after 10 years of normoglycemia by pancreas transplantation (Fioretto et al. 1998) with the same immunosuppression that allowed lesions to develop in the renal transplant recipient with type 1 diabetes. Finally, diabetic nephropathy lesions do not develop in nondiabetic members of identical twin pairs discordant for type 1 diabetes, despite presumably equal genetic propensity to autoimmune endocrinopathies (Steffes et al. 1985). However, although these studies all indicate the critical requirement and importance of glycemia to the development and progression of diabetic nephropathy, the above arguments do not exclude the contribution of autoimmunity and/or inflammatory processes in the genesis or progression of diabetic nephropathy lesions.

Interestingly, the presence of T-lymphocytes was identified in the region of the juxtaglomerular apparatus (JGA) (where renin is produced) in 60 % of type 1 diabetic patients with and without abnormal urinary albumin excretion (Paulsen et al. 1994). Moriya et al. (2004) found that JGA T-cell positive patients had shorter duration of diabetes (mean 6.7 years for T-cell positive vs. 9.2 years for T-cell negative patients, $p = 0.011$) and lower urinary albumin excretion but similar A_{1c} values compared to T-cell negative patients (Moriya et al. 2004). GBM width and mesangial fractional volumes were similar in the two groups, but filtration surface per glomerulus was greater in the 37 T-cell positive vs. 38 T-cell negative young type 1 diabetic research patients (Moriya et al. 2004). This inflammatory process was presumed to represent an autoimmune process, part of the polyendocrinopathy which is highly associated with the autoimmune β-cell destruction leading to type 1 diabetes (Moriya et al. 2004). Reduction in glomerular filtration surface is an important component for the loss of glomerular filtration function in diabetic nephropathy. Thus, the possibility exists that this presumed JGA autoimmune process, perhaps through reduction in local renin production, may, in fact, be beneficial.

In patients with type 1 diabetes, there is markedly increased localization of plasma proteins mainly albumin and immunoglobulin (IgG) in extracellular basement membranes, including glomerular and tubular basement membrane (GBM, TBM), and Bowman's capsule (Michael and Brown 1981). This occurs irrespective of the severity of the underlying diabetic nephropathy

lesions but has the appearance of greater intensity and extent when these basement membranes are thickened. Binding of plasma proteins to basement membrane is charge-selective since the IgG found in these renal basement membranes is restricted to the IgG4 subclass, with its relatively low isoelectric point, in contrast to anti-GBM diseases, where all IgG subclasses are bound to GBM (Melvin et al. 1984). Nevertheless, the mechanism whereby there is increased binding of anionic proteins to the presumably positively charged renal basement membrane in diabetic nephropathy is still unclear. The importance is that diabetes should not be confused with anti-GBM antibody diseases, a distinction greatly facilitated by the diagnosis of diabetes, the increased albumin localization on renal extracellular basement membranes, and the absence or paucity of glomerular inflammatory cells in diabetic patients.

Plasma proteins are not only observed in renal basement membrane but also in glomerular arteriolar hyalinosis lesions appearing by light microscopy as periodic acid-Schiff (PAS) stained-positive opaque ground glass. These afferent and efferent arteriolar hyaline lesions can be found only after a few years of diabetes (Harris et al. 1991). Accumulations beneath the internal elastic lamina can extend into and replace arteriolar smooth muscle cells and ultimately occlude the vascular lumina. When advanced they are associated with increased numbers of globally sclerotic glomeruli (Harris et al. 1991). Immunohistochemical studies of these exudative lesions have identified the presence of albumin, immunoglobulins, complement, fibrinogen, and other plasma proteins (Falk et al. 1983). Identical hyaline accumulations can occur as subendothelial deposits in glomerular capillaries which, through a process of adhesion and extraction (personal observations), can evolve to capsular drops, that is, hyaline deposits along Bowman's membrane. The plasma proteins localized in these exudative lesions can fix heterologous guinea pig complement, indicating their inflammatory potential (Burkholder 1965). However, these lesions are rarely associated with visible tissue inflammation (personal observations). Additionally, immunofluorescent studies using antibodies to C5–9 complement components of the membrane attack complex (MAC) revealed extensive localization of MAC in the mesangium, juxtaglomerular area, Bowman's capsule, afferent and efferent arterioles, and TBM in patients with advanced diabetic nephropathy as well as in other non-nephritic renal diseases such as hypertension, amyloidosis, and obstructive uropathy (Falk et al. 1983). Thus, these findings are not specific for diabetic nephropathy, more likely represent inflammation consequences of advanced renal injury, but may be very important in mechanisms of advanced renal disease progression. Thus, the deposition of immunoglobulins and complement components from the classical and alternative pathway is present in sclerosed glomeruli in end-stage renal disease specimens regardless of the cause the kidney failure.

Several additional studies have also suggested the involvement of complement activation in the pathogenesis of diabetic nephropathy. Mannose-binding lectin or MBL, which is primarily synthesized in the liver and specifically binds to the glycosylated surface of microorganisms, can activate the complement pathway through MBL-associated serine proteases. Elevated circulating MBL levels were found in patients with type 1 diabetes and positively correlated with urinary albumin excretion (Hovind et al. 2005). Moreover, serum MBL levels were significantly higher in patients with nephropathy compared to normoalbuminuric patients (Hovind et al. 2005), and higher MBL levels in early course of type 1 diabetes are associated with later development of persistent albuminuria (Hovind et al. 2005). Although the deposition of MBL in the diabetic kidney has not yet been evaluated, MBL-mediated complement activation could contribute to diabetic microvascular complications. However, the MBL-mediated complement pathway is not specific to diabetes. Glomerular deposition of MBL and MBL-associated serine protease are also found in patients with Henoch-Schönlein purpura and IgA nephropathy. Whether complement activation, particularly through the MBL pathway, plays a specific role in the pathogenesis of diabetic kidney complications or contributes as a common pathway to nonspecific inflammation in diabetes needs to be elucidated.

It is important to understand that although direct tissue pathologic findings of renal inflammatory processes are limited at the earlier stages of the development of classical diabetic nephropathy lesions, the nature and patterns of the lesions change as the disease progresses. Thus, when proteinuria appears, which in type 1 diabetes is virtually always associated with advanced mesangial expansion, new pathologic changes emerge which are rarely seen earlier in the disease. These include tuft adhesions and focal segmental glomerulosclerosis lesions at or close to the glomerular-tubular junction, along with varying degrees of severity of damage to the early portion of the proximal tubule (Najafian et al. 2006). Associated with tubular damage, there is increased interstitial fibrosis and influx of inflammatory cells into the interstitium and tubules (Najafian et al. 2006). In more advanced cases, with elevated serum creatinine levels above 1.5 mg dl, these inflammatory changes become increasingly severe and are, together with interstitial fibrosis, associated with further glomerular filtration rate decline and progression to end-stage renal disease (Bohle et al. 1987). However, these changes are not unique to diabetic nephropathy and appear to represent final common pathways of progressive renal injury as end-stage renal disease is approached in a wide variety of renal disorders. This inflammation may be the downstream consequence of proteinuria per se and/or the scavenger tissue responses to advanced nephron cellular injury and death (Abbate et al. 2006).

There are, however, a number of lines of evidence supporting the view that mediators of inflammation may become activated earlier in the course of diabetic nephropathy. A number of studies have connected diabetic nephropathy status and risk with inflammatory cytokines. Thus, Dalla Vestra et al. (2005) in studies of research biopsies in type 2 diabetic patients found that increased GBM width was associated with greater levels of serum amyloid protein, C-reactive protein, and interleukin-6, and GBM width was directly correlated with fibrinogen levels ($r = 0.33$, $p < 0.002$) and interleukin-6 ($r = 0.25$, $p < 0.05$, respectively) (Dalla Vestra et al. 2005). Interleukin-18 was overexpressed in tubular cells in most biopsies of type 2 diabetic patients with overt nephropathy, while this was rarely the case in minimal change nephrotic syndrome patients, suggesting that this was not the consequence of proteinuria per se (Miyauchi et al. 2008). Nakamura et al. (2005) in studies of type 2 diabetic patients found direct correlations between albumin excretion rate and serum and urine interleukin-18 levels ($r = 0.53$, $p < 0.001$ and $r = 0.31$, $p = 0.005$, respectively) (Nakamura et al. 2005).

Importantly, in a study of 249 Japanese type 2 diabetic patients, elevated IL-18 levels strongly predicted transition from normoalbuminuria to microalbuminuria [(OR 3.695 % (I 1.2–10.4) for serum interleukin-18 levels above the median] (Araki et al. 2007). Moreover, in patients with interleukin-18 serum levels above the median, the annual rate of decline of glomerular filtration rate (−2.1 [interquartile range −0.5–3.0] ml/min/1.73 m^2/year) was greater than in patients with lower interleukin-18 serum values (−1.1 [interquartile range −0.2 −2.9] ml/min/1.73 m^2/year), $p = 0.036$ (Araki et al. 2007).

More recently, two important papers were published which further solidified the importance of inflammatory cytokine variables as predictors of diabetic nephropathy risk and progression. In 625 type 1 diabetic patients with normal estimated glomerular filtration rate and high normal albumin excretion rate ($n = 146$) or microalbuminuria ($n = 482$), the risk of the subsequent development of estimated glomerular filtration rate values <60 ml/min/1.73 m^2 was strongly related with the baseline quintile distribution of the levels of circulating tumor necrosis factor (TNF) receptors 1 and 2 obtained 5–12 years earlier (Gohda et al. 2012). A second study from this same group described TNF receptors 1 and 2 levels in 410 (85 % Caucasian) type 2 diabetic patients with chronic kidney disease stages ≤3 (Niewczas et al. 2012). On follow-up 8–12 years later, they were categorized as alive, end-stage renal disease, or deceased without end-stage renal disease. The end-stage renal disease group had much higher baseline albumin excretion rate and lower estimated glomerular

filtration rate values than the other groups (Niewczas et al. 2012). Markers of endothelial function and cytokines, including intercellular adhesion molecule-1, vascular intercellular adhesion molecule-1, plasminogen activator inhibitor-1, interleukin-6, and C-reactive protein, were similar in all groups, while TNF pathway markers (free TNFα, total TNFα, and TNF receptors 1 and 2) were highest in the end-stage renal disease group and intermediate in the deceased without end-stage renal disease group. TNF receptors 1 and 2 were the strongest predictors. These findings remained statistically significant after controlling for baseline glycemia, albumin excretion rate, and estimated glomerular filtration rate (Niewczas et al. 2012).

Other renal diseases can develop or be superimposed on diabetic nephropathy in patients with types 1 or 2 diabetes. Immunologic-related renal diseases such as minimal change nephrotic syndrome and membranous nephropathy may occur more commonly in the patient with type 1 diabetes than in nondiabetic patient. Less than 1 % of type 1 diabetic patients who had diabetes more than 10 years and fewer than 4 % of those who had proteinuria were found to have renal disorders other than diabetic nephropathy when the biopsies were performed for research purposes (Mauer M, personal observation). Moreover, there are no reports suggesting that autoimmune renal diseases, such as anti-GBM antibody or lupus nephrites, are more common in people with vs. without diabetes. Different patterns of renal injury in diabetic patients biopsied for clinical indications are substantially influenced by the criteria or indication using for biopsy. Diabetic glomerulosclerosis was observed more commonly in patients in institutions where there was less restrictive renal biopsy indication, whereas the incidence of other glomerulonephritis superimposed or without diabetic kidney disease was remarkably higher in patients at institutions with more restrictive biopsy criteria which limited biopsy to patients with more atypical clinical presentations (Mazzucco et al. 2002). Thus, patients with atypical courses, for example, proteinuric type 1 diabetic patients whose diabetes duration is less than 10 years or proteinuric type 2 diabetic patients with albuminuria and/or reduced glomerular filtration rate but without retinopathy, should be carefully evaluated for renal disorders other than diabetes, and renal biopsy should be considered in these cases.

Conclusion

In summary, although evidence that autoimmune renal injury is important in the genesis and progression of diabetic nephropathy is not compelling, there are strong indicators that inflammatory processes are involved in the genesis and progression of diabetic nephropathy in patients with type 1 and type 2 diabetes. Moreover, the progression of many renal diseases from stages of well-established parenchymal damage to end-stage renal disease may include elements of autoimmunity processes (Bohle et al. 1987) that remain to be fully explored. It is not yet clear if targeting such inflammatory processes may be therapeutically beneficial in diabetic nephropathy.

Autoinflammatory Diseases

Ahmet Gül
Department of Internal Medicine, Division of Rheumatology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey

Synonyms

Autoinflammatory disorders; Hereditary periodic fever syndromes; Hereditary recurrent fever syndromes

Definition

Autoinflammatory diseases were originally described as a group of hereditary disorders characterized by recurrent, seemingly unprovoked inflammatory episodes without involvement of the adaptive immune response, i.e., absence of high-titer pathogenic autoantibodies or self-antigen-specific T lymphocytes (McDermott et al. 1999).

Its definition has recently been updated to encompass a larger group of inflammatory disorders mediated predominantly by the innate immune system and associated with a significant host predisposition, either as a Mendelian or a complex trait (Kastner et al. 2010). This definition does not rule out the contribution of adaptive immune response to the inflammatory process, but it aims to distinguish autoinflammatory diseases from autoimmune disorders, which are thought to develop through the effector responses of T and/or B cells directed against self-antigens.

Autoinflammatory Features

The typical features of autoinflammatory disorders include:

- Recurrent and self-limited episodes of inflammation
- Varying degrees of fever during attacks
- Localized inflammatory manifestations, including peritonitis, pleuritis, arthritis, skin rash, intraocular inflammation, and/or neurologic findings
- Inflammatory attacks lasting several hours to weeks (depending on the underlying disease)
- Spontaneous resolution of the clinical findings and elevated inflammatory markers after each acute episode

Patients are usually normal between attacks, but some manifestations may be persistent. Although episodes of inflammation are typical, recurrence rates may change without a clear periodicity. With the identification of underlying pathogenic mechanisms such as inflammasome-associated inflammation, several other manifestations, such as vasculitic rash, vitiligo, or lipodystrophy, have been included into the autoinflammatory spectrum.

Manifestations and Differential Diagnosis

Distinctive features of the most common hereditary autoinflammatory disorders are summarized in Table 1. Familial Mediterranean fever (FMF), the prototypical and most common autoinflammatory disorder, is characterized by recurrent attacks of fever and serosal, synovial, or cutaneous inflammation lasting 12–72 h. Abdominal pain resulting from peritonitis presents as an "acute abdomen" and typically resolves within a few days. FMF usually starts during childhood, but milder or atypical forms can be seen after the age of 40. It usually demonstrates an autosomal recessive inheritance pattern and is quite commonly seen in patients with Jewish, Armenian, Turkish, Arab, or other Mediterranean ancestries. FMF has been associated with the variations of the MEFV gene, which encodes pyrin protein. Pyrin is expressed in neutrophils, monocytes, dendritic cells, and fibroblasts and is thought to be involved in the regulation of inflammasome function. Most of the disease-associated variations occur in the carboxy-terminal (C-terminal) PRY-SPRY domain of the pyrin protein. The carrier rate is quite high in Eastern Mediterranean populations. Recent observations suggest a more complex pattern of inheritance than a recessive model including some FMF patients with single or no MEFV variations or with dominantly inherited mutations (Masters et al. 2009; Booty et al. 2009; Lachmann 2011; Savic et al. 2012).

The tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS) was originally described as familial Hibernian fever. It can be seen in all ethnic groups, but it is more common in Northern European populations. It usually starts during childhood, and inflammatory attacks last a few weeks. During attacks, patients may experience fever, abdominal pain, arthralgia or

Autoinflammatory Diseases, Table 1 Features of common hereditary autoinflammatory diseases (Masters et al. 2009; Lachmann 2011; Savic et al. 2012; Goldbach-Mansky 2012)

	Gene/protein	Ethnicity	Length of attacks	Distinctive clinical features
Autosomal recessively inherited				
FMF	MEFV/Pyrin	Jewish, Armenian, Turkish, Arab	12–72 h	Peritonitis, pleuritis, arthritis, erysipelas-like erythema
HIDS	MVK/ mevalonate kinase	Dutch, Northwestern Europe/All	3–7 days	Abdominal pain, cervical nodes, oral aphthous ulcers, maculopapular rash, arthralgias
DIRA	IL1RN/IL-1Ra	All	Continuous	Pustular skin rash, multifocal osteomyelitis, periostitis
Autosomal dominantly inherited				
TRAPS	TNFRSF1A/ Type 1 TNF receptor	Northern European/All	>5 days, 1–4 weeks	Periorbital edema, headache, abdominal pain, arthralgia/myalgia, fasciitis
Cryopyrin (NLRP3)-associated periodic syndromes				
FCAS	NLRP3/NLRP3	Northern European/All	Usually <24 h	Cold-induced fever, urticarial rash, conjunctivitis, arthralgias
MWS	NLRP3/NLRP3	Northern European/All	24–48 h or continuous	Urticarial rash, conjunctivitis, sensorineural deafness
NOMID	NLRP3/NLRP3	Northern European/All	Continuous with exacerbations	Urticarial rash, bony overgrowth/arthropathy, sensorineural deafness, aseptic meningitis, mental retardation, papilledema
PAPA syndrome	PSTPIP1/ PSTPIP1	Northern European	Days/weeks	Pyoderma gangrenosum, cystic acne, migratory pyogenic arthritis
Blau syndrome	NOD2 (CARD15)	All	Continuous	Granulomatous polyarthritis, uveitis and rash; camptodactyly

FMF familial Mediterranean fever, *HIDS* hyper-IgD and periodic fever syndrome, *DIRA* deficiency of IL-1Ra, *TRAPS* TNF receptor-associated periodic syndrome, *FCAS* familial cold autoinflammatory syndrome, *NOMID* neonatal onset multisystem autoinflammatory disease, *PAPA* pyogenic arthritis, pyoderma gangrenosum and cystic acne syndrome

myalgia with centripetal migration, reticular or serpiginous erythematous rash, periorbital edema, and headache. However, some of the manifestations may be continuous. TRAPS is associated with dominant variations in the type-1 (p55) TNF receptor gene (TNFRSF1A), and most of the disease-associated variants occur in the extracellular part of the receptor, particularly in the first two cysteine-rich domains (McDermott et al. 1999; Lachmann 2011).

Cryopyrin-associated periodic syndromes (CAPS) or cryopyrinopathies consist of three disorders caused by variations in the NLRP3 gene and are associated with overlapping manifestations starting during infancy. A continuum in disease severity may span from the mildest familial cold autoinflammatory syndrome (FCAS) to moderate Muckle-Wells syndrome (MWS) and to the most severe form, neonatal onset multisystem inflammatory disease (NOMID or alternatively named as chronic infantile neurologic cutaneous and articular syndrome, CINCA). FCAS is characterized by cold-induced inflammatory attacks of fever, a neutrophilic urticarial rash, conjunctivitis, and arthralgia, lasting for 24 h or less. MWS has been associated with more severe inflammatory findings lasting 1–2 days which may be complicated by the development of sensorineural deafness and secondary (type AA) amyloidosis. NOMID is associated with continuous inflammation starting at the neonatal period with chronic aseptic meningoencephalitis, developmental retardation, bony overgrowth and deforming arthropathy, deafness, and papilledema/optic

atrophy (Masters et al. 2009; Lachmann 2011). CAPS-related NLRP3 mutations have an autosomal dominant inheritance pattern, but de novo mutations are frequently observed especially in NOMID patients. In almost half of the patients with CAPS phenotype, no NLRP3 mutation can be detected. However, an increasing number of CAPS patients with somatic mosaicism have been observed with parallel deep sequencing (Tanaka et al. 2011).

Mevalonate kinase deficiency (MKD) or hyper-IgD and periodic fever syndrome (HIDS) is a rare autoinflammatory disease with an autosomal recessive inheritance pattern. MKD is more prevalent in the Netherlands, probably due to a founder effect. It usually starts during early childhood with recurrent episodes of fever, cervical lymphadenopathy, abdominal pain, vomiting, and/or diarrhea. Other manifestations may include splenomegaly, arthralgia or arthritis, headache, erythematous macules and papules, as well as oral and genital aphthous ulcers. Elevation of serum IgD levels is not specific for MKD, and it may not be present in all patients. Disease-associated variations are related to mutations in the mevalonate kinase (MVK) gene, which is involved in the biosynthesis of cholesterol, farnesyl, and isoprenoid.

Rarer forms of autoinflammatory syndromes include deficiency of the interleukin-1 receptor antagonist (DIRA), Blau syndrome, pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome, and others (Goldbach-Mansky 2012). DIRA is an autosomal recessive disease and starts at the neonatal period with widespread pustular rash. Inflammatory findings include joint swelling, osteolytic lesions, periostitis, and heterotopic bone formation around the proximal femur. Similarly, a homozygous missense mutation in the IL36RN gene (which encodes the interleukin-36 receptor (IL-36R) antagonist) leads to deficiency of the IL-36R antagonist (DITRA) and is associated with generalized pustular psoriasis. Another pyogenic disease, PAPA syndrome, is associated with mutations in the proline-serine-threonine phosphatase-interacting protein-1 (PSTPIP1) gene and characterized by severe cystic acne, pyoderma gangrenosum, and sterile pyogenic arthritis. Skin and joint findings may develop following minor trauma in patients with PAPA syndrome. Blau syndrome, a NOD2 (nucleotide-binding oligomerization domain 2)-associated autoinflammatory disorder, is characterized by granulomatous uveitis, skin findings, and arthritis. Disease-associated mutations usually occur in the nucleotide-binding domain. Relatively common variations in the leucine-rich repeat domain of the same NOD2 gene have also been associated with Crohn's disease. Additionally, lack of interleukin-10 signaling due to IL10RA or IL10RB mutations has been shown to be causing early-onset inflammatory bowel disorders.

Triggers

In most of the hereditary autoinflammatory disorders, an obvious trigger for exacerbation of inflammation cannot be identified. However, some inflammatory episodes may develop as a result of environmental triggers and gene-environment interactions. Known exogenous triggers include cold exposure in FCAS, vaccinations in HIDS, minor physical trauma in TRAPS, PAPA and DIRA syndromes, strenuous exercise, psychological stress, and menstrual cycles in FMF (Masters et al. 2009; Lachmann 2011; Savic et al. 2012). Also, most of the autoinflammatory disorders show a tendency for ameliorated inflammatory episodes during late adulthood.

Amyloidosis Risk

FMF has been associated with an increased risk for amyloidosis (type AA), and historical data reveals amyloidosis-related nephrotic syndrome and renal failure as the main cause of morbidity and mortality. Development of amyloidosis may be associated with both genetic (MEFV and SAA genotypes) and environmental factors with a higher risk among those with a history of childhood in countries with high infant mortality rates (Touitou et al. 2007). Increased risk of secondary amyloidosis has also been shown in other autoinflammatory disorders, i.e., MWS, NOMID, TRAPS, and even in HIDS and FCAS.

Differential Diagnosis

Exclusion of other possible diagnoses, such as infections, malignancies, and autoimmune disorders, is crucial (Kallinich et al. 2013). Narrowing the differential diagnosis of a patient with autoinflammatory disease is challenging, especially because the clinical features overlap extensively. A few distinctive clinical features, duration of attacks, asymptomatic periods and periodicity of attacks, ancestry, family history, and mode of inheritance may provide some help (Table 1), but it may not be possible to differentiate among these disorders based only on their clinical findings. Genetic diagnosis is also a challenge, and there are several cases with typical manifestations and no variations in the relevant autoinflammatory genes. Also, novel disorders with limited number of cases and newly identified genes continue to be added to the list of autoinflammatory diseases, such as NALP12-associated periodic syndrome (Jéru et al. 2008), and Nakajo-Nishimura syndrome (also known as chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature, CANDLE), associated with proteasome protein PSMB8 mutations.

Acquired or Complex Conditions with Autoinflammatory Features

Following the identification of mutations affecting the functions of the inflammasome complexes and other intracellular danger-sensing pathways as the underlying mechanism of hereditary autoinflammatory diseases, similar clinical and inflammatory features have been recognized in the pathogenesis of several acquired conditions. Multifactorial or complex diseases with autoinflammatory features include gout, pseudogout, asbestosis, silicosis, systemic onset juvenile idiopathic arthritis, Behçet's disease, PFAPA (periodic fever with aphthous stomatitis, pharyngitis, and cervical adenopathy) syndrome, Schnitzler syndrome, chronic recurrent multifocal osteomyelitis, SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome, type-2 diabetes mellitus, and atherosclerosis. Identification of the relevant inflammatory pathways will not only provide insight into their pathogenesis but may also elucidate new treatment targets (McGonagle et al. 2007; Kastner et al. 2010; Goldbach-Mansky 2012).

Pathogenic Mechanisms

Hereditary autoinflammatory diseases are usually associated with missense sequence variations in a limited number of genes involved in innate immune response. Most mutations are found in the genes encoding proteins involved in intracellular macromolecular complexes (inflammasomes). (An updated list of mutations can be found at the INFEVERS database, http://fmf.igh.cnrs.fr/ISSAID/infevers/). Inflammasomes are formed by NOD-like receptors (NLRs) and retinoic acid-inducible gene-I (RIG-I)-like helicases (RLHs), which function by scanning microbial insults or endogenous danger signals similarly to Toll-like receptors (TLRs). Activation of TLRs causes production of pro-IL-1β and pro-IL-18 through NF-κB activation. However, a second signal, inducing the assembly of cytosolic inflammasome platforms, is necessary for the autocatalytic regulation of inflammatory caspases, mainly caspase-1, and proteolytic activation of its main substrates, IL-1β, IL-18, and possibly IL-33 (Martinon et al. 2009; Hoffman and Brydges 2011; Lamkanfi and Dixit 2012; Strowig et al. 2012).

The recognition mechanisms of intracellular threats by inflammasome proteins, through conserved pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs), have not yet been clarified. A decrease in intracellular potassium levels, activation of purinoreceptor P2X7 by extracellular ATP, or pore-forming bacterial toxins have been shown to induce inflammasome assembly (Martinon et al. 2009; Lamkanfi and Dixit 2012; Strowig et al. 2012).

Mutations in the NLRP3 gene are associated with CAPS, and these dominantly inherited gain-of-function variations result in increased IL-1β production by mononuclear cells in response to microbial or environmental (such as cold temperature) triggers, even in the absence of a second

signal like extracellular ATP or potassium efflux. Constitutively hyperactive inflammasome and spontaneous IL-1β secretion have been involved in the pathogenesis of CAPS manifestations, and blocking of IL-1β activity has provided dramatic improvement.

Deregulated inflammasome activation has also been suggested in other hereditary autoinflammatory conditions, such as FMF, or acquired conditions like gout, pseudogout, or other crystal-induced diseases including silicosis and asbestosis. Pyrin has been considered a regulatory inflammasome protein, but it has not yet been clarified whether FMF-associated variations, mainly occurring in the C-terminal PRY-SPRY domain, are loss-of-function or gain-of-function mutations (Chae et al. 2011; Hesker et al. 2012). Pyrin interacts with ASC, an adaptor protein, and with caspase-1. Additionally, mutations in the PSTPIP1 gene, which encodes another pyrin-interacting protein, are associated with PAPA syndrome. PAPA-related mutations result in increased pyrin affinity, but how it affects inflammasome function is not yet known.

Different mechanisms have been proposed to explain the autoinflammatory features of TRAPS. Of note, TRAPS is associated with mutations of TNFRSF1A, a gene that does not produce an inflammasome-related protein. Dominant mutations in TNFRSF1A have been suggested to be associated with prolonged signaling due to abnormal type 1 TNF receptor trafficking and its intracellular retention rather than the original hypothesis of defective receptor shedding. Also, hyperresponsiveness to LPS stimulation of TRAPS patients has been shown to be associated with higher activation of mitogen-activated protein kinase (MAPK) due to mitochondria-derived reactive oxygen species (ROS). ROS may also play a critical role in NLRP3-associated disorders, as a final common pathway of different secondary signals (Simon et al 2010; Bulua et al. 2011).

The pathogenesis of HIDS, which is associated with mutations in the MVK gene, is even less clear. Recessively inherited MVK variations result in a defect in the metabolic mevalonate pathway, which leads to a deficiency of geranylgeranyl pyrophosphate and aberrant activation of Rac1. This GTPase defect has been suggested to cause inflammasome activation (van der Burgh et al. 2012).

In addition to the mechanisms associated with constitutive or induced hyperactivation of inflammasomes, other pathogenic mechanisms of autoinflammatory disease have been proposed. These include NF-κB activation (Crohn's disease), protein misfolding, activation of complement component H (atypical hemolytic-uremic syndrome, age-related macular degeneration), abnormal cytokine signaling (Cherubism), macrophage activation (familial hemophagocytic lymphohistiocytosis), and proteasome disability (Nakajo-Nishimura syndrome) (Masters et al. 2009; Kastner et al. 2010).

The revised definition of autoinflammatory diseases has fuelled studies on innate immune recognition and regulation of the inflammatory response. On the other hand, both innate and adaptive immune responses are involved at different degrees in the pathogenesis of many complex inflammatory diseases, suggesting a continuum between the autoinflammatory and the autoimmune disorders (McGonagle et al. 2007).

Treatment

The management of autoinflammatory disorders is directed both at controlling the acute attacks and preventing recurrences and complications. For acute attacks, treatment is usually symptomatic and may include antipyretics and nonsteroidal anti-inflammatory drugs. Attacks of TRAPS patients may respond to high-dose corticosteroids.

Colchicine has long been known as a potent anti-inflammatory drug, and it has been used as an effective and safe medication in FMF patients for the prevention of exacerbations and secondary amyloidosis. However, some FMF patients do not tolerate colchicine treatment or tolerated doses may be inadequate to control disease activity.

In CAPS patients, blockade of IL-1 activity by anakinra (recombinant IL-1 receptor antagonist), rilonacept (IL-1 receptor fusion protein), or anti-IL-1β monoclonal antibody canakinumab, has been shown to be an effective and safe treatment (Goldbach-Mansky 2012).

No treatment has been licensed for TRAPS and HIDS patients, but IL-1 blockade may be a helpful option. Efficacy of IL-1 blockade has also been shown in FMF patients with inadequate response to colchicine and in some complex autoinflammatory conditions, such as systemic juvenile idiopathic arthritis and gout (Goldbach-Mansky 2012).

Although TRAPS is associated with defective TNF receptor signaling, the role of anti-TNF drugs is controversial in its treatment. Some TRAPS patients may respond to etanercept, but worsening of symptoms was observed with infliximab.

Biologic agents that block IL-6 signaling may also be an option for the treatment of resistant patients with hereditary or acquired autoinflammatory diseases.

Conclusions

Hereditary autoinflammatory diseases have been characterized by recurrent, self-limited inflammatory episodes predominantly mediated by genetic variations affecting the innate immune system. However, similar inflammatory pathways are recognized to be associated with the pathogenesis of a growing number of complex disorders. Autoinflammatory diseases are usually linked to spontaneous or induced hyperactivity of cytosolic multiprotein inflammasome complexes, but other genetic variations affecting proteins that are involved in intracellular recognition and processing of danger signals may also play a role in the increased inflammatory response. Identification of IL-1 as the critical inflammatory mediator has led to the development of effective treatment options for several hereditary autoinflammatory disorders, and it also has provided new therapeutic opportunities for complex conditions with autoinflammatory features.

Definition

B cell central tolerance is defined as a process by which negative selection mechanisms operate during early stages of B cell development in the bone marrow (BM) to diminish the incidence of autoimmunity by preventing self-reactive immature B cells to become mature effector B cells.

Introduction

The ability of B cells to produce antibodies against almost any foreign antigen is the outcome of random assembly of immunoglobulin (Ig) genes. The resultant huge diversity of the B cell repertoire enables our body to thwart pathogens. However, the randomness of Ig gene rearrangement process leads in high frequency to the generation of self-reactive B cells that might mature and enter the secondary lymphoid organs and tissues outside the BM. Without efficient selection processes to impose tolerance of the immune system to self-antigens, this could result in an autoimmune response and production of autoantibodies, some of which may be pathogenic. Thus, autoimmunity, defined as various physiological disorders characterized in unwanted response against self-tissues, reflects a breakdown in self-tolerance.

Self-Reactive B Cells and Autoimmunity

B lymphocytes are important mediators of autoimmunity as autoantibodies are primary cause of many systemic (such as systemic lupus erythematosus – SLE and rheumatoid arthritis – RA) and organ-specific (such as Graves' disease) diseases (Azulay-Debby and Melamed 2007). B cells may also promote autoimmunity as they function to regulate differentiation of effector T cells (Mauri and Bosma 2012; Mizoguchi and Bhan 2006), secrete cytokines which affect innate and adaptive immune cells (Kwan-Morley and Albert 2007; Lipsky 2001; Lund and Randall 2010), and present antigens (Chan et al. 1999; Salinas et al. 2013). Autoreactive

B cell clones are parts of the normal peripheral repertoire (Koenig-Marrony et al. 2001; Rice et al. 2005), but they are kept in low frequency and mostly in an unresponsive state due to central and peripheral mechanisms of self-tolerance (Edry and Melamed 2004; Klinman 1996; Nossal 1994; Rajewsky 1996; Shlomchik et al. 2001). The exact cause for breakdown of these tolerance mechanisms is not fully understood. Nevertheless, antigenic mimicry and bystander activation of autoreactive clones have been proposed (Christen and von Herrath 2004; Marrack et al. 2001; Shlomchik et al. 2001). Prolongation of immature B cell short half-life also favors B cell–driven autoimmunity (von Boehmer and Melchers 2010). Immune dysregulation, leading to tolerance breakdown, is a precondition; yet, genetic predisposition and environmental factors are also major contributors to the development of autoimmune disorders (Ermann and Fathman 2001).

B Cell Development

B lymphocytes are blood cells that develop in the BM (a central lymphoid organ) and migrate to the spleen (periphery) to complete their maturation (Osmond 1991; Rajewsky 1996). Each B cell expresses a unique surface receptor for antigen (B cell receptor; BCR). During development in the BM, B cells proliferate and progress through a highly regulated process that is guided by successive attempts to assemble and express immunoglobulin heavy (IgH) and light (IgL) chain genes to form the BCR. Several selection checkpoints have been discovered, which allow (positive selection) or prevent (negative selection) this developmental progression (Hartley et al. 1993; Rolink et al. 2001). Upon completion of BCR gene rearrangement and expression at the progenitor (pro) and precursor (pre) stages, B cells differentiate into the immature stage where the newly generated BCR is expressed as surface IgM (sIgM) (Martin and Kearney 2000). The BCR of immature B cells is critical not only for negative selection but also for generation of appropriate tonic signals to promote B cell maturation and migration from the BM to the spleen, a process referred as positive selection (Bannish et al. 2001; Keren et al. 2004; Kraus et al. 2001; Levine et al. 2000). Immature B cells that emigrate from the BM to the periphery are called transitional B cells, and are subjected to further selection steps (Meffre et al. 2000). Only 3 % of the immature B cells generated in the BM become mature B cells (Osmond 1991; Rajewsky 1996). This stringent selection is attributed in part to the fact that the majority (55–75 %) of the BCRs, randomly assembled in the BM, are self-reactive (Nemazee 1996; Wardemann et al. 2003). Most of this self-reactivity is extinguished by central tolerance mechanisms (Azulay-Debby and Melamed 2007).

Central Tolerance Mechanisms

The expression of sIgM by immature B cells is a critical selection check-point in B cell developmental progression. If the strength of BCR cross-linking and intracellular signaling exceeds a certain threshold by binding to a self-antigen, the immature B cell rapidly internalizes the aberrant BCR and temporarily aborts its maturation program (Goodnow et al. 2005). This B cell autoreactivity is extinguished in the BM mainly by three cellular mechanisms.

First, cells displaying self-reactive receptors can be triggered to die, as originally envisaged in Burnet's concept of *clonal deletion* (Goodnow et al. 2005), in a process called activation-induced cell death (AICD) (Donjerkovic and Scott 2000). It has been shown that clonal deletion is a major mechanism for membrane-immobilized autoantigens (Klinman 1996; Nemazee and Burki 1989; Norvell et al. 1995).

Second, autoreactive B cells can escape clonal deletion by revising their antigen receptors through a process of secondary Ig gene rearrangements at the IgL locus, a mechanism known as *receptor editing* (Nemazee 2000; Nemazee and Weigert 2000).

Third, intrinsic biochemical and gene-expression changes can reduce the ability of the cells to be triggered by self-reactive receptors. This mechanism is termed *clonal anergy*

(Goodnow et al. 2005), and is generally imposed by soluble low-avidity self-antigens (Goodnow et al. 1988; Nossal 1996).

Clonal Deletion

Immature B cells mount heighten sensitivity to AICD imposed by BCR signaling relative to mature B cells (Meffre et al. 2000). This has been demonstrated following addition of anti-BCR antibodies to BM cultures containing both immature and mature recirculating B cells. In these experiments, a high rate of immature B cell apoptosis was observed whereas mature B cells were spared (King and Monroe 2000). In vivo experiments revealed that elimination of immature B cells occurs within 1–2 days, either in the BM or shortly after arriving in the spleen (Hartley et al. 1993; Niiro and Clark 2002). A major cause for the heighten sensitivity to AICD is the increased expression of *Pten* in immature B cells relative to the levels found in mature B cells (Cheng et al. 2009). *Pten* encodes for a lipid phosphatase that directly antagonizes the activity of pro-survival phosphoinositide 3-kinase (PI3K) by dephosphorylating PIP_3 into PIP_2 (Suzuki et al. 2003). The pro-apoptotic Fas/FasL pathway does not appear to play a role in the BCR-induced death of immature B cells (King and Monroe 2000). However, clonal deletion by AICD involves an increased expression of the pro-apoptotic protein BIM (BCL-2- interacting mediator of cell death) (Strasser and Bouillet 2003) as well as mitochondria dysfunction, which facilitates release of cytochrome *c* and activation of caspases (Niiro and Clark 2002). In addition, autoreactive immature B cells maintain low levels of receptors for B cell activating factor (BAFF), a circulating cytokine required for survival of peripheral B cells (Mackay et al. 2003).

Receptor Editing

B cells expressing defective and/or self-reactive receptors may undergo secondary Ig gene rearrangement at the IgL locus to alter the specificity of their receptor, rather than undergoing a default apoptosis (Azulay-Debby and Melamed 2007; Edry and Melamed 2004). This salvage mechanism was first characterized in central tolerance of immature B cells undergoing negative selection, and termed receptor editing (Gay et al. 1993; Tiegs et al. 1993). Receptor editing is facilitated by replacing the entire preexisting VκJκ through secondary recombination of an upstream Vκ to a downstream Jκ (Nemazee 2000). Alternatively, recombination of the conserved element known as recombining sequence (RS) into the Cκ inactivates the locus and allows IgL rearrangement and expression from the other kappa allele or from the lambda locus from either allele (Retter and Nemazee 1998). Receptor editing has been demonstrated by re-induction or continuous expression of RAG-1 and RAG-2, (recombination-activating gene 1 and 2, which encode the core enzymes for V(D)J recombination), resulting in alteration in Jκ gene usage and increased λ -expressing cells in normal and transgenic (Tg) immature B cells undergoing negative selection (Melamed and Nemazee 1997; Radic et al. 1993). Central tolerance mouse models indicate that autoreactive B cells are very efficiently rescued by receptor editing at the IgL locus, although multiple rearrangements are often required until the appropriate Vκ is selected (Li et al. 2001). Studies have shown that receptor editing is regulated developmentally as immature B cells advancing in their development lose the ability to undergo receptor editing and concomitantly acquire sensitivity to antigen-mediated apoptosis (Melamed et al. 1998). Thus, negative selection of immature B cells in the BM is mainly facilitated by receptor editing whereas that of transitional B cells in the spleen is facilitated by AICD (Sandel and Monroe 1999). Recently, it has been demonstrated that receptor editing appears to have an important contribution to positive selection of B cells as well, since BCR that fails to gain appropriate tonic signals undergoes extensive receptor editing in the BM (Diamant et al. 2005; Shivtiel et al. 2002; Tze et al. 2005).

Secondary rearrangements have also been shown to occur in high frequency at the IgH locus. These rearrangements utilize a conserved heptameric sequence that is embedded in the VH to allow a recombination of an upstream VH gene into the existing VDJ (Nemazee 2000). It is

thought that receptor editing at the IgH locus is activated in pro-B cells where it remediates impaired assembly and/or signaling of the pre-BCR for positive selection, rather than it avoids negative selection induced by autoreactivity (Azulay-Debby and Melamed 2007).

Clonal Anergy

Self-reactive B cells that fail to edit their receptors are deleted or anergized. Anergy was originally observed in cultures of developing B cells exposed to intermediate concentrations of anti-IgM antibodies. This allowed B cell development but abrogated normal B cell function, as determined by decreased proliferation and antibody production upon mitogen exposure (Meffre et al. 2000). Using Ig transgenic mouse models, it has been demonstrated that chronic exposure of immature B cells to low affinity antigens in the BM can lead to clonal anergy characterized by 20–50-fold reduction in membrane IgM expression levels, and by incompetent signaling through the BCR (Fulcher and Basten 1994). Loss-of-function mutations in a series of molecules in the BCR signaling pathway have also indicated that BCR signaling is downregulated in anergic B cells. The resultant "paralyzed" anergic B cells are short-lived, and fail to develop from the immature to the long-lived B cell compartment in the spleen (Meffre et al. 2000). Activation of anergic B cells through their BCR stimulates AICD rather than proliferation (Goodnow 1996). The intrinsic biochemical changes that govern cellular mechanisms of anergy in the cells displaying self-reactive receptors are reversible if the BCR stops binding to the self-antigen, as would occur if the BCR is edited to lose self-reactivity through somatic hypermutation in germinal centers (Goodnow et al. 2005).

Summary

Self-tolerance in the B lineage is regulated during the development in the BM and the spleen in order to prevent autoimmunity and to maintain the integrity of the organism (Diamant and Melamed 2004). Clonal deletion, receptor editing, and clonal anergy are the main mechanisms known to impose B cell central tolerance in the BM. Yet, these mechanisms are incomplete, and probably affect only the highest affinity self-reactive lymphocytes (Shlomchik et al. 2001). Likewise, a certain proportion of autoreactive B cells may bind self-antigen with too low affinity to trigger an autoimmune response, but may bind strongly enough to invading pathogens to exert a protective host-defense effect (von Boehmer and Melchers 2010). Experimental and human data clearly indicate that leaky central tolerance increases the risk for subsequent development of autoimmune disease but that a number of additional factors control this progression (Salinas et al. 2013). Autoreactive B cells that escape central tolerance mechanisms are actively regulated and prevented from effector functions in the periphery (Shlomchik et al. 2001), and failure to maintain this regulation may progress into autoimmunity.

B Cell Tolerance

Shiv Pillai
Medicine and Health Sciences and Technology, Massachusetts General Hospital Cancer Center, Harvard Medical School, Boston, MA, USA

Synonyms

B cell clonal deletion; B cell peripheral tolerance; Receptor editing

Definition

B cell tolerance refers to mechanism by which B cells are prevented from inducing immune responses to self-antigens.

Introduction

Tolerance at the B cell level is at least as important as T cell tolerance for a number of reasons. At least 75 % of the starting human B cell repertoire in the bone marrow is self-reactive (Wardemann et al. 2003). Multivalent membrane-bound antigens can activate self-reactive B cells in a T-independent manner, and therefore, B cells that recognize such antigens need to be tolerized independently of T cell tolerance mechanisms (see entries ▶ B Cell Central Tolerance: Controlling Self-reactive B Cells in the Bone Marrow and ▶ B Cell Tolerance). Even weakly self-reactive B cells can be induced to undergo somatic hypermutation if they receive T cell help so such B cells must be tolerized. Helper T cells that are specific for foreign antigens can be easily subverted to help B cells that recognize self-antigens, if a foreign antigen forms a complex with a self-antigen. Under these circumstances, a self-reactive B cell may internalize the self-antigen complexed to a foreign protein and present foreign peptides to a T cell

clone and thus be driven into a T-dependent response that can drive autoimmunity (see entry ▶ Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis).

Tolerance mechanisms in the B lineage can be divided into central and peripheral categories. Central B cell tolerance refers to tolerance that occurs in developing or immature B lymphocytes in central or generative organs – primarily the bone marrow. Peripheral tolerance occurs in mature B lymphocytes in peripheral lymphoid organs.

Central B Cell Tolerance

The major mechanism of central B cell tolerance is receptor editing (Tiegs et al. 1993; Gay et al. 1993; Pelanda et al. 1997; Hippen et al. 2005). Other mechanisms include clonal deletion (Nemazee and Burki 1989; Hartley et al. 1991) and anergy (Goodnow et al. 1988). (See entry ▶ B Cell Central Tolerance: Controlling Self-reactive B Cells in the Bone Marrow.)

Receptor Editing

Strongly autoreactive immature B cells that encounter self-antigen in the bone marrow can be induced to revert to the small pre-B stage of development wherein Rag-1 and Rag-2 (recombinase-activating genes 1 and 2) are reexpressed and initially the Igκ light chain locus is made accessible for recombination. The re-induction of V(D) J recombination results in additional rearrangements at the κ locus that result in the deletion of the original self-reactive κ light chain. The number of "chances" for a productive V-J recombination event to occur at the κ light chain locus varies depending on which Jκ gene is initially involved in the rearrangement process and whether a nonproductive rearrangement already exists on one of the two chromosomes. If the self-reactive B cell fails to make a new productive κ light chain rearrangement, signals from the BCR induce nuclear proteins to delete the entire κ light chain locus on both chromosomes, resulting in rearrangements being attempted at the λ light chain locus. This process of deleting a self-reactive rearranged κ light chain gene and inducing a new productive κ or λ light chain rearrangement is known as receptor editing.

Clonal Deletion

Autoreactive B cells can be clonally deleted by apoptosis. This typically occurs at the transitional B cells stage in the spleen just before immature B cells mature into follicular or marginal zone B cells. Evidence from B cell receptor transgenic animals suggests that clonal deletion is a back-up mechanism that facilitates the induction of central tolerance whenever receptor editing proves insufficient.

Clonal Anergy

Clonal anergy in B cells refers to a state of unresponsiveness generally induced by the chronic exposure of immature and mature B cells to an antigen, usually a soluble protein antigen. Repeated B cell receptor triggering leads to a state of enhanced dependency on BAFF/Blys for survival. Anergic B cells do not compete as well as naive B cells for BAF in follicles and therefore have shortened life spans.

Peripheral B Cell Tolerance

Peripheral B cell tolerance is mediated by a number of mechanisms. These include clonal deletion and anergy as discussed above in the context of central tolerance but also include the phenomenon of clonal ignorance and potentially tolerance mediated by regulatory T cells (Tregs).

Clonal Ignorance Mediated by Siglecs

One of the pathways of peripheral tolerance is mediated by inhibitory receptors of the Siglec family (Cornall et al. 1998; Pao et al. 2007; O'Keefe et al. 1999; Pillai et al. 2009). Siglecs are sialic acid binding lectins that contain Ig domains. The best studied Siglec in the

B lineage is CD22. CD22 contains extracellular Ig domains, the two outermost of which bind to α2-6-linked sialic acid on *N*-glycans. This Siglec contains cytosolic ITIMs (immunoreceptor tyrosine-based inhibitory motifs) that are exposed upon ligation and phosphorylated by Lyn. The phosphorylated ITIM tyrosines recruit the SH2 (Src homology 2) domain-containing tyrosine phosphatase SHP-1 (SH2 domain-containing phosphatase-1) which dampens B cell receptor signaling. An autoimmune phenotype is observed in mice harboring mutations in Lyn. A similar phenotype is observed when SHP-1 is conditionally mutated in the B lineage. This pathway mediates B cell tolerance in the periphery.

Tolerance in Germinal Centers

In patients with the autoimmune lymphoproliferative syndrome, mutations in Fas lead to a break in B cell tolerance. Germinal center B cells express high levels of Fas. It is presumed that B cells that are of lower affinity against foreign antigens as well as some self-reactive B cells are eliminated in germinal centers in a Fas-dependent manner. It is unclear if T follicular helper cells express sufficient levels of Fas ligand to mediate this elimination event.

Other Mechanism of Peripheral B Cell Tolerance

There is some evidence supporting peripheral B cell deletion by self-antigens, as well as evidence for anergy (discussed above). Regulatory T cells may also exert peripheral B cell tolerance in a poorly understood way.

B Cell Trafficking

John D. Mountz and Hui-Chen Hsu
Department of Medicine, Division of Clinical Immunology and Rheumatology, University of Alabama at Birmingham, School of Medicine, Birmingham, AL, USA

Synonyms

B cell homing; B cell migration; B cell retention; B cell trafficking

Definition

B cell trafficking involves network interactions of well-controlled events among chemokines/chemokine receptors, their downstream G protein signals, and site-specific adhesion molecules. This enables migration of different stages of B cells from one compartment to another, followed by their retention in a specific niche to facilitate their development, maintenance, and execution of functions.

Overview

B cell trafficking plays a central role not only in B cell physiologic and pathologic effector functions, but it also orchestrates B cell development. B cell development occurs after precursors move from one specific niche and location to another. These niches and locations result in B cell development into well-defined stages with specific functional properties. For example, B cell maturation initially occurs in the bone marrow, which exports B cells to the secondary lymphoid organs (lymph nodes (LN), spleen, and other immune sites). There, through migration, retention, and thus interactions with other immune cells, including macrophages and T cells, B cells develop through well-defined stages in specific immune compartments. After development in secondary lymphoid organs, B cells undergo controlled release or egress. In the case of long-lived plasma cells, B cells migrate back to special niches in the bone marrow where they produce antibodies including autoantibodies in the case of autoimmunity. B cells can also develop into memory B cells which egress from secondary lymphoid organs and home to sites of autoimmune inflammatory sites such as the synovium (rheumatoid arthritis), skin (psoriasis), thyroid gland (thyroiditis), salivary gland (Sjögren's syndrome), pancreas (diabetes), granulomatous tissue ($ANCA^+$ vasculitis), and brain (multiple sclerosis) (Coca and Sanz 2012). For each stage of development, specific chemokines or adhesion molecules are produced to either attract or retain the B cells at these sites or, once development has occurred, are downregulated to enable migration of the B cells to a subsequent stage of development. This entry emphasizes mechanisms of B cell migration and chemokine receptor desensitization that results in development of spontaneous germinal centers (GCs) in the spleen during autoimmune diseases. Although autoantibody production in the spleen is most relevant to development of autoimmune disease, this entry includes insights from studies of GC development in both spleen and LN, which has many similarities. Furthermore, studies of B cell migration in LN are important to consider since, due to their ectopic location, direct visualization of B cell migration has been achieved and has provided important insights into GC development. A key difference is that the LN lacks marginal zone and marginal zone B cells, which play an important role in trapping apoptotic cells and transport of autoantigens to the GC in the spleen (Li et al. 2013). Current technology does not enable comprehensive studies of B cell migration in humans. Therefore, this review summarizes B cell migration derived primarily from mouse models, including autoimmune models. Although human marginal zone B cells can recirculate whereas rodent marginal zone B cells are sessile, studies have shown that the

cellular and molecular mechanisms of human B cell migration largely parallel what has been found in the mouse. This entry describes three key sites of B cell localization, the bone marrow, spleen, and peripheral tissues as well as the adhesion molecules and chemokines that enable the localization and development of B cells at these specific locations.

Bone Marrow

The bone marrow is the major organ for development and early maturation of B cells. B cells are generated from common lymphoid precursors (CLP) in the bone marrow before they egress into peripheral blood to reach secondary lymphoid organs. Specific stromal cells niches promote B cell development by signaling through cKit (CD117) and IL-7R (CD127). CXC-chemokine ligand 12 (CXCL12), also known as stromal cell-derived factor 1 (SDF-1), plays a role in pre-pro-B cells and less in pro-B cells B cell development (Hardy et al. 2007). The importance of the CXCR4/CXCL12 in B cell development became apparent in 1996 with the discovery that CXCL12 can attract early-stage B cell precursors via the chemokine receptor CXCR4 and have a key role of B cell lymphopoiesis. Regulation of CXCR4/CXCL12 has also been extensively analyzed due to its central role in regulation of cancer metastasis. The bone marrow is also the site to which terminally differentiated antibody-producing plasma cells home to and are maintained through the CXCR4/CXCL12.

An important goal for treatment of autoimmune disease is to deplete or limit the production of autoantibody-producing plasma cells. Bone marrow plasma cells do not express markers such as CD20 and, therefore, cannot be depleted by anti-CD20 therapies (Rituximab, Rituxan) (Coca and Sanz 2012). Other therapies including anti-CD22 (Epratuzumab) targets B cells and results in modulation of B cell function and migration, as CD22 regulates adhesion and inhibits B cell receptor (BCR) signaling. However, CD22 is not expressed by plasma cells or memory B cells (Ding et al. 2008). Depletion of plasma cells can be potentially achieved via blocking the homing and interactions of these cells with the supporting stromal cells. The persistence of plasma cells in the bone marrow is supported by soluble factors in cell-cell contact in the bone marrow microenvironment. Stromal cells provide growth factors such as IL-6 and cell contact-dependent signals, including very late antigen 4 (VLA4 or CD49d). Plasma cells also express other surface markers related to cell adhesion, rolling, tethering, and migration including integrin lymphocyte function-associated antigen 1 (LFA-1: also known as αLβ2 integrin or CD11a) and CD44 (Underhill et al. 2002). Co-blockade of LFA-1 and VLA-4 adhesion molecules has been shown to temporarily deplete long-lived plasma cells from the bone marrow. In addition, IgG plasma cells exhibit a unique property to interact specifically with E-selectin but not P-selectin despite the expression of P-selectin glycoprotein ligand 1 (PSGL-1). Such specificity has been found to be associated with the expression of alpha1,3-fucosyltransferase-VII (*Fut7*), but the selective downregulation of core 2 beta1-6-*N*-glucosaminyltransferase (Underhill et al. 2002).

Entry of B Cells to Secondary Lymphoid Organs Through High Endothelial Venules (HEV)

The interaction of lymphocytes with high endothelial venules (HEV) has been extensively studied in LN (Girard et al. 2012). B cell entry in LN is initiated by the lymphocyte homing receptor L-selectin (also known as CD62L), which mediates tethering and rolling of lymphocytes along HEV walls (Butcher and Picker 1996). The L-selectin recognizes a family of mucin glycoproteins, which are heavily sulfated fucosylated, expressed by HEV endothelial cells of peripheral lymph nodes, such as CD34 and the Lewis x antigen. HEV-mediated entry of naïve B cells into LN occurs through a multi-step adhesion and migration cascade. The lymphocyte rolling on the HEV cell walls first undergoes chemokine-induced activation of the integrin

LFA-1, which mediates lymphocyte arrest (sticking) on the HEV endothelium. LFA-1, which binds intercellular adhesion molecule 1 (ICAM-1 and ICAM-2) on endothelial cells, is a major integrin for B cell arrest in HEVs of peripheral lymph nodes. After crossing the HEVs, T and B cells migration follows different signals. T cells migrate along CCL19/21 chemokine-expressing fibroreticular cells (FRCs) using their prominently expressed CCR7 chemokine receptor to access the LN deep cortex, whereas B cells rely on their prominent CXCR5 expression to access the LN follicle (Reif et al. 2002). Newly resident B cells migrate toward the follicle centers, sites of high CXCL13 (the CXCR5 ligand) expression, whereas long-term LN follicle residents move toward the edges closer to egress sites.

Positioning within the Spleen or Lymph Node, Central Role of Desensitization of Chemokine Signaling

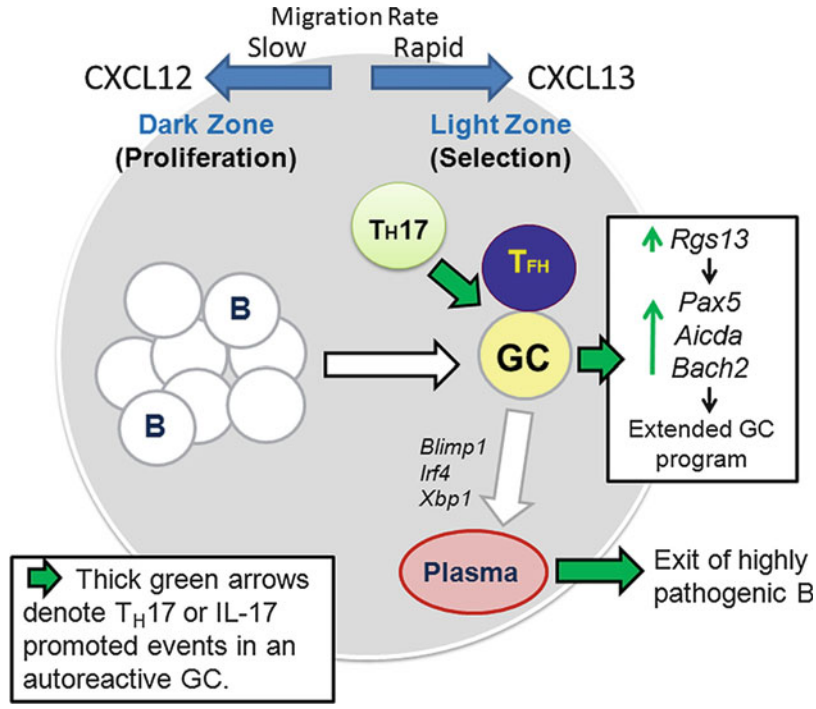
In the spleen, afferent lymphatics enter the marginal sinus as a source of antigen that interacts with B cells, especially marginal zone B cells, but newly formed transitional T1 B cells mostly enter through the central artery of the spleen through initial adhesion molecule interactions followed by chemokine gradients. During follicle development, B cells crawl on a fibroblastic reticular cell (FRC) network to reach B cell follicles, using CXCL13 and CXCR5 signaling (Pillai and Cariappa 2009). During the migration in the spleen, B cells upregulate the expression of a receptor for Sphingosine-1-phosphate (S1P), and after some time, they desensitize their chemokine receptors CXCR5 to sense the S1P-mediated egress signal at the edge of the follicles (Cinamon et al. 2004). Full development of marginal zone B cell precursors into marginal zone (MZ) B cells in the spleen does not occur until B cells reach the marginal zone (Pillai and Cariappa 2009). It is known that follicular (FO) B cell recirculate, whereas MZ B cells are sessile in that they are strategically positioned at the interface of the white pulp lymphoid follicles and red pulp cords in mouse spleen. Thus, once B cells enter the spleen marginal zone, expression of LFA-1 and $\alpha 4\beta 1$ by MZ B cells enables capture of MZ B cells by ICAM-1 and VCAM-1 expressed by resident stromal cells (Lu and Cyster 2002), leading to stabilization and maintenance of MZ B cells. Interestingly, MZ B cells produce lymphotoxin, which is a critical cytokine to induce the expression of ICAM-1 and VCAM-1 (Lu and Cyster 2002). Thus, MZ B cells also exhibit a unique property to maintain the integrity of MZ barrier in the spleen.

Role of Type I Interferons

Type I interferons (IFNs) are is primarily produced by plasmacytoid dendritic cells and they exhibit a unique mechanism to desensitize MZ B cells to S1P. High levels of Type I IFNs have been associated with autoimmunity, including systemic lupus erythematosus. Although Type I IFNs are frequently associated with B cell activation and maturation, they can also act on B cells in the marginal zone and possibly on the T2 to T3 transition B cells to induce their migration away from the marginal zone and into the spleen follicles. Type I IFNs can upregulate CD69, which leads to the downregulation of S1PR1 signaling, resulting in lack of localization of MZ B cells in the marginal zone. In addition, this can result in B cell capture of antigen in the marginal zone of the spleen and translocation of B cell carrying antigen into the follicle. In autoimmunity, such antigen-transporting B cells have been characterized as marginal zone precursor B cells, which also express high levels of Class II MHC, CD80, and CD86 and are therefore potent antigen-presenting cells (Wang et al. 2010).

Regulation of Migration within the Germinal Center

The cardinal feature of autoimmunity is the development of pathogenic autoantibodies, which occurs through tolerance loss in a germinal center reaction. Uncleared apoptotic cells coming into the spleen marginal zone can be transported into the spleen follicles by shuttling B cells to the GC light zone follicular dendritic cell (FDC) network region in autoimmune mice (Li et al. 2013). These B cells bearing



B Cell Trafficking, Fig. 1 IL-17-promoted GC production of pathogenic autoantibodies (Figure provided by John D. Mountz and Hui-Chen Hsu)

apoptotic cell antigens also exhibit the property to stimulate $CD4^+$ T cells (Li et al. 2013). Deposits of antigens or immune complexes in the FDC network and activation of $CD4^+$ T cells are important for the initiation of a GC response. Interestingly, the structure of spontaneous GC developed by autoimmune mice is very similar to that of GC developed after immunization, in that they are polarized into a FDC-enriched light zone and a B cell densely packed dark zone. In immunized GCs, intravital two-photon imaging revealed that B cells undergo interzonal migration between the light zone and the dark zone (Fig. 1). CXCL13-producing FDCs attract CXCR5-expressing follicular helper T (T_{FH}) cells as well as CXCR5-expressing B cells into what is known as the light zone of the GC for selection and affinity maturation, whereas CXCL12-producing stromal cells attract $CXCR4^+$ B cells to migrate to the GC dark zone for proliferation. It is further observed that, within the GC, B cell migration from dark zone to the light zone is much faster as compared to migration from the light zone to the dark zone (Victora et al. 2010). Such observation is consistent with the importance of B cell selection that takes place in the light zone where GC B cells must compete for antigen provided by immune complex deposits on FDCS as well as cytokines and stimulatory signals provided by T_{FH} cells to ensure their selection and survival. This suggests an important concept that within the GC light zone and dark zone compartments, there are additional signaling events that can regulate the arrest and thus the tempo of GC B cell migration.

Chemokine receptors are G protein-coupled receptors. One critical mechanism for desensitization of GC B cell migration response has been identified to be a class of GTPase-accelerating proteins called "regulator of G protein signaling (RGS)" (Druey 2009). RGS proteins can rapidly switch off G protein-coupled receptor signaling pathway by promoting GTP hydrolysis by the alpha subunit of heterotrimeric G proteins. In the GCs, RGS1, RGS13, and RGS16 are the critical RGS proteins that can switch off lymphocyte migration responses to CXCL12 and

CXCL13 (Mountz et al. 2011). Thus, exogenous factors that can upregulate the upregulation of RGS proteins can be critical to regulate GC B cell somatic hypermutation, class-switch recombination, affinity maturation, and selection process.

In a spontaneous autoimmune GC, IL-17-producing $CD4^+$ T cells (T_H17) upregulate RGS13 and RGS16 in B cells through the classical NF-κB pathway. This results in the dephosphorylation or inactivation of the G protein signaling pathway, thus making the B cell less responsive to CXCL12 and CXCL13 (Hsu et al. 2008; Xie et al. 2010). This migration arrest of GC B cells plays a role to enhance GC B cell maturation via extended interactions between GC B cells and $CD4^+$ T cells. In addition, this process sequesters B cells in GCs for a prolonged period of time through a process known as "delayed driven diversity," which enables upregulation of the GC-specific genes including *Aicda*, *Bach2*, and *Pax5* and downregulation of the plasma cell differentiation genes including *Blimp1*, *Irf4*, and *Xbp1* (Wang et al. 2013) (Fig. 1). Within the spontaneous autoimmune GCs, T_H17 cells have been found to be present mostly in the light zone, thereby promoting the necessary close contact between GC B cells and $CXCR5^+$ T_{FH} cells (Ding et al. 2013).

Control of Lymphocyte Egress from the Secondary Lymphoid Organs

S1P and its G protein-coupled receptor have been shown to be required for egress of both B and T cells from the spleen and LN. S1P was first implicated in the exit of lymphocytes from LN during homeostasis, when it was discovered that the immunosuppressive drug FTY720 (also known as Fingolimod), a potent inhibitory agonist of S1P receptors including S1P1 and S1P3, induced the sequestration of lymphocytes in the LN by inhibiting their egress into the lymph. Further analysis revealed that FTY720 acts by downregulating S1P1 signaling to prevent lymphocyte egress from the secondary lymphoid organs. S1P is generated in vivo by sphingosine kinases, particularly on red blood cells. S1P1 signaling appears to act principally by overcoming retention mediated by the Gαi-coupled receptors (CXCR5 and CCR7). FTY720 (Fingolimod, Gilenya) has been studied for applications to several autoimmune diseases including lupus and has become especially important as the first oral drug found to be highly efficacious in treatment of multiple sclerosis.

B Cell Migration to Peripheral Organs to Promote Autoimmunity as an Antigen-Presenting Cells

The above B cell migration focuses primarily on B cell development as antibody-producing cells and their homing back to the bone marrow to produce autoantibodies in autoimmunity. The role of B cells in inflammation was most dramatically demonstrated by the highly efficacious action of anti-CD20 that greatly ameliorate autoimmunity (lupus, RA) but do not greatly diminish autoantibodies production by plasma cells, which do not express CD20 (Coca and Sanz 2012). B cells are potent modulators of T cell responses by presenting antigen, providing co-stimulation, and secreting cytokines. B cell production of cytokines, including IFNγ, IL-6, and IL-4, can act as antigen-presenting cells as they express class II MHC, and express co-stimulatory molecules including CD80/86 and ICOS-L, and have been proposed to play a critical role in peripheral tissue inflammation. Furthermore, it is becoming clear that the different effector functions of B cells are tightly controlled and that these tasks are carried out by functionally and phenotypically distinct effector and regulatory B cell subsets. Regulatory B cells that produce IL-10 have been proposed to downregulate tissue inflammation. B cell migration to inflamed tissue is primarily mediated by similar mechanisms as found for their migration to peripheral lymphoid organs. A combination of adhesion molecules primarily selectins; integrins, including VCAM, ICAM/LFA-1; and chemokines, including CXCR4/CXCL12 and CXCR5/CXCL13, is thought to regulate migration of effector B cells to sites of inflammation (Stein and Nombela-Arrieta 2005).

Conclusion

Altered B cell migration can promote the development of autoimmunity and enhance T cell responses. Increased signaling and sensitivity of B cells within LN or spleen, as well as increased retention in the light zone with high activation-induced cytidine deaminase, result in autoantibody production and increased survival of autoantibody-producing B cells as plasma cells in bone marrow niches. Targeting of lymphocyte migration, including B cells, has been successful in treating autoimmune diseases, with anti-CD22 (Epratuzumab), which targets B cells and results in modulation of B cell function and migration and with the S1P inhibitor FTY720 (Fingolimod, Gilenya), which prevents egress of lymphocytes from lymphoid organs. Future therapies will include kinase inhibitors, which inhibit chemotaxis and migration primarily by inhibiting B cell activation, and specific chemokine or chemokine receptor blockade. Also, a key role for interferon in promoting B cell-driven germinal center responses by enabling translocation of antigen delivery B cells may be targeted through anti-interferon therapy.

Definition

B1 cells constitute a small innate-like subpopulation of normal B lymphocytes whose most important role is constitutive secretion of protective (so-called natural) antibody.

Introduction

B cells are the terminal effectors of serological immunity and are responsible for the generation of life-preserving antibody in reaction to invasion by pathogenic microorganisms. This adaptive response develops over a period of days, and thus is not available at the time of initial infection; in fact, the delay in generation of adaptive immunity is the reason why immunizations to raise specific antibodies must occur well in advance of need. Beyond prior infection and immunization, however, the immune system is not devoid of early antibody protection. Preexisting, or "natural" antibody is provided by B1 cells. B1 cells secrete antibody constitutively and spontaneously, in the absence of exogenous stimulation, that recognizes many microbial determinants. In this way, B1 cells establish and maintain an initial antibody shield that defends against subsequent incipient infection. In recent years, additional functions have been ascribed to B1 cells that include housekeeping removal of cellular debris, as well as stimulation, polarization, and suppression of T cells.

History

Identification of B1 cells emerged from the initial finding over 30 years ago that malignant cells of mouse and human B cell leukemias and lymphomas express CD5. CD5 (formerly Ly-1 or Lyt-1 in the mouse system and Leu-1 or T1 in the human system) is a T cell surface antigen that would not be expected to be present on malignant cells of B cell origin. Further work revealed that CD5 expression is characteristic of a small subpopulation of normal B cells, as well as malignant B cells. Notably, CD5 expression in this subpopulation is low and B1 cell CD5 stains much less brightly with fluorochrome-conjugated anti-CD5 antibodies than CD5 on T cells, for which reason the recognition of $CD5^+$ B cells depends on flow cytometry with its use of photomultiplier detectors, rather than fluorescence microscopy. In mice, CD5 expression marks B cells that are phenotypically distinct from conventional (adaptive) B cells in expressing $IgM^{hi}IgD^{lo}CD45^{lo}CD23^{lo/-}CD43^+$ (plus $CD9^+$ shared with splenic marginal zone B cells and $CD11b^+$ for those $CD5^+$ B cells located in the peritoneal cavity). This subpopulation of B cells is now termed "B1" whereas the predominant population of conventional B cells is termed "B2." In mice, the B1 population is divided between B1a cells with the surface marker phenotype noted above, and B1b cells that share the same phenotypic markers ($IgM^{hi}IgD^{lo}CD45^{lo}CD23^{lo/-}CD43^+$) except that they are CD5 negative. B1a and B1b cells are regulated separately and behave somewhat differently, the latter sharing with B2 cells the capacity to respond to antigen stimulation in the form of vaccination or infection.

CD5 has been used in the past to define human B1 cells, and numerous early studies reported on the nature of human B1 cell antibodies and the activity of human B1 cells in various disease

states (Casali and Notkins 1989). However, in contrast to the situation in mice, CD5 is not a reliable marker for human B1 cells because it is promiscuously expressed by several different human B cell populations (including pre-naïve, transitional and activated B cells). Recent work indicates that the surface marker phenotype of human B1 cells is $CD20^+CD27^+CD43^+CD70^-$ (Griffin et al. 2011). Most of these human B1 cells express CD5, but the majority of $CD5^+$ human B cells do not express $CD20^+CD27^+CD43^+CD70^-$ and are not B1 cells.

Properties of Mouse B1 Cells: Natural Antibody

Mouse B1 cells have been accurately identified, isolated, and examined for decades whereas the new definition of human B1 cells is of much more recent vintage. Thus, much of what is known about B1 cells derives from studies of B1 cells in mice (Baumgarth 2011). This information points to critical roles for B1 cell-derived "natural" antibody in antimicrobial defense and housekeeping homeostasis, and potential roles in presentation of antigen and regulation of T cells.

Natural antibody is predominantly IgM and in mice, where the origin of antibodies can be accurately assessed, approximately 80–90 % of resting serum IgM, and approximately 50 % of resting serum IgA (the major isotype of switched B1 cell immunoglobulin) is generated by B1 cells. IgM is produced predominantly by B1 cells in the murine spleen (and bone marrow) that bear B1 cell surface markers and are not typical plasma cells. Although the highest concentration of mouse B1 cells is in the peritoneal cavity, peritoneal B1 cells produce only small amounts of antibody. Under certain activation conditions, however, B1 cells in the peritoneal cavity migrate to the spleen and there become high-secreting B1 cells. To an unknown extent, high-secreting splenic B1 cells may at times become quiescent and return to the peritoneal cavity as memory B1 cells.

Natural antibody produced by B1 cells tends to be polyreactive, autoreactive, and antimicrobial, at relatively modest affinity. B1 cell natural antibody is very effective in creating a line of defense against invasive pathogens – it has been shown for a number of microorganisms that recovery from experimental infection in mice requires the joint action of both B1 and B2 cell-derived antibodies (Baumgarth et al. 2000). It is accepted that preexisting B1 cell-derived antibodies counteract microbial activity during the lag period required for germinal center formation and B2 cell adaptive antibody production. In keeping with this, a substantial fraction of natural antibody recognizes phophorylcholine (PC), an invariant antigenic determinant of Gram-positive microbial membranes, including *S. pneumonia*, a major pathogen. However, anti-PC antibodies do not solely bind bacteria, as PC is present on autologous apoptotic cell membranes and oxidized lipids (Binder 2010). Another fraction of natural antibody recognizes phosphatidylcholine (PtC), a key constituent of senescent red blood cell membranes. These and other examples of autoreactivity have led to the concept that a second, parallel, function of B1 cell natural antibody lies in speeding the elimination of dead and dying cells and attendant cellular debris. In this way, potentially inflammatory and toxic molecules can be removed before damage in the form of immune cell priming or direct tissue injury can occur, thereby avoiding generation of adaptive autoantibody formation and instigation of destructive autoimmune disease (Kaveri et al. 2012). So natural antibody produced by mouse B1 cells fulfills two important functions: immediate defense against microbial pathogens and housekeeping removal of cellular and toxic debris.

The structure of mouse B1 cell natural antibody is distinctly more germline-like than B2 cell-derived adaptive antibody, by virtue of little or no somatic hypermutation and reduced N-region addition. This means that B1 cell antibodies more closely reflect $V_HD_HJ_H/V_LJ_L$ sequences as they are encoded in inherited DNA, in comparison with B2 cell antibodies.

In keeping with this, enforced N-addition in transgenic mice interferes with anti-pneumococcal defense, a substantial portion of which is provided by B1 cell germline-like antibodies. Because B1 cell antibodies tend to reflect sequences as encoded in the genome, and because B1 cell antibodies fulfill a crucial role in antimicrobial defense, it is considered that the B1 cell repertoire reflects Darwinian precepts such that sequences functioning to promote survival are retained. In this way, the B1 cell repertoire may be "tuned" over evolutionary time. In contrast, B2 cell antibodies that contain N-addition and undergo somatic mutation are selected on the basis of affinity, rather than functional efficacy. Together, B1 and B2 antibodies act in concert to thwart existential threats of an infectious nature.

A long-running controversy regarding the origin of mouse B1 cells has been resolved with the discovery of a distinct B1 cell progenitor ($CD45^{lo/-}CD19^{+}$), indicating that B1 cells constitute a separate and unique B cell lineage (Montecino-Rodriguez et al. 2006). Commitment to the B1 cell lineage appears to occur at a point in development even before the identified B1 cell progenitor, namely, at the common lymphocyte precursor (CLP) stage. Many adoptive transfer experiments have shown that fetal hematopoietic tissue (e.g., fetal liver) gives rise to B1 cells whereas adult hematopoietic tissue (e.g., bone marrow) largely does not. In keeping with this, B1 cells appear first in ontogeny, followed by B2 cells, which is the reason why B1 cells are "1" and B2 cells are "2" (Herzenberg 2000). In adult life, mouse B1 cells are thought to maintain themselves primarily through self-renewal, in which mature surface immunoglobulin-bearing B1 cells give rise to their own progeny, whereas B2 cells are continually replenished by stem cell differentiation. The ontologic switch from B1 cell to B2 cell generation occurs during the neonatal period and suggests "layering" of the B cell arm of the immune system in which a phylogenetically early, innate-type B cell population is overlain by a more recently evolved, adaptive-type B cell population. Because similar changes in T cell development (from γδ to αβ antigen receptors) and red blood cell development (from fetal to adult hemoglobin) occur in the same time frame, the B1/B2 cell dynamic may be part of a generalized ontological switch involving multiple hematopoietic lineages that occurs around the time of birth, and may be directed by the RNA-binding protein, Lin28b (Yuan et al. 2012).

Properties of Mouse B1 Cells: Immunoregulation

Beyond secretion of natural antibody, B1 cells affect other immune system constituents in both positive and negative ways. B1 cells strongly stimulate activation and proliferation of naïve T cells in allogeneic co-cultures, indicating that B1 cells efficiently present antigen. This depends, at least in part, on constitutively elevated expression of the co-stimulatory molecule, CD86, and, to a lesser extent, on elevated expression of CD80. CD86 expression joins several other characteristics of unstimulated B1 cells that are similar to features of stimulated B2 cells, a list that includes phosphorylated extracellular signal-regulated kinase (ERK), which is a key protein in B cell receptor signal transduction. Both constitutively elevated CD86 and phospho-ERK result from a state of chronic signaling in B1 cells that may be dictated by autoreactive specificities.

Beyond triggering T cell expansion, B1 cells can influence T cell function toward inflammation by inducing naïve $CD4^{+}$ T cells to differentiate into IL-17-expressing pro-inflammatoryTh17 cells. In contrast, B2 cells cannot induce Th17 cell differentiation unless stimulated first. Conversely, B1 cells can negatively influence T cell function through immunosuppression produced by secretion of IL-10, although B1 cells are not alone in the ability to produce IL-10 and, in addition, other means of immunosuppression have been described for B cells and other immune cells. Inasmuch as B1 cells can present antigen to T cells, can stimulate T cell expansion, can induce Th17 cell differentiation, and can suppress T cell activity, B cells

appear to be in a position to strongly influence the nature and direction of T cell responses, depending on whether stimulatory or suppressive activities dominate, although the extent to which this occurs in vivo has not been determined.

In addition to surface antigen expression, natural antibody secretion, chronic intracellular signaling, and T cell stimulation, differentiation, and suppression, B1 cells differ from B2 cells in a number of other respects that include overall size, viability in vitro, developmental requirements, signaling characteristics, and expression of a number of gene transcripts and proteins.

Properties of Human B1 Cells

The unsatisfactory nature of CD5 as the defining feature of human B1 cells impelled new efforts to characterize the B1 cell surface marker phenotype in humans. A new phenotypic definition of human B1 cells emerged from a "reverse engineering" approach, in which several functional features of mouse B1 cells – spontaneous secretion of IgM, chronic intracellular signaling, and efficient T cell stimulation – were combined as a set of qualifying criteria that any putative human B1 cell population should satisfy. Testing individual populations of human B cells expressing various combinations of surface markers revealed a small population of B cells (identified by CD20 rather than CD19 to avoid immunoglobulin-secreting plasmablasts that lose CD20 but maintain CD19) which co-expresses CD27 and CD43 and fulfills the functional criteria above, and is thus denoted B1 cells (Griffin et al. 2011). $CD20^+CD27^+CD43^+$ B1 cells are routinely found in umbilical cord blood, where CD43 expression more or less coincides with CD27 expression, and in adult peripheral blood, where CD43 identifies a subpopulation within the larger population of $CD27^+$ B cells. Because CD27 is an acknowledged marker for human memory B cells, identification of human B1 cells as a subpopulation of $CD27^+$ B cells indicates that what had been considered a homogeneous memory B cell population is actually heterogeneous by virtue of containing $CD27^+CD43^+$ constituents that are B1 cells. These results suggest that B1 cells should be removed prior to conducting studies on memory B cells defined by CD27 expression.

By definition, human B1 cells recapitulate three key B1 cell features identified in the mouse system, as noted above, because these are qualifying criteria for designation of B cells as "B1." In addition, $CD20^+CD27^+CD43^+$ B cells preferentially bind PC, and preferentially bind the DWEYS peptide mimetope of DNA, in comparison to naïve and memory B cells, mirroring the activities of mouse B1 cells in producing antimicrobial and autoreactive specificities and thereby supporting the phenotypic designation of human B1 cells. Human B1 cells also secrete immunosuppressive IL-10, establishing still another parallel with mouse B1 cells, although only a subset of human B1 cells functions this way. There is as yet no evidence relating human B1 cells and Th17 cell differentiation, so it is not known whether B1 cells share this role across species.

Enumeration of human B1 cells by flow cytometry (Kaminski et al. 2012) depends on a number of parameters that have not been standardized among laboratories. These include, among others, efficiency of antibody binding, choice of fluorophore reagents, sensitivity of fluorescence detection, hierarchy of gating strategy, and competency of computerized algorithms for data analysis. This is one reason, in addition to the genetic and environmental heterogeneity of the human population, why normal values for B1 cells in healthy individuals have not yet been established. However, it is generally considered that B1 cells constitute on the order of 1–9 % of circulating B cells, but may, on occasion, fall outside that range. Whereas mouse B1 cells are predominantly located at serosal surfaces, no reservoir of human B1 cells has been discovered and there is no evidence that human B1 cells are especially located in the peritoneum.

Recognition of human B1 cells requires special considerations. CD43 is an activation antigen and can be expressed by stimulated human naïve

and memory B cells. In the latter case, $CD20^+CD27^+$ memory B cells that acquire CD43 expression would recapitulate the marker profile of human B1 cells. However, stimulated human naïve and memory B cells that express CD43 also express CD69 and CD70 activation antigens whereas human B1 cells do not. To exclude putative stimulated memory B cells, the formal phenotypic characterization of human B1 cells has been expanded to include CD70-negativity, so that B1 cells are fully defined as $CD20^+CD27^+CD43^+CD70^-$ (Griffin et al. 2011).

B1 cell recognition can suffer from doublet formation. In peripheral blood, the number of T cells far outweighs the number of B cells, and most T cells express CD27 and CD43. Thus, any stochastic tendency of a naïve or memory B cell to form a doublet would likely produce a B:T combination in which the B cell contributes CD20 (or CD20 and CD27) and the T cell contributes CD27 and CD43 expression. In other words, B:T doublets containing naïve or memory B cells could masquerade as $CD20^+CD27^+CD43^+$ B1 cells, producing false-positive counts. Several methods can be utilized to exclude putative B cell-containing doublets either before or after acquisition of flow cytometric data (Griffin and Rothstein 2012).

Clinical Correlations

The precise roles of human B1 cells in generating natural antibody, in establishing antimicrobial defense, in fulfilling housekeeping homeostasis, and in regulating T cell activity have not been determined, despite suggestive evidence garnered from in vitro and in vivo assays. It is unknown whether human B1 cell-derived natural antibody functions to oppose or delay the onset of cancer, atherosclerosis, neurodegenerative disease, and/or other dyscrasias of aging, as suggested by recent studies (Kyaw et al. 2011; Rodriguez-Zhurbenko et al. 2013; Boutajangout et al. 2011). It is unknown to what extent human B1 cells are pathogenically connected to autoimmune diseases such as lupus and rheumatoid arthritis, as suggested by mouse models (Duan and Morel 2006). And it is unknown to what extent B1 cells are lost following B cell depletion therapy to treat autoimmunity, chronic lymphocytic leukemia (CLL), and lymphoma, or to what extent B1 cells are repopulated from adult stem cells after bone marrow transplantation. However, to the extent that B1 cells are responsible for serum natural antibody in *H. sapiens* as in *M. musculus*, clinical conditions of agammaglobulinemia and common variable immunodeficiency (CVID) are likely to be associated with abnormal loss or abnormal function of human B1 cells, in keeping with the severe derangement of baseline serum immunoglobulin levels in these conditions. The extent to which human B1 cells play a role in other clinical situations and immune dyscrasias remains to be elucidated.

Conclusion

B1 cells are small in number but large in function, in mice and presumably other species including our own. B1 cells are considered part of the innate immune system and produce natural antibody that is essential to defense against microbial infection and removal of cellular debris. B1 cells also stimulate, differentiate, and suppress T cells, although the extent to which this takes place in vivo has not been clarified. Human B1 cells were initially characterized as CD5 positive, but this definition has been supplanted by identification as a $CD43^+$ subpopulation of $CD27^+$ B cells. Although human B1 cells recapitulate many of the functions described for mouse B1 cells, the role and function of B1 cells in human health and disease remains to be determined.

Definition

T cell costimulation is a signal required for the full activation of naïve T lymphocytes in the presence of T cell receptor signal. T cell coinhibition is a signal required for inhibition of activated T lymphocytes in the presence of T cell receptor signal.

Introduction

According to the two-signal model, optimal activation of a naïve T cell requires the simultaneous occurrence of two signals. Signal 1 is an antigen-specific signal generated by T cell receptor (TCR) recognition of peptide-MHC presented by an antigen-presenting cell (APC)(Bour-Jordan et al. 2011; Zang and Allison 2007). Signal 2, called costimulation, is an antigen-independent signal produced by the interaction between CD28 on T cells and ligand B7-1 (CD80) or B7-2 (CD86) on APC. Activation through the TCR (Signal 1) in the absence of costimulation (Signal 2) leads to functional inactivation or clonal deletion of T cells. After activation, T cells express CTLA-4 (CD152), a homolog of CD28. CTLA-4 also binds B7-1 and B7-2, which results in coinhibition attenuating T cell responses. T cell

B7 and CD28 Families, Table 1 Structure, expression, and function of the B7 ligand family and the CD28 receptor family

Ligands			Receptors and binding partners			Function
Name	Structure	Expression	Name	Structure	Expression	
B7-1 (CD80)		APC, activated T cells	CD28 CTLA-4 (CD152) PD-L1		T cells, Treg, NK activated T cells, Treg	Costimulation Coinhibition
B7-2 (CD86)		APC, activated Tcells	CD28 CTLA-4		T cells, Treg, NK activated Tcells, Treg	Costimulation Coinhibition
ICOS-L (CD275, B7h, B7RP-1, GL50, B7H2, LICOS)		APC, tissues	ICOS (CD278)		activated T cells, Treg	Costimulation
PD-L1 (CD274, B7-H1)		APC, T cells, tissues, tumors	PD-1 (CD279) B7-1		activated T and B cells, Treg myeloid cells, thymocytes	Coinhibition
PD-L2 (CD273, B7-DC)		DC, macrophages	PD-1		activated T and B cells, Treg myeloid cells, thymocytes	Coinhibition
B7-H3 (CD276)	 	DC, macrophages, tissues, activated T cells, tumors	unidentified receptors		activated T cells, NK	Costimulation Coinhibition
B7x (B7-H4, B7S1)		tissues, tumors	unidentified receptors		activated T cells	Coinhibition

costimulatory and coinhibitory pathways are essential orchestrators and regulators of the adaptive immune response. In recent years, the CD28 receptor and B7 ligand families have been expanded to include a total of four [CD28, CTLA-4, ICOS (CD278), and PD-1 (CD279)] and seven members [B7-1 (CD80), B7-2 (CD86), ICOS-L (CD275), PD-L1 (CD274), PD-L2 (CD273), B7-H3 (CD276), B7x (B7-H4 or B7S1)], respectively (Table 1).

The B7-1/B7-2/CD28/CTLA-4 Pathway

This pathway is the most extensively characterized T cell costimulatory and coinhibitory pathway. Ligands B7-1 and B7-2 have extracellular IgV-IgC domains, and it is the IgV domain that is responsible for receptor binding and dimerization (Chattopadhyay et al. 2009). Both B7-1 and B7-2 are mainly expressed on APC such as dendritic cells (DCs), macrophages, and B cells, but their expression kinetics differ. APC activation is necessary for induction of B7-1 expression, whereas B7-2 is constitutively expressed on resting APC in low levels and is enhanced upon APC activation. Similarly, B7 receptors CD28 and CTL antigen-4 (CTLA-4) are both expressed on T cells, but differ in their expression kinetics as well. CD28 is constitutively expressed on naïve and activated T cells, whereas CTLA-4 expression is induced in response to TCR signal, so it is detectable on activated T cells and regulatory T cells (Treg) but not on naïve T cells. Both CD28 and CTLA-4 have an extracellular IgV domain, but they differ markedly in their localization in T cells (Rudd et al. 2009). CD28 is localized on the cell surface. By contrast, the majority of CTLA-4 is found in intracellular compartments such as the trans-Golgi network, endosomes, and lysosomes. Therefore, factors that regulate CTLA-4 protein access to the cell surface can spatially and temporally determine the extent to which CTLA-4

regulates T cell function. Although B7-1 and B7-2 can bind both CD28 and CTLA-4 via the same MYPPPY motif, the affinity of CTLA-4 for these ligands is much higher compared to that of CD28. Clearly, expression kinetics, location, and binding affinity are diverse among the ligands and receptors in this pathway.

In the presence of TCR signal, CD28 co-localizes with TCR in the central region of the immunological synapse, where the interaction between B7-1/B7-2 on APC and CD28 on T cells leads to costimulation. The costimulatory pathway not only amplifies phosphorylation of TCR-dependent kinases but also establishes a distinct signaling and transcriptional program (Rudd et al. 2009). CD28-mediated costimulation can also drive the formation of a mature immunological synapse partially via the recruitment of lipid rafts to the synapse. The cytoplasmic tail of CD28 contains several motifs responsible for binding of signaling molecules. The proximal motif can be phosphorylated by Src family kinases and then binds PI3K, Grb2, and GADS; the distal motif can be phosphorylated by Lck and Fyn kinases and then binds Grb2 and Filamin-A; a proline-rich region is associated with Itk binding. One of the most important functions of CD28-mediated costimulation is to markedly promote the production of T cell growth factor IL-2 and the expression of the high-affinity IL-2 receptor, which is pivotal for optimal clonal expansion of naïve T cells. CD28-mediated costimulation also controls T cell survival by enhancing expression of the anti-apoptotic factor Bcl-X_L. Finally, CD28-mediated costimulation is able to increase glucose uptake and glycolysis in order to meet the elevated metabolic requirement following T cell activation. B7-1/B7-2/CD28-mediated costimulation is essential for the initial activation of naïve T cells, while effector and memory T cells are less dependent on this pathway to maintain their function. Most normal tissue cells do not express B7-1 or B7-2, and immature APC express only low levels of B7-2, so these cells cannot provide enough ligands to bind CD28 on naïve T cells that may recognize MHC-peptide complex presented by these cells. The consequence is that these tissue cells will not fully activate the naïve T cells they bind, but rather, results in anergy, functional inactivation of T cells. This is one of the fundamental mechanisms the immune system has to maintain self-tolerance and prevent autoimmune responses against self-tissues.

In contrast to the costimulatory activity of CD28, the interaction of B7-1 or B7-2 with CTLA-4 is essential for limiting the proliferative response of activated T cells to antigen and CD28-mediated costimulation (Egen et al. 2002). The importance of CTLA-4 function is evidenced by the fact that *CTLA-4* gene knockout mice develop a lethal lymphoproliferative disorder and human *CTLA-4* gene polymorphisms are strongly linked with some autoimmune diseases (Scandiuzzi et al. 2011). T cell coinhibition by CTLA-4 is achieved mainly through two mechanisms: competition for ligands and induction of an inhibitory signal. Like CD28, CTLA-4 also moves to the immunological synapse, but its accumulation in the immunological synapse is proportional to the strength of the TCR signal (Egen et al. 2002). At the immunological synapse, CTLA-4 can compete with CD28 for B7-1/B7-2 engagement. Because CTLA-4 has greater affinity for B7 ligands than does CD28, CTLA-4 can sequester B7-1/B7-2 molecules, which in turn reduces CD28-dependent costimulation. Crystal structures reveal that CTLA-4 and B7 pack in a strikingly periodic arrangement in which bivalent CTLA-4 homodimers bridge bivalent B7 homodimers, therefore allowing the formation of a zipper-like protein lattice that could, in theory, assemble in the immunological synapse to compete with CD28 and/or to initiate inhibitory signal (Chattopadhyay et al. 2009; Schwartz et al. 2002). CTLA-4 can induce an inhibitory signal through its cytoplasmic tail that is 100 % conserved among mammalian species. The cytoplasmic tail of CTLA-4 contains two tyrosine residues that can be phosphorylated and subsequently recruit phosphatases like SH2 domain-containing phosphatase-2 (SHP-2). These phosphatases then dephosphorylate TCR-ζ as well as other components of the TCR proximal signal molecules such as linker for activation of

T cells (LAT), tyrosine kinases Fyn and Lck, and ζ chain-associated protein kinase of 70 kDa (ZAP-70). CTLA-4's cytoplasmic tail also contains a lysine-rich motif which can be bound by the serine/threonine protein phosphatase 2A (PP2A) resulting in thereby repression of CTLA-4 inhibitory function. In addition, CTLA-4 can inhibit the CD28 signal. Some signaling molecules such as PI3K and PP2A are able to bind cytoplasmic tails of both CTLA-4 and CD28, and CTLA-4 may sequester these molecules thereby reducing availability to induce CD28-dependent costimulation. CTLA-4 may also bring phosphatases in proximity to CD28's cytoplasmic tail, thereby repressing CD28-mediated costimulation. Although the precise nature of the signals transmitted through CTLA-4 remains controversial, it is likely that CTLA-4 can antagonize both TCR-dependent and CD-28-dependent signals (Rudd et al. 2009). In addition to activation of naïve T cells, B7/CD28 interactions are needed for the development and maintenance of regulatory T cells (Treg). Treg constitutively express high levels of CTLA-4 on their surface, and CTLA-4 may have an important cell-autonomous inhibitory function in Treg. In summary, the pathway of B7-1/B7-2/CD28/CTLA-4 has critical roles in naïve T cell activation and Treg homeostasis.

The ICOS-L/ICOS Pathway

ICOS (inducible costimulator, CD278) is the third member of the CD28 family (Nurieva et al. 2011; Zang and Allison 2007). Unlike CD28, ICOS is not expressed on naïve T cells but is induced after T cell activation. Both TCR and CD28 signals enhance ICOS expression, whereas the RING-type ubiquitin ligase family member Roquin mediates degradation of ICOS mRNA. ICOS-L (also called B7h, B7RP-1, GL50, B7H2, and LICOS) is the ligand for ICOS and is constitutively expressed on B cells, macrophages, and DCs and can be induced in nonlymphoid tissues by inflammatory stimuli. ICOS-L expression on B cells is downregulated by signaling through the B cell receptor and IL-4 receptor or after interaction with ICOS as a negative feedback loop.

The cytoplasmic tail of ICOS has an YMFM motif that, after tyrosine phosphorylation, binds to the P85α and P50α subunits of PI3K. Compared to CD28, ICOS stimulates greater PI3K activity and a concomitant increase in Akt signal. However, unlike CD28, the ICOS YMFM motif does not bind Grbs which is critical for IL-2 production. Therefore, ICOS engagement has little effect on IL-2 secretion, but increases production of IL-4, IL-5, IL-6, IL-10, interferon-γ (IFN-γ), and granulocyte-macrophage colony-stimulating factor (GM-CSF) by T cells. The ICOS signal promotes T cell activation, differentiation, and effector responses.

The ICOS-L/ICOS pathway provides critical T cell help to B cells. Chemokine CXC motif receptor 5 (CXCR5)-positive follicular helper CD4 T (Tfh) cells are a unique T cell subset which provide help to B cells and promote the formation of long-lived antibody responses, and ICOS-L engagement of ICOS on CD4 T cells provides signals required for initiation and maintenance of Tfh differentiation (Crotty 2011). At the time of DC priming, the expression of ICOS on CD4 T cells is required for the expression of transcription factor Bcl6, a master regulator of Tfh differentiation. After priming, $Bcl6^{+}CXCR5^{+}$ Tfh cells express an elevated level of ICOS and migrate to the T-B border where the B cell-dependent phase of Tfh differentiation occurs. B cell-expressed ICOS-L and Tfh-cell expressed ICOS are required for the production of IL-21, a cytokine for B cell maturation, as well as the formation of a germinal center. Due to the vital role of the ICOS-L/ICOS in Tfh generation and promotion of humoral immunity, deficiency of ICOS or ICOS-L results in substantially reduced numbers of Tfh cells, impaired germinal center formation, and dysfunctional isotype switching.

ICOS deficiency accounts for the full spectrum of manifestations in a proportion of patients with common variable immunodeficiency (CVID) (Scandiuzzi et al. 2011; Yong et al. 2009). Specifically, a homozygous partial deletion of the *ICOS* gene in some CVID

patients results in deficiency in the expression of ICOS protein on activated T cells. As a consequence, the patients cannot generate or sustain normal numbers of memory B cells and have markedly reduced levels of serum IgG and IgA. Even after vaccination these patients lack detectable amounts of specific IgG. The genetic linkages between ICOS deletion and the clinical features of CVID emphasize the critical role of the ICOS-L/ICOS pathway in antibody production.

The PD-L1/PD-L2/PD-1 Pathway

PD-1 (programmed death-1, CD279) is a member of the CD28 family (Keir et al. 2008; Okazaki and Honjo 2007). The extracellular part of PD-1 contains a single IgV domain but lacks the membrane proximal cysteine that mediates the interchain disulfide bond, so it is monomeric on the cell surface (Chattopadhyay et al. 2009). PD-1 is expressed during thymic development but is absent on mature naïve T cells. In contrast to the restricted expression of other CD28 family members to T cells, PD-1 is induced on T cells, B cells, and some myeloid cells after activation. PD-1 has two ligands, PD-L1 (B7-H1, CD274), which also binds B7-1, and PD-L2 (B7-DC, CD273). PD-L1 is widely expressed on hematopoietic cells including APC and on several parenchymal tissues including the vascular endothelium and epithelium of several organs, whereas PD-L2 expression is mostly restricted to DCs and macrophages. IFN-γ is a major regulator of PD-L1 expression for a wide range of cell types (Barach et al. 2011). The different expression patterns of the PD-1 ligands may relate to their distinct functional abilities. Although both ligands have extracellular IgV-IgC domains and PD-L2 has greater affinity for PD-1 than PD-L1, PD-L1 is usually more effective than PD-L2 at triggering PD-1-mediated T cell inhibition.

The PD-L/PD-1 pathway plays an important role in the control of tolerance and autoimmunity (Sharpe et al. 2007), which was first revealed when it was observed that *PD-1* gene knockout mice slowly developed spontaneous autoimmune diseases. PD-1 engagement during TCR signaling can inhibit T cell proliferation, cytokine production, cytolytic function, and T cell survival. PD-1 is more effective at attenuating weak TCR signals than strong ones. Unlike CTLA-4, PD-1 function solely depends on its cytoplasmic tail which contains an immunoreceptor tyrosine-based switch motif (ITSM) (Okazaki and Honjo 2007; Sharpe et al. 2007). Ligation of PD-1 and TCR leads to tyrosine phosphorylation of the ITSM which can then be bound by SHP-1 and SHP-2; these phosphatases can dephosphorylate TCR-associated CD-3ζ and ZAP-70, resulting in inhibition of PI3K and downstream Akt. In contrast, CTLA-4 inhibits Akt activation but does not alter PI3K activity. PD-1 ultimately decreases induction of cytokines and cell survival proteins. During autoimmune responses, this pathway limits the initial phase of activation and expansion of self-reactive T cells and restricts self-reactive effector T cells and targets organ damage.

The PD-L1/PD-1 pathway contributes critically to T cell exhaustion and viral persistence during some chronic infections (Hofmeyer et al. 2011). Cytotoxic CD8 T lymphocytes (CTLs) play a pivotal role in the control of infection by killing infected cells. During chronic viral infection, the persistent presentation of antigen causes highly upregulated PD-1 on CTLs and upregulated PD-L1 on APC or resident tissue cells. As a consequence, activated CTLs become exhausted, lose effector function, and are unable to eliminate infection. Therefore, the PD-L1/PD-1 pathway is emerging as one of major regulators converting effector CTLs into exhausted CTLs during chronic infection with human immunodeficiency virus, hepatitis B virus, hepatitis C virus, and other pathogens capable of establishing chronic infections.

The B7-H3 and B7x Pathways

B7-H3 (CD276) and B7x (B7-H4 or B7S1) are the most recently discovered members of the B7 family, and their contribution to immune

response has not yet been clearly defined. Furthermore, the receptors for B7-H3 and B7x are currently unidentified.

B7-H3 has two major isoforms. Mouse B7-H3 contains extracellular IgV-IgC domains, whereas human B7-H3 has tandemly duplicated IgV-IgC-IgV-IgC domains because of exon duplication (Collins et al. 2005). However, no functional difference has been observed between these two isoforms. B7-H3 protein is induced on APC, NK cells, T cells, fibroblasts, fibroblast-like synoviocytes, and some epithelial cells. microRNA-29 represses B7-H3 translation. The physiological function of B7-H3 on T cell proliferation and cytokine production remains controversial (Hofmeyer et al. 2008); B7-H3 binds activated T cells, leading to costimulation in some cases and to coinhibition in others. Similarly, studies in *B7-H3* gene knockout mice support a costimulatory role in some disease models and a coinhibitory role in others. The function of B7-H3 in cancer immune responses is also controversial (Barach et al. 2011; Zou and Chen 2008). In some murine models of cancer, expression of B7-H3 on cancer cells actives tumor-specific CTLs and slows tumor growth. In contrast to mouse tumor studies, the majority of studies with human cancers demonstrate that patients with strong B7-H3 expression on cancer cells are more likely to have poor clinical outcome, suggesting a coinhibitory role. It remains to be determined whether the contrasting roles of B7-H3 in T cell function are attributed to multiple receptors.

B7x, like most other B7 family members, is composed of extracellular IgV-IgC domains linked by a transmembrane region to a very short cytoplasmic tail. B7x mRNA is broadly expressed across a wide range of organs but exhibits an expression pattern inverse of that of B7-2 mRNA, with higher B7x mRNA expression in peripheral nonlymphoid tissues and very low expression in the hematopoietic compartment. B7x protein is hardly detectable on immune cells even after culture in various stimulating, suppressive, and maturation conditions, but is found on epithelial cells of some organs and β cells of the pancreas. B7x inhibits both CD4 and CD8 T cell proliferation and cytokine production in vitro (Zang and Allison 2007; Zou and Chen 2008). The combination of the in vivo expression pattern and the in vitro T cell coinhibitory capability of B7x suggests that the B7x pathway may be important in regulating tolerance and autoimmunity in nonlymphoid organs. The in vivo function of the B7 pathway, however, remains largely unknown. Although B7x protein expression is rare in healthy tissues, it is abundant in human malignancy (Barach et al. 2011), including cancers of the prostate, ovary, brain, lung, breast, kidney, pancreas, gut, esophagus, uterus, and skin. Importantly, overexpression of B7x in cancer often correlates with disease progression and poor clinical outcome, suggesting the B7x pathway may be exploited by cancer cells to evade antitumor immune responses.

Drugs Developed Based on the B7 and CD28 Families

The fundamental importance of costimulatory and coinhibitory signals for lymphocyte activation have spurred a large amount of effort in developing new immunotherapies by manipulating the pathways of the B7 and CD28 families. In 2005, the US Food and Drug Administration (FDA) approved Abatacept (CTLA-4-Ig) for the treatment of adult rheumatoid arthritis; a few years later, its use was extended to juvenile idiopathic arthritis (Felix et al. 2010). Abatacept is a fusion protein consisting of the extracellular domain of human CTLA-4 and the Fc portion of human IgG1, which has been modified and does not bind complement nor the Fc receptors. Compared to CD28, CTLA-4 has much higher affinity for B7-1 and B7-2; therefore, Abatacept can hamper B7-1/B7-2/CD28-mediated costimulation, resulting in increased cell death, anergy induction, and blockade of cell differentiation of T cells. Belatacept, the second generation of Abatacept, has higher affinity and is being tested in clinical trials for use in organ transplantation. In 2011, the US

FDA approved ipilimumab for the treatment of metastatic melanoma (Sharma et al. 2011). Ipilimumab, a human monoclonal antibody against CTLA-4, functions to block the interaction of CTLA-4 with B7-1 and B7-2, while leaving TCR and CD28 signals intact, which results in increased T cell function against cancer cells. Ipilimumab is currently in clinical trials in patients with other types of cancers. Clearly, research on T cell costimulation and coinhibition holds promise for the development of novel therapies and diagnoses.

Conclusion

Costimulation and coinhibition control appropriate T cell activation, proliferation, differentiation to effector function, and memory cell generation. The intense efforts towards understanding B7 and CD28 molecules over the past two decades have shaped much of our understanding regarding the immune system and disease mechanisms. The B7-1/B7-2/CD28/CTLA-4 pathway serves as the main switch regulating the clonal expansion of activated naive T cells as well as Treg homeostasis; the ICOS-L/ICOS pathway provides critical T cell help to B cells and germinal center formation; the PD-L1/PD-L2/PD-1 pathway controls effector T cell function and T cell exhaustion. PD-L1, B7-H3, and B7x are expressed in the peripheral tissues and may therefore act as gatekeepers for immune cells in nonlymphoid organs to prevent self-attack, whereas cancer and chronic infectious pathogens exploit these pathways to achieve immune evasion. While further studies are required to better understand the molecular mechanisms of these pathways and their particular roles in various diseases, the pathways of T cell costimulation and coinhibition are promising drug targets and already being developed for their therapeutic potential.

BAFF and APRIL and Their Receptors

Anne Davidson
Feinstein Institute for Medical Research,
New York, NY, USA

Synonyms

APRIL (a proliferation ligand): TALL-2, TNFSF13; BAFF (B cell activating factor): zTNF4, BLyS, TALL-1, THANK, TNFSF13B; BAFF-R: Bcmd1, BR3, TNFRSF13C, CD268; BCMA: TNFRSF13A, CD269; TACI: TNFRSF13B, CD267

Definition

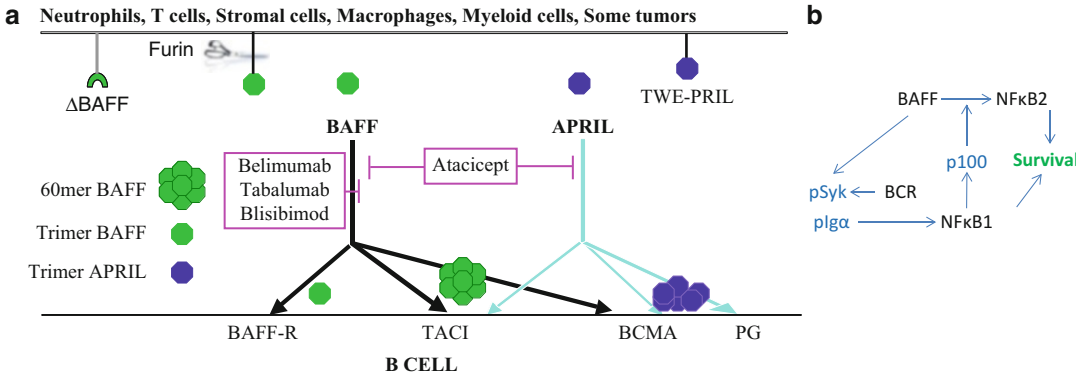
BAFF and APRIL are homologous homotrimeric cytokines belonging to the TNF family.

BAFF and APRIL Ligands and Receptors

BAFF (B cell activating factor: also named zTNF4, BLyS, TALL-1, THANK, TNFSF13B) and APRIL (a proliferation ligand: also named TALL-2, TNFSF13) are homologous TNF-like cytokines that are made by a wide variety of cell types including myeloid cells, stromal cells, activated lymphocytes, epithelial cells, and some cancer cells. Their major function is to support the survival and differentiation of B cells. BAFF binds to three receptors, BAFF-R (also named Bcmd1, BR3, TNFRSF13C, CD268), TACI (TNFRSF13B, CD267), and BCMA (TNFRSF13A, CD269), that are expressed on B cells at different developmental stages, whereas APRIL binds only to TACI and BCMA (Fig. 1a). BAFF-R is the predominant receptor on transitional, naïve, and memory B cells: TACI, the predominant receptor on marginal zone B cells and short-lived plasma cells, and BCMA, the predominant receptor on long-lived plasma cells (reviewed by Davidson (2010); Mackay et al. (2010); Mackay and Schneider (2009)). BAFF receptors may also be expressed on other immune cell types including activated T cells and dendritic cells (DCs) as well as on non-immune cells such as cancer cells (Vincent et al. 2013).

BAFF and APRIL are type II transmembrane proteins that are cleaved either at the cell membrane (BAFF) or in the Golgi apparatus (APRIL) to generate soluble forms. Several splice isoforms of both cytokines exist including ΔBAFF, a transmembrane form lacking an exon that may act as a negative regulator of BAFF function, and TWE-PRIL, a fusion protein of the extracellular domain of APRIL with the intracellular domain of TWEAK, thereby yielding a transmembrane form of APRIL. BAFF and APRIL may also form a small amount of heterodimers (reviewed by Mackay and Schneider (2009); Vincent et al. (2013)).

In mice, BAFF-R is a high affinity receptor for BAFF and binds to BAFF in its trimeric form. Although the BAFF trimer can bind to TACI, activation of the TACI receptor by BAFF requires multimerization to a 60-mer form



BAFF and APRIL and Their Receptors, Fig. 1 (**a**) BAFF, APRIL, and their receptors. BAFF is generated as a cell surface molecule that is cleaved by a furin protease. BAFF circulates either as a trimer but also forms 60 mers made of 20 trimers that have a higher affinity than the trimer and can activate TACI. APRIL is cleaved intracellularly and secreted as a trimer that can be multimerized by binding to proteoglycans on cell surfaces. BAFF binds to all three receptors with varying affinities (BAFF-R > TACI > BCMA). APRIL binds to TACI and BCMA. Alternate forms of the ligands and receptors include ΔBAFF, a cell surface form missing an exon and TWE-PRIL, a fusion of APRIL with the intracellular domain of TWEAK. The interaction of the ligands and receptors can be blocked by antibodies to BAFF (belimumab and tabalumab) or fusion proteins of the receptors with Fc (atacicept, blisibimod). These may interfere with the binding of BAFF to its three receptors, leaving APRIL functions intact BAFF (belimumab, tabalumab, and blisibimod) or may interfere with the binding of both BAFF and APRIL with all three receptors (atacicept). (**b**) Signaling interactions between BAFF-R and BCR. In late transitional cells, BCR signals through the NFkB1 pathway provide p100, a substrate for the NFkB pathway activated by BAFF-R. Conversely, BAFF-R enhances BCR-mediated signals by increasing phosphorylation of Syk and Igα. Together these signals cooperate to enhance B cell survival. If the BCR is downregulated as a result of encounter with autoantigen in the early transitional phase, there will be an increased dependence on BAFF

(Bossen et al. 2008). APRIL similarly binds better to its receptors when it is multimerized, in this case by binding to heparin sulfate proteoglycans on cell surfaces (Ingold et al. 2005) (Fig. 1a).

The Role of BAFF/APRIL in Naïve B Cell Development and Survival

Neither BAFF nor APRIL is required for the maturation of B cells in the bone marrow; however, the interaction of BAFF with BAFF-R is essential for the survival of B cells past the early transitional (T1) stage with only a minor contribution from TACI and none from APRIL or BCMA (reviewed by Davidson (2010); Mackay and Schneider (2009)). The earliest transitional cells are subject to deletion or anergy induction when they receive a BCR signal, because their immature rafts contain insufficient cholesterol to assemble signaling molecules. In the transitional type 2 (T2) stage, BCR signaling through the classical NFkB pathway upregulates expression of BAFF-R and also generates p100, an essential substrate for the non-classical NF-κB signaling pathway used by BAFF-R (Stadanlick et al. 2008). Upon receiving both BCR- and BAFF-mediated signals, T2 cells can now differentiate and migrate either to the marginal zone or to the B cell follicles, where they require a source of BAFF for their continued survival. BAFF-R signaling also enhances phosphorylation of Syk, a signaling molecule required for optimal BCR signaling (Schweighoffer et al. 2013) (Fig. 1b). This cross-talk between the BCR and BAFF-R is essential for the survival of most transitional type 2, marginal zone and mature naive B cells.

Autoreactive B cells are particularly dependent on BAFF, because if they downregulate their BCR as a consequence of antigen encounter

at the T1 stage, they will produce less p100 and compete poorly for BAFF as they progress to the T2 stage. When B cell numbers and BAFF levels are normal, stringent deletion of autoreactive B cells occurs. However, an increase in serum BAFF levels, such as occurs during B cell lymphopenia or perhaps during inflammatory states, may result in relaxation of B cell selection, with survival of more autoreactive B cells (reviewed by Liu 2011). Importantly however, the effect of excess BAFF on naïve B cell selection can be quite variable, and not all autoreactive B cells are equally susceptible to either excess BAFF or BAFF inhibition at the transitional B cell checkpoint (reviewed by Liu 2011). Furthermore, excess BAFF not rescue autoreactive B cells that are targeted for deletion in the bone marrow.

In addition to cross-talk with the BCR, TACI and BAFF-R also interact with the TLR system. Stimulation through either TACI or BAFF-R results in upregulation of endosomal TLRs Katsenelson et al. (2007); TACI also binds to the TLR adaptor MyD88, although at a different site than do the TLR molecules (He et al. 2010). Conversely, TLR signals can upregulate expression of both TACI and BAFF-R on B cells, rendering them more sensitive to BAFF or APRIL signals (Treml et al. 2007). This innate immune amplification loop may enhance inflammation in the setting of chronic diseases.

TACI mutations are found in approximately 10 % of CVID patients. The causative mechanism is complex since there is incomplete penetrance of an immune deficient phenotype in family members with the same TACI mutations (Salzer et al. 2009). BAFF-R mutations are more rarely associated with CVID, and similar to TACI, there is variable penetrance within families.

The Role of BAFF/APRIL in Antigen-Driven B Cell Development and Survival

The role of BAFF and APRIL and their receptors changes once B cells begin to encounter antigen. The most important receptor for T cell–independent humoral responses is TACI that is highly expressed on B1 and marginal zone B cells and on the short-lived plasma cells that arise during the T-independent response (Mackay and Schneider 2008). Both BAFF and APRIL can mediate these responses, but the interaction of TACI with APRIL is relatively more important than that of TACI with BAFF for IgA responses and IgA is deficient in APRIL knockout mice (reviewed by Mackay and Schneider 2009). By contrast, BAFF and BAFF-R are required for optimal germinal center responses and germinal centers are smaller and of shorter duration when either the ligand or receptor is missing (reviewed by Liu and Davidson 2011b; Kalled 2006). Whether BAFF regulates selection of B cells in the germinal center is still not known.

Although BAFF receptors are expressed on memory B cells, maintenance of class switched B cell memory appears to be independent of either BAFF or APRIL in both mice and humans (Scholz et al. 2008; Benson et al. 2008; Jacobi et al. 2010), although there is some in vitro data suggesting that BAFF may costimulate memory B cell reactivation in the setting of inflammation. In adult mice, the establishment of long-lived plasma cells in the bone marrow following immunization is dependent on both BAFF and APRIL via their interaction with BCMA and TACI. Nevertheless, other components of the bone marrow niche may substitute for BAFF and APRIL once the niche is established or during inflammation (Ramanujam and Davidson 2008). Indeed, in humans, there is only a modest effect of BAFF/APRIL inhibition on antibody titers to recall antigens such as tetanus toxin and influenza. Mouse BAFF binds only weakly to the BCMA receptor, and since expression of TACI in neonatal mice is poor, neonatal plasma cells depend on the interaction between APRIL and BCMA and are deficient in APRIL knockout mice. Since human BAFF binds to BCMA, it is not clear whether this finding also pertains to humans, but B cells from infants express less BAFF receptors than do adult B cells.

The Role of BAFF and APRIL in Other Cell Types

BAFF-R is expressed on activated T cells and the interaction of BAFF with BAFF-R on CD4 T cells enhances their production of IFNγ and IL-17 (Zhou et al. 2011). Modulation of BAFF-R on T cells has been shown to influence the severity of transplant rejection and the progression of the autoimmune disease, Systemic Lupus Erythematosus (SLE). BAFF also supports the survival of monocytes and enhances their differentiation. Human myeloid DCs stimulated in vitro with BAFF upregulate co-stimulatory molecules, lose phagocytic ability, and produce inflammatory cytokines (Chang et al. 2008). In a mouse model of arthritis, BAFF silencing in synovial DCs prevented their maturation; these cells failed to produce the IL-6 required for the differentiation of T helper type 17 (Th17) cells (Lai Kwan Lam et al. 2008); IL-6 is also required for optimal plasma cell differentiation and for the differentiation of regulatory T cells.

BAFF and APRIL and their receptors are upregulated during infections as a result of a response to Type I interferons and increased TLR expression. Inappropriate BAFF and APRIL secretion in the setting of chronic infections has been linked to a potential risk for hematologic malignancy. BAFF and APRIL have also been implicated in the maintenance of some malignancies including CLL and multiple myeloma (reviewed by Vincent et al. 2013).

Signaling Through BAFF Receptors

Signaling through BAFF-R activates the alternative NFκB pathway by depleting the TRAF3 protein that constitutively suppresses activation of NF-κB2. BAFF enhances long-term B cell survival primarily through this pathway by upregulating anti-apoptotic proteins including Mcl-1. Signaling through BAFF-R also activates several other important survival pathways. Signaling through Mek/Erk (extracellular signal regulated kinase) and through Akt/mTOR (molecular target of rapamycin) mediate cell survival by repressing the proapoptotic protein Bim (reviewed in Mackay et al. 2010). BAFF-R signaling prevents nuclear translocation of protein kinase Cδ (PKCδ), preventing its proapoptotic effects. BAFF-R ligation results in signals through Pim2 that increase metabolic fitness by inducing a metabolic bias toward glycolysis. In this way, BAFF keeps B cells in a state of readiness to respond to BCR activation. Finally, as mentioned above, signals through BAFF-R induce phosphorylation of both Syk and the BCR-associated Igα signaling subunit, and therefore amplify BCR-mediated signals (Schweighoffer et al. 2013).

TACI is a potent stimulator of the classical NF-κB1 pathway and also activates both the Jnk (c-Jun N-terminal kinase)/p38 pathway and calcium-modulating cyclophilin ligand (CAML), which leads to activation of nuclear factor for activated T cells (NFAT) (reviewed in Mackay et al. (2010)). As mentioned above, TACI also interacts directly with MyD88 and amplifies innate immune signals through this mechanism (He et al. 2010). TACI has also been considered a negative signaling molecule because TACI deficiency results in B cell expansion and activation (Mackay and Schneider 2008). However, this may be due to a relative increase in BAFF and APRIL availability when TACI is absent, resulting in enhanced binding of BAFF to BAFF-R.

BCMA is a target of the plasma cell transcription factor BLIMP1 and is expressed on plasma cells as well as on several different types of tumor. Like TACI, BCMA activates the classical NFκB pathway as well as the JNK, p38, and ERK pathways.

BAFF and Autoimmunity

BAFF transgenic mice that have 30–100 fold increased BAFF levels develop a mild form of autoimmunity with features of Sjogren's syndrome and SLE. Conversely, inhibition of BAFF or of both BAFF and APRIL attenuates lupus in

multiple mouse models. The mechanism for the induction of autoimmunity in normal mice by transgenic expression of high concentrations of BAFF is due to T cell–independent but MyD88-dependent activation of innate B cells that produce autoantibodies, particularly those of the IgA isotype. High levels of BAFF also result in loss of stringency of B cell selection and may promote isotype switching in a T cell–independent manner. No autoimmunity is induced in APRIL transgenic mice, but these mice develop B1 cell lymphomas with age (reviewed by Mackay and Schneider 2009).

High levels of BAFF (2–5 folds increased) have been observed in a proportion of patients with multiple autoimmune and inflammatory diseases, and high local expression of BAFF has been observed in inflamed organs. These observations have led to the development of several drugs that inhibit either BAFF alone or both BAFF and APRIL. These drugs include antibodies directed at BAFF or fusion proteins of the BAFF-R or TACI receptors with the Fc portion of Ig. Although BAFF inhibition abrogates arthritis in mouse models, several BAFF antagonists have failed in human clinical trials of rheumatoid arthritis. Disappointingly, the first use of the BAFF/APRIL inhibitor atacicept (TACI-Ig) in multiple sclerosis resulted in disease worsening, by mechanisms that are not well understood. The recent finding that BAFF may bind to the CNS receptor Nogo-66 may help to explain these findings (reviewed by Vincent et al. 2013). By contrast, the first anti-BAFF antibody to be developed, belimumab, was successful in two large Phase 3 studies of SLE and was approved by the FDA for the treatment of SLE in 2011. Studies of large numbers of SLE patients treated with either standard of care therapy or standard of care therapy with belimumab have shown that belimumab induces a 30–40 % decrease in circulating autoantibody titers, an increase in serum complement levels, and a significantly greater clinical response than in patients receiving standard of care therapy alone. Post-hoc analyses have indicated that the drug is most effective in a subset of patients with high levels of serum anti-DNA levels and low complement levels (reviewed by Boneparth and Davidson 2012).

How Does BAFF Inhibition Work?

Two types of BAFF inhibitors have been developed. Selective inhibitors block the interaction of BAFF with BAFF-R whereas the non-selective inhibitor TACI-Ig blocks both BAFF and APRIL, preventing the interaction of both cytokines with all their receptors (Fig. 1a). Both types of inhibitors effectively prevent SLE in mouse models, suggesting that the interaction of BAFF with BAFF-R is the dominant interaction that mediates this disease. Nevertheless, studies using knockout mice have shown that while deficiency of BAFF attenuates disease in lupus models, absence of BAFF-R has no effect. This could be because the profound B cell depletion in BAFF-R deficient mice results in a marked increase in serum BAFF levels, recapitulating the physiology of the BAFF transgenic mouse. As discussed above, TACI-Ig has a greater effect than selective BAFF inhibitors on both short-lived and long-lived plasma cells although the decrease in serum levels of IgM and IgA is considerably greater than the decrease of serum IgG. The mechanism for this difference, whether it is intrinsic to the switched cells or to their environment, is not known.

Mechanistic studies in SLE-prone mice have shown that both BAFF-R-Ig and TACI-Ig deplete B cells past the T1 stage but have only modest effects on IgG autoantibody production and renal immune complex deposition and no apparent effect on somatic mutation or autoantibody affinity. Nevertheless, there is a significant attenuation of renal disease. Whether this is due to an alteration in the pathogenicity of the deposited autoantibodies has not yet been determined. Part of this effect may be secondary to B cell depletion with a decrease in the overall size of secondary lymphoid organs and therefore a decrease in the total number of activated inflammatory cells. An alternate explanation is that there is a direct

inhibition of renal inflammation through effects on renal cells (reviewed by Liu and Davidson 2011b).

Studies in humans with SLE have shown treatment with the anti-BAFF antibody belimumab depletes peripheral blood naïve B cells and non-class switched memory cells but not class switched memory cells. Indeed an unexplained finding in humans is a two fold increase in CD19+/CD27+ cells within 2–4 weeks of starting either belimumab or TACI-Fc (atacicept) therapy. There is a modest effect on circulating plasmablasts with a preferential effect on IgM- and IgA- rather than IgG-producing cells (Jacobi et al. 2010). These results are consistent with observations in the mouse models. More work is needed to determine whether BAFF inhibition alters selection of human B cells or impacts on the function of T cells or DCs.

The Future of BAFF and APRIL Therapeutic Targeting

Based on the initial success of belimumab in the treatment of SLE, a number of other BAFF and BAFF/APRIL inhibitors have been developed (reviewed by Liu and Davidson 2011b; Fairfax et al. 2012). Selective inhibitors include other antibodies to BAFF (Tabalumab) or fusion proteins of BAFF-R or part of BAFF-R with Fc (Blisibimod). The non-selective inhibitor atacicept is a fusion protein of TACI with Fc. Potential indications include other autoimmune diseases in which B cells play an important role and/or BAFF levels are elevated as well as B cell malignancies and transplant rejection. Clinical trials in several of these indications are planned. Atacicept has a more robust effect on plasma cell survival than do the selective inhibitors and in patients with SLE, high doses have been associated with a decrease in serum immunoglobulin levels and an increased rate of infections. Nevertheless, atacicept should be a more efficacious reagent than selective BAFF inhibitors with respect to elimination of plasma cells. The next few years should see results of a large number of clinical trials that should better clarify the indications for BAFF and BAFF/APRIL inhibitors and their mechanism of action.

Definition

Regulating T and B cell development and peripheral homeostasis is critical to prevent aberrant immune responses. Apoptosis is a form of programmed cell death crucial for maintaining homeostasis of T and B cells. During T and B cell development, apoptosis is involved in eliminating self-reactive cells, which is necessary to prevent autoimmunity. In the case of an infection, activated T and B cells undergo expansion in response to antigen stimulation and subsequently develop effector functions. After this expansion period, most cells are eliminated through apoptosis and some develop into memory cells.

This selective process of contraction and memory development is crucial in resetting T and B cell homeostasis and promoting protective immunity. Studies show that the Bcl-2 family members are critical regulators of apoptosis, contributing to the regulation of T and B cell development and contraction of immune responses. The focus of this review will be on the Bcl-2 family members that are critical in determining T and B cell fate during development, homeostasis and activation, and how functional mutations in the Bcl-2 family members may lead to autoimmunity (▶ Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis).

Introduction

The Apoptotic Pathways

There are two major pathways of apoptosis – the death receptor-mediated or extrinsic pathway and the Bcl-2-regulated or intrinsic pathway. The extrinsic apoptotic pathway (▶ Fas/Fas Ligand) is initiated by the trimerization of a target cell's death receptors to their cognate death ligands. The death ligands are a part of the tumor necrosis factor (TNF) family and include TNF-α, Fas ligand (FasL/CD95L), and TNF-related apoptosis-inducing ligand (TRAIL). The death receptors, such as Fas/CD95 and TRAIL-receptor 1, contain death domains that recruit pro-caspase 8 through the protein Fas-associated death domain (FADD), resulting in caspase-8 activation and subsequent activation of the effector caspases 3, 6, and 7 (Kurtulus et al. 2010). While death receptor signaling plays an essential role in lymphocyte homeostasis, its importance has been discussed elsewhere and will not be a major subject of this review.

The intrinsic mitochondrial pathway is initiated by a variety of signals, such as cytokine/growth factor withdrawal, T/B cell receptor (TCR/BCR) crosslinking, and DNA damage (Strasser 2005). These signals alter the expression and activation state of anti- and pro-apoptotic Bcl-2 family members, thereby controlling cell survival. The Bcl-2 family is comprised of anti-apoptotic and pro-apoptotic proteins that have up to four α-helix Bcl-2 homology domains (Youle and Strasser 2008). The anti-apoptotic proteins Bcl-2, Bcl-xL, and Bcl-W contain BH1-4, A1 contains BH1-2, and Mcl-1 contains BH1-3 domains. Genetically deficient mice have revealed roles for Bcl-2 and Mcl-1, but not Bcl-xL, in hematopoietic and lymphocyte survival; roles for Bcl-xL in neuronal and embryonic development and thymocytes, but not peripheral T cells; and roles for Mcl-1 and Bcl-xL in reproductive organ development (Youle and Strasser 2008). These anti-apoptotic molecules are crucial for protecting cells from death driven by pro-apoptotic molecules. Pro-apoptotic Bcl-2 family members contain two major subgroups: (i) the Bax-/Bak-like molecules including Bax, Bak, and Bok which contain BH1-3 domains and (ii) a second larger class of pro-apoptotic proteins (Bim, Bad, Bid, Bmf, Noxa, Puma, Nik, Bik, Hrk) whose only homology to Bcl-2 is a 9–10 amino acid region called the BH3 domain. This BH3 domain is essential for the ability of BH3-only molecules to drive apoptosis. Generation of genetically deficient animals has revealed roles for Bax in sperm cell development; Bim in thymocyte negative selection and peripheral T cell homeostasis; Puma and Noxa in responses to DNA damage stimuli; and Bad, Bim, and Puma in growth factor withdrawal of lymphocytes and other cell types (Youle and Strasser 2008). Although most cell types express multiple Bcl-2 family members, there is a degree of tissue-specific expression, particularly in terms of expression of BH3-only molecules. In addition, recent data suggest there is specificity and hierarchy that governs mechanistic interactions among Bcl-2 family members.

An important hierarchical relationship between pro-apoptotic Bcl-2 family members was uncovered when it was found that the ability of BH3-only proteins to induce apoptosis required the expression of both Bax and Bak (Lindsten et al. 2000; Zong et al. 2001). There are two proposed models that explain Bax-/Bak-like molecule activation (Kurtulus et al. 2010). The first model proposes that BH3-only proteins sequester anti-apoptotic proteins away

from Bax-/Bak-like molecules, inducing their self-oligomerization and activation. The second model proposes that BH3-only proteins interact directly with Bax-/Bak-like molecules and thereby induce their activation. Evidence exists supporting both models, and it is important to note that these models likely are not mutually exclusive, as the cell type and dominantly expressed Bcl-2 family members may govern how apoptosis is initiated. Indeed, one critical study genetically swapped the BH3 domain of pro-apoptotic molecules in knockin mice and demonstrated that both mechanisms are likely involved in initiating apoptosis (Merino et al. 2009). It is also possible that both mechanisms are operative simultaneously in the same cell. Whatever the mechanism, the activation of Bax-/Bak-like molecules drives mitochondrial outer membrane permeabilization and the release of cytochrome c. Cytosolic cytochrome c forms a complex with pro-caspase 9 and apoptotic protease-activating factor-1 (APAF-1) called the apoptosome, leading to caspase 9 activation and subsequent effector caspase activation (Opferman 2008). Both the extrinsic and intrinsic pathways lead to florid caspase activation, which is critical for the morphologic features associated with apoptosis.

Bcl-2 Family Members in T Cell Development, Homeostasis, and Activation

T Cell Development

T cell development in the thymus goes through several checkpoints to ensure that a functional T cell receptor (TCR) is rearranged and that the TCR does not recognize self-antigens with enough avidity to drive overt autoimmunity. Bcl-2 family members play critical roles to ensure only thymocytes that produced a functional TCR with adequate avidity to self-antigen/major histocompatibility complex (MHC) complexes survive. At earlier stages (up to the double-positive (DP) stage), thymocytes are dependent on IL-7 signaling (Peschon et al. 1994). IL-7 may function through multiple mechanisms to promote thymocyte survival as it has been shown to induce expression of Bcl-2 (Kim et al. 1998) and Mcl-1 (Opferman et al. 2003), as well as to inhibit the expression of Bax (Khaled et al. 1999; Kim et al. 1998) and Bad (Li et al. 2004). In mice, transgenic overexpression of Bcl-2 or the loss of Bim can restore thymocyte atrophy in IL-7Rα-deficient mice, suggesting the intersection of IL-7 signaling with prevention of apoptosis in vivo (Akashi et al. 1997; Pellegrini et al. 2004). How IL-7 normally controls pro- versus anti-apoptotic Bcl-2 family member expression/function remains incompletely understood, although some mechanistic details are emerging. For example, it was shown that the loss of Bax could restore early thymocyte development in the absence of IL-7Rα or in mice deficient in Bcl-2 (Khaled et al. 2002). However, in neither of these instances was the absence of Bax able to restore peripheral T cells. Thus, it is likely that Bax plays stage-specific roles in controlling Bim-mediated apoptosis. Indeed, mice deficient in Bax and Bim have a distinct, albeit subtle, thymic phenotype compared to mice deficient in Bak and Bim (Hutcheson et al. 2005). Thus, early in thymocyte development (or at an earlier stage), IL-7Rα/Bcl-2 may counteract Bax and Bim, but at later stages, and in peripheral T cells, Bim may also signal through Bak to promote T cell death. Why there is differential involvement of Bax and Bak at these early stages is unclear, but is likely reflective of Bak function rather than simple lack of Bak expression.

The anti-apoptotic molecule Mcl-1 may be an important clue here, as Mcl-1 can be induced by IL-7 and it regulates the survival of thymocytes at earlier stages (Opferman et al. 2003) by inhibiting Bak-mediated death in a way that is independent of Bcl-2, Bax, and Bim (Dunkle et al. 2010). In support of this model, another study showed that Mcl-1 deficiency-induced neutropenia could be rescued by deletion of Bax and Bak, but not Bim or PUMA (Steimer et al. 2009). These studies suggest a model where Bim and Bcl-2 balance-regulated survival is upstream of Mcl-1 and Mcl-1 inhibits Bak- mediated death in thymocytes.

As thymocytes begin to rearrange TCR-β chain, they go through a process called "β-selection" which requires ligand-independent signaling through a functional pre-TCR for survival and differentiation of thymocytes. Bcl-2 does not protect thymocytes from apoptosis at this stage (Maraskovsky et al. 1997). One other Bcl-2 family protein, A1, has been shown to be induced by pre-TCR signaling (Mandal et al. 2005). Further, knockdown of A1 can decrease survival of pre-T cell lines, whereas its overexpression in $Rag1^{-/-}$ thymocytes can induce development into DP stage (Mandal et al. 2005). Unfortunately, these results could not be confirmed by genetic deletion of the A1d gene in mice, which is abundantly expressed in pre-T cells.

As the cells start to rearrange TCR α chain, they are tested for successful TCR rearrangement. T cells that do not express a functional TCR undergo death by neglect; the ones with high affinity for self-peptide/MHC complexes die by negative selection, and DP thymocytes that are positively selected by proper interactions between TCR and peptide/MHC complexes transit into $CD4^+$ or $CD8^+$ single-positive (Lenschow et al. 1994) thymocytes. During this selection process, survival of DP thymocytes is provided by Bcl-xL (Grillot et al. 1995; Ma et al. 1995; Motoyama et al. 1995; Zhang and He 2005). Overexpression of Bcl-xL protects DP thymocytes from a variety of apoptotic stimuli including anti-CD3 stimulation (Grillot et al. 1995). However, Bcl-xL overexpression does not protect DP thymocytes from negative selection (Chao and Korsmeyer 1997; Grillot et al. 1995). Bcl-2 overexpression, on the other hand, partially rescued DP thymocytes from negative selection as demonstrated in anti-HY TCR transgenic male mice and superantigen-induced deletion models (Strasser et al. 1991a, b). However, Bcl-2 does not restore development of DP thymocytes that fail to be positively selected (Strasser et al. 1994b). This demonstrates the requirement for TCR signals for differentiation and maturation of thymocytes in addition to their survival. While survival is critical for thymocytes at certain stages, simple restoration of survival may not be sufficient to overcome a lack of TCR signals critical for differentiation and maturation of thymocytes.

Negative selection of self-reactive DP thymocytes is critical to prevent autoimmunity. Bim is the critical regulator of the death induced by negative selection. $Bim^{-/-}$ mice have accumulation of lymphocytes in the periphery, and these mice develop spontaneous lymphoid hyperplasia and autoimmunity as they age (Bouillet et al. 1999). Bim deficiency protects DP thymocytes from cell death induced by anti-CD3, Staphylococcus enterotoxin B (SEB) superantigen, or endogenous mouse mammary tumor viral (MMTV) superantigens in vivo (Bouillet et al. 2002). However, the latter result is somewhat controversial as another group found only a partial role for Bim in the negative selection of MMTV-reactive thymocytes (Jorgensen et al. 2007). A possible explanation for this discrepancy may have to do with analysis of the data. For example, thymocytes undergoing negative selection in the absence of Bim downregulate their CD4 and CD8 co-receptors. In most studies these so-called double-negative (DN) cells are excluded from analysis, as most people gate on DP thymocytes to analyze the population of MMTV-reactive cells. However, the majority of MMTV-reactive cells in mice that lack Bim reside in the DN compartment. Similar results in terms of thymocyte negative selection as well as accumulation of aberrant DN cells are observed in mice lacking expression of Bax and Bak. Thus, it appears that, during negative selection, Bim is activated and drives apoptosis of autoreactive thymocytes by activating Bax and Bak. Mechanism(s) that underlie Bim activation are unclear. One component likely involves decreased expression of IL-7Rα along with the Bim antagonist Bcl-2, but another mechanism may involve increased expression of Bim (Liston et al. 2004).

Peripheral T Cell Homeostasis

When single-positive (SP) T cells egress from thymus into the peripheral organs, they are maintained by common γ chain cytokines, mainly IL-7, and TCR-self-peptide/MHC

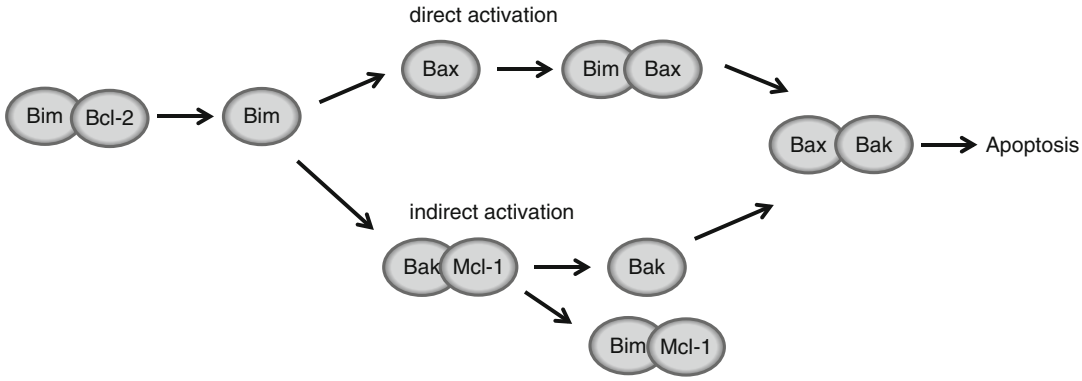
interactions (Surh and Sprent 2008). The downstream targets of TCR signaling that are important for naïve T cell homeostasis remain unclear. However, IL-7 signaling can enhance expression of the anti-apoptotic proteins Bcl-2 and Mcl-1 (Kondrack et al. 2003; Opferman et al. 2003), which are highly expressed in naïve $CD4^+$ and $CD8^+$ T cells (Hildeman et al. 2007). In vitro, IL-7 was unable to fully rescue naïve T cells from apoptosis in the absence of Bcl-2, suggesting that Bcl-2 is downstream of IL-7 signaling and is required for optimal naïve T cell survival (Wojciechowski et al. 2007). In support of this in vitro study, in vivo overexpression of Bcl-2 restores naïve T cell homeostasis in the absence of IL-7R signaling (Akashi et al. 1997; Maraskovsky et al. 1997).

Despite the complex biochemical interactions, genetic models have shown that Bcl-2 is critical for naïve T cell survival through combating Bim. This has been demonstrated using $Bim^{+/-}$ $Bcl2^{-/-}$ mice, which have a dramatic loss in total number of naïve $CD8^+$ T cells, loss that is restored with the deletion of the second Bim allele ($Bim^{-/-}$ $Bcl2^{-/-}$ mice) (Bouillet et al. 2001; Wojciechowski et al. 2007). Interestingly, naïve $CD4^+$ T cells were not as sensitive to the absence of Bcl-2, suggesting an additional anti-apoptotic protein (possibly Mcl-1) is critical in antagonizing Bim in naïve $CD4^+$ cells (Wojciechowski et al. 2007). Indeed, in naïve T cells, Bim has been found complexed to Bcl-2, Bcl-xL, and Mcl-1 (Liu et al. 2006; Opferman et al. 2003). However, deletion of Bcl-xL did not affect naïve T cell survival, although it is unclear if Bcl-xL can function redundantly with Bcl-2 in promoting naïve $CD4^+$ T cell survival. Mcl-1 may also be critical in maintaining naïve T cells, as Mcl-1-deficient mice have reduced peripheral $CD4^+$ and $CD8^+$ T cell numbers (Opferman et al. 2003). A recent paper showed that additional loss of Bak, but not Bim, was sufficient to restore naïve T cell survival in Mcl-1-deficient cells in vitro (Dunkle et al. 2010). Thus, these combined data suggest that Mcl-1 functions to antagonize pro-apoptotic molecules downstream of Bim, while Bcl-2 functions largely to antagonize Bim to maintain peripheral $CD8^+$, and to a lesser extent $CD4^+$, T cell survival.

Apoptosis of Activated T Cells

In an acute infection, T cells that are activated undergo 15–20 rounds of division. When the pathogen is cleared, a massive elimination of the activated T cells occurs through apoptotic cell death (Kawabe and Ochi 1991). Early reports suggested that death receptor signaling is required for this clearance of activated T cells (Brunner et al. 1995; Dhein et al. 1995). It is important to note that all of these models required repetitive TCR stimulation, something that is mimicked by chronic infections/autoimmunity, but not during acute responses. Consistent with this, Fas signaling has been reported to be involved in controlling T cell contraction during chronic infection (Hughes et al. 2008; Hutcheson et al. 2008). However, it remains unclear whether the effects of Fas in these models are T cell intrinsic as recent work suggested that the failure of killing germinal center B cells via Fas could contribute to activated T cell accrual (Hao et al. 2008).

Instead, recent data suggest a dominant role for Bcl-2 family members in the contraction of T cell responses to acute infection (Bouillet et al. 1999; Erlacher et al. 2006; Hildeman et al. 2002). Bim appears to be the major molecule required for the death of activated T cells after acute viral infection. The absence of Bim spares more than 80 % of the activated, effector T cells that die in wild-type mice (Hildeman et al. 2002; Wojciechowski et al. 2006). Similar results have been obtained in mice deficient in both Bax and Bak, suggesting that nearly all of the effects of Bim in this model require Bax and Bak (Rathmell et al. 2002). Although overexpression of Bcl-2 or Bcl-xL was initially reported to not impair contraction in viral infection models (Petschner et al. 1998), expression of the transgenes used in these studies was not robust, particularly when cells were activated. Instead, Bcl-2 was found to be critical for the survival of particular subsets of effector $CD8^+$ T cells (▶ Cytotoxic T Lymphocytes), and it protected them from Bim-mediated death



Bcl-2 Family Members and Lymphocyte Homeostasis, Fig. 1 *Models of Bax/Bak activation*. In T cells, the majority of Bim is found complexed to Bcl-2. Following activation, Bcl-2 is transcriptionally downregulated, freeing Bim to either directly interact with Bax and/or Bak (direct activation model) or titrate pro-apoptotic molecules away from Bax/Bak (indirect activation model). Once activated Bax/Bak oligomerize on the mitochondrial outer membrane and drive outer membrane permeability and apoptosis

(Kurtulus et al. 2011) similar to naïve T cells (Wojciechowski et al. 2007). Interestingly, higher expression of Bcl-2 allowed these effector cells to tolerate higher levels of Bim and survive. Effector cells that had lower levels of Bcl-2 were more susceptible to Bim-driven death and were lost during the contraction of the response (Kurtulus et al. 2011). While Bcl-2 appears to be a fulcrum for setting the sensitivity of effector T cells, experiments examining Bim expression in Bax-/Bak-deficient T cells revealed a massive transcriptional upregulation of Bim. Thus, decreased expression of Bcl-2 coupled with transcriptional increases in Bim likely ensures the demise of most activated, effector T cells.

Besides Bim, a role for Puma in activation-induced cell death has been shown in an HSV infection model; although the effect of PUMA deletion was only marginal (Fischer et al. 2008). T cells from $Bim^{-/-}$ $Puma^{-/-}$ mice were more resistant to cytokine withdrawal compared to those from $Bim^{-/-}$ or $Puma^{-/-}$ mice (Erlacher et al. 2006). However, in vivo, the additional loss of Puma did not significantly increase the survival of Bim-deficient T cells.

In addition to Bcl-2, Mcl-1 is also important for the survival of activated T cells in vitro (Dzhagalov et al. 2008). However, the degree to which Mcl-1 combats Bim to maintain effector T cell survival remains unclear. Similar to thymocyte and neutrophil survival (Steimer et al. 2009), Mcl-1 seems to regulate effector T cell survival by inhibiting Bax and/or Bak independent of Bcl-2 and Bim (Tripathi, unpublished data). The anti-apoptotic molecule A1 is also induced in activated T cells (Hildeman et al. 2007; Tomayko et al. 1999). However, its exact role in activated T cell survival in vivo remains to be determined. Thus, current knowledge suggests a model where T cell activation disrupts the balance between Bim and Bcl-2 and unleashed Bim either directly or indirectly activates Bax/Bak molecules by sequestering away Mcl-1 from Bak (Fig. 1). Activated T cells that can navigate a balance between Bim and Bcl-2 can progress into memory cells.

Memory T Cells

Surviving effector T cells go on to become memory T cells (▶ T Cell Memory); a recent study showed that cells expressing low levels of KLRG-1 but high levels of CD127 are enriched for cells with the potential to differentiate into memory T cells. The transitional survival of these effector T cells required both IL-7 and IL-15 (Rubinstein et al. 2008; Tripathi et al. 2010). IL-2 is also involved in the regulation of the magnitude of the immune response and may contribute at the effector stage to long-term memory survival (Obar et al. 2010; Pipkin et al. 2010;

Williams et al. 2006). All three cytokines have been shown to regulate the expression of Bcl-2 in effector cells (Berard et al. 2003; Blattman et al. 2003; Tripathi et al. 2007), which was shown to be dependent on Stat5 (Tripathi et al. 2010). Utilizing CD127 mutant mice that cannot induce STAT5 phosphorylation in response to IL-7 stimulation, one study has shown that memory $CD8^+$ T cell homeostasis was impaired (Osborne et al. 2007). Although in vitro induction of Bcl-2 expression in response to IL-7 stimulation was normal, in vivo analysis showed low expression of Bcl-2 within T cells. Thus, there is clearly a requirement for IL-7-driven STAT5 activation to maintain normal levels of Bcl-2 and to promote memory $CD8^+$ T cell homeostasis in vivo.

Similar to naïve T cells and subsets of effector $CD8^+$ T cells, memory T cells are also maintained by a balance between Bim and Bcl-2 (Kurtulus et al. 2011; Wojciechowski et al. 2007). Whether other anti-apoptotic molecules play a role in the maintenance of memory T cells is not very clear as it is difficult to confine the effects to the memory stage. Conditional deletion of Bcl-xL in T cells did not suggest a role for Bcl-xL in the effector or memory T cells (Zhang and He 2005). The effects of Mcl-1 deletion in memory T cells could not be studied, as the survival of effector cells was severely impaired which did not allow tracking into the memory stage. Further work needs to be done using inducible knockout mice to determine the critical molecules required to promote memory T cell survival.

Bcl-2 Family Members in B Cell Development, Homeostasis, and Activation

B Cell Development

B cell development in the bone marrow is dependent on B cell receptor (BCR) and IL-7 receptor alpha (IL-7Rα) signaling. Like T cells, B cells undergo V(D)J recombination to form a functional BCR, a process that begins at the pro-B cell stage ($B220^+$ IgM^- $CD2^+$) with the rearrangement of the heavy Ig chain gene (Marsden and Strasser 2003). A properly formed pre-BCR provides critical survival signals, likely combating the pro-apoptotic proteins through Bcl-2 or Bcl-xL, as overexpression of Bcl-2 or Bcl-xL in $Rag^{-/-}$ and SCID mice rescues B cell development (Fang et al. 1996; Strasser et al. 1994a; Tarlinton et al. 1997). However, these mice also displayed reduced B cell maturation, demonstrating that pre-BCR and BCR signaling provides differentiation signals as well as survival signals (Tarlinton et al. 1997).

IL-7 is critical for B cell differentiation at the early stages of development, and in its absence B cell numbers are dramatically decreased in the bone marrow and peripheral lymphoid organs in mice. In the absence of IL-7 or IL-7Rα signaling, Bcl-2 overexpression or genetic deletion of Bim cannot rescue B cell development, specifically during the differentiation of common lymphoid progenitors (CLPs) to pro-B cells ($B220^+$ IgM^- $CD2^-$) and the conversion of pro-B cells into pre-B ($B220^+$ IgM^- $CD2^+$) and immature B cells ($B220^+$ IgM^+) (Maraskovsky et al. 1998; Oliver et al. 2004). However, the absence of Bim can rescue B cell development in the presence of limiting IL-7 (Huntington et al. 2009; Oliver et al. 2004). Thus, IL-7R signaling is required for more than just B cell survival during development; it is required for B cell differentiation by promoting expression of necessary transcription factors for B lineage commitment, such as early B cell factor (EBF) and Pax5, and by promoting BCR rearrangement (Corcoran et al. 1998; Dias et al. 2005; Miller et al. 2002).

The random rearrangement of the BCR is critical for the vast diversity of antigen receptors; however, the random antigen receptor generation allows for potential reactivity to self-antigen. Like T cells, B cells undergo negative selection during development to delete autoreactive cells, and this occurs during the transition from pre-B cell to immature B cell when the cells express a fully rearranged BCR. A double-transgenic mouse model expressing membrane-bound hen egg lysozyme (mHEL) and anti-HEL Ig is commonly used to study self-reactive B cells, and these mice have been used to elucidate the roles of intrinsic and extrinsic pathways of apoptosis. Using this model system, Rathmell and Goodnow

found that chronically HEL-stimulated B cells were eliminated by HEL-specific T cells, while naïve HEL-specific B cells were stimulated to undergo proliferation and antibody production after interaction with HEL-specific T cells (Rathmell et al. 1995). The former process was largely dependent upon Fas/FasL interactions. However, another group found that Bcl-2 overexpression rescued self-reactive B cells from death in vivo, indicating the mitochondrial pathway is involved in autoreactive B cell elimination (Hartley et al. 1993). Genetic deletion of Bim resulted in significantly more HEL reactive B cells in the periphery, albeit still less than mice that did not express the HEL antigen (Enders et al. 2003). These data suggest that either additional BH3-only proteins or Fas are partially redundant with Bim in eliminating autoreactive B cells or that there may be partial contributions of both Bim and Fas. Overall, both Bim and Fas may contribute to B cell central tolerance by mediating apoptotic driven elimination of autoreactive B cells.

B Cell Homeostasis

Immature B cells ($B220^+$ IgM^+) downregulate the expression of IL-7Rα and are no longer as dependent upon IL-7 for survival but instead are dependent on BAFF (B cell activating factor of the TNF family). BAFF is a cytokine critical for B cell activation, maturation, and survival in response to BCR signals and can break anergic B cell unresponsiveness (discussed below) (Batten et al. 2000; Ekland et al. 2004; Mackay and Browning 2002; Oliver et al. 2006). BAFF signals through the NF-κB pathway and has been shown to transiently increase Bcl-xL and A1 expression in mature B cells; however, A1 was not required for BAFF-induced survival (Hatada et al. 2003; Hsu et al. 2002). BAFF may also promote survival by downregulating Bim and increasing Bim phosphorylation through Erk activation (Craxton et al. 2005). Bim phosphorylation may regulate Bim activity by altering its binding to pro-apoptotic Bax (Harada et al. 2004) and/or anti-apoptotic Bcl-2 proteins. Thus, BAFF may function through several redundant mechanisms to counteract apoptosis in B cells.

B cells that escape negative selection during development may be regulated by anergy in the periphery. These anergic B cells have a reduced ability to respond to antigen, mature, and produce antibodies and exhibit a shortened lifespan. Similar to the mouse model of autoreactive B cell elimination, the mouse model for peripheral anergic B cells utilizes the anti-HEL Ig and soluble HEL (sHEL) double-transgenic mice. The Bcl-2 family members can influence the life of anergic B cells, as overexpression of Bcl-2 or Bcl-xL increased the survival of anergic B cells in the periphery, prolonged antibody responses, and elicited onset of autoimmune disease (Hartley et al. 1993; Strasser et al. 1991b). The genetic deletion of Bim in the anti-HEL/sHEL mouse model also increased peripheral B cell survival and promoted maturation of the anergic B cells (Oliver et al. 2006). This increased B cell maturation and increased autoantibody production was due to a reduced threshold requirement for BAFF-mediated maturation, thereby allowing the cells to break anergy (Oliver et al. 2006). Thus, Bcl-2 family members can affect peripheral tolerance/anergy by both affecting survival and BAFF-driven maturation thresholds in B cells.

B Cell Activation

Similar to T cells, B cells undergo expansion in response to an antigen, followed by a contraction of the B cell response and B cell memory development. One model used to look at BCR activation of B cells utilizes SpA superantigen, which binds a conserved V_H domain on BCR and induces activation independent of T cells and antigen processing (Goodyear et al. 2007). There is evidence that Bim mediates the death of superantigen-activated B cells, as Bim-deficient B cells are resistant to superantigen-induced death and exposure to BAFF in vitro ameliorated the superantigen-induced death of Bim-sufficient cells (Goodyear et al. 2007). Additional BAFF signaling may counteract Bim-mediated death by regulating Bim and Bcl-2 expression levels, as well as disrupting Bim-Bcl-2 complexes and inhibiting Bax/Bak activation, thereby promoting cell survival (Batten et al. 2000; Craxton et al. 2005). Bcl-2 is also critical for memory B cell

development in response to alum-adjuvant (NP-KLH) stimulation, as blocking of Bcl-2 by a pharmacological drug, ABT-737, inhibited the formation and maintenance of memory B cells (Carrington et al. 2010). However, whether these effects were due to direct effects of ABT-737 on B cells or were due to effects on T cell help were not clear. Overall, Bim and Bcl-2 may be the critical Bcl-2 family members involved in regulating activated B cell fate downstream of BAFF signaling, but further work is necessary to understand the particular molecules involved.

Conclusion

In summary, Bcl-2 family members are critically involved in different stages of lymphocyte survival. The interplay between Bim and Bcl-2 is the crucial factor in most of these stages. Regulation of downstream Bax/Bak molecules by Mcl-1 is also essential, but functions largely downstream of Bim and Bcl-2. Other Bcl-2 family members also are expressed in the lymphocyte lineage; their roles are either not decisive or function redundantly in lymphocyte survival.

Aberrant expression of anti-apoptotic Bcl-2 family members or loss of pro-apoptotic Bcl-2 molecules could result in loss of immune tolerance. Mouse models have shown that genetic deletion of Bim or overexpression of Bcl-2 can cause lymphoid neoplasia or late-onset spontaneous autoimmune diseases. Therefore, targeting Bcl-2 family members could prove to be useful in treatment of autoimmune diseases. There are BH3 mimetics available that can bind and inhibit a variety of anti-apoptotic Bcl-2 family members that may have therapeutic potential to prevent autoimmunity.

BCR Signaling

Roberta Pelanda
Integrated Department of Immunology, National Jewish Health and University of Colorado School of Medicine, Denver, CO, USA

Synonyms

B cell receptor (BCR) signaling; BCR signal transduction; BCR signaling cascade

Definition

BCR signaling refers to the signal(s) that the B cell receptor transmits into a B cell from the cell surface. This signal is translated into various activities ranging from gene transcription, protein expression, cell survival, mitosis, apoptosis, etc., depending on the type of signal and the context. Two types of BCR signaling have been identified: a basal (also known as tonic) that appears to be ligand-independent, and an antigen-induced that is generated upon the receptor binding to cognate antigen.

Introduction

The B cell receptor and its signaling function are necessary for the development, function, and survival of B cells (Conley et al. 2009). These cells are specialized in making antibodies that react with any type of molecule. With their enhanced specificity and reactivity and their capacity for modulating the activity of other blood cell types, B cells are an effector component of the adaptive immune system and, as such, their development, selection, and activation require proper regulation. This regulation is partly imparted by BCR signaling. BCR signaling has multiple roles depending on the maturation stage of the B cell. During B cell development, BCR signaling guides the maturation of B cells from the B cell precursor stage in the bone marrow to the mature B cell stage in peripheral tissue (Thomas et al. 2006). Genetic mutations that preclude appropriate BCR signaling lead to B cell deficiencies and hypogammaglobulinemia. Between the immature and mature developmental B cell stages, BCR signaling is also important for tolerance induction, directing the selection of B cells such that the majority of cells within the mature B cell pool are specific for foreign molecules and only a minority reacts with self-antigens (Pelanda and Torres 2012). Thus, defects in BCR signaling can result in higher numbers of autoreactive B cells with the potential for autoimmunity. Within mature naive B cells, basal BCR signaling functions to maintain their survival, while antigen-induced BCR signaling promotes their activation and differentiation into effector cells such as memory B cells and antibody-forming cells (plasmablasts and plasma cells) (Thomas et al. 2006; Mackay et al. 2010). Overall, therefore, BCR signaling controls the formation of the B cell and antibody repertoire.

Structural Components of the BCR

The BCR is composed of four B cell–specific proteins: immunoglobulin (Ig) heavy and Ig light chains and the Ig-α (CD79A) and Ig-β (CD79B) polypeptides (Reth et al. 2000; Kurosaki 2011). The Ig heavy and light chains (two each per receptor) pair to form an immunoglobulin or antibody that serves as the antigen-specific portion of the BCR. Each B cell expresses unique Ig heavy and light chain variable sequences that convey the cell specificity for an antigen; the Ig heavy chain contains in addition a transmembrane region that anchors the Ig in the plasma membrane. One Ig-α/Ig-β heterodimer associates with one of the Ig heavy chain in each BCR to form its signaling portion. All four proteins must be expressed for proper BCR assembly and translocation onto the cell surface from where the receptor signals into the cell. Ig-α and Ig-β are transmembrane proteins that contain Immunoreceptor Tyrosine-based Activation Motifs (ITAMs) within their respective cytoplasmic portions. The tyrosine residues within the ITAMs are absolutely required for the transmission of the BCR signaling inside the cell and are the main signaling components of the BCR (Kraus et al. 2001). The Ig heavy chain can also participate in BCR signaling depending on the constant region they display and, specifically, the length of their cytoplasmic tails. While μ and δ constant regions (IgM and IgD receptors) have short (3 amino acids) cytoplasmic tails that are unable to signal, γ, ε, and α (IgG, IgE, and IgA receptors) exhibit extended tails with conserved tyrosines that contribute to BCR signaling.

Signal Initiation

BCR signaling begins when the tyrosine residues of Ig-α/Ig-β ITAMs are phosphorylated by tyrosine kinases (Yang and Reth 2010; Kurosaki 2011). This protein modification activates the BCR signaling cascade inside the cell, but the extent of this signal transduction event depends on the level of ITAM phosphorylation in each receptor and between receptors. Studies performed prevalently in cell lines indicate that the BCR is constitutively associated with tyrosine kinases that, in a naive state (i.e., in the absence of BCR stimulation), display low phosphorylation activities. These basal activities have been proposed to result in a low level of BCR phosphorylation that initiates and maintains the activity of

the tonic or basal BCR signaling cascade (Pierce and Liu 2010). Upon binding antigen, the BCR is rapidly and extensively phosphorylated, an event associated with full activation of the receptor proximal tyrosine kinases and receptor clustering, and leading to the activation of the BCR signaling cascade and its biological consequences. The precise manner by which BCR signal transduction is initiated is not yet fully understood. Relocation of the BCR into specialized plasma membrane regions, specific interactions with the cytoskeleton, and conformational changes are some of the mechanisms under consideration (Harwood and Batista 2010; Pierce and Liu 2010; Yang and Reth 2010).

The tyrosine kinases responsible for the phosphorylation of the BCR and the initiation of BCR signal transduction are the Src family kinases (mainly Lyn, Blk, and Fyn) and the Syk family kinases (mainly Syk). Genetic mutations that lead to the deletion or inactivation of these kinases have severe consequences on B cell development and function, indicating their prominent role in B cell biology (Xu et al. 2005; Conley et al. 2009; Mocsai et al. 2010).

The BCR Signaling Cascade

The BCR proximal tyrosine kinases of the Src and Syk families contain Src homology 2 (SH2) domains with which they dock to the BCR via binding to the phosphorylated tyrosines (Cambier and Getahun 2010; Yang and Reth 2010; Kurosaki 2011). Syk, in particular, contains tandem SH2 domains that dock to the two phosphotyrosines in the ITAM. This binding leads to further activation of the Src and Syk kinases and the recruitment and/or activation of additional elements of the BCR signaling cascade including the BLNK/SLP-65 and BCAP adaptor proteins, the Tec family kinase Btk, and the Vav guanine nucleotide exchange factors, which are all phosphorylated by Syk (Mocsai et al. 2010). Activation of these proximal elements of the BCR signaling cascade leads to activation of further downstream signaling pathways including PLC-γ, Ras, PI3K, and Rac/cdc42 (Thomas et al. 2006; Mackay et al. 2010; Baracho et al. 2011; Kurosaki 2011). The phospholipase C-γ (PLC-γ), an enzyme that hydrolyzes phosphatidylinositol-4,5-biphosphate (PIP_2) into inositol triphosphate (IP_3) and diacylglycerol (DAG), induces extracellular Ca^{++} influx and activation of the NFAT and NF-κB-mediated gene transcriptional programs. The small GTPase Ras family members not only induce the activation of the Mitogen-Activated Protein Kinase (MAPK) Erk pathway, but also contribute to the activation of PI3K and other pathways. The phosphatidylinositide-3-kinase (PI3K) promotes the activation of the Akt and mTOR downstream pathways, while the Rho family GTPase Rac can lead to the activation of the MAPK JNK pathway. Significant cross-modulation exists between these pathways and it involves several types of protein modifications, the most prevalent of which are tyrosine, serine, and threonine phosphorylation (activating or inhibiting depending on the specific protein domain); ubiquitination leading to protein degradation; tyrosine, serine and threonine dephosphorylation by phosphatases; and GTP/GDP exchanges. Downstream pathways of BCR signaling involve DNA binding factors (such as NFAT, NF-κB, Erk, and JNK) that translocate into the nucleus to switch on, switch off, or modulate the transcription of several genes that control changes at the cellular level.

Consequences of BCR Signaling

Tonic BCR signaling in immature B cells leads to the basal activation of the Erk and the PI3K pathways and to the expression of the BAFF cytokine receptor BAFFR that initiates its own signal transduction upon binding BAFF (Werner et al. 2010; Pelanda and Torres 2012). These pathways promote the further differentiation of immature B cells into mature B cells and inhibit Ig gene recombination, establishing allelic exclusion and monoclonal antibody expression. In mature naive B cells, tonic BCR signaling is essential for cell survival, a process mediated via the activities of the

PI3K-Akt pathway and the increased expression of prosurvival Bcl-2 family members (Mackay et al. 2010; Werner et al. 2010; Baracho et al. 2011).

Antigen-mediated BCR signaling has more diverse cellular consequences, depending on the stage of B cell maturation and the type of costimulation. A consequence of antigen-induced BCR signaling is receptor internalization, which in mature B cells provides a mean for internalizing and processing antigens and then present antigen-derived peptides to T cells (Harwood and Batista 2010). At the immature B cell stage of B cell development, the stage at which B cells first express surface IgM, antigen-induced BCR signaling leads to B cell tolerance. This is a process evolved to revise (i.e., receptor editing), eliminate (i.e., clonal deletion), or inactivate (i.e., anergy) B cells that react with self-antigens, thus promoting the formation of a mature B cell pool that is only minimally autoreactive (Shlomchik 2008; Pelanda and Torres 2012). Low levels of antigen-induced BCR signaling, however, are compatible with selection of immature B cells into the mature B cell pool and, in fact, direct entry into specific mature B cell subsets such as the follicular (no signal) and the B1 and marginal zone (low signal) B cell subsets (Thomas et al. 2006).

At the mature B cell stage, antigen-induced BCR signaling causes either B cell tolerance or B cell activation and these differential outcomes depend on the presence of costimulation (Shlomchik 2008; Goodnow et al. 2010). Upon BCR signaling but in the absence of additional stimuli, B cells may undergo initial blasting, but do not further progress in activation and differentiation. In fact, if the BCR signaling is chronic, such as that mediated by a self-antigen, the B cell becomes anergic (i.e., nonfunctional) and eventually dies. In the presence of signals mediated by certain co-receptors, on the other hand, B cells undergo extensive activation characterized by high levels of CD86, CD69, and MHC class II expression. Moreover, these cells undergo proliferation and clonal expansion, and also differentiation into antibody-forming cells and memory B cells. Stimuli that lead to full activation of antigen-binding B cells are those coming from T cells that react with peptides presented by the B cells within the context of a cognate (i.e., antigen specific) interaction. During these close encounters, T cell–expressed CD28 and CD154 bind the CD80/CD86 (also known as B7-1/B7-2) and CD40 co-receptors on B cells, respectively, and IL-4 produced by T cells binds to the B cell IL-4 receptor, and these ligands induce signals essential for B cell activation. Additional T cell-derived signals (e.g., IL-21) further contribute to the successful participation of B cells in germinal center reactions. These reactions include somatic hypermutation, affinity maturation, and class switch recombination of the Ig genes, which lead to the expression of IgG, IgA, and IgE antibodies with higher affinity for the selective antigen. Furthermore, germinal center reactions lead to the differentiation of B cells into memory B cells and short- and long-lived plasma cells.

Antigen-stimulated B cells can also undergo activation and differentiation in the presence of T cell–independent signals (Rawlings et al. 2012; Swanson et al. 2013). For instance, microbe-specific molecules can bind to Toll-like receptors (TLRs) on the surface of B cells, and TLR signaling synergizes with BCR signaling to induce B cell proliferation and B cell differentiation into short-lived plasmablasts and plasma cells.

Modulation and Termination of BCR Signaling

BCR signaling can be further modulated by co-receptor molecules in either a positive or negative manner. Some of these co-receptors are CD19, CD21/35, CD22, CD32 (FcγRIIB), and CD72. Among these, CD19 and FcγRIIB deserve a special mention. CD19 is a positive regulator of BCR signaling and acts at many stages of B cell maturation, during B cell development in the bone marrow and in antigen-specific B cell responses in peripheral tissue (Del Nagro et al. 2005). Tyrosine residues in the CD19 chain are phosphorylated upon BCR signaling mainly by the Src family kinases Lyn and Fyn. These phosphorylation events recruit and activate PI3K, thus

mediating some of the cellular changes associated with the PI3K pathway in BCR-stimulated B cells (Baracho et al. 2011). Moreover, CD19 together with CD21 is involved in the binding of complement, positively modulating BCR signaling in B cells that bind antigen in complex with complement (Del Nagro et al. 2005).

FcγRIIB, an inhibitory member of the Fcγ receptor family, modulates B cell activation upon binding the Igγ constant region of IgG-antigen immune complexes (Nimmerjahn and Ravetch 2010). FcγRIIB signal transduction involves the activation of the tyrosine and phosphatidylinositol phosphatases SHP-1 and SHIP-1, respectively (Cady et al. 2008). These phosphatases decrease the activity of the BCR signaling cascade, negatively modulating B cell activation. In the presence of antigen-specific circulating IgG, a B cell that simultaneously binds immune complexes via the BCR and the FcγRIIB receives both positive (BCR) and negative (FcγRIIB) signals. Only B cells with high affinity for antigen retain enough positive BCR signaling to continue their activation. Thus, CD19 and FcγRIIB play an important role in antibody responses, such that both low affinity cross-reactive as well as high affinity and highly specific antibodies are represented within the repertoire.

Termination of BCR signaling is needed to prevent sustained activation of B cells once the antigen has been removed. Phosphatases such as the SHP-1 and SHIP-1 described above are largely responsible for the termination of BCR signaling that follows antigen-mediated activation, as indicated by the pathological activation of B cells in mice that lack these enzymes (Cambier and Getahun 2010; Waterman and Cambier 2010). However, many other feedback inhibitory pathways exist along the BCR signaling cascade and that ensure that each of the signaling mediators is recalibrated to the baseline activity.

Conclusion

BCR signaling is an indispensable biological process for the generation, survival, and activation of B cells and is, therefore, of crucial importance for adaptive and, particularly, humoral immune responses. BCR signaling is initiated by the BCR, is mediated by a variety of intracellular molecules, and is modulated by several co-receptors. Given its role in regulating B cell development and activation, genetic polymorphisms and mutations that affect its function can result in a broad array of symptoms and diseases including immunodeficiency and autoimmunity.

Definition

Dermatomyositis – Inflammation of the skin and underlying muscle tissue, typically occurring as an autoimmune condition or associated with internal cancer.

Introduction

Dermatomyositis (DM) is an acquired skeletal muscle disease with characteristic skin and extramuscular manifestations and is generally classified as an idiopathic inflammatory myopathy. Though DM has a wide range of phenotypic presentations and clinical overlap with other idiopathic inflammatory myopathies, including polymyositis (PM) and inclusion body myositis (IBM), DM is a distinct disorder with a unique pathophysiology. This entry will review the clinical signs and symptoms, workup, treatment, and prognosis of DM and its subtypes. The immunopathology and pathophysiology of DM is emphasized within the entry, as there has been a rapidly growing body of literature in these areas.

Epidemiology

Dermatomyositis can affect a wide age group with two peaks of onset, including 5–10 years of age and 30–50 years of age. The incidence is roughly 1 per 100,000 annually (Dalakas and Hohlfeld 2003), and it is about twice as common in women than men. There is no racial predilection.

Clinical Signs/Symptoms

Given the considerable clinical overlap between the idiopathic inflammatory myopathies, neuromuscular disorders, and many connective tissue disorders, definitive diagnosis has long been a challenging issue. In 1975, Bohan and Peter created a set of diagnostic criteria for polymyositis and dermatomyositis that included clinical symptoms and signs, muscle pathology, serum biochemical markers, and electromyographic data. With the advent of more advanced

Cancer and Dermatomyositis, Fig. 1 A violaceous hue with periorbital edema is consistent with heliotrope sign of dermatomyositis (Source: Dr. George I. Varghese)

Cancer and Dermatomyositis, Fig. 2 (**a**) Gottron's papules are seen prominently on the MCP joints of the dorsal hands (**b**) Gottron's papules can also be found on the elbows as seen in this African American woman (Source: Dr. George I. Varghese)

immunological research, these criteria have since been modified (Callen 2000; Dalakas and Hohlfeld 2003).

Clinically, the most salient feature that distinguishes DM from other inflammatory myopathies is the skin involvement. It is often the first manifestation and, in a subset of people with DM, can be the sole manifestation as well (Callen 2000). The heliotrope rash, a violaceous macular erythema symmetrically involving the periorbital skin, with or without underlying edema, is pathognomonic for DM (Fig. 1). It may be subtle, only involving the eyelid margin. Gottron's papules, also specific for DM, are raised violaceous papules and plaques with a scaly eruption over the bony prominences of the body, especially the metacarpophalangeal joints (Fig. 2). Poikiloderma is another common feature found in DM that consists of hyperpigmented, variegated, telangiectasias along photosensitive areas of skin, often along the upper chest and back (the "shawl sign").

Other nonspecific cutaneous features that may be seen in DM include malar erythema, violaceous erythema along extensor surfaces, and psoriasiform erythema along the scalp, often associated with non-scarring alopecia (Callen 2000). Telangiectasias at the base of the fingernails and cuticular hypertrophy are common in DM (Fig. 3). Cutaneous lesions less characteristic of DM, but reported to occur, include panniculitis, urticaria, hyperkeratosis of the palms causing a rough and cracked appearance (mechanic's hands), ichthyosis, follicular hyperkeratosis, oral mucosal lesions, and, rarely, erosive vesiculobullous lesions and exfoliative erythroderma (Callen 2000).

Usually, skin findings occur prior to the development of muscle weakness, though it should be noted that this is not an absolute: muscle disease may occur concurrently or even before a rash is evident (Dalakas and Hohlfeld 2003). Muscle weakness is characteristically symmetric, proximal, and slowly progressive. It is often noted by patients as fatigue when performing certain actions, such as climbing stairs, rising from a sitting position, combing one's hair, or reaching for items above one's shoulders. Pain and tenderness in the muscles is actually not commonly seen, occurring in less than 30 % of patients (Dalakas and Hohlfeld 2003).

Cancer and Dermatomyositis, Fig. 3 Thickening of the proximal nail fold with telangiectasias can give an appearance of "ragged" cuticles in patients with dermatomyositis (Source: Dr. George I. Varghese)

A subset of DM, called amyopathic dermatomyositis or dermatomyositis sine myositis, includes cases in which there are typical skin findings of DM but an absence of muscle weakness on exam or history. Ten to twenty percent of patients with DM are amyopathic, and some experts believe that this may actually underestimate the true number (Gerami et al. 2006). The most common associated symptoms are lethargy, fatigue, arthralgias, and photosensitivity (Euwer and Sontheimer 1991). Some researchers contend that there is subclinical muscle involvement in these patients seen on EMG, biopsy, or imaging (e.g., MRI, ultrasound, spectroscopy), suggesting that this subset is in reality just part of the mild end of phenotypic variance seen in dermatomyositis (Dalakas and Hohlfeld 2003). It is difficult to say for certain, however, as patients with no clinical muscle involvement generally do not get further testing and are often diagnosed with amyopathic dermatomyositis on a clinical basis alone. As a practical point, Euwer and Sontheimer (1991) do point out that these tests are not indicated, as they do not affect treatment.

Juvenile dermatomyositis looks, for the most part, like the adult-onset form, though certain characteristics of the disease do set it apart, aside from age of onset (defined as below 18 years of age). Clinical symptoms in children often have an insidious onset and can be nonspecific, including fatigue, irritability, arthralgias, pruritus, and facial flushing. In one study, an extremity rash (usually violaceous to erythematous scaly plaques on extensor surfaces) was the most common initial presentation, followed by the heliotrope rash (Peloro et al. 2001). This study also showed that, in children, scalp dermatitis might be more common than previously thought, affecting 25 % of the cohort studied. Flexion contracture of the ankles, causing a tiptoe gait, is common (Dalakas and Hohlfeld 2003). Calcinosis is a frequent complication in up to 40 % of children but may not develop until later in the course, and might be prevented with early aggressive therapy (Callen 2000). The incidence of malignancy in juvenile DM is much lower than adult DM (Hiketa et al. 1992). An amyopathic form of DM may occur in children as well (Gerami et al. 2007).

There are myriad systemic manifestations of dermatomyositis, many of which are shared with polymyositis. General symptoms may include fever, malaise, and arthralgias. Joints are commonly affected, and symptoms can range from nonerosive joint swelling to joint contractures. Raynaud's phenomenon can be seen with DM. Dysphagia and dysphonia can occur due to involvement of the striated muscles of the oropharynx and upper esophagus. Cardiac findings include conduction defects, dysrhythmias, and myocarditis. Respiratory symptoms may occur from weakness of the thoracic muscles, interstitial lung disease, or pneumonitis and may occur in 15–30 % of patients (Callen 2000). Calcinosis of the subcutaneous tissue is more common in children with DM. On exam, calcifications are seen as firm, yellow, or flesh-colored nodules over bony protuberances; in some cases, they can extrude through the skin, causing pain and ulceration. Rarely, a fulminant clinical course can develop consisting of one or more of the following: diffuse alveolar damage, rapidly progressive interstitial pneumonitis, adult respiratory distress syndrome, and severe vasculopathy causing cutaneous, cerebral, and gastrointestinal infarcts (Magro et al. 2009).

Etiology

The etiology of DM remains unknown and likely multifactorial. Studies have demonstrated a genetic component through an association with certain HLA genes (Dalakas and Hohlfeld 2003), and a tumor necrosis factor polymorphism linked to photosensitivity (Werth et al. 2002). Autoantibodies are certainly linked to inflammatory myopathies, though their etiological significance is uncertain. Viral triggers have been postulated and may interact with an immunogenetic predisposition for developing DM, but no clear proof of causation has been established (Callen and Wortmann 2006; Magro et al. 2009). Some medications including hydroxyurea, quinidine, and penicillamine have been noted to trigger DM-like symptoms (Callen 2000).

Immunopathophysiology

The pathogenesis of dermatomyositis has been studied and discussed, but not fully elucidated, given the complex nature of a disease affecting multiple organ systems. There appears to be both immune and nonimmune-mediated destruction of muscle fibers as well as ischemic vasculopathic changes in both muscle and skin.

To understand DM pathophysiology, it is important to understand what is seen histopathologically. Myofiber alteration with microvascular and secondary ischemic changes provide the basis of the pathology seen in patients with dermatomyositis (Greenberg 2008). Muscle biopsies in DM show perifascicular atrophy and a pauci-inflammatory response surrounding myofibers. Within the perifascicular areas are microinfarcts, consisting of small foci of contiguous necrotic or regenerating fibers. Focal loss of myosin within the perifascicular areas gives the myofibers a "honeycomb-like" appearance. Further studies have shown significant vascular damage playing a role in DM. Capillary damage and dropout occurs early within the perifascicular areas and may be due to a number of factors including endothelial hyperplasia due to abnormal filamentous structures, known as tubuloreticular inclusions, found within capillary endothelial cells, as well as early deposition of complement C5b-9 membranolytic attack complex (MAC) on endothelial cells (Kissel et al. 1986). Inflammatory infiltrates composed of mononuclear cells, including T lymphocytes, B lymphocytes, and macrophages, also contribute to the immune-mediated response in the muscle.

Immune and Nonimmune Pathways in DM Pathogenesis

Adaptive Immune System

The adaptive immune system, composed of the humoral and cell-mediated immune response, has been strongly implicated in DM largely due to the numerous antibodies that bind to specific autoantigens of DM, the presence of an inflammatory infiltrate, and its associations with HLA-DR genotypes and other autoimmune and vascular diseases.

Up to 80 % of patients with either DM or PM have specific autoantibodies or antinuclear antibodies. There are a number of specific antibodies that directly relate to distinct clinical features of the disease. Anti-helicase (Mi2) antibodies show a strong association with the cutaneous findings of DM, including Gottron's papules, heliotrope rash, V-sign, and the shawl sign (Targoff 2006). Aminoacyl transfer RNA (tRNA) synthetases are specific to myositis and are associated with a distinct clinical entity known as antisynthetase syndrome. Its features include myositis, interstitial lung disease, nonerosive arthritis, Raynaud's phenomenon, and mechanic's hands. To date, eight different antisynthetase antibodies have been isolated, the most common being anti-histidyl-tRNA synthetase (anti-Jo1). All the antisynthetase antibodies share a common clinical feature, interstitial lung disease. There are other antibodies that are not specific, but associated with myositis, including anti-snRNP, anti-Ro/SSa, anti-Ku, and anti-PMS1 (Nagaraju and Lundberg 2011).

The humoral immune response is quite prevalent given the number of circulating B cells and plasma cell infiltrates found within muscle in patients with myositis. Antigens, whether

autoantigens or exogenous cross-antigens (viruses or other infectious agents), localized to the muscle may potentially drive a B cell antigen-specific response in myositis (Bradshaw et al. 2007). The pathogenesis of these specific autoantibodies is still unclear because these are not muscle-specific autoantibodies. Rather, they are directed toward ubiquitous intracellular proteins. However, there is evidence that the autoantibodies do show differential organ expression, specifically with histidyl-tRNA synthetase, where there is a higher expression in the epithelial cells of the bronchi related to other healthy organs and conformations within the lung suggesting autoimmunity to histidyl-tRNA synthetase (Levine et al. 2007).

The cell-mediated response occurs through two lymphocytic pathways that drive the immune response in muscle tissue. The first pathway is composed of CD4+ T lymphocytes, B lymphocytes, macrophages, plasma cells, and dendritic cells predominately found in perivascular and perimysial areas of tissue (Dalakas and Hohlfeld 2003). This pathway is primarily directed toward blood vessels creating a vasculopathy. The capillaries are predominately affected as a result of immune-mediated complement deposition in the vessels. Capillaries within muscles decrease in size and may show hyperplasia and necrosis, leading to ischemic changes and subsequent muscle damage. Clinically, the pathology of this pathway is manifested through nail fold telangiectasias seen in DM. The second pathway is dominated by CD8+ T lymphocytes, CD4+ T lymphocytes, macrophages, and dendritic cells found in an endomysial distribution, with inflammatory cells invading non-necrotic muscle fibers (Dalakas and Hohlfeld 2003). This pathway is directed exclusively to muscle fibers and is usually found in patients with myositis without skin rash or polymyositis. CD8+ T lymphocytes recognize major histocompatibility complex (MHC) class I receptors on muscle fibers which may cause muscle fiber damage. There is clonal proliferation of perforin-expressing CD8+ T lymphocytes within the muscle, demonstrating cytotoxicity against autologous myotubules.

Nonimmune Mechanisms

Hypoxia may be involved in DM pathogenesis. It is hypothesized that muscle fatigue in DM is related to local tissue hypoxia, a result of upregulation of vascular endothelial growth factor (VEGF) in muscle tissue. Muscle weakness improves with exercise, which is related to reduced levels of energy substrates, including ATP and phosphocreatine, indicating an acquired metabolic disturbance in these inflammatory myopathies (Grundtman et al. 2008).

MHC class 1 molecules play a critical role in initiating and perpetuating antigen-specific immune responses, by presenting antigenic peptides to CD8+ T lymphocytes and regulating the activities of natural killer (NK) cells. However, MHC class 1 cells also have nonimmune functions involved with synaptic connections of neurons and signal transduction in different cell types (Oliveira et al. 2004). They are generally not expressed, or expressed in low levels, on skeletal muscle cells but can be readily induced by proinflammatory cytokines. Activation of nuclear factor (NF)-kB subsequently activates several target genes including MHC class 1. Mouse models of myositis show that MHC class 1 molecules potentially mediate muscle fiber damage through innate (classical immune) and nonimmune (endoplasmic reticulum stress) mechanisms in the absence of lymphocytes (Nagaraju and Lundberg 2011).

Effector molecules, cytokines, and chemokines, produced by muscle fibers, are thought to contribute to the pathogenesis of myositis. Many proinflammatory cytokines are found in muscle tissue of patients with DM, namely, IL-1 alpha, TNF alpha, type 1 interferon, and HMGB1 protein. IL-1 alpha and HGMB1 are consistently found in inflammatory cells, endothelial cells, and muscle fibers in patients with persistent muscle weakness (Nagaraju and Lundberg 2011). The type I interferon system (including interferon alpha, interferon beta) has been thought to propagate autoimmune diseases by breaking tolerance and has been observed in systemic lupus erythematosus. Similarly, there seems to be a similar mechanism in the muscle and peripheral blood in DM. Type 1 interferons

are strongly associated with anti-Jo-1 and anti-SSA antibodies and correlate with MHC class 1 expression in muscle fibers (Eloranta et al. 2007). HMGB1 is a ubiquitous nonhistone molecule present in all nucleated cells and co-localizes with MHC class 1 cells. In pathogenic muscle fibers, HMGB1 is overexpressed compared to MHC class 1 cells, and in this tissue, there is an irreversible decrease in calcium release leading to a decreased effect of muscle contractility.

Finally, apoptosis of the cells are not seen in muscle specimens of myositis. Instead, necrosis and muscle fiber degeneration are evident histopathologically. Some studies have shown that antiapoptotic molecules are expressed in muscle tissue and mediate other forms of cell death, including endoplasmic reticulum (ER) response and autophagy. The ER stress response is found in patients with myositis due to an overexpression of MHC class 1 molecules in myofibers. Increased expression of ER chaperones, involved in the folding, exporting, and processing of new proteins, may be associated with further muscle fiber damage (Nagaraju and Lundberg 2011).

The pathophysiology of dermatomyositis is complex, and there are multiple interconnected immune and nonimmune mechanisms that work synergistically within the muscle and skin. Further studies are needed to fully explain muscle weakness and damage in DM and other autoimmune myositis conditions.

Workup

Clinical suspicion of DM is confirmed through a variety of tests, including biochemical markers, electromyography, and muscle biopsy. Similar findings are found in both the adult-onset and juvenile forms (Peloro et al. 2001). Creatine kinase (CK) is believed to be the most sensitive and specific marker; it can be elevated up to 50 times normal in active disease (Dalakas and Hohlfeld 2003). In amyopathic DM, however, the CK levels may be normal (Gerami et al. 2007). Other markers may be elevated in DM, including erythrocyte sedimentation rate, aldolase, lactate dehydrogenase, and aspartate/alanine aminotransferases. Elevation of these enzymes may precede clinical evidence of myositis (Mammen 2010).

Findings on EMG confirm destructive myopathy, including spontaneous activity in the form of fibrillation potentials and positive sharp waves, complex repetitive discharges, and polyphasic, short duration, small amplitude motor-unit potentials (Dalakas and Hohlfeld 2003; Bohan and Peter 1975b part 2).

Muscle biopsy in DM shows perifascicular distribution of atrophic, degenerating, and regenerating muscle fibers. A decrease in the number of capillaries is seen, though this is nonspecific, as it is also found in PM (Mammen 2010). Also seen are perivascular and *inter*fascicular inflammatory infiltrates, unlike PM in which one can see *intra*fascicular infiltrates. These lymphocytic infiltrates are primarily B cells with a smaller number of what may be CD4+ cells, though a recent study suggests they might be plasmacytoid dendritic cells (Greenberg 2008).

Skin biopsy typically shows a mild inflammatory infiltrate at the dermal-epidermal junction with vacuolar changes. It may also show perivascular inflammation of T helper cells and membrane attack complex in the dermis. It should be noted that these skin findings are not specific and may be identical in systemic lupus erythematosus (SLE). Increase in dermal mucin may be a diagnostic feature in DM compared to SLE (Smith et al. 2009). Muscle biopsy can distinguish between the two (Mammen 2010).

Myositis-specific autoantibody assays are not routinely performed for diagnostic purposes, as they occur in less than 30 % of DM patients. However, for their prognostic value, these antibodies are indeed often checked during the workup, as they can be associated with various systemic findings that may accompany DM. For instance, anti-Jo-1, associated with antisynthetase syndrome, is a commonly tested autoantibody. Anti-Mi-2 is found in 25 % of DM patients, is specific but not sensitive, and

tends to carry a more favorable prognosis with a decreased incidence of malignancy and a better response to steroid therapy (Targoff 2006). Anti-polymyositis-Scl is associated with the overlap of DM and scleroderma, and Anti-KL6 is associated with interstitial lung disease. Anti-155/140, though only found in 13–21 % of patients with DM, is highly specific for the disease and is associated with a higher rate of malignancy and lower rates of interstitial lung disease (Targoff 2006). The antibody was detected in 23 % of patients with juvenile dermatomyositis.

The association between dermatomyositis and malignancy is well known (Bohan and Peter 1975a part 1; Callen 2001). The risk of having an underlying cancer is significantly higher with DM than with PM (Hill et al. 2001). Studies confirm that there is also a high association of cancer and DM with the amyopathic form as well, though it is possible that the risk is slightly smaller compared to myopathic DM (el-Azhary and Pakzad 2002). Cancer is typically found within 1 year after the DM diagnosis, though many patients had been diagnosed with cancer several years prior to developing DM symptoms, suggesting that there might be a paraneoplastic component to the disease (Mammen 2010). Adenocarcinomas make up the majority of the malignancies diagnosed in association with DM, though there is a broad range of different types. Ovarian cancer is common but may be overrepresented in the literature (Callen 2000). Asian patients with DM commonly have nasopharyngeal cancer (Callen 2002). Most cancers tend to be discovered because of abnormal histories, physical findings, or routine laboratory testing, suggesting that doing a more extensive malignancy evaluation may not be fruitful (Callen 2002). Other studies suggest further imaging, including CT scans and ultrasounds, are in fact justified (Hill et al. 2001; Sparsa et al. 2002). Interestingly, one study showed that elevated CA-125 levels at the time of DM diagnosis was associated with an increased risk of developing cancer over the following 5 years, and this may prove to be a useful biomarker to check when performing a malignancy screen (Amoura et al. 2005).

Treatment and Management

The goals of therapy for DM aim first and foremost to improve muscle weakness and ameliorate skin disease and other systemic symptoms. Further management aims to improve quality of life, as well as routinely evaluate for associated malignancies. Generally, following the patient clinically in terms of muscle strength and dermatological improvement is the best way to determine if a particular treatment is working. Muscle enzymes can be used as a marker of improvement in muscle strength, but this does not always correlate (Miller et al. 1992) and can lead to a problem of "chasing" lab values instead of appropriately treating the patient (Dalakas and Hohlfeld 2003).

First-line treatment is corticosteroids, usually prednisone (Iorizzo and Jorizzo 2008). A typical regimen includes 80–100 mg per day for several weeks followed by a slow taper over 2–3 months. Though many patients respond well to steroids (more so in DM than PM generally), some patients require other medications for various reasons including ineffectiveness of the steroids, inability to taper the steroids without relapse of symptoms, and side-effect complications. Common, and sometimes debilitating, side effects include weight gain, acne, osteoporosis, susceptibility to infection, muscle weakness (steroid myopathy), and glucose intolerance. Prior to starting steroid treatment, one should check for tuberculosis and consider adding medications to prevent *Pneumocystis carinii* pneumonia and osteoporosis (Greenberg 2008).

Second-line treatments include a variety of immunosuppressive medications. Methotrexate is commonly used first among the immunosuppressive agents, often in conjunction with corticosteroids, in particularly severe cases of myositis. Liver toxicity is a concern, and patients with diabetes mellitus should be closely monitored (Iorizzo and Jorizzo 2008). Other immunosuppressants have been used with similar efficacy to methotrexate, though side-effect profiles may limit their long-term use. These include mycophenolate mofetil, azathioprine, cyclosporine, and cyclophosphamide (especially for

interstitial lung disease). Newer treatments such as rapamycin (Nadiminti and Arbiser 2005), anti-TNF agents such as infliximab (Iorizzo and Jorizzo 2008), and leflunomide (Boswell and Costner 2008) have been reported in case studies. A recent Cochrane review summarized IVIG to be the only efficacious systemic immunomodulator compared to placebo after 3 months for refractory DM (Dalakas et al. 1993; Gordon et al. 2012). Case reports have also demonstrated utility in patients with esophageal manifestations (Marie et al. 2010) as well as safety and efficacy when using IVIG to treat a pregnant patient suffering from DM (Mosca et al. 2005). Plasmapheresis, on the other hand, does not appear to be effective (Miller et al. 1992).

When muscle weakness is minimal and skin findings predominate, a different treatment algorithm may be pursued. Simple measures such as sun avoidance and sunscreen help prevent worsening of photosensitive rashes. Though most patients will need systemic therapy to control skin manifestations of DM, topical treatment consisting of moisturizers, antipruritics, corticosteroids, and tacrolimus/pimecrolimus can be tried first (Sontheimer 2004). First-line systemic therapy for dermatologic manifestations consists of antihistamines and 4-aminoquinoline antimalarials (hydroxychloroquine, quinacrine, chloroquine) (Woo et al. 1984). Use of hydroxychloroquine may be limited by a side effect of pruritic cutaneous eruptions (Pelle and Callen 2002). For refractory cases, systemic corticosteroids can be tried, followed by immunosuppressants and IVIG (Sontheimer 2004).

Screening for systemic involvement includes barium swallow, esophageal motility studies, chest X-ray, pulmonary function tests, and electrocardiography. Treatment of gastrointestinal and cardiopulmonary symptoms should be undertaken when appropriate. Physical therapy to prevent joint contractures should not be forgotten. A thorough history and routine examinations for malignancy screening should be done yearly for at least 3 years after diagnosis, with careful follow-up thereafter (Callen 2000, 2002; Sontheimer 2004).

Prognosis

Overall, the prognosis of DM is good. The mortality rate is somewhat unclear due to diagnostic difficulties and methodological limitations in prior studies, but a broad range of 8.9–52 % has been cited, with a lower mortality rate of 0–1.5 % in the juvenile form (Iorizzo and Jorizzo 2008). Certain characteristics portending a poorer prognosis include older age, severe muscle weakness, malignancy, cardiopulmonary involvement, and calcinosis (Marie et al. 2001). One study showed that interstitial lung disease in DM is particularly refractory to steroids, carries a poorer prognosis, and should be treated early with intensive immunosuppressive therapy. The use of corticosteroids or immunosuppressive therapies improves the prognosis (Callen and Wortmann 2006; Iorizzo and Jorizzo 2008).

Cancer and Fever

Marie P. Shieh and Jae C. Chang
Division of Hematology & Oncology, Department of Medicine, Chao Family Comprehensive Cancer Center, University of California Irvine School of Medicine, University of California Irvine Medical Center, Orange, CA, USA

Synonym

Fever in cancer; Neoplastic fever

Definition

A significant fever in patients with cancer is always a serious concern. Though it usually indicates the presence of an infection, a source is sometimes difficult to detect – and is not always found – even after an extensive investigation. This often leaves the caring physician perplexed and concerned. As cancer patients undergo several types of treatments such as antineoplastic chemotherapy, immunotherapy, targeted therapy, radiation therapy, surgery, and blood transfusions, the differential diagnosis for fever can become more complicated and requires a carefully measured evaluation. Among the variety of causes of fever, one of not uncommon etiology is fever of paraneoplastic manifestation, which is a febrile condition occurring as a result of the biologic effects from cancer itself.

Fever that occurs as a paraneoplastic manifestation is seen frequently in Hodgkin's disease and non-Hodgkin lymphomas, acute and chronic leukemias, multiple myeloma, and other solid tumors such as renal cell cancer. This paraneoplastic fever, which is defined as fever caused by cancer itself, has been shown to be the cause of fever of unknown origin (FUO) in approximately 20 % of cases as shown in Table 1 (Jacoby and Swartz 1973; Vanderschueren et al. 2003).

In this entry, several aspects of paraneoplastic fever will be discussed. The aim is to examine the differential diagnosis for various causes of fever with particular emphasis on diagnostic approaches. In addition, clinical characteristics, possible pathogenesis, and management of paraneoplastic fever will be evaluated.

Pathophysiology of Fever

"Pyrogen" is termed to describe any substance that produces fever. The pathogenesis of fever in man begins with the production of endogenous pyrogens by phagocytic leukocytes in response to exogenous pyrogens (i.e., toxins from bacteria, fungi, and yeasts, including endotoxins, exotoxins, and enterotoxins, as well as drugs such as bleomycin and cisplatin). Endogenous pyrogens, which are now known as pyrogenic cytokines, are produced as the result of an infectious as well as inflammatory process in the body. These pyrogenic cytokines are specific cytokines produced upon activation of toll-like

Cancer and Fever, Table 1 Classic causes of fever of unknown origin (FUO) in the general population (Jacoby and Swartz 1973; Vanderschueren et al. 2003)

Category	Percentage of FUO population (%)	Common
Infectious diseases	30–40 %	Tuberculosis, abscesses, osteomyelitis, endocarditis, cytomegalovirus, cat scratch disease
Connective tissue disease	20–30 %	Adult Still's disease, polymyalgia rheumatica, giant cell arteritis, polyarteritis nodosa, systemic lupus erythematosus, late-onset rheumatoid arthritis
Neoplastic disorders	20–30 %	Lymphoma, leukemia, renal cell carcinoma, hepatocellular carcinoma or other tumors metastatic to the liver, primary or metastatic central nervous system tumors
Miscellaneous disorders	15–20 %	Drug fever, alcoholic cirrhosis, Crohn's disease, subacute thyroiditis, factitious fever

receptor (TLR) (Mackowiak et al. 1992), and further regulate immune, inflammatory, and hematopoietic processes.

There are several well-known pyrogenic cytokines which include interleukin (IL)-1, IL-6, tumor necrosis factor (TNF), ciliary neurotrophic factor (CNTF), and interferon-α (IFN-α) (Dinarello 1999; Shapiro et al. 1993). Fever is produced by an interaction between pyrogenic cytokines and specialized receptors on or near thermosensitive neurons in the thermoregulatory center of the anterior hypothalamus. This interaction may cause local hypothalamic production and release of prostaglandins, monoamines, and, possibly cyclic AMP, which are all thought to have a role in fever. From the anterior hypothalamus, information is transmitted through the posterior hypothalamus to the vasomotor center, which directs sympathetic-nerve fibers to constrict peripheral vessels and decrease heat dissipation (Dinarello and Wolf 1978). Some data has suggested that although up to 70 % of patients with cancer have fever, it is more often infection or localized obstruction caused by the tumor that is responsible for the fever in the majority of the cases (Browder et al. 1961).

The pathophysiology of paraneoplastic fever in patients without overt infection or obstruction is still uncertain. However, the mechanism for paraneoplastic fever does seem to be distinct from that for fever due to infection. Research has suggested the involvement of various cytokines. Indeed, cancer cells and the immune system appear to overexpress a range of cytokines such as IL-1, TNF, IL-2, IL-6, IL-12, and interferon in patients with malignancies.

Under normal circumstances, the hematopoietic and immune systems do not produce many of the known cytokines at significant levels. However, cancer cells may produce high levels of cytokines, such as IL-1 or IL-6. Patients with lymphoma have high levels of IL-6 and IL-10. Additionally serum levels of IL-6 have correlated with the presence of B-symptoms in diffuse large cell lymphoma (Seymour et al. 1995). In patients with renal cell carcinomas, increased IL-6 levels have been associated with an increased incidence of paraneoplastic fever as well as shorter survival (Blay et al. 1992; Blay et al. 1997; Kurzrock 2001).

These cytokines can go on to act as autocrine growth factors that stimulate tumor growth and also induce production of other cytokines through the immune system. It is one of the axioms of cytokine research that virtually every cytokine induces many other cytokines and a "snowball" effect occurs once these pathways are deregulated (Kurzrock 2001).

Another mechanism for paraneoplastic fever may be related to inflammation due to tumor necrosis, which some investigators have attributed to the release of TNF and other endogenous pyrogens from dead tissue (Johnson 1996). For example, bone marrow necrosis is due to malignancy in the vast majority of cases, and fever has been documented in 68 % cases of bone marrow

necrosis. Bone marrow necrosis may also cause the release of toxins and cytokines from damaged cells (Janssens et al. 2000).

Infectious fever is produced by a combination of exogenous and endogenous pyrogens that are responsible for prostaglandin-mediated activation of thermoregulatory neurons of the anterior hypothalamic area while paraneoplastic fever is most likely primarily mediated by IL-6 and TNF, which have direct effects to thermoregulatory neurons to elevate body temperature. These differences in pathophysiology may explain not only the different clinical features between fever of infection and fever from malignancy but also the distinctly different response of the two conditions to the naproxen test.

Cancer and Fever, Table 2 Causes of fever in patients with cancer

Causes	Examples
Neoplastic origin	Hodgkin and non-Hodgkin lymphomas, acute and chronic leukemias, multiple myeloma, solid tumors such as renal cell cancer
Infections	Bacterial, fungal, viral, and/or parasitic
Drug reaction	Amphotericin B
Chemotherapy-related	Asparaginase, bleomycin, interferons
Central nervous system metastasis	Hypothalamic involvement, meningeal carcinomatosis
Radiation-induced	Radiation pneumonitis
Endocrine disorder	Steroid-induced adrenal insufficiency or crisis
Blood transfusion reaction	

Fever in Cancer

Fever, whether it presents with or without infection, requires immediate attention in cancer patients because delayed diagnosis and treatment will result in significant morbidity and mortality. Early recognition of a life-threatening infection such as pneumonia or sepsis is crucial. Additionally, the understanding of the cause of a fever and its clinical manifestations will provide timely evaluation and treatment, as well as reduce patient discomfort and unnecessary expenses. The various conditions that can cause fever in patients with cancer are summarized in Table 2.

Neutropenic Fever

In patients with cancer, especially in an immunocompromised and marrow-suppressed state, the most common cause of fever is infection. Infections may be of bacterial, viral, fungal, or parasitic origin. Fever can sometimes be the only manifestation of infection in cancer patients, particularly in those who are neutropenic, because signs and symptoms of inflammation are typically attenuated.

Fever occurs frequently during chemotherapy-induced neutropenia: 10–50 % of patients with solid tumors and >80 % of those with hematologic malignancies will develop fever during one more cycles of chemotherapy associated with neutropenia (Klastersky 2004). For most of these patients, no infectious etiology is documented. Clinically documented infections occur in 20–30 % of febrile episodes, with the intestinal tract, lung, and skin being common sites of tissue-based infection (Freifeld et al. 2011).

Most experts consider high-risk patients to be those with anticipated prolonged (>7 days duration) and profound neutropenia (absolute neutrophil count $\leq$100 cells/mm^3 following cytotoxic chemotherapy) and/or significant medical comorbid conditions, including hypotension, pneumonia, new-onset abdominal pain, or neurologic changes (Freifeld et al. 2011). During the initial assessment, a detailed history should include elicitation of new site-specific symptoms, infection exposures, and prior documented infections. Physical examination of febrile neutropenic patients requires a thorough search to detect subtle signs and symptoms. Close attention to sites which are most commonly infected is warranted. These sites include skin (including sites of procedures or central lines), oropharynx, lungs, and perineum. Laboratory tests should include a complete blood count (CBC) with differential, comprehensive metabolic panel, and at least two sets of blood cultures. In addition,

if clinically indicated, experts also recommend culture specimens from other sites of infection and a chest X-ray.

Patients with cancer and febrile neutropenia after require hospitalization for empiric IV antibiotic therapy. Monotherapy with an anti-pseudomonal B-lactam agent, such as cefepime, is initially recommended. Other antimicrobials may be added to the regimen for management of complications or if antimicrobial resistance is suspected or documented.

Drug Reaction

Another common cause of fever in cancer patients is fever caused by a reaction to drugs. Drugs utilized in the care of patients with cancer fall into two major categories – those used for supportive care and those given to treat the cancer itself (i.e., chemotherapy).

Drugs that are known to cause fever include growth factors such as filgrastim and sargramostim. Allopurinol is an uncommon but important cause of drug fever, as it is frequently used in patients with leukemia and lymphoma to prevent or diminish tumor lysis syndrome. Allopurinol-induced drug fever is often accompanied by hepatotoxicity, deterioration of renal function, severe rash, and eosinophilia (Arellano and Sacristan 1993). Amphotericin B, a parenteral agent often used in cancer patients for broad antifungal coverage, is commonly known to cause fevers, chills, and malaise 15 min to 3 h after infusion. Withdrawal of the offending drug usually results in defervescence within 72–96 h, which helps to confirm the diagnosis, but delays of 5–7 days have been observed.

The most common example of fever as an extension of the pharmacologic effect of the drug is the fever observed following chemotherapy for various solid tumors, lymphomas, and leukemias. Cell necrosis and lysis release various pyrogenic substances from damaged cells. The resulting inflammatory response is also accompanied by cytokine activation of the febrile response. Fever commences 2–3 days after chemotherapy and may last for 1 week or more. This early febrile response usually can be distinguished from febrile neutropenia which rarely develops before the 2nd week after chemotherapy.

Fever can also occur within hours after chemotherapy administration, most likely via other mechanisms. For example, a link between cytosine arabinoside (Ara-C) and fever was described in 1972, but the first systematic description was not until 1981 by Castleberry et al., who coined the term "Ara-C syndrome." Four patients with non-Hodgkin lymphoma and two with acute lymphocytic leukemia (ages 4 and 4 months to 16 years and 6 months) exhibited a unique reaction to intravenously administered Ara-C given alone as a part of the previously reported LSA2-L2 treatment protocol. The syndrome was characterized by fever, myalgia, bone pain, and occasionally by chest pain, maculopapular rash, and conjunctivitis (Castleberry et al. 1981).

More recently, a larger retrospective review was performed of 169 courses of high-dose Ara-C treatment (HDAC) administered to 57 pediatric patients. Fever occurred during 113 of the 169 HDAC courses. The fever began an average of 26 h after the start of the first infusion, with the average peak temperature 39.1 °C. In 12 of the 169 courses, an antibiotic was administered because of suspected sepsis during HDAC. All 12 of these patients had negative blood cultures, and the antibiotics were stopped after 1–3 days without relapse of fever (Ek et al. 2005). Similarly, fever after vincristine administration has also been described (Ishii et al. 1988). Interestingly, all patients were in the maintenance phases of therapy, making apoptotic tumor cells an unlikely source.

The exact mechanism of these fevers is unknown. It was previously demonstrated that pro-inflammatory cytokines such as TNF-α, IL-6, and IFN-γ are released during HDAC and probably mediate the reaction, acting as endogenous pyrogens (Ek et al. 2001). In the case of vincristine-associated fever, Kaufmann and colleagues have speculated that in patients treated with large doses of vincristine, the mechanism of fever may occur due to direct hypothalamic stimulation. However, in both of the above reports, hypersensitivity reactions could not be

ruled out, as symptoms were prevented with corticosteroids.

Hypersensitivity is in fact the most common cause of drug fever (Tabor 1986). Despite a large number of available antineoplastic agents, hypersensitivity reactions are not common except with platinum compounds, epipodophyllotoxins (etoposide), asparaginase, taxanes, and procarbazine (Shepherd 2003). Various mechanisms can cause drug fever, including the formation of circulating antibody-antigen complexes and/or a T cell immune response provoked by a drug or its metabolites. Any one episode may involve multiple antigenic determinants and mechanisms. Fever may be the sole manifestation of a hypersensitivity reaction.

As demonstrated, in most cases of fever associated with antineoplastic agents, the fever is self-limiting and can be prevented or alleviated with premedication. However, in rare cases, hyperpyrexia associated with high mortality can occur. Review of the literature reveals reported cases of fatal hyperpyrexia with bleomycin both in patients receiving the drug for the first time and also in patients who had received previous bleomycin therapy (Carter et al. 1983; Leung et al. 1989; Ma and Isbister 1980). In these cases, patients developed severe rigors and chills, with temperatures rising to as high as 42.5 °C.

Blood Transfusion

Cancer patients may develop a fever as a reaction to receiving a blood transfusion. The most common transfusion reaction is a febrile, nonhemolytic transfusion reaction (FNHTR). The clinical manifestations of this reaction include fever, chills, and sometimes mild dyspnea within 1–6 h after transfusion of red cells or platelets. FNHTRs are benign, causing no lasting sequelae, but are uncomfortable and sometimes frightening to the patient. Furthermore, since fever, with or without a chill, also may be the sign of a severe, acute hemolytic transfusion reaction or infection, FNHTRs cannot be ignored.

The management of FNHTRs should include stopping the transfusion and determining whether or not a hemolytic reaction is taking place as well as administration of antipyretics or meperidine for moderate chills and rigors. Leukoreduction of blood products before transfusion can lessen the reaction (Sirchia et al. 1987). The possibility of fever due to receiving blood products can also be lessened by giving patients acetaminophen or antihistamines before the transfusion.

Paraneoplastic Fever

When an infectious etiology of fever is not detected and noninfectious causes of fever are excluded after careful clinical examination, extensive laboratory, and imaging studies, then paraneoplastic fever should be suspected. It is estimated that paraneoplastic origin is the cause of fever in approximately 10–20 % of both immunocompetent patients and cancer patients.

Fever can be a common presentation with many malignancies. Hodgkin's disease has classically been associated with fever. However, acute leukemia, non-Hodgkin's lymphoma, renal cell carcinoma, bone sarcoma, adrenal carcinoma, neuroblastoma, and pheochromocytoma are also associated with paraneoplastic fever (Pizzo et al. 1982). Solid tumors of the breasts, lungs, and colon do not usually cause paraneoplastic fever, but the presence of liver metastases from these tumors may result in fever (Dalal and Zhukovsky 2006). In addition, any solid tumor causing obstruction can result in fever.

Definition of Paraneoplastic Fever

No clinical features reliably differentiate paraneoplastic fever from fever due to infection, fever associated with collagen-vascular disease, or fever due to other causes. Thus, paraneoplastic fever is often a diagnosis of exclusion, established after a rigorous and thorough work-up of other possible causes of fever in patients with cancer, as discussed above.

Fever due to infection is often characterized by tachycardia, hypotension, and severe chills or rigors. Shock may occur with gram-negative bacteremia. Patients are often in a very toxic state. Proportional tachycardia in response to the degree of fever occurs owing to increased basal metabolic rate and circulatory disturbances.

In contrast, patients with paraneoplastic fever tend to have persistently remittent fevers for long periods of time without much toxic effects though temperatures can be elevated above 40 °C. Chills and tachycardia are infrequent and mild, if present. The usual symptoms are excessive sweating and feelings of warmth. Almost always, paraneoplastic fever is intermittent throughout the day and night. The fever may be short lived or long lasting (Chang 1989). Paraneoplastic fever may persist for more than several months even though complete or partial remission of the cancer is achieved (Chang and Gross 1985).

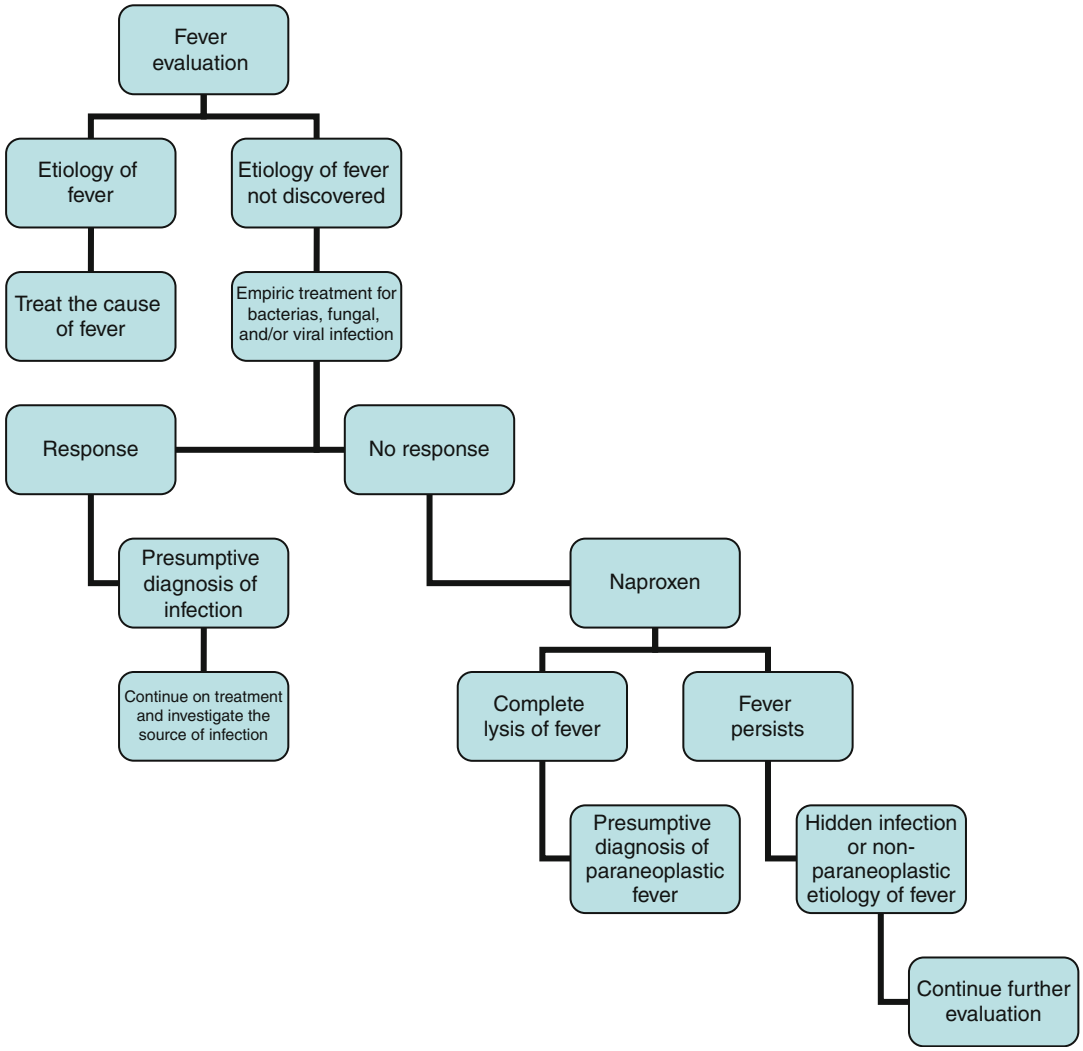
Undoubtedly, establishing the diagnosis of paraneoplastic fever on the basis of clinical findings is difficult. In addition, it should be emphasized that the degree of fever is not a distinguishing feature between infectious and paraneoplastic fevers. Objective methods, other than extensive studies to exclude infections and other causes of fever, have been introduced to help differentiate between fever due to infection and fever due to paraneoplastic fever. The nitroblue tetrazolium test was used to differentiate between fever due to bacterial infection and that due to nonbacterial infection (Feigin et al. 1971; Park et al. 1968). However, this test was later determined to be of uncertain value. In one particular study, the nitroblue tetrazolium test (NBT) showed positive reactions in all of 22 patients with Hodgkin disease and in 9 of 12 patients with malignant lymphoma. No correlation was noted in the degree of NBT reduction, activity of the diseases, presence of fever, leukocytosis, stage of the disease, or treatment modality (Chang et al. 1974).

C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are commonly used nonspecific markers of inflammation. These tests have also been investigated as potential markers for differentiating fever due to an infection from paraneoplastic fever. Kallio et al. studied CRP and ESR levels in 66 hospitalized patients (56 with fever due to infection and 10 with paraneoplastic fever) on admission and compared these levels to follow-up CRP levels on hospital day 5. It was determined that CRP and ESR levels at admission were not clinically useful in differentiating paraneoplastic fever from fever due to infection. Interestingly, follow-up CRP levels were significantly lower in patients with fever due to infection when compared with those for paraneoplastic fever (Kallio et al. 2001). More recently, a systematic review of 90 studies summarized the published evidence for an association between circulating concentrations of C-reactive protein (CRP) and cancer. In most studies, CRP concentrations were found to be higher in patients with cancer than in healthy controls or controls with benign conditions. Of the nine large prospective studies identified in this entry, four reported no relationship between circulating CRP levels and breast, prostate, or colorectal cancers, and five studies found that CRP was associated with colorectal or lung cancers. However, the authors of the entry determined that most of the studies evaluating CRP as a diagnostic marker of cancer did not present relevant statistical analyses and provided no strong evidence for a causal role of CRP in cancer (Heikkila et al. 2007).

Establishing the Diagnosis of Paraneoplastic Fever

For the initial diagnosis of a fever secondary to paraneoplastic cause in a patient with fever of unknown origin, important aspects of the workup should include the careful review of clinical histories of malignancies. Attention should be paid to the presence or absence of night sweats, pruritus after a hot bath or shower, and weight loss – particularly when accompanied by a dramatic decrease in appetite. A thorough physical examination should include evaluation for abnormalities of the cranial nerves, the eyes, the throat, heart murmur, adenopathy, hepatosplenomegaly, sternal tenderness, and bone tenderness (Cunha 2007).

Ascertaining the diagnosis of paraneoplastic fever in patients with an established diagnosis of cancer should also include a careful clinical history and physical examination. In addition, the appropriate laboratory studies and imaging studies should be ordered. After these initial diagnostic steps, the following decision tree is recommended (Fig. 1).



Cancer and Fever, Fig. 1 Proposal for the diagnosis of paraneoplastic fever in patients with cancer (Adapted with permission from Chang 1989)

While awaiting laboratory results, empiric treatment with standard broad-spectrum antibacterial agents, combined with or without antifungal agents and vancomycin in certain circumstances, is warranted for at least 7 days. During this time, the clinical response and the febrile response should be followed closely. If the patient has an improved clinical response, the antibiotic therapy should be continued, even if a source of infection has not been identified (Zell and Chang 2005). If no resolution of fever occurs after empiric antibiotics and there are no contraindications (i.e., severe thrombocytopenia or allergy to nonsteroidal anti-inflammatory medications), the naproxen test can be initiated with 375 mg orally every 12 h, for at least a 36-h period (Chang 1989). The complete resolution of fever indicates a positive response to the naproxen test, which would establish a presumptive diagnosis of paraneoplastic fever. A summary of proposed criteria for establishing the diagnosis of paraneoplastic fever is shown in Table 3 (Zell and Chang 2005).

Cancer and Fever, Table 3 Proposed criteria for neoplastic fever (Adapted with permission from Zell and Chang 2005)

I. Temperature >37.8 °C at least once daily
II. Duration of fever over 2 weeks
III. Lack of evidence of infection on the following:
A. Physical examination
B. Laboratory examinations, e.g., cultures from blood, sputum, urine, stool, spinal fluid, pleural fluid, bone marrow, and discharge from local lesions
C. Radiologic examinations, e.g., chest radiographs, computerized tomography of the head, chest, abdomen, and pelvis
IV. Absence of allergic mechanisms such as drug allergy (including chemotherapy), transfusion reaction, and radiation
V. Lack of response of fever to an empiric, adequate trial of antibiotic therapy for at least 7 days
VI. Prompt and complete lysis of fever after the naproxen test, with sustained normal temperature while receiving naproxen

The Naproxen Test

The naproxen test was first described by Chang and Gross in 1984 as a reliable method in assisting in the differential diagnosis of infectious fever and paraneoplastic fever in patients with cancer and fever of undetermined origin. Twenty-two patients with cancer and fever of undetermined origin for more than 7 days were treated with naproxen 250 mg twice daily to control fever when there was no evidence of infection after a careful evaluation. Moreover, in most of these cases, antibiotic therapy had failed to resolve fevers. In this report, 14 of 15 patients with paraneoplastic fever had a complete, sustained lysis of fever while being treated with naproxen. None of five patients with infectious fever had responses to naproxen. In those patients with paraneoplastic fever, lysis was complete within 24 h, and the afebrile state continued as long as the patients were maintained on naproxen (Chang and Gross 1984).

Other nonsteroidal anti-inflammatory drugs such as indomethacin, ibuprofen, and diclofenac have also been shown to be useful in treating paraneoplastic fever. In a randomized trial of naproxen, indomethacin, or diclofenac used to ameliorate cancer-induced fever, all three drugs were equally effective in bringing the temperature down to normal. Naproxen had the most rapid effect (Lusch et al. 1968; Tsavaris et al. 1990).

Corticosteroids have been shown to cause suppression of fever caused by various etiologies, including allergic reactions, collagen-vascular diseases, and malignancy. The antipyretic effect of corticosteroids was compared to naproxen for treating paraneoplastic fever (Chang 1988). In a retrospective study of 39 patients with advanced cancer and established diagnosis of paraneoplastic fever, treatment with naproxen led to defervescence in 36 patients. Twelve of these patients also received corticosteroids at another time; all had previously responded with complete lysis of fever to naproxen. Corticosteroids induced complete lysis in only six of these patients. Though the sample size was small, these observations suggest that naproxen is more effective than corticosteroids as an antipyretic agent in the management of paraneoplastic fever.

Utility of the Naproxen Test

Follow-up data on the efficacy of the naproxen test included a total of 68 cancer patients with FUO. Statistical analysis of these data provides insight into the value of the naproxen test. In the previously mentioned report, the prevalence of paraneoplastic fever was 74 % (50 of 68 patients). The other patients described included those with infectious fever, autoimmune disease-related fever, and radiation-related fever. In the group of patients with paraneoplastic fever, 46 had complete responses, two had partial responses, and two patients had no response to naproxen. Of the 13 patients with infectious fever, all but one had no response to naproxen (Chang 1987).

Based on this data, the sensitivity and specificity of the naproxen test has previously been calculated: sensitivity is 92 % (95 % CI, 80–97 %), specificity is 100 % (95 % CI, 78–100 %), the positive predictive value is 100 % (95 % CI, 90–100 %), and the negative predictive value is 82 % (95 % CI, 59–94 %). Therefore, in a patient with a high clinical suspicion of paraneoplastic fever, the naproxen test

is highly predictive of true paraneoplastic fever (Zell and Chang 2005).

Given the high specificity of the test, if naproxen administration fails to result in complete defervescence of the patient, other etiologies need to be sought. It is still possible that a hidden or masked infection, for example, may be present. A meticulous work-up should be continued.

As an example, a 63-year-old Filipino male was undergoing treatment for acute myeloid leukemia at the local academic institution. Prior to induction with standard idarubicin and cytarabine chemotherapy, he was afebrile. However, on day #16 status-post chemotherapy, when pancytopenia had developed, the patient began to have daily fevers, as high as 39.3 °C. An extensive work-up for an infectious etiology included blood, urine, and sputum cultures, as well as computed tomography (CT) imaging of the chest, abdomen, and pelvis. Broad-spectrum antibiotics were started immediately. And yet, fevers persisted. A bone marrow biopsy performed on day #25 showed no evidence of leukemic cells. At that time, the patient was given naproxen 375 mg q12 h for 3 days. However, fevers continued, which prompted further work-up, including a lumbar puncture and transesophageal echocardiogram – neither of which revealed an infectious source. He felt clinically well, aside from poor appetite.

He did have notable findings of rising liver function enzymes. Finally, approximately 1 month after his daily fevers began, the patient underwent laparoscopic exploratory laparotomy. The surgeons noted white nodules on the gallbladder and spleen and biopsied several sites. One week later, these biopsies grew mycobacterium in culture. He had defervescence soon after treatment was initiated with ritampin, isoniazid, pyrazinamide, ethambutol (RIPE) and clarithromycin (Fig. 2).

In this complicated case, the patient's fevers could easily have been attributed to his leukemia. However, the negative naproxen test prompted the treating physicians to continue a painstaking search for a cause of fevers, ultimately requiring an invasive procedure for diagnosis. Without the naproxen test, the patient might have gone on to receive consolidation chemotherapy, putting him at great risk in the setting of serious occult infection.

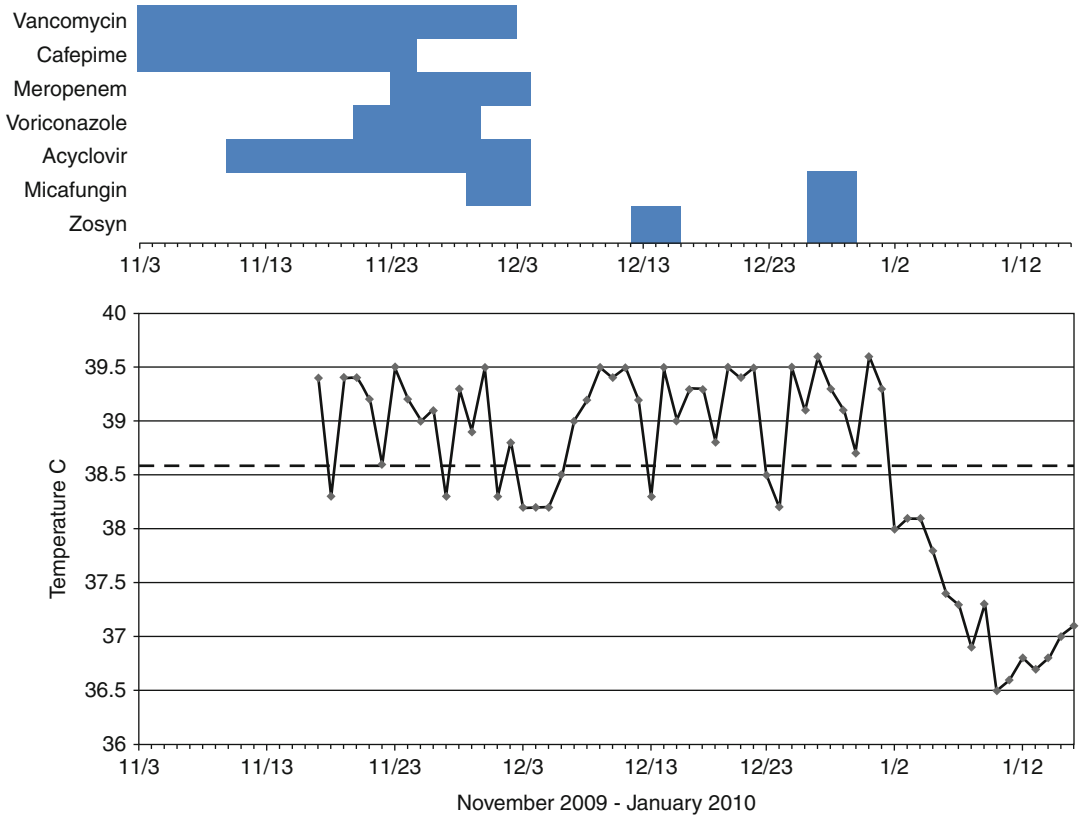
The usefulness of the naproxen test has been confirmed by others in patients with paraneoplastic fever associated with gynecologic malignancies. In one study, naproxen (250 mg orally every 8 h) was given to 12 patients with daily fevers for at least 3 days and negative work-up for infection. Within 24 h of starting naproxen therapy, 10 patients' fever responded, with subjective improvement in patient malaise and fatigue. Two patients did not respond to naproxen therapy in 24 h; thus, it was stopped and the fever work-up was continued. Of these two patients, one was eventually diagnosed with bacteremia after multiple negative blood cultures and initially no response to antibiotics (Economos et al. 1995).

Palliating Paraneoplastic Fever

Fever in patients with cancer can be extremely troubling. It is often associated with fatigue. In addition, as illustrated in the above case, fever with an unknown source demands thorough clinical examinations and a myriad of diagnostic tests which do not always carry a benign risk. Disease-specific chemotherapy may alleviate paraneoplastic fever, if the tumor is responsive to the treatment.

These findings indicate that nonsteroidal anti-inflammatory drugs can provide safe and effective palliation for distressful paraneoplastic fever as well. If naproxen is used, clinicians need to be mindful of weighing the symptomatic benefits against possible side effects such as gastritis and gastrointestinal bleeding. In addition, naproxen is to be used with caution in patients with thrombocytopenia. Other relative contraindications for naproxen use may include cardiac, renal, and hepatic dysfunction.

In some patients, paraneoplastic fever will recur if naproxen is discontinued after a short-term treatment. In a study of recurrent fever in patients with paraneoplastic fever, though naproxen induced sustained fever lysis in some



Cancer and Fever, Fig. 2 Febrile course of a 63-year-old male with acute myelogenous leukemia. Following induction chemotherapy, the patient as expected became pancytopenic but also developed unexplained fever for more than 1 month. The naproxen test on December 1 did not result in resolution of fever, prompting further work-up. After diagnosis of tuberculosis, treatment was initiated on December 29 (Figure courtesy of M. Bryan Shieh)

patients, the fever returned to pretreatment levels in a small subset of patients after naproxen withdrawal. This recurrence typically happened within 24 h after withdrawal. A detailed history taking may reveal the patient has not been compliant with naproxen. Retreatment typically results in complete and sustained fever lysis. However, if the fever is not resolved, reevaluation for infection and other causes is necessary.

Conclusions

Patients with cancer often have complicated medical courses. They can be plagued by symptoms and side effects not only from the primary malignancy but from the cancer treatment itself – whether the modality is antineoplastic, immunologic, targeted, or radiation therapy. If fever occurs, the differential diagnosis will be broad and the treating physician must work carefully through the complexities of the case to come to a solution. Especially in the case of febrile patients with cancer, establishing the correct etiology to fever in a timely manner is paramount to reducing morbidity and mortality.

As the majority of fever in cancer patients is related to infection, thorough clinical evaluations and microbiologic studies should be able to provide the diagnosis; appropriate antibiotics would resolve the fever. However, some patients do not

have responses to antibiotics, and an infectious cause cannot be identified. In these situations, it will be crucial to be able to differentiate infectious fever from paraneoplastic fever.

In difficult circumstances, the naproxen test is an additional useful agent when working through the differential diagnosis of a febrile cancer patient. This inexpensive and relatively safe medication produces complete lysis of paraneoplastic fever. It can be both a valuable diagnostic and therapeutic tool for physicians confronting fever of unknown origin.

Cancer and Joint Pain

Jochanan E. Naschitz
Faculty of Medicine, the Technion-Israel Institute of Technology, Haifa, Israel,
The Flieman Hospital, Haifa, Israel

Definition

Musculoskeletal disorders associated with malignancy may be classified as due to (A) direct tumor involvement of bones, joints, and muscles; (B) paraneoplastic syndromes; (C) altered immune surveillance; and (D) adverse reactions to anticancer therapy. Paraneoplastic rheumatic disorders are those cancer-associated rheumatic syndromes that occur at a distance from the primary tumor or metastases, and induced by the malignancy through hormones, peptides, autocrine and paracrine mediators, antibodies, and cytotoxic lymphocytes. Paraneoplastic rheumatic disorders may precede the diagnosis of the underlying tumor, occur at the same time as the tumor becomes manifest, or arise when metastases develop. In contrast to paraneoplastic syndromes, malignant transformation in the course of certain rheumatic disorders is the result of immune dysregulation; the time interval between the onset of the rheumatic disorder and diagnosis of the secondary malignancy may be as long as 20 years (Naschitz 2001; Andras et al. 2006).

Diversity of Clinical Syndromes

An expanding array of rheumatic disorders is associated with cancer (Naschitz 2001; Andras et al. 2006; Naschitz and Rosner 2008), ranging from the well-established connections with hypertrophic osteoarthropathy, cancer polyarthritis, dermatomyositis, and palmar fasciitis with polyarthritis to various more recently described associations (Table 1). Clinically, it may be difficult to distinguish paraneoplastic rheumatic disorders from direct involvement of the articular and periarticular structures by tumor.

Cancer and Joint Pain, Table 1 The spectrum of paraneoplastic rheumatic disorders[a]

Arthropathies
Local articular involvement by cancer
Rheumatoid arthritis
Cancer polyarthritis
Hypertrophic arthropathy
Polymyalgia rheumatica and atypical polymyalgia rheumatica
Palmar fasciitis and arthritis
Gout
Relapsing polychondritis
Remitting seronegative symmetrical synovitis with pitting edema
Sacroiliitis
Adult-onset Still's disease
Muscular disorders
Dermatomyositis, polymyositis, and dermatomyositis sine myositis
Localized nodular myositis
Necrotizing myopathy
Lambert-Eaton myasthenic syndrome
Scleroderma, panniculitis, and fasciitis
Systemic sclerosis
Eosinophilic fasciitis and fasciitis-panniculitis syndrome
Erythema nodosum
Panniculitis-arthritis
Vasculitides
Miscellaneous rheumatic syndromes
Reflex sympathetic dystrophy
Sjogren's syndrome
Osteomalacia
Skeletal hyperostosis
Antiphospholipid antibody syndrome
Cryoglobulinemia
Erythromelalgia

[a]Adopted from Naschitz (Naschitz 2001)

Evidence of Causality

Interpretation of causal determinism between malignancy and rheumatic disorders is affected by a number of potential sources of error. First, small series of patients are biased toward a positive association. Second, when patients, but not controls, are drawn from a hospital referral population, a "Berkson's bias" may be present, in which the possibility of referral of a patient with both a primary rheumatic disorder and malignancy is much higher than for a patient with a rheumatic disorder alone. Third, ascribing causality based only on the statistical strength of an association between two disorders, as illustrated by standardized incidence ratio (SIR) or odds ratio (OR), may be misleading, because a mere connection between two disorders does not prove causality. An association between two disorders may occur by chance or may reflect a causal relationship other than the one it suggests. For evaluation of a causal relationship between cancer and rheumatic disorders, beyond the strength of the association, additional features of the relationship need to be assessed. Sir Austin Bradford Hill proposed criteria to establish an argument of causation, and these criteria have since been widely applied (Villa et al. 2000; Hill et al. 2001).

Bradford Hill's criteria have been summarized as including (1) the demonstration of a strong association between the causative agent and the outcome; (2) consistency of the findings across research sites and methodologies; (3) the demonstration of specificity of the causative agent in terms of the outcomes it produces; (4) the demonstration of the appropriate temporal sequence, so that the causative agent occurs prior to the outcome; (5) the demonstration of a biological gradient, in which more of the causative agent leads to a poorer outcome; (6) the demonstration of a biologic rationale, such that it makes sense that the causative agent causes the outcome; (7) coherence of the findings, such that the causation argument is in agreement with what we already know; (8) experimental evidence; and (9) evidence from analogous conditions.

These nine Bradford Hill criteria give a measure of the degree in which evidence of causality between a factor and a disease may be established. However, there is no accepted scoring system of the Bradford Hill criteria. Temporal relationship is the only absolutely essential criterion, inasmuch as exposure always precedes the outcome. Clinical judgment is important when considering the guidelines together. In spite of their inherent limitations, the Bradford Hill criteria have been extensively utilized for differentiating causality from association. Two studies

applied the Bradford Hill criteria to cancer-associated musculoskeletal disorders (Naschitz and Rosner 2008; Villa et al. 2000).

Paraneoplastic Rheumatic Syndromes

In applying the Bradford Hill criteria to the association of rheumatic syndromes with cancer, Villa et al. (Villa et al. 2000) found good evidence that solid tumors are determinants of dermatomyositis (based on temporality, strength, consistency, plausibility, coherence, and analogy). The evidence that solid tumors are determinants of polymyositis was not convincing (only temporality, plausibility, coherence, and analogy criteria were satisfied).

The literature abounds in case reports and small case series describing associations between musculoskeletal disorders and cancer. However, the available database is usually insufficient for statistical analysis or judgment of causality based on Bradford Hill criteria. Based on clinical impression, but not yet supported by sufficient evidence, the following rheumatic syndromes may be paraneoplastic in nature: hypertrophic osteoarthropathy, cancer polyarthritis, palmar fasciitis and polyarthritis, and relapsing seronegative symmetric synovitis with pitting edema (Naschitz 2001; Andras et al. 2006; Guegan et al. 2006; Liozon et al. 2006).

Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy is a prototype of rheumatic paraneoplastic syndrome (Naschitz 2001; Andras et al. 2006). The syndrome consists of clubbing of the phalanges; stiffness and swelling of joints, especially the wrists, ankles, and interphalangeal articulations; evidence of periosteal and subperiosteal new bone formation along the shaft of long bones and phalanges on radiographs; and increased vascular endothelial growth factor (VEGF) in the blood. Approximately 90 % of cases are paraneoplastic, with the remaining cases found in association with conditions such as pulmonary fibrosis, endocarditis, Graves' disease, and inflammatory bowel disease. Hypertrophic osteoarthropathy is associated with bronchial carcinoma, lung metastases, and pleural mesothelioma. Resection of the tumor is often followed by remission of the arthropathy and decrease in plasma VEGF. Other treatment options include bisphosphonates, opiate analgesics, nonsteroidal anti-inflammatory drugs, and localized palliative radiation.

Cancer Polyarthritis

Cancer polyarthritis arises predominantly in the elderly and may be oligoarticular or polyarticular, sometimes resembling adult-onset Still's disease or rheumatoid arthritis. Cancer polyarthritis differs from typical rheumatoid arthritis by generally occurring in elderly patients, having an explosive onset, being more often seronegative and asymmetric, and having no family history of rheumatoid arthritis. The lower extremities are usually involved, sometimes with sparing of the small joints of the hands and wrist. The patient does not exhibit rheumatoid nodules. Cancer polyarthritis is often refractory to conventional treatment such as NSAIDs and steroids. Lung cancer is the most common association. The onset of arthritis can precede the diagnosis of cancer by several months. Remission of the arthritis after successful treatment of the neoplasia is the post factum proof of the paraneoplastic nature of the arthritis. Only a few case series of patients with paraneoplastic arthritis have been published. A recent nationwide study from France recruited 26 patients, with a mean age 57.5 years. All had symmetrical polyarthritis involving wrists and hands (85 %). Extra-articular symptoms occurred in 84 %. There was no specific biologic or radiographic feature. The delay between the diagnoses of rheumatism and neoplasia was up to 21.2 months, with a mean of 3.6 months. Tumors were usually diagnosed after articular symptoms occurred (88.5 %). Twenty patients had a solid cancer, usually pulmonary adenocarcinoma, and six had a hematological malignancy. The tumors were diagnosed at an early stage, which may explain the relative long median survival of 1.21 years, with a mean follow-up of 1.9 years. The percentage of resolution of the articular symptoms is higher in patients with solid tumors, as compared to patients with hematological malignancy. In cases of tumor relapse, the rheumatic symptoms did not recur (sic) in 75 % of patients (Morel et al. 2008).

Palmar Fasciitis and Polyarthritis Syndrome

Palmar fasciitis ranges from diffuse globular swelling with warmth and erythema to Dupuytren's contracture. Rheumatoid factor and antinuclear antibodies are negative. This syndrome was described in association with carcinoma of the ovary, endometrium, stomach, breast, prostate, chronic lymphocytic leukemia, and Hodgkin's disease. The shoulders, metacarpophalangeal, and proximal interphalangeal joints are involved. Magnetic resonance imaging and biopsy of palmar nodules reveal inflammation and fibrosis. Anti-inflammatory treatment is usually ineffective. The rheumatic syndromes may precede tumor diagnosis by months. The tumors are often rapidly progressive. Improvement in palmar fasciitis and inflammatory arthritis often occurs following successful treatment of the ovarian carcinoma. Digital contractures, however, may persist. Gynecological examination is warranted in any woman presenting with the sudden onset of unexplained hand pain, palmar inflammatory fasciitis, palmar fibromatosis, and digital contractures (Martorell et al. 2004).

Relapsing Seronegative Symmetric Synovitis with Pitting Edema Syndrome (RS_3PE)

Relapsing seronegative symmetric synovitis with pitting edema syndrome sometimes occurs in association with malignant diseases. The symptoms appear in the form of arthritis and edema surrounding the metacarpophalangeal and interphalangeal joints and wrists. Rheumatoid factor is negative. The patients are generally elderly and male. The associated malignancy may be T cell lymphoma; myelodysplastic syndrome; colon, lung, gastric, prostate, or undifferentiated pelvis cancer; and endometrial carcinoma. In the paraneoplastic forms, symptoms typically are severe and do not respond to the established treatment. Systemic symptoms, such as fever and weight loss, often occur (Naschitz 2001; Guegan et al. 2006).

Relapsing Polychondritis

Relapsing polychondritis is a rare, chronic, inflammatory disease, with episodes of inflammation of the cartilage in the nose, ears, tracheobronchial tree, and joints. It has been reported in association with myelodysplastic syndromes, possibly as an immune response against type II collagen. There have been a few reported cases of relapsing polychondritis associated with malignant lymphoma (Yanagi et al. 2007).

Atypical Polymyalgia Rheumatica

Studies reporting cancer risk after polymyalgia rheumatica and temporal arteritis are few. Between 1965 and 2006, among 35,918 patients hospitalized for polymyalgia rheumatica and temporal arteritis, 3,941 patients developed subsequent cancer, giving an overall SIR of 1.19; for cancer diagnosed later than 1 year of follow-up, the SIR was 1.06. Hence, a marginally increased risk of cancer was noted in the first year after hospitalization (Ji et al. 2010). Clinicians should consider the possibility of underlying cancer in certain instances of polymyalgia rheumatica, although prospective studies do not suggest a general excess incidence of malignancy (Naschitz 2001; Andras et al. 2006). Atypical features such as young age, asymmetrical symptoms, relatively low erythrocyte sedimentation rate, and poor response to corticosteroid treatment should raise the suspicion of bone metastases as the cause of the patients' symptoms that resemble polymyalgia rheumatica.

Malignant Transformation During of Rheumatic Disorders

In contrast to the limited evidence of the occasional paraneoplastic nature of rheumatic syndromes, there is adequate support for the causal determinism between chronic inflammatory disorders and subsequently occurring malignancies.

The Risk of Neoplasia in the Course of Rheumatoid Arthritis

Large population-based studies have found little evidence of an increased risk of carcinoma in rheumatoid arthritis (Ekstrom et al. 2003; Bernatsky et al. 2006). The risk of cancer of the lower gastrointestinal tract may be decreased, possibly attributable to nonsteroidal anti-inflammatory drugs. On the other hand, there is an increased risk for lymphoma occurring late in

the course of rheumatoid arthritis. The largest study supporting this association involved 76,527 patients identified through the Swedish hospitalization database between 1964 and 1999 (Ekstrom et al. 2003). Five hundred and thirty five cases of lymphoma were identified, yielding SIR 2.00. Wolfe found SIR 1.9 for lymphoma among patients with rheumatoid arthritis recruited from rheumatology practices. Using population-based linked registry data from Sweden and Denmark, Landgren found an increased risk of non-Hodgkin lymphoma in patients with rheumatoid arthritis (OR 2.7). In the analysis by Villa et al. (Villa et al. 2000), six Bradford Hill criteria supported determinism of lymphoma by rheumatoid arthritis, including strength, consistency, temporality, plausibility, coherence, and analogy.

Recent studies addressed the pathogenesis of lymphoma during the course of chronic inflammation in general and rheumatoid arthritis in particular (Bernatsky et al. 2006). Nearly all B cell non-Hodgkin lymphomas express the B cell receptor, suggesting that chronic antigen stimulation plays a central role in their emergence. Failure of the antigenic stimulus to subside, as occurs with endogenous autoantigens or with persistent infections, can increase the chance of B cell transformation. Other examples of chronic stimulation by antigens leading to lymphoma include hepatitis C, Helicobacter pylori, and Epstein-Barr virus.

Methotrexate treatment has been linked to lymphomas, often Epstein-Barr virus positive, characterized by spontaneous regression once methotrexate is withdrawn. In patients who were treated by methotrexate for rheumatoid arthritis and developed non-Hodgkin's lymphoma, remission can be observed following methotrexate withdrawal, especially in non-Hodgkin's lymphoma with latency type III Epstein-Barr virus infection. The analysis of Epstein-Barr virus infection, including the latency types, might be useful to decide the optimum therapeutic strategy (Miyazaki et al. 2007). There is also data suggesting an increased risk of malignancies in rheumatoid arthritis patients who were treated with anti-TNF antibody (Breedveld et al. 2006).

Ankylosing Spondylitis

The association between ankylosing spondylitis and malignant lymphomas was assessed in a nationwide, population-based, case–control study of 50,615 cases of lymphoma, and 92,928 matched controls, by using prospectively recorded data on lymphomas from the Swedish Cancer Register (1964–2000) and data on pre-lymphoma hospitalizations for ankylosing spondylitis from the Swedish Inpatient Register (1964–2000). There was no increased risk of lymphoma among patients with ankylosing spondylitis (Askling et al. 2006).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is associated with a long-term risk of developing malignant lymphoma. The association between SLE and malignancy fulfilled five Bradford Hill criteria demonstrating causality (strength, temporality, plausibility, coherence, and analogy) (Villa et al. 2000).

Systemic Sclerosis

The association between systemic sclerosis and malignancy fulfilled six Bradford Hill criteria in Villa's study (strength, consistency, temporality, plausibility, coherence, and analogy); the authors concluded that there is evidence of causality between systemic sclerosis and lung cancer (Villa et al. 2000).

Sjogren's Syndrome

An increased risk of developing lymphoma has been identified in Sjogren's syndrome (Soderberg et al. 2006). The association between Sjogren's syndrome and lymphoma fulfilled six Bradford Hill criteria (strength, consistency, temporality, plausibility, coherence, and analogy); the authors concluded that there is evidence of causality between Sjogren's syndrome and lymphoma (Villa et al. 2000).

Which Work-Up for Which Patients?

Paraneoplastic musculoskeletal disorders may precede the diagnosis of cancer by months or years, thus representing a potential marker for occult malignancy (Naschitz 2001; Andras et al. 2006). Diagnosing some of those syndromes may

be challenging because certain paraneoplastic musculoskeletal disorders are rare and the clinician's opportunity to gain experience with such syndromes is limited. The prevalence of paraneoplastic rheumatic syndromes in a cohort of 3,770 patients with newly diagnosed solid tumors was 2.65 %, with arthritis and Raynaud's prevailing: both paraneoplastic syndromes were linked to malignancies of the urogenital system. The patients' immunologic status did not help differentiate between paraneoplastic and other arthritides (Rugienė et al. 2011). Further difficulty stems from the fact that paraneoplastic rheumatic syndromes may be clinically indistinguishable from disorders caused by infiltration of musculoskeletal organs by cancer cells, whether primary or metastatic. It is generally accepted that an extensive search for malignancy in most patients with recent-onset musculoskeletal disorders of unknown etiology is not cost-effective and thus not to be recommended, unless a patient presents additional findings suggestive of malignancy. Rheumatic syndromes that may be clues of occult neoplasia have been reviewed elsewhere (Naschitz 2001; Andras et al. 2006).

The question of whether "tumor markers" and markers of altered immunity may be useful in the work-up of patients with recent-onset musculoskeletal disorders has not been settled (Rugienė et al. 2011). Recent studies revealed a layer of genetic programmatic coordination by which cells determine their fate; this layer involves posttranscriptional regulation of gene expression by microRNAs. Defining the molecular taxonomy of tumors by microRNAs patterns and applying molecular taxonomy patterns to the diagnosis of neoplasia are tasks for future studies.

An increased incidence of antinuclear antibodies (ANA) has been detected in malignant conditions, but no ANA specificities (anti-ENA, anti-DNA) have been recognized in patients with malignancies. Hypocomplementemia was present in a quarter of patients with Sjogren's syndrome and correlated with lymphoproliferative disorders and mortality (Ramos-Casals 2004). Circulating monoclonal immunoglobulins were detected in one-fifth of patients with Sjogren's syndrome, most commonly monoclonal IgG (Brito-Zeron et al. 2005). Relevance of the latter immunologic finding for diagnostic purposes has not been established (Naschitz 2001; Andras et al. 2006).

Conclusions

There is firm epidemiologic evidence that cancer may present with paraneoplastic dermatomyositis, less so for polymyositis. Additionally, there is a prevailing clinical impression, but scarce epidemiological evidence, that certain musculoskeletal disorders may be paraneoplastic in nature. The role of specific clinical findings and biological markers, as hints of a possible neoplastic etiology of musculoskeletal syndromes, has not been solved. Strong evidence has accumulated on the role of longstanding rheumatoid arthritis, Sjogren's syndrome, systemic lupus erythematosus, and systemic sclerosis as premalignant conditions.

Focal segmental glomerulonephritis; IgA nephropathy; Light chain nephropathy; Membranoproliferative glomerulonephritis; Membranous glomerulonephritis; Minimal change disease; Paraneoplastic glomerulonephritis; Rapidly progressive glomerulonephritis; Renal amyloidosis

Definition and Background

Nephrotic syndrome describes the onset of heavy proteinuria (>3.0 g/24 h), hypertension, hypercholesterolemia, edema, and microscopic hematuria. The term *nephrotic range proteinuria* is used when patients demonstrate heavy proteinuria without the aforementioned clinical manifestations. Nephrotic syndrome has been described in a number of renal syndromes including but not limited to minimal change disease (MCD), focal segmental glomerulonephritis (FSGS), membranous glomerulonephritis, and renal amyloidosis (Lewis and Neilson 2012).

Nephrotic syndrome is a rare complication of both solid and hematologic malignancies that is often described as a paraneoplastic syndrome. Paraneoplastic nephropathies are not directly related to tumor burden, invasion, or metastasis, but are caused by the secretion of hormones, growth factors, cytokines, and tumor antigens by the tumor itself (Ronco 1999). The first series of paraneoplastic glomerulonephritis was published by Lee et al. in 1966 (Lee et al. 1966).

While membranous nephropathy in patients with solid tumors and minimal change disease in patients with Hodgkin's lymphoma are considered the classic glomerulonephropathies associated with malignancy, cancer-associated nephrotic syndrome encompasses a plethora of glomerulonephropathies including FSGS, membranoproliferative glomerulonephritis (MPGN), IgA nephropathy, and rapidly progressive glomerulonephritis (RPGN). Paraneoplastic glomerulonephritis improves with the remission of the underlying malignancy. Therefore, early recognition of these disorders is important as treatment differs from idiopathic glomerulonephropathies. While paraneoplastic glomerulonephritis must be considered if nephrotic range proteinuria occurs in the setting of malignancy, diagnosis is established when proteinuria remits with treatment of the malignancy and/or recurs with recurrence of the underlying malignancy (Lefaucheur et al. 2006; Bacchetta et al. 2009).

Solid Tumors

Membranous Nephropathy

Membranous nephropathy has been most consistently linked to malignancy. The largest series of patients with membranous nephropathy demonstrated a 10 % prevalence of cancer (Lefaucheur et al. 2006). Paraneoplastic membranous nephropathy is more comment in older individuals (age >50), current or former tobacco users (>20 pack-year history), and male gender (Lefaucheur et al. 2006; Ronco 1999). Membranous nephropathy has been seen most commonly in prostate adenocarcinoma and lung carcinoma; however, it has also been reported in breast carcinoma, renal cell carcinoma, gastric adenocarcinoma, colon adenocarcinoma, neuroblastoma, neuroendocrine tumors, GIST, hepatocellular carcinoma, choriocarcinoma, carcinoid tumor, and nasopharyngeal carcinoma (Becker et al. 1996; Lefaucheur et al. 2006; Wagrowska-Danilewicz and Danilewicz 2011).

On pathology, membranous nephropathy is characterized by subendothelial immune complex deposition. An autopsy series of patients with malignancy demonstrated that 17 % of kidneys contained glomerular deposits on immunofluorescence (Beaufils et al. 1985). Another series suggests that by electron microscopy, 55 % of patients with cancer have immune complex deposition consistent with membranous nephropathy (Pascal et al. 1976). While carcinoembryonic antigen, prostate-specific antigen, and melanoma antigens have been associated with membranous nephropathy, it is not clear that they are the causative agents. Ohanti et al. demonstrated that patients with paraneoplastic membranous nephropathy have significantly more IgG1 and IgG2 deposition compared to those with idiopathic membranous nephropathy. However, IgG4 was equally expressed in both paraneoplastic and idiopathic membranous nephropathy (Ohtani et al. 2004). As IgG1 and IgG2 formation is regulated by the type 1 T-helper (Th1) cell release of cytokines (i.e., IL-12 and interferon), some hypothesize that Th1-mediated responses in malignancy may drive membranous nephropathy (Ohtani et al. 2004; Lien and Lai 2011).

Minimal Change Disease (MCD)

MCD has been observed in lung, colorectal, and renal cancers. Some theorize that MCD in malignancy may be related to increased expression of vascular endothelial growth factor (VEGF). This is supported by pediatric studies that show increased VEGF expression in the podocytes of patients who have nephrotic syndromes (Ostalska-Nowicka et al. 2005). VEGF has been associated with increased membrane permeability (Taniguchi et al. 2004). Taniguchi et al. reported a case in which a patient with rectal adenocarcinoma had elevated VEGF and nephrotic syndrome at diagnosis; however, after resection of the tumor, proteinuria resolved and VEGF normalized.

Membranoproliferative Glomerulonephritis (MPGN)

MPGN has been rarely reported in lung, renal, and gastric cancers. While some cases have demonstrated improvement in nephrotic syndrome with resection of the malignancy, others have

improved with prednisone (Ahmed et al. 2008). Therefore, some hypothesize that MPGN may be associated with immune complex deposition induced by tumor antigens.

Rapidly Progressive Glomerulonephritis (RPGN)

RPGN has been reported in renal call, lung, and gastric cancers. However, many of the cases reported were prior to elucidation of anti-neutrophil cytoplasmic antibodies (ANCA). It is known that ANCA-associated vasculitides carry a higher risk for development of malignancy. Additionally, cases in which RPGN resolved with treatment of the underlying malignancy inevitably required immunosuppressive therapy, which would concomitantly treat an underlying vasculitis (Lien and Lai 2011). The correlation between RPGN and malignancy is less clear.

IgA Nephropathy

IgA nephropathy has been identified in patients with carcinomas of the respiratory tract, nasopharynx, and renal cell. There have been cases of Henoch-Schonlein purpura in lung cancers and other malignancies (Pertuiset et al. 2000; Flynn et al. 2011). Anticancer therapy has been used to treat this disorder but the pathophysiology of paraneoplastic IgA nephropathy is not well understood (Mustonen et al. 1984).

Thrombotic Microangiopathy

Thrombotic microangiopathy is characterized by thrombocytopenia, microangiopathic hemolytic anemia, neurologic alteration, and acute kidney injury. It is believed to be caused by microvascular tumor emboli. Therefore, thrombotic microangiopathy is not classified as a paraneoplastic syndrome, but often presents with nephrotic range proteinuria as well. It has been described in gastric, lung, and breast cancers and carries a poor prognosis. In the Oklahoma thrombocytopenic thrombotic microangiopathy (TTP)/hemolytic uremic syndrome (HUS) registry, 10 patients with cancer-associated thrombotic angiopathy were identified; none of these patients improved with plasma exchange, and all died after diagnosis. This demonstrates that thrombotic microangiopathy causing nephrotic syndrome carries a different pathophysiology compared to TTP.

Hematologic Malignancies

Minimal Change Disease (MCD)

MCD occurs in approximately 1 % of patients with Hodgkin's lymphoma. It has also been reported in chronic lymphocytic lymphoma (CLL), even in early stage disease (Alzamora et al. 2006), myelodysplastic disorders, and in thymomas as well, particularly lymphocyte-predominant thymomas. In the post-allogeneic transplant setting, appearance of MCD is considered to be a presentation of graft-versus-host disease (GVHD), as donor T cells have been observed to infiltrate the renal parenchyma (Romagnani et al. 2005). Immunosuppressive treatment for GVHD has also improved proteinuria in these cases (Silva et al. 2007).

In Hodgkin's lymphoma, MCD has been associated with increased inflammatory markers, particularly type 2 T-helper cell (Th2) cytokines. In a rat model, it has been shown that overexpression of IL-13 (a Th2 cytokine) results in a MCD-like nephropathy (Lai et al. 2007). It is known that IL-13 is also overexpressed in Hodgkin's disease (Ohshima et al. 2001). While there appears to be an association between IL-13 and MCD, it is not clear whether IL-13 itself directly causes increased membrane permeability that results in MCD. The relationship between Th2 response and MCD has been further demonstrated in thymomas. In lymphocyte-predominant thymomas, MCD persists even after tumor excision and improves with steroid treatment (Karras et al. 2005). Rat models of thymoma show a similar phenomenon in which MCD persists despite thymectomy. In these rats, there is increased Th2-mediated cytokines, and suppression of the Th2 axis improves the degree of proteinuria (Le Berre et al. 2005). Models in thymoma and Hodgkin's disease suggest that regulation of the Th2 axis may be helpful in the treatment of MCD.

Focal Segmental Glomerulonephritis (FSGS)

FSGS occurs in 0.1 % of patients with Hodgkin's lymphoma and in approximately 3 % of patients with myeloproliferative disorders (e.g., polycythemia vera, essential thrombocythemia). It has also been seen in myelodysplastic disorders. Patients with high platelet counts in particular have elevated platelet-derived growth factor (PDGF), which has been found to enhance mesangial proliferation and fibrosis in vitro (Gersuk et al. 1989). Supporting this hypothesis, PDGF is not elevated in chronic myelogenous leukemia that is not associated with FSGS (Floege et al. 2008).

Membranoproliferative Glomerulonephritis (MPGN)

MPGN has been seen in CLL, non-Hodgkin's lymphomas, and hairy cell leukemia. Some cases have been associated with a mixed cryoglobulinemia (types I and II) involving a monoclonal immunoglobulin. Additionally, patients with hepatitis C-associated mixed cryoglobulinemia whose proteinuria does not respond to traditional hepatitis C therapy have been found to respond to rituximab, an anti-B-cell antibody (anti-CD-20). These findings may imply that B cell proliferation has a role in the development of MPGN (Cacoub et al. 2008).

Membranous Nephropathy

Membranous nephropathy has been rarely seen in CLL, chronic myelomonocytic leukemia, and non-Hodgkin's lymphomas. When it occurs, it presents with subepithelial deposits and monoclonal IgG kappa light chain deposits, suggesting that antibodies produced by monoclonal B cells may play a role in the development of membranous nephropathy (Evans et al. 2003).

IgA Nephropathy

IgA nephropathy has been associated with cutaneous T cell lymphomas. As the Th2 cytokine profile is dominant in cutaneous T cell lymphomas, skewed immunoregulation has been implied in the development of IgA nephropathy in this disorder (Bajel et al. 2009).

Light Chain Related Nephropathy

Both multiple myeloma and amyloidosis cause nephrotic range proteinuria through a number of mechanisms. Kappa and lambda free light chains produced in both disorders are freely filtered across the glomerulus. They overwhelm the ability of the proximal tubule cells to endocytose them. Therefore, they form tubular casts with Tamm-Horsfall protein (uromodulin) that can cause tubular obstruction, which decreases the glomerular filtration rate. It is believed that the Tamm-Horsfall proteins interact with the variable regions of the light chains, which may explain why light chain burden does not correlate directly with the degree of nephropathy (Comenzo et al. 2001). Additionally, the endocytosed light chains in the renal tubule cells induce a proinflammatory response (activation of nuclear factor kappa B and release of IL-6, IL-8, and tumor necrosis factor-a), which subsequently causes deposition of matrix protein that further disrupts glomerular integrity (Sengul et al. 2002). Lastly, the deposition of immunoglobulins themselves, in the form of amyloid and non-amyloid, through every portion of the kidney independently cause nonselective proteinuria (Dimopoulos et al. 2008).

Summary

Both solid and hematologic malignancies are associated with nephrotic range proteinuria through various mechanisms. Specific glomerulonephropathies have been associated with different types of malignancies. It appears that monoclonal formation of antibodies, as well as polarized Th1 versus Th2 responses, are mediators of the development of paraneoplastic glomerulonephropathies. However, the exact pathophysiology underlying these disorders has yet to be better elucidated.

Synonyms

Immune-mediated neuropathy in cancer; Inflammatory neuropathy associated with malignancy; Paraneoplastic neuropathy; Peripheral neuropathy in cancer; Polyneuropathy in cancer

Definition

Neuropathy refers to the injury or dysfunction of the peripheral nerves. The peripheral nerves are those that are located outside of the brain and spinal cord, providing sensory, motor, and autonomic innervation to all organs and structures of the body. Depending on the cause of the neuropathy, sensory nerves, motor nerves, and/or autonomic nerve fibers may be affected to varying degrees. As a result, interruption of normal peripheral nerve function can result in pain, tingling, numbness, weakness, clumsiness, gait imbalance, and/or autonomic dysfunction, such as blood pressure fluctuations, temperature dysregulation, and gastrointestinal dysfunction.

Patients with cancer are subject to the development of peripheral neuropathy on a number of bases. Neuropathic dysfunction of the peripheral nerves in patients with cancer occurs most frequently as a side effect of chemotherapeutic agents used for treatment. Additional etiologies include direct tumor invasion of the peripheral nerves or nerve plexi, involvement of spinal nerves in leptomeningeal carcinomatosis, and collateral damage to nerve structures from radiation treatment.

In addition, several *paraneoplastic* syndromes have been identified in which peripheral neuropathy is either the presenting or the predominant characteristic. Paraneoplastic syndromes are broadly defined as a symptom constellation that occurs as a remote effect of cancer on the nervous system, mediated by an immunological process. In some cases, a specific type of neuropathy with characteristic features is associated with an identifiable antibody (*onconeural* antibody) and specific types of tumor. In the malignant plasma cell proliferative disorders, direct activity of monoclonal immunoglobulins is implicated in the pathogenesis of various neuropathies (Antoine and Camdessanche 2007; DeAngelis and Posner 2009).

Basic Characteristics

Paraneoplastic Neuropathy Associated with Onconeural Antibodies

The most widely recognized antibody associated with neuropathy occurring on a paraneoplastic basis is the *anti-Hu antibody*, also referred to as the *antineuronal nuclear antibody-1 (ANNA-1)*. First described by Denny-Brown in 1948, the anti-Hu paraneoplastic syndrome is characterized by sensory neuronopathy and/or encephalomyelitis associated with serum autoantibodies directed against antigens expressed by certain tumors, most commonly small cell lung cancer (Dalmau et al. 1992).

The classical presentation of this disorder is development of an acute-subacute pure sensory neuropathy without motor involvement. It affects women more than men, with an age of onset typically between 50 and 80 years old. Concomitant encephalomyelitis is present in about 25–50 % of cases. Neuropathic symptoms include pain and numbness, often asymmetric at onset, evolving over weeks to months to involve all extremities and occasionally the face and trunk. Sensory ataxia may be severe, affecting the ability to walk or even sit unsupported. Deep tendon reflexes are typically absent. Less commonly, anti-Hu antibodies are implicated in other neuropathy phenotypes, including mixed sensorimotor and predominantly motor neuropathies. Motor weakness of the limbs and rarely face may therefore be present, in rare cases manifesting as the prominent symptom. Dysautonomia and cranial neuropathies, though even more rare, may also occur.

The diagnosis is made by a combination of clinical signs and symptoms as well as detection of anti-Hu antibodies in either the serum or CSF. The majority of patients diagnosed with the syndrome do not have a known cancer diagnosis at the time of onset of the neurological symptoms. The time to definitive diagnosis of identifiable cancer can range from several months to several years. Small cell lung carcinoma accounts for 70–90 % of these cases, though many other cancer types have been implicated, including prostate, breast, ovarian, pancreatic, neuroendocrine, thymic, and bladder.

In addition to anti-Hu, other onconeural antibodies have been associated with specific neuropathy syndromes in patients with cancer.

Anti-CV2 onconeural antibodies have been associated with sensory and sensorimotor neuropathy in the setting of small cell lung cancer and less frequently thymoma and non-Hodgkin's lymphoma. CV2 antibodies are also associated with cerebellar ataxia and uveitis.

Ganglionic nicotinic acetylcholine receptor binding antibodies are associated with a syndrome of acute autonomic neuropathy, presenting with severe orthostatic hypotension, nausea and vomiting after meals, reduced sweating, dry eyes and mouth, sexual dysfunction, and/or bladder dysfunction. In about 20 % of cases, sensory neuropathy is also present, usually prominently affecting the small fiber nerves and manifesting as pain. As with anti-Hu and anti-CV2 neuropathies, this paraneoplastic neuropathy syndrome is also most frequently observed in patients with small cell carcinoma of the lung, although it has also been reported in patients with other malignancies, particularly thymoma (Rudnicki and Dalmau 2005).

The pathophysiology of these syndromes is believed to occur via an immune response triggered by the neoplasm in which an antibody generated against the tumor becomes misdirected toward a tissue that expresses the same (or sufficiently similar) antigen. In the case of the paraneoplastic neuropathies, the antibodies target various sites along the peripheral neurons and/or nerves, resulting in the injury and dysfunction of these structures. This theory is supported by studies showing that in patients with anti-Hu antibodies, tumors tend to be smaller and may even spontaneously regress (Dalmau et al. 1999).

Neuropathies and Plasma Cell Proliferative Disorders

Multiple myeloma, osteosclerotic myeloma, Waldenstrom's macroglobulinemia, as well as other plasma cell dyscrasias are often associated with peripheral neuropathy (as is monoclonal gammopathy of uncertain significance or MGUS). Multiple neuropathy variants occur in disorders associated with monoclonal paraproteins, including inflammatory demyelinating neuropathies, as well as those with features of predominantly axonal injury. Usually, specific autoantibodies known to target peripheral nerve antigens are not identified.

Clinical studies have demonstrated evidence of preexisting peripheral neuropathy in up to 25 % of patients with multiple myeloma prior to their treatment with potentially neurotoxic chemotherapy agents. Osteosclerotic myeloma is a rare variant of myeloma with a very high prevalence of peripheral neuropathy. Many patients with this disorder will present with symptoms of neuropathy, either

as part of the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes) associated with this type of cancer or as an isolated feature. The incidence of peripheral neuropathy in Waldenstrom's macroglobulinemia is possibly as high as 47 %.

In the plasma cell dyscrasias resulting in monoclonal gammopathies, it is believed that in some cases the paraproteins react immunologically with specific peripheral nerve or neuron structures, in some cases acting as antibody. In patients with IgM monoclonal gammopathy and neuropathy, antibodies with reactivity directed against the myelin-associated glycoprotein (anti-MAG) may be present. *Anti-MAG* neuropathy predominantly involves sensory nerves, and prominent tremor and sensory ataxia are commonly seen features. Anti-MAG antibodies have been identified in 5–45 % of patients with Waldenstrom's macroglobulinemia. In other cases, IgM or IgG reactivity toward specific ganglioside subtypes is associated with specific phenotypes of neuropathy (Latov 1995; Ropper and Gorson 1998).

Treatment

There are two main modes of treatment for immune-mediated neuropathies associated with cancer: suppressing the immune response and treating the underlying malignancy. Immune suppression typically consists of using corticosteroids, cyclophosphamide, azathioprine, plasma exchange, and/or intravenous immunoglobulin to curb the autoantibody activity directed against the peripheral nerves. Unfortunately, immunomodulatory treatment is often unsatisfactory, leading to stability of symptoms in some patients but only very rarely improvement. Treatment of the underlying malignancy generally yields the greatest improvement. Studies have demonstrated that antitumor therapy is the most significant factor in creating stabilization and improvement in patients with anti-Hu syndrome, and in approximately two-thirds of multiple myeloma patients, the neuropathy responds to successful treatment of the cancer.

Definition

The central nervous system (CNS) may be effected by cancer both directly, through metastatic disease and direct tumor extension, or indirectly. Damage to the nervous system, remote from the site of tumor and not associated with toxicity or metabolic abnormalities associated with cancer or its treatment, is termed paraneoplastic neurological syndromes (PNS). PNS, which are believed to exert their effect through an immune-mediated mechanism (Darnell 1996), may affect any neuronal cell type in the peripheral or central nervous system. While PNS may present as a generalized or diffuse disorder, such as a paraneoplastic encephalomyeloneuritis, there are several recognized or classical clinical syndromes which may affect certain anatomic locations of the central nervous system. The clinical characteristics and pathophysiology of the recognized paraneoplastic syndromes of the CNS, including limbic encephalitis, paraneoplastic cerebellar degeneration, opsoclonus-myoclonus, retinopathies, and stiff person syndrome will be the focus of this entry.

Clinical Presentation and Diagnosis

PNS usually present in an acute to subacute manner, over days to weeks, producing severe disability followed by stabilization. Laboratory evaluation usually demonstrates evidence of inflammation in the cerebral spinal fluid (CSF) such as lymphocytic pleocytosis, elevated protein, and oligoclonal banding, as well as brain magnetic resonance imaging (MRI) abnormalities on fluid attenuation inversion recovery (FLAIR)/T2 sequences. In the majority of cases, the PNS will likely be the initial presentation, the underlying cancer only discovered after a recognized syndrome spurs a search for malignancy.

Key to the diagnosis of PNS is the discovery of antineuronal antibodies in the serum and CSF leading to the postulate of autoimmunity as the pathophysiological basis of PNS. When these antibodies are markers of an underlying cancer, they are termed onconeural antibodies (Musunmuru et al. 2001). Over the years, certain well-characterized onconeural antibodies have been associated with certain clinical presentations representing classic PNS as well as certain underlying malignancies (Table 1). These include anti-Hu, anti-Yo, anti-CV2, anti-Ri, anti-Ma2, and anti-amphiphysin. When found, these may help focus the search for cancer to a few organs.

Recently, these onconeural antibodies have been classified as belonging to one of two groups. Antibodies from group 1 are found to target intracellular neuronal antigens; those from group 2 target neuronal surface antigens (Graus et al. 2010). It has proven difficult to produce animal models of disease based on passive transfer of group 1 antibodies, which include the well-characterized onconeural antibodies, suggesting these antibodies are likely not directly pathogenic but may represent the humoral component of a more complex cellular response (Tanaka et al. 2004). Antibodies from group 2, which usually target synaptic cell surface membrane proteins, appear to have a more direct pathogenic role given their good response to immunotherapy, sometimes regardless of disease duration, and correlation of disease response to antibody titer (Dalmau 2011). While there is a strong association in this second group with certain characteristic CNS syndromes, a paraneoplastic syndrome is less certain as there may or may not be an associated malignancy.

Classic PNS of the CNS

While PNS may present with diffuse or multifocal encephalomyeloneuritis, there are certain distinct classical clinical presentations

CRMP collapsin response mediator protein, *ANNA* antineuronal nuclear antibody, *PCA* Purkinje cell autoantibody, *VGKC* voltage-gated potassium channel, *NMDA N*-methyl-D-aspartate, *GABA* γ-aminobutyric acid-B, *AMPA* alpha-amino-3-hydroxy-5-methyl-4-isoxazoleprionic acid, *VGCC* voltage-gated calcium channel, *mGLuR1* metabotropic glutamate receptor type 1, *TULP1* tubby-like protein 1, *PTB* polypyrimidine-tract binding, *GAD* glutamic acid decarboxylase. Well-characterized onconeural antibodies are in bold

historically discussed in the context of PNS of the CNS. A number of these are discussed below.

Limbic Encephalitis

Paraneoplastic limbic encephalitis (PLE), first named 40 years ago, represents an inflammatory process affecting the mesial temporal lobes and limbic mesial cortical structures. PLE will usually present rapidly, within days to weeks. Patients typically present with memory loss, confusion, psychiatric abnormalities, and seizures. The initial personality changes and psychiatric manifestations including hallucinations, agitation, anxiety, and depression may lead to a presumptive diagnosis requiring admission to a psychiatric hospital, before the development of seizures and altered consciousness spur further evaluation.

The discovery of onconeural antibodies aids in diagnosis, although up to 10 % of patients with PLE will be seronegative or express uncharacterized antibodies (Graus et al. 2008). Eighty percent of patients have MRI T2-weighted and FLAIR hyperintensity in the bilateral mesial temporal lobes, although these areas rarely demonstrate gadolinium (GAD) enhancement. Focal or generalized slowing, and epileptiform activity, maximal in the temporal lobes, is seen on electroencephalography (EEG) in all (Lawn et al. 2003). CSF examination frequently shows

signs of inflammation with elevated protein, lymphocytic pleocytosis, and oligoclonal banding.

Small-cell lung cancer is associated with PLE in 50–60 % of patients, followed by testicular germ cell tumors (20 %) and breast cancer (8 %) (Gultekin et al. 2000). Other cancers associated with PLE include thymoma, ovarian teratoma, non-SCLC, and Hodgkin's disease (Table 1).

Limbic encephalitis (LE) has come to be characterized based on the location of target antigens, being either intracellular or neuronal cell surface receptors (Rosenfeld et al. 2010). Anti-Hu and anti-Ma2 are the most commonly discovered onconeural antibodies to intracellular antigens in LE. Anti-Hu, seen in up to 60 % of cases where antibodies are present, is the most common intracellular paraneoplastic antibody and, when positive in limbic encephalitis, denotes a 94 % correlation with underlying SCLC (Gultekin et al. 2000). Many patients with anti-Hu-associated PLE will have involvement in other areas of the nervous system, such as a subacute sensory neuronopathy (SSN). Anti-Hu antibodies, also frequently found in patients with SCLC without PLE, though in much lower titers, are associated with an intranuclear RNA-binding protein which functions in cell cycle regulation (Dalmau et al. 1990). Anti-Ma2 is a second intracellular antibody, primarily seen in young men who develop PLE in association with an underlying testicular germ cell tumor (Dalmau et al. 2004). They may have involvement outside the limbic system, including the hypothalamus, producing excessive daytime sleepiness, REM-sleep abnormalities, and hyperphagia. Treatment response is poor in these patients, as with other less frequently discovered intracellular antibodies, including anti-collapsin response mediator protein (CRMP) (CV2) and anti-amphiphysin (Tüzün et al. 2007). However, a dramatic response can be seen in anti-Ma2-associated PLE following immunotherapy and cancer treatment.

A more recently emerging discovery is limbic encephalitis associated with antibodies directed towards cell surface or synaptic proteins including the voltage-gated potassium channel (VGKC) (Vincent et al. 2004), the *N*-methyl-D-aspartate (NMDA) receptor (Irani et al. 2011), the γ-aminobutyric acid-B ($GABA_B$) (Boronat et al. 2011) receptor, and the alpha-amino-3-hydroxy-5-methyl-4-isoxazoleprionic acid (AMPA) receptor (Bataller et al. 2010). These newly discovered cell surface receptor antibodies may account for a majority of the patients with PLE and SCLC who were previously found to be seronegative for the well-characterized intracellular antibodies (Boronat et al. 2011). Unlike the well-characterized onconeural antibodies, these newly discovered antibodies, directed towards cell surface proteins, may in some cases be associated with an idiopathic or autoimmune neurological syndrome with no underlying malignancy. In addition, the antibodies are likely themselves pathogenic, and consequently, patients with these syndromes usually improve with immunotherapy aimed at removing antibodies form serum, such as IVIg and plasma exchange, as well as with treatment of the underlying tumor.

LE associated with VGKC antibodies is found to be paraneoplastic in about 30 % of cases, commonly occurring with SCLC and thymoma (Dalmau et al. 2008). A percentage of these patients may also develop a peripheral nerve hyperexcitability syndrome, such as neuromyotonia or Morvan's syndrome (neuromyotonia with CNS symptoms of hallucinations, delusions, and insomnia). NMDA receptor-associated LE is often described, in about 60 %, as occurring in a paraneoplastic form in young women with ovarian teratoma (Irani et al. 2011). In addition to the psychiatric symptoms and seizures common in PLE, these patients also have prominent dysautonomia, with labile heart rate and blood pressure, frequent hypoventilation, as well as a characteristic movement disorder with semi-repetitive orofacial and limb movements and dystonic posturing (Dalmau et al. 2008). Early and prominent seizures are a common presentation of LE associated with antibodies to the $GABA_B$ receptor. This syndrome is associated with SCLC in about

50 % of cases. $GABA_B$ receptor antibodies may be present, with glutamic acid decarboxylase (GAD) antibodies (Boronat et al. 2011). Anti-AMPA receptor encephalitis, usually seen in middle-age women, has an approximately 70 % association with an underlying tumor of the breast, lung, or thymus (Dalmau et al. 2010).

Cerebellar Degeneration

Paraneoplastic cerebellar degeneration (PCD), the first PNS to be recognized, is the best described and well documented and one of the most common paraneoplastic presentations of cancer. Sometimes preceded by a prodromal viral-like illness, cerebellar symptoms, including truncal and appendicular ataxia, nystagmus, and dysarthria, dominate the clinical picture. PCD may begin abruptly, progress over weeks to months, and then stabilize, usually leaving the patient significantly impaired, unable to walk or sit unassisted, and unable to perform fine motor tasks such as writing or eating. The degree and probability of severe impairment correlates somewhat with the underlying cancer and type of antineuronal antibody present.

As in PLE, there is usually evidence of inflammation in the CSF, though MRI usually does not demonstrate pathology until cerebellar atrophy develops late in the disease. MRI evidence of cerebellar swelling and enhancement of the cerebellar folia are reported by some (Darnell et al. 2006). During the early stages, fluorodeoxyglucose-PET may demonstrate cerebellar hypermetabolism, followed by evidence of hypometabolism in late stages (Dalmau et al. 2008). Histological findings, in the cerebellar cortex and deep cerebellar nuclei, include extensive loss of Purkinje cells with inflammatory infiltrates present at early stages of disease (Verschuuren et al. 1996).

Malignancies commonly associated with PCD include gynecologic cancers of the breast and ovary, SCLC, and Hodgkin's disease. Though not hard and fast, a correlation exists between certain paraneoplastic antibodies occurring in PCD and certain clinical features and cancer types. Breast or gynecologic cancer is usually detected with anti-Yo positivity (Peterson et al. 1992). Present in 38 % of patients in whom antibodies are detected, anti-Yo is the most common antibody in PCD. It targets the cdr2 antigen, normally expressed on Purkinje cells in the cerebellum and aberrantly expressed in ovarian and breast cancers.

With anti-Yo PCD, cerebellar symptoms usually present in isolation, often leaving patients with significant long-term disability resulting from irreversible Purkinje cell destruction. Similar to other antibodies that target intracellular neuronal antigens, treatment response is poor, although aggressive cancer treatment and immunotherapy, if initiated early in the course of disease, may improve the possibility of success (Dalmau et al. 2008). There are a few case reports of IVIg, given at a dose of 2 g/kg divided over 2–5 days, resulting in neurological improvement in patients with PCD and detectable anti-Yo antibodies. However, this is the exception rather than the rule (Widdess-Walsh et al. 2003). Patients who improved were treated within 1 month of symptom onset and usually received concurrent cancer therapy. Treatment at 1–3 months resulted in stable disease, and treatment outside 3 months usually had a poor outcome (Widdess-Walsh et al. 2003). Anti-Hu antibodies with SCLC also herald a poor prognosis, and while the cerebellar symptoms may predominate, other symptoms coexist, suggesting a more diffuse encephalomyelitis.

Hodgkin's disease and anti-Tr antibodies are also commonly associated with PCD. While anti-Yo antibodies are found in older women with PCD, anti-Tr antibodies are more commonly present in young men, reflecting the demographics of the underlying tumor. Hodgkin's disease, in contrast to other tumors, usually precedes the diagnosis of PCD, possibly because B symptoms lead to earlier diagnosis (Hammack et al. 1992). Patients with anti-Tr antibodies have a better neurological prognosis than those with Yo or Hu antibodies.

PCD, as is the case in LE, may also occur in the setting of antibodies directed against cell

surface antigens. P/Q type voltage-gated calcium channel (VGCC) antibodies are associated with SCLC and Lambert-Eaton myasthenic syndrome (LEMS). PCD sometimes occurs in SCLC, with LEMS, and high titers of VGCC antibodies. These patients may not exhibit any other recognized anti-Purkinje cell autoantibody and may harbor VGCC antibodies without developing LEMS, suggesting a role in the pathogenesis of cerebellar dysfunction (Mason et al. 1997). However, in that study, treatment with immunotherapy, as opposed to other paraneoplastic syndromes associated with neuronal receptor antibodies, did not alter the course of PCD. There have also been reports of PCD in the setting of Hodgkin's disease and antibodies against a glutamate receptor, metabotropic glutamate receptor type 1 (mGLuR1) (Sillevis Smitt et al. 2000).

Other associated antibodies include anti-CRMP5 and anti-Zic4 with SCLC. In patients with encephalomyelitis and testicular cancer, the presence of anti-Ma1 and anti-Ma2 antibodies correlated with development of cerebellar dysfunction (Darnell 2004).

Opsoclonus-Myoclonus

Opsoclonus-myoclonus (OM) syndrome comprises myoclonic jerks of the limbs and trunk, with opsoclonus, involuntary, arrhythmic, high-amplitude, and multidirectional saccades of the eyes. Opsoclonus may be constant, even during sleep, and may cause oscillopsia or blurring and oscillation of vision. OM is often associated with cerebellar ataxia, most often in children, and commonly referred to as opsoclonus-myoclonus-ataxia syndrome, though adult forms exist. Besides the classic triad of opsoclonus, myoclonus, and ataxia, pediatric patients in particular may exhibit sleep disturbance, cognitive dysfunction, and behavioral disruption. Neurological symptoms, especially in children, may resolve spontaneously or with treatment but may relapse. Brain MRI is usually normal but a mild CSF pleocytosis may be seen.

Pediatric OM etiology is diverse, including para- and post-infectious, toxic, and paraneoplastic causes. Pediatric OM is paraneoplastic in 40 % of patients, always associated with neuroblastoma. It is the most common pediatric paraneoplastic neurological syndrome in the medical literature, although it remains quite rare, occurring in 2–3 % of pediatric neuroblastoma (Rudnick et al. 2001). As the neurological symptoms in many cases of pediatric paraneoplastic OM respond well to immunotherapy, including IVIg, corticosteroids, and adrenocorticotropic hormone (ACTH), there does not appear to be permanent neuronal degeneration. More likely, transient antibody-mediated dysfunction occurs (Wong 2007). Furthermore, despite normal CSF cell counts, there is B cell expansion, which has been proposed as a candidate biomarker for the disease (Gorman 2010). A recent study demonstrated clinical improvement and reduced CSF B cells with rituximab, an agent that targets B cells, supporting a B-cell-mediated process (Pranzatelli et al. 2006). However, it has been difficult to consistently isolate specific autoantibodies, although recently, antibodies to surface proteins in cerebellar granular neurons in OM have been reported, and these exhibit a cytotoxic effect on neuroblastoma cells (Blaes et al. 2005). This antitumor immune response may explain the favorable prognosis for survival in children with coincident OM and neuroblastoma.

Among adults, paraneoplastic OM and anti-Ri antibodies are associated, usually in women with underlying breast cancer (Pittock et al. 2003). The Ri antibody recognizes the RNA-binding protein, Nova, which is strictly neuron specific and may regulate neuronal RNA metabolism (Musunuru et al. 2010). OM is also seen in patients with SCLC but predominately without the identification of a paraneoplastic antibody. However, anti-Hu and anti-amphiphysin are documented (Bataller et al. 2001). In contrast to children, adult paraneoplastic OM does not respond well to immunotherapy. Partial or complete neurological recovery may be seen with treatment of the underlying tumor (Bataller et al. 2001).

Retinopathies

PNS affecting the visual system predominantly involve the retina and optic nerve. Three distinct paraneoplastic visual syndromes are recognized: cancer-associated retinopathy (CAR), melanoma-associated retinopathy (MAR), and paraneoplastic optic neuropathy (PON) (Damek 2005).

Patients with CAR often describe progressive, painless visual loss, over weeks to months, with photosensitivity, peripheral and ring scotomata, and flickering, light-induced glare. Clinically, evidence of cone- and rod-mediated abnormalities are seen on electroretinogram, and while initially normal, fundoscopic exam may demonstrate arteriolar narrowing (Damek 2005). Several antiretinal antibodies are associated with CAR, the most common and well-characterized being anti-recoverin, usually associated with underlying SCLC (Bataller et al. 2004). Recoverin is found in photoreceptor cells, and is thought to modulate dark and light adaptation through a calcium-dependent mechanism. Pathogenesis appears to relate directly to the anti-recoverin antibody, as it induces retinal cell apoptotic death in vitro (Shiraga et al. 2002), and may be found in the aqueous humor of CAR patients (Ohguro et al. 2002). Anti-enolase, a second commonly encountered antibody, is, unlike anti-recoverin, found in non-paraneoplastic retinopathy as well (Adamus et al. 2004). Other target antigens include tubby-like protein, photoreceptor cell-specific nuclear receptor, and polypyrimidine-tract-binding protein-like protein. Treatment, comprising tumor resection and immune suppression, including high-dose steroids and alemtuzumab (Campath), a monoclonal protein directed against CD52, has shown to improve vision in CAR (Alabduljalil et al. 2007).

Symptom onset in MAR, unlike CAR, is usually abrupt and includes night blindness and flickering light phenomena, with normal visual acuity. MAR is almost exclusively associated with melanoma, except for a few reports of a MAR-like syndrome with colon cancer (Jacobson et al. 2001). MAR generally presents months to years after the diagnosis of cancer, usually in the setting of tumor progression. It is believed that MAR antibodies react with retinal bipolar cells, although the exact target antigen is unclear. Recently, mitofilin, a mitochondrial protein, and titin, a striated muscle protein, have been suggested as possible targets. Both are present in retina and tumor cells, and antibodies are seen only in patients with melanoma and MAR (Pföhler et al. 2006). Response to immunosuppressive treatment is usually poor.

Paraneoplastic optic neuropathy rarely occurs alone; it is usually associated with other neurological manifestations including cerebellar degeneration, sensory neuropathy, LEMS, or an encephalomyelopathy. Patients usually present with unilateral, painless, visual loss, progressing to involve both eyes, with spots and flashes before the eyes (Damek et al. 2005). Paraneoplastic optic neuropathy usually occurs in the presence of antibodies to collapsin response mediator protein-5 (CRMP5) in association with SCLC (Cross et al. 2003).

Stiff Person Syndrome

Stiff person syndrome (SPS) is characterized by the gradual onset of stiffness and rigidity, initially in axial muscles, and progressing to proximal limb muscles, primarily involving the legs. Continuously contracting antagonist muscles, described as rock-hard or board-like to palpation, produce a rigid posture, making ambulation difficult, resulting in frequent falls. This muscle rigidity is typically absent during sleep. Patients experience sudden, painful muscle spasms, usually precipitated by touch or involuntary movement, sudden loud noise, or emotional stress. Because of its unusual presentation, SPS was believed to be a functional disorder and many patients were labeled hysterical.

Diagnosis is based on the clinical picture and electromyography (EMG) findings of continuous motor unit activity in affected muscles, which is, however, indistinguishable from normal voluntary muscle contraction. MRI and CSF

examination is usually normal. Other clues to diagnosis include muscle contraction in response to electrical stimulation, termed spasmodic reflex myoclonus, and a dramatic response to diazepam in relieving the stiffness. Differential diagnosis includes tetanus, hyperekplexia, and myelopathy.

SPS has both a non-paraneoplastic and paraneoplastic variant, both autoimmune. Glutamic acid decarboxylase (GAD) antibodies, found in 80 % of SPS patients, are associated with the non-paraneoplastic variant, usually in patients with other autoimmune diseases, particularly diabetes mellitus type 1 (Solimena et al. 1988). GAD catalyzes the decarboxylation of L-glutamate to γ-aminobutyric acid (GABA), the most common inhibitory neurotransmitter in the brain and spinal cord. Paraneoplastic SPS, seen in 5 % of SPS patients (Alexopoulos et al. 2010), is clinically similar to the non-paraneoplastic form, though arm involvement may be more prominent. Amphiphysin antibodies are most commonly detected in paraneoplastic SPS, usually in breast cancer patients, although SCLC and Hodgkin's disease are also reported (Pittock et al. 2004). Case reports of other antibodies associated with SPS include anti-Ri in a patient with lung cancer (McCabe et al. 2004), anti-gephyrin in a patient with mediastinal cancer (Butler et al. 2000), and rare reports of anti-GAD acting as a paraneoplastic antibody (Schiff et al. 2006).

Symptom response to immunotherapy, and the recent discovery that passive transfer of anti-amphiphysin IgG from patients with SPS produced dose-dependent stiffness in rats, suggests a B-cell-mediated process and direct pathogenesis of the antibody. IVIg was effective in 2 placebo-controlled studies in treating the non-paraneoplastic form of SPS associated with anti-GAD antibodies (Dalakas et al. 2001). The evidence for IVIg in paraneoplastic SPS is less substantial, only demonstrated in a few case reports. However, given that both GAD and amphiphysin are part of the presynaptic GABA/glycine inhibitory synapse and likely have similar disease-causing mechanisms, it is reasonable to suspect IVIg, in combination with rigorous treatment of the underlying cancer, may be effective in paraneoplastic SPS as well and may reduce or eliminate the need for benzodiazepines, such as diazepam and clonazepam.

Definition

Thrombosis is defined as presence of a blood clot in a vein or an artery. If a part of the obstructing clot dissociates and travels in the blood stream, it is termed as "thromboembolism." Venous thromboembolism is one of the common causes of cancer-related morbidity.

Introduction

The relationship between cancer and venous thromboembolism (VTE) has been recognized for almost two centuries. Historically, the French physicians, Bouillaud and Trousseau, are credited with initially describing the relationship between VTE and cancer. Multiple studies have provided considerable evidence for a two-way clinical association between VTE and cancer. While the risk for arterial thrombosis may also be increased in the setting of cancer, this entry will focus on the relationship of malignancy and VTE.

VTE is a common cause of morbidity and mortality in patients with cancer. Patients with cancer are at 2–20-fold higher risk of VTE than patients without cancer, and on average, 15 % of patients develop deep vein thrombosis (DVT) or pulmonary embolism (PE) during the clinical course of their cancer (Chew et al. 2006). The MEGA (Multiple Environmental and Genetic Assessment) study clearly indicated that patients with cancer have an elevated risk for VTE, particularly during the first few months after diagnosis and in the presence of distant metastases (Blom et al. 2005). Conversely, the risk for the diagnosis of cancer seems elevated for at least 2 years after a first episode of idiopathic VTE (Murchison et al. 2004). The data from several large prospective observational and retrospective studies suggest that mortality rate was significantly and consistently greater among cancer patients who developed VTE as compared to patients who did not (Khorana et al. 2007).

Pathophysiology and Risk Factors for Thrombosis in Cancer

Hemostatic and Fibrinolytic Activation

The hemostatic system has been shown to be highly activated in most cancers. Even in the absence of clinical thrombosis, the majority of patients with cancer have increased levels of coagulation factors V, VIII, IX, and XI, as well as increased levels of markers of hemostatic activation (e.g., thrombin-antithrombin; prothrombin fragment 1,2; fibrinopeptide; and D-dimer) (Hoffman et al. 2001). In addition, patients with disseminated malignancies seem to have deficient activity of von Willebrand factor

(vWF)-cleaving protease (ADAMTS13), resulting in unusually large vWF multimers, a key adhesive protein involved in primary hemostasis (Oleksowicz et al. 1999). Many tumors have shown an abnormal expression of high levels of the procoagulant molecule tissue factor (TF) (Rickles and Brenner 2008) and may express an additional cysteine protease cancer procoagulant (Falanga and Gordon 1985). In addition to the expression of TF, tumor cells enhance coagulation by expressing proteins that regulate the fibrinolytic system, including plasminogen activators and plasminogen-activator receptor, leading to an imbalance of fibrinolysis. Acute promyelocytic leukemia is notorious for causing both coagulopathy and hypercoagulable states, with leukemic cells with TF on their cell surface driving the coagulation disarray.

Stasis

At the organism level, malignancy, its complications, and treatments often lead to debility in patients associated with increased rates of sedentary behavior and decreased mobility (Osborne et al. 2008). These directly lead to stasis within the veins of the lower extremities, the sites of most thrombus formation. Venous catheters also lead to local disturbance in blood flow, which is associated with increased rates of thrombosis at the sites of catheters commonly associated with malignancy (Aw et al. 2012). Solid tumors, and lymphomas with large mass effect, may compress vessels and lead directly to vascular stasis, increasing the risk of clotting distal to the obstruction. Most commonly this is seen in the SVC-syndrome associated with mediastinal lymphomas, germ cell tumors, and primary cancers of the thoracic organs. Abdominal and lower extremity veins may be affected by any large, intra-abdominal tumor. Renal cell tumors present a unique situation, as vascular invasion by the tumor itself occurs, occasionally with extension as far as through the right atrium and into the pulmonary vasculature. Differentiating thrombosis from tumor may be difficult in these situations. Hepatobiliary tumors are often associated with portal vein thrombosis, both in the setting of cirrhosis and from portal vein flow reversal.

Vascular Damage

The vasculature is also intimately linked to both the oncologic process and its associated hypercoagulable state. As tumors grow, new vessel growth is required to furnish oxygen and other nutrients, as well as to clear the metabolic waste associated with highly active tumor cells. Cancer therefore stimulates new vessel growth via release of factors such as VEGF, which recruit endothelial cells for new vessel growth (albeit relatively disorganized and ineffectual, leading to the hypoxic and acidic microenvironment found in most tumors beyond a certain size). The same inflammatory mediators that lead to activation of the hemostatic system also lead to widespread activation of the vascular endothelium, which itself becomes a nidus for propagation of the coagulation cascade and ultimately thrombogenesis.

Central catheters and chemotherapeutic agents (see below) are also associated with vascular damage (Bona 1999). The direct physical irritation of blood vessels by central catheters leads to endothelial damage and clot formation and may lead to morbidity and mortality (Aw et al. 2012). Indwelling catheters are associated with a 27–67 % incidence of catheter-associated DVT (Bona 1999; Verso and Agnelli 2003). Chemotherapeutic agents are distributed to the tissues of the body by the vasculature, and these toxic agents may lead to endothelial activation. Some chemotherapeutic agents also appear to directly activate other components of the blood vessels (Otten et al. 2004), as can be seen with cisplatin treatment and arterial events (Moore et al. 2011).

Inflammation and Host Response

The close interactions between the inflammatory/immune system and the hemostatic system are a large part of what underlies the hypercoagulability found and associated with malignancy. Inflammatory mediators are produced by the immune effector cells in response to malignancy as part of the mechanisms to control and eradicate the rogue cancer cells. The hemostatic and inflammatory systems are linked most closely at the start of the intrinsic coagulation cascade, where factor XII is converted to its active form

by multiple members of the inflammatory system, including kininogen. In this way, besides TF acting on the extrinsic pathway, the intrinsic pathway is also recruited to amplify the coagulation cascade and thereby exacerbate the prothrombotic state (Rickles and Brenner 2008). Tumor-infiltrating macrophages may lead to downstream production of TF, and cytokine response to tumor and/or therapy may increase thrombotic tendencies.

Inflammation is also associated with both chemotherapeutic treatment and the infections caused by the immune-compromised state associated with chemotherapeutic treatments. Indeed, some of the highest rates of thrombosis in cancer patients are found during periods of hospitalization when patients are both immobilized, and the immune system is mounting high levels of inflammatory responses (Esmon 2003).

Cancer therapy also increases the risk for VTE, including surgery, chemotherapy, anti-angiogenic therapy, and hormonal therapy. Oncologic surgery is associated with an increased rate of VTE compared to noncancer surgery (White et al. 2003; Clagett and Reisch 1988). Chemotherapy has been known to increase the risk of thrombosis for some time (Lee and Levine 1999; Levine et al. 1988). In a prospective, multicenter, observational study, the overall incidence of VTE in an ambulatory population starting new chemotherapy was 1.93 % with a median follow-up of 2.4 months. The rate of VTE observed in this study (0.8 % per month) was substantially in excess of the estimated rate of approximately 0.04 % per month for the entire cancer population (Blom et al. 2004). Similarly, anti-angiogenic therapies may have significant effects on VTE incidence (Nalluri et al. 2008). Hormonal therapy is also recognized to increase the risk for VTE (Lee and Levine 1999; Ehdaie et al. 2011).

Specific factors increasing the risk for VTE include cancer type (e.g., pancreatic cancer, brain cancer, lymphoma) and stage (Levitan et al. 1999; Blom et al. 2005). In addition to the histology and type of cancer, there are various other factors that contribute towards the development of VTE in the setting of malignancy. Such factors have been identified using data from population-based databases, registries, hospital records, retrospective cohorts, prospective observational studies, and clinical trials (Table 1).

Although the development of VTE in a patient with known cancer is the most common presentation, in some patients VTE may precede the diagnosis of malignancy (Murchison et al. 2004). Both retrospective and prospective studies have identified this phenomenon (Nordstrom et al. 1994; Sorensen et al. 1998). The variation in clinical presentation is likely due to the heterogeneous biology of different tumor types and reflects the limitations of detection or available diagnostic methods. Accumulating evidence now

suggests that oncogenic events also trigger activation of the coagulation cascade, leading to a thrombotic environment that not only manifests as VTE but also promotes the growth of the malignancy (Rickles and Brenner 2008).

Clinical Risk Stratification

It is increasingly recognized that ambulatory patients (especially those receiving systemic therapy) are at increased risk for VTE, and the vast majority of patients with cancer are in the ambulatory setting. The five-item Khorana model has been validated, using data from the Vienna Cancer and Thrombosis Study in a much broader range of patients (Khorana et al. 2008). The major advantage of this model is the easy availability of these common clinical markers, while the major limitation is the generalizability of the results. This model identifies about 7 % of cancer patients receiving chemotherapy in the ambulatory setting as high risk of VTE. Furthermore, the model is able to identify about 30 % of patients as low risk for VTE. This model is also being tested in an ongoing study, funded by the National Heart, Lung, and Blood Institute (www.clinicaltrials.gov NCT00876915).

Treatment and Secondary Prophylaxis of VTE in Cancer

Venous thromboembolic disease is a leading cause of death among cancer patients (Khorana et al. 2007). In addition, patients with cancer and thrombosis are at increased risk of VTE recurrence compared with noncancer patients and at increased risk of death due to malignancy compared to cancer patients without VTE (Levitan et al. 1999; Sorensen et al. 2000).

The recommended treatment for cancer-associated thrombosis is low molecular weight heparin (LMWH). For the initial treatment phase, post hoc data from randomized trials suggest comparable efficacy between unfractionated heparin (UFH) and LMWH. Based upon several prospective studies (see Table 2), recommendations for the treatment of proximal lower extremity DVT and/or pulmonary embolism in the setting of active cancer are with the use of extended LMWH therapy (Lyman et al. 2007; Geerts et al. 2008), and this therapy appears to be feasible. Some of the new anticoagulants including dabigatran and rivaroxaban are comparable to warfarin in efficacy and safety in a general patient population, but these trials include only a minority of cancer patients and have not been compared directly with LMWH.

Primary Prophylaxis

Primary anticoagulant prophylaxis is recommended in all oncology patients admitted to the hospital for surgical or medical reasons (Lyman et al. 2007). Although there are data for UFH, low molecular weight heparin (LMWH), fondaparinux, and warfarin for primary prophylaxis, contemporary studies have largely studied LMWH (Geerts et al. 2008). The ACCP, ASCO, NCCN, and ESMO guidelines recommend antithrombotic prophylaxis for cancer surgery for at least 7–10 days postoperatively (Lyman et al. 2007; Geerts et al. 2008). The benefit of extended prophylaxis for VTE following cancer surgery was first demonstrated by the ENOXACAN II study (ENOXACAN study group 1997). The role of antithrombotic prophylaxis in the prevention of central venous catheter-related thrombosis is controversial, and the international guidelines do not recommend prophylaxis for this indication (Lyman et al. 2007; Geerts et al. 2008).

The benefit of antithrombotic prophylaxis in ambulatory cancer patients receiving chemotherapy has been evaluated in several studies that have demonstrated efficacy. An early high-quality study utilized low-dose warfarin to decrease VTE in women receiving therapy for breast cancer (Levine et al. 1994). More recently, prophylactic treatment with LMWH in

Cancer and Thrombosis, Table 2 Clinical trials for long-term use of LMWH in patients with VTE and cancer

Study	Trial design	Arms	Results	Comments
CANTHANOX (Meyer et al. 2002)	Randomized open label multi-institutional study	1. Enoxaparin	For enoxaparin group: 8 (11.3 %) had PE, 19 (26.8 %) had DVT, and 44 (62 %) had both DVT/PE	No statistically significant difference in combined primary outcome between enoxaparin group (7/67, 10.5 %) and warfarin group (15/71, 21.1 %, p = 0.09). Use of long-term LMWH in cancer patients was found to be more effective and safe
		2. Warfarin	For warfarin group: 11 (14.7 %) had PE, 25 (33.3 %) had DVT, and 39 (52 %) had both	
ONCENOX (Deitcher et al. 2006)	Randomized open label multi-institutional trial	1. Enoxaparin 1 mg/kg SC 2 times/day for 5 days, followed by 1 mg/kg SC 1 time/day for 175 days	Regarding primary outcomes, compliance rates were 97.9 % and 97 % for the two enoxaparin groups, and 90.1 % for warfarin group	Treatment with enoxaparin was feasible, generally well tolerated, and effective for a 180-day period in secondary prevention of VTE in cancer patients
		2. Enoxaparin 1 mg/kg SC 2 times/day for 5 days, followed by 1.5 mg/kg SC 1 time/day for 175 days	Secondary results for efficacy showed no difference in recurrent VTE rates for enoxaparin 1 mg/kg SC once daily group (1/29, 3.4 %), enoxaparin 1.5 mg/kg SC once daily group (1/32, 3.1 %), or warfarin group (2/30, 6.7 %, no p-value)	
		3. Enoxaparin 1 mg/kg SC twice daily for at least 5 days, until they reached therapeutic INR. Warfarin was started on day two of treatment and continued until patients received 180 total days of anticoagulation		
CLOT (Lee et al. 2003)	Randomized multi-institutional study	1. Dalteparin + coumarin derivative	27/336 (8.0 %) patients in dalteparin group had recurrent VTE, compared to 53/336 (15.8 %) patients in oral anticoagulant group (hazard ratio, 0.48; p = 0.002)	Dalteparin was more effective than oral anticoagulant in reducing the risk of recurrent VTE, without increasing bleeding risk
		2. Dalteparin alone		
LITE (Hull et al. 2007)	Randomized open label multi-institutional study	1. Tinzaprin	Of 737 patients, 18/369 (4.8 %) receiving tinzaparin had recurrent VTE at 3 months compared with 21/368 (5.7 %) receiving Vitamin K antagonist	Tinzaparin is similar in effectiveness to the usual-care vitamin K antagonist treatment for preventing VTE in a broad population of patients
		2. Vitamin K antagonist		
Tinzaparin prospective study (Tagawa et al., 2010)	Single-arm dual-center prospective study including biomarkers	Tinzaparin for 6 (up to 12) months at investigator discretion	11.3 % recurrent VTE rate (including unsuspected VTE on staging imaging); 3 % major bleeding	Increase in D-dimer at 1 month was associated with recurrent VTE (p = 0.009)

Cancer and Thrombosis, Table 3 Clinical trials of prophylactic anticoagulation in cancer patients receiving chemotherapy

Trial name	Patient population	Treatment arms	No. of patients	Results	Comments
Levine et al. (1994)	Women with breast cancer receiving chemotherapy	1. Warfarin 2. Placebo	311	There were 6 DVT, 1 PE in placebo group and 1 PE in warfarin group, a relative risk reduction of about 85 % ($p = 0.031$). Bleeding occurred in 2 placebo recipients and 1 warfarin-treated patient	Very-low-dose warfarin is a safe and effective method for prevention of VTE in patients
PROTECHT (Agnelli et al. 2009)	Patients with lung, breast, gastrointestinal, ovarian, or head and neck cancer receiving chemotherapy	1. Nadroparin 2. Placebo	1,150	Incidence of symptomatic venous and arterial thromboembolic events in nadroparin arm was 2 % versus 3.9 % in placebo group	High rates of VTE in lung (8.8 %) and pancreatic cancer patients (5.9 %) suggest need for more trials in these groups
CONKO 004 (Riess et al. 2009)	Advanced pancreatic cancer patients receiving chemotherapy	1. Enoxaparin 2. Observation	312	Sixty-five percent relative risk reduction of symptomatic VTE following use of enoxaparin 5 % versus 14.5 % for observation group	No overall survival difference between two groups
FRAGEM (Maraveyas et al. 2012)	Advanced pancreatic cancer patients eligible to receive gemcitabine	1. Gemcitabine + Dalteparin 2. Gemcitabine alone	123	Incidence of all-type VTE during the entire follow-up was 12 % in dalteparin group versus 28 % in those receiving chemotherapy alone	No significant difference in survival or bleeding events
SAVE-ONCO (Agnelli et al. 2012)	Metastatic or locally advanced solid tumors who were beginning to receive a course of chemotherapy	1. Semuloparin 2. Placebo		Occurrence of VTE was 1.2 % in semuloparin group versus 3.4 % in placebo group; HR 0.36; 95 % CI 0.21–0.60	No significant survival benefit found at 1-year follow-up

ambulatory patients receiving chemotherapy has been demonstrated to be efficacious with risk reductions VTE (see Table 3). However, it remains to be seen if these studies will change clinical practice, and no prospective studies have examined cost-effectiveness. Currently, VTE prophylaxis in ambulatory patients is recommended only for patients with multiple myeloma receiving thalidomide or lenalidomide-based combination chemotherapy (Lyman et al. 2007).

While not the subject of this entry, anticoagulants may have anticancer properties. Several retrospective studies pointing towards a survival benefit independent of VTE incidence led to a number of prospective studies with response or survival endpoints. Overall, pooled data point towards a reduction in the risk of death in subjects receiving anticoagulation therapy (Akl et al. 2007, 2010).

Conclusion

Venous thromboembolism is a significant source of morbidity and mortality in patients with cancer. Tumor factors, host factors, and treatment lead to the increased risk of VTE in the setting of

malignancy. Patients with cancer and thrombosis should be viewed as a special population and treated differently than similar patients with thrombosis in the absence of malignancy. The onset of idiopathic VTE may be the first manifestation of malignancy. In high-risk settings particularly, such as hospitalized and perioperative situations, VTE prophylaxis is indicated. Primary VTE prophylaxis in the ambulatory setting decreases the incidence of thrombosis, though the cost-effectiveness of this approach has not yet been demonstrated. Lastly, in addition to decreasing the risk of onset or recurrence of VTE, anticoagulants (in particular LMWH) may have antitumor properties which may lead to prolonged survival in the setting of malignancy.

Definition

Historical Background

CD40 is a type I integral membrane protein and a member of the tumor necrosis factor receptor (TNFR) family of molecules that functions as a major communication link between antigen-presenting cells (APCs) (B cells, macrophage, and dendritic cells (DCs)) and CD4 T cells. In the years prior to the discovery of CD40, there was widespread appreciation that antigen-specific activation of naïve B cells required contact-dependent interactions with activated T cells. However, only subsequent to demonstrating that contact was independent of cognate MHC interactions did it become clear that B-T cell contact required interactions with membrane-associated factors and not just cytokines (Banchereau et al. 1994; Lederman et al. 1993). CD40 was initially discovered as a B cell surface protein that could drive the proliferation and enhance the differentiation of B cells following stimulation with anti-CD40 antibodies (van Kooten and Banchereau 2000). CD40 expression occurred at all stages of B cell development (except for late-stage plasmablasts), whereas its ligand known as CD154 or CD40L was transiently expressed primarily on activated CD4 T cells. The absolute requirement for CD40-CD40L signaling in humoral immunity was first demonstrated in patients expressing a severe form of immunodeficiency termed X-linked hyper-IgM syndrome (HIGM1). These individuals displayed deficient CD40L expression, which resulted in significantly increased levels of IgM with a corresponding lack of "switched" isotypes (IgG, IgA, or IgE). Also, patients failed to form germinal centers (GCs) in their lymph nodes in response to antigenic challenge. Further work with animal models lacking either functional CD40 or CD40L confirmed that CD40 signals were essential for establishing both humoral and cell-mediated immune responses (Lougaris et al. 2005).

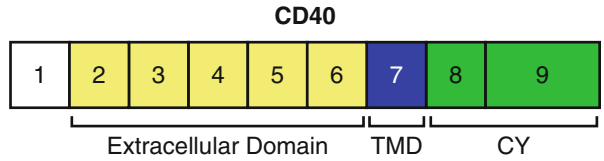
Structure of CD40 and CD40L

The structure of human CD40 was deduced from a cDNA isolated from a B cell expression library and shown to be a type I integral membrane protein comprised of 277 amino acids with a 193-amino-acid extracellular domain and a 62-amino-acid intracellular tail (Fig. 1) (van Kooten and Banchereau 2000). A comparison of the human and mouse forms of the protein uncovered a high level of identity at the amino acid level 62 % and complete conservation of 32 amino acids at the carboxyl terminal end of the protein. Also, all four of the extracellular cysteine residues are highly conserved, suggesting that the folding of the structural regions between mouse and human CD40 are identical. The mouse CD40 gene is located on the distal region of chromosome 2, which is syntenic to human chromosome 20Q11–Q13, harboring the human CD40 gene. CD40 exists as multiple spliced isoforms, and these different forms are correlated with distinct functional responses (Tone et al. 2001).

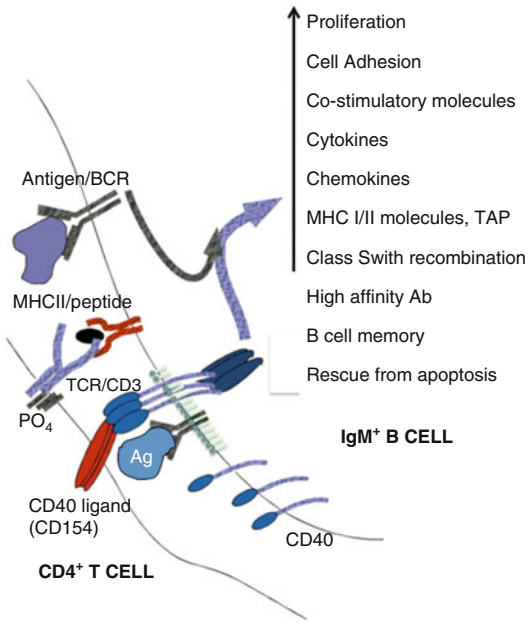
The structure of the CD40L protein was initially identified as a 33–39 kDa type II integral membrane protein that shared a high degree of homology to TNF-α. X-ray crystallographic data structure consisting of a sandwich of two β-sheets with jellyroll topology and revealed a surface topography that was homotrimeric with three-way symmetry. This type of 3-dimensional organization was reminiscent of both TNF-α and LT-α proteins. In addition to the full-length protein, two shorter, soluble versions of the CD40L protein were identified (31 and 18 kDa), and these forms retained their ability to trimerize and deliver biological signals through engaging CD40 (van Kooten and Banchereau 2000).

CD40 and B Cell Function

The initial discovery of CD40 was followed by an intense and productive period of investigation by many laboratories that focused primarily on the characterization of CD40-mediated functional responses in B cells. In vitro experiments revealed that CD40 was required for multiple B cell processes including proliferation, differentiation, and Ig production of both immature and mature B cell subsets (Banchereau et al. 1994; Noelle 1995; van Kooten and Banchereau 2000). In addition, early studies highlighted the critical



CD40, Fig. 1 Molecular organization of human CD40. Exons (1–9) are indicated by *boxes* and depicted as components of the extracellular domain, transmembrane domain (*TMD*), or cytoplasmic domain (*CY*)

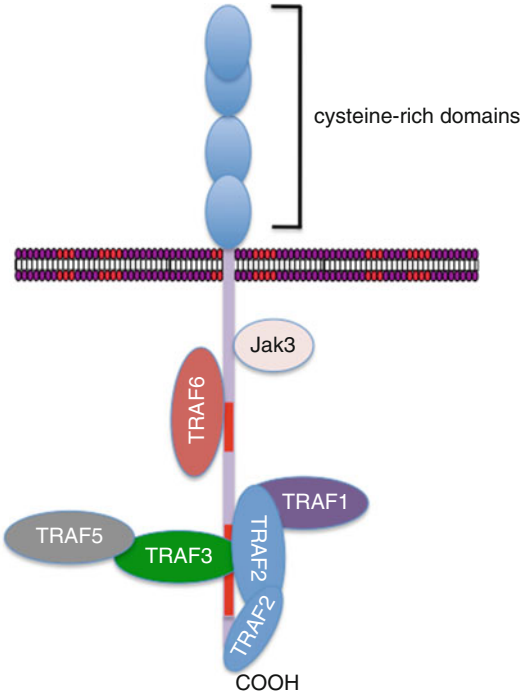


CD40, Fig. 2 CD40 signaling is provided to B cells that have encountered antigen (*Ag*) through the B cell receptor (*BCR*). These signals lead to a multitude of phenotypic changes that form the basis of the humoral immune response

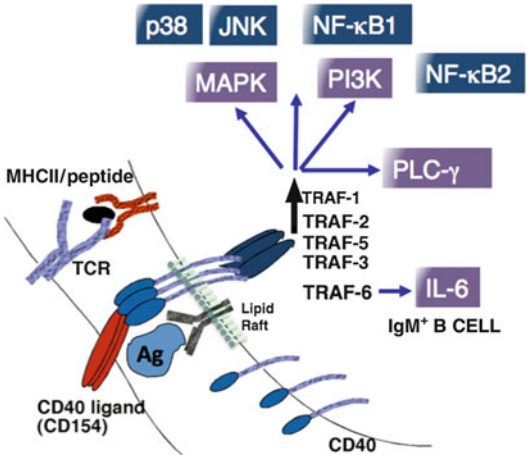
role of CD40 in the B cell maturation program including rescue from apoptosis, GC formation, isotype switching, somatic hypermutation, and B cell selection and development into memory cells. CD40 signals also directly affected cytokine production and expression of adhesion molecules and costimulatory receptors and increased the expression of MHC class I, MHC class II, and TAP transporter molecules (Fig. 2) (van Kooten and Banchereau 2000). However, CD40 signaling was shown to be dispensable for thymus-independent (TI) antibody responses, as evidenced by the fact that responses mounted to TI antigens (TNP-LPS and TNP-Ficoll) were similar between CD40-deficient and wild-type mice (van Kooten and Banchereau 2000). Overall, these findings revealed that CD40 is essential for generating responses to thymus-dependent (TD) antigens, responses that inherently result in the development of B cell memory and the corresponding production of somatically mutated, high-affinity antibodies.

Signaling Through Tumor Necrosis Factor Receptor-Associated Factors (TRAFs)

CD40 is distributed randomly throughout the plasma membrane and upon CD40L engagement clusters into cholesterol- and glycolipid-rich microdomains (termed lipid rafts). These unique membrane structures consist of concentrated pools of signaling molecules and are sites of initiation of signaling pathways for many different receptors including the B cell Receptor (BCR) and the T cell (TCR) receptor (Bishop et al. 2007). CD40 lacks intrinsic signaling capability and therefore is dependent on TNFR-associated factor (TRAF) adapter proteins to transmit CD40-mediated signals. This family of molecules is composed of six members, designated TRAF1 through TRAF6, that function by binding to discrete sites within the conserved carboxyl domain of TNFR family members including CD40 (termed the TRAF domain). Mapping experiments revealed that TRAF1, TRAF2, and TRAF3 bind to overlapping sites within the distal end of the CD40 intracytoplasmic tail that contains the consensus sequence PxQxT. A second, noncanonical binding site for TRAF2 resides adjacent to the carboxyl terminus (Elgueta et al. 2009). In contrast, the TRAF6 consensus site lies in the membrane proximal domain of CD40 (Fig. 3). The TRAF2/3 consensus site is required for the induction of



CD40, Fig. 3 The cytoplasmic domain of CD40 has two major binding sites for TRAF molecules which are situated proximal (TRAF6) and distal (TRAF1, 2, 3, and 5) from the membrane. A second TRAF2 binding site has been identified at the carboxyl end of the protein.



CD40, Fig. 4 Schematic of signaling pathways and transcription factors activated in response to CD40-CD40L engagement

NFκB, mitogen-activated protein kinase (MAPK)-JNK and MAPK-p38 pathways; however, in B cells, TRAF2 is a strong positive regulator and TRAF3 is a negative regulator of the canonical and noncanonical (NF-κB) pathways (Bishop et al. 2007; Elgueta et al. 2009). Accordingly, loss of TRAF3 is associated with an increased incidence of B cell lymphomas in both mice and humans (Bishop and Xie 2007). TRAF1 primarily binds to CD40 indirectly by forming multimers with TRAF2 and TRAF1 can bind directly to CD40 in the absence of TRAF2. TRAF5 does not directly bind to the CD40 tail but forms heterotrimers with TRAF3 upon CD40-CD40L contact. Lastly TRAF6 binding is required for the production of IL-6 by B cells. The binding of TRAF molecules as homo- or heterotrimers or as higher-order oligomers most likely drives the diverse array of downstream effector functions that are the consequence of CD40 signaling.

The engagement of TRAF signaling by CD40 results in the activation of multiple signaling cascades including the MAPK JNK and -p38 phosphoinositide 3-kinase (PI3K), and the phospholipase Cγ (PLCγ) pathways, leading to the induction of multiple signaling pathways including the canonical and noncanonical NF-κB-signaling pathways (Fig. 4). More recent findings suggest that TRAF-independent signaling may occur through the direct binding of Janus family kinase 3 (Jak3) to a consensus site within the intracytoplasmic domain of CD40. Binding of Jak3 induces the phosphorylation of signal transducer and activator of transcription 5 (STAT5). Together, these complex pathways transmit the essential transcription-dependent and transcription-independent signals that underlie CD40-specific functions (Bishop et al. 2007; Elgueta et al. 2009). Numerous studies suggest that the strength and duration of CD40 signals are critical for inducing specific downstream responses. This is observed at the level of different stimuli where anti-CD40 antibodies trigger only a subset of responses compared to trimeric CD40L (Bishop et al. 2007; Elgueta et al. 2009). For example, aggregating CD40 through binding to membrane-bound or trimeric CD40L is required for TRAF6 binding which results in the production of IL-6.

CD40 and the GC Response

It has been recently appreciated that the strength and duration of CD40 signaling have a major impact on the fate of antigen-selected B cells in secondary lymphoid tissues. B cells require CD40 signals to generate GCs as evidenced by the fact that an absence of signal fails to give rise to GC formation. The quality of CD40 signaling markedly influences the differentiation outcome of B cells in the GC such that when a high level of stimulus is provided in the context of an ongoing immune response, B cells are selected to differentiate into plasmablasts and are precluded from entering the GC reaction. However, once B cells are selected to colonize the B cell follicles and initiate GC formation, daughter centrocytes with enhanced BCR affinity for antigen will engage CD40L on follicular T helper cells, resulting in an effective block in Fas-dependent apoptosis through Bcl-XL- and c-FLIP-dependent mechanisms. In contrast, if a B cell expresses a BCR with weak antigen affinity, it fails to receive adequate BCR and CD40 survival signals and is deleted from the repertoire (Benson et al. 2007). The effects of graded levels of CD40 signals have been analyzed for affects in other APCs. Accordingly, strong and weak CD40 signals resulted in phenotypic and functional changes in both macrophage and DCs (Benson et al. 2007).

Expression of CD40 in Other Cell Types

Although early work focused on the critical role of CD40 in B cell biology, it became increasingly clear that CD40 was expressed in a much broader context and by a number of distinct cell types including myeloid cells, DCs, follicular DCs, endothelial cells, fibroblasts, epithelial cells, and keratinocytes (Elgueta et al. 2009; van Kooten and Banchereau 2000). Also, the spectrum of cells expressing CD40L was expanded to include mast cells, basophils, eosinophils, and activated platelets (Elgueta et al. 2009). Thus, the scope of effector functions that were controlled by CD40-CD40L signaling was greatly elaborated to more accurately reflect the expression pattern of these two molecules. Importantly, CD40-CD40L interactions were found to be critical for effective macrophage and DC function and to strongly influence T cell priming and consequently, T cell-mediated functions. The critical role of the receptor-ligand pair in APC function reflects the fact that CD40 signaling directly results in the upregulation of costimulatory molecules CD80 and CD86 on APCs. Ligation of these proteins by CD28 expressed on T cells leads to the induction of effector functions such as CD8 cytotoxic activity and the expression of multiple cytokines and chemokines critical for inflammatory responses (van Kooten and Banchereau 2000). Thus, in addition to roles in humoral immunity, CD40 and CD40L are central players in inflammatory processes and the cell-mediated immune responses to infection (Elgueta et al. 2009; Grewal and Flavell 1997; van Kooten and Banchereau 2000).

CD40 Expression and Macrophage Function

The interpretation of CD40 signals by macrophage and monocytes is known to be highly dependent on the tissue source of cells and most likely reflects the priming effect of the tissue environment (Elgueta et al. 2009). Generally, CD40 ligation of on macrophage/monocytes produce a proinflammatory signature including the production of cytokines (IL-1α and IL-1β, TNF-α, IL-6, and IL-12) and chemokines (MCP-1, RANTES, MIP-1α, and MIP-1β) and the upregulation of MHC class II and costimulatory molecules (CD80 and CD86) (Elgueta et al. 2009). Importantly, CD40 engagement also induces the expression of matrix metalloproteinases and nitric oxide (NO), mediators required for the destruction of damaged or infected cells. Interestingly, treatment of tumor-bearing mice with an agonistic anti-CD40 mAb was found to activate macrophage cytostatic activity, which led to the suppression of tumor cell growth (Loskog and Totterman 2007). Whereas TGF-β, a cytokine that inhibits CD40 responses and is expressed by many different tumor types, is capable of rendering tumor-associated macrophage incapable of mounting an attack on the tumor. Thus, the tissue environment and the nature of the delivery of the CD40 stimulus dictate the cellular outcomes that either can be protective from disease or contribute to disease progression.

The Role of CD40 in Infection

As mentioned earlier, CD40-CD40L interactions are critical for the development of CD8 T cell immunity, which in turn mediates immune responses to intracellular pathogens and tumors. Optimal activation of CD8 T cells requires engagement of the Ag receptor (TCR by Ag/MHC class I) and costimulatory signals through CD80/86 and CD28. In addition, some CD8 T cell responses require additional signals from CD4 T cells and/or dendritic cells. It is thought that CD4 T cells provide signals to dendritic cells via CD40L-CD40 interactions to prime and form CTL memory. Another hypothesis is that CD4 cells stimulate CD8 T cells directly by binding to CD40 expressed on CD8 T cells (Grewal and Flavell 1998; Munroe, 2009). Both $CD40^{-/-}$ and $CD40L^{-/-}$ mice exhibit impaired *Chlamydia muridarum* infection clearance compared to WT mice, as well as increased susceptibility to *Leishmania* infection. Also, $CD40^{-/-}$ mice have increased susceptibility and mortality to West Nile virus infection. Accordingly, patients with HIGMI have increased susceptibility to *Toxoplasma gondii* infection and other opportunistic infections including *cryptosporidium*, *Pneumocystis carinii*, *mycobacteria*, and cytomegalovirus, underscoring the fact that cell-mediated immunity is jeopardized in these patients (Etzioni and Ochs 2004). Thus, CD40 signaling is required for effective pathogen clearance through the induction of an array of effector functions and at multiple stages of infection.

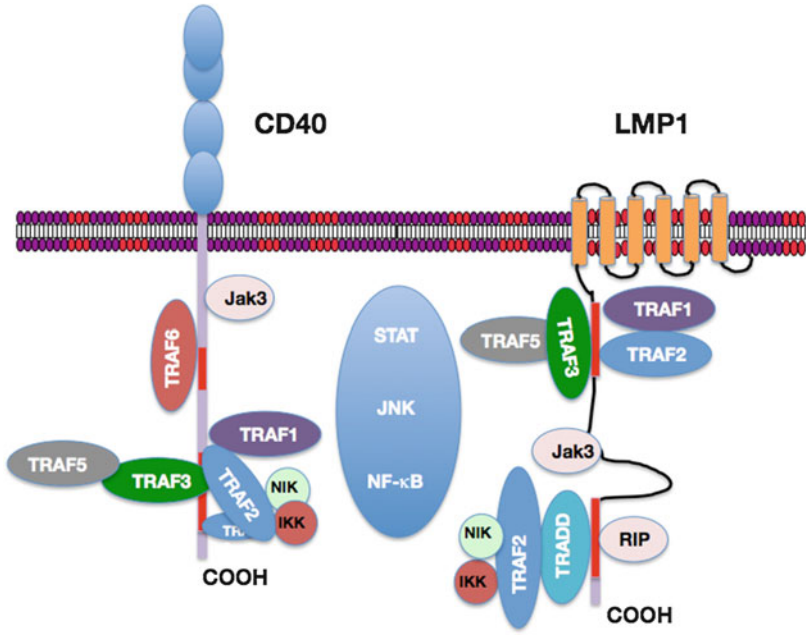
CD40 and Autoimmunity

The importance of CD40-CD40L interactions in mediating inflammatory responses formed the basis of investigating a possible role in autoimmune disorders. Not surprisingly, deregulated CD40-CD40L expression was found to be prominently featured in both systemic and tissue-specific autoimmunity (Peters et al. 2009). Importantly, anti-CD40L treatment was able to suppress autoantibody production in models of collagen-induced arthritis, systemic lupus erythematosus (SLE) nephritis, and experimental autoimmune encephalomyelitis (EAE). In addition, treatment of mice with anti-CD40L antibodies blocked the development of T cell-mediated disorders through interfering with the priming of self-recognizing T cells. In all cases, treatments were accompanied by a reduction in damage and/or infiltration of leukocytes to target tissues. Because many autoimmune disorders have a complex pathophysiology, the levels at which the blocking antibodies are acting are most likely highly variegated and include antigen presentation, antibody production, and induction of inflammatory cytokines (Peters et al. 2009). For both lupus nephritis and EAE, blocking antibodies interfered with ongoing disease, indicating that CD40-CD40L interactions are essential for the effector phase of disease.

In many autoimmune diseases, there is a significant increase in CD40 and/or CD40L expression; however, in most cases, heightened expression is not correlated with genetic polymorphisms at the respective loci. An exception to this observation is a CD40 polymorphism associated with the development of Graves' disease (GD). This disease leads to loss of thyroid gland function and is associated with autoantibodies against the thyroid-stimulating hormone receptor. In this particular case, linkage studies revealed that the CD40 gene locus was strongly linked with GD. This association is due to a C/T polymorphism in the Kozak consensus sequence that flanks the ATG start codon and is essential for translation initiation. Enhanced CD40 expression has been identified in thyroid tissue of GD patients bearing the C polymorphism and is thought to be a contributing factor to the pathogenesis of disease (Maier and Hafler 2009).

The Impact of CD40 on Atherosclerosis

Activated T cells and macrophages are important factors in the generation of inflammatory atherosclerotic plaques, and associated immune responses may, in some cases, constitute an autoimmune response against an unidentified antigen (Anand et al. 2003). Endothelial cells (EC), smooth muscle cells (SMC), and macrophage participate in atherogenesis (Anand et al. 2003). Importantly, human EC express CD40 and ligation through CD40L engagement leads to upregulation of adhesion molecules, which are



CD40, Fig. 5 A comparison of the intracellular domains of CD40 and LMP1 showing the approximate sites of TRAF binding as well as binding of Jak3, TRADD, RIP, NIK, and IKK. Listed within the *blue oval* are the pathways activated by those two molecules

also critical biomarkers of human atheromas. CD40 and CD40L are co-expressed on vascular endothelium and SMC in atherosclerotic lesions. Therefore, CD40L expressed by both the vascular wall and resident T cells is capable of ligating to CD40 expressed on EC, SMC, and infiltrating macrophage. This signaling cascade ultimately results in the expression of cytokines, matrix metalloproteinases, and adhesion molecules, all proteins normally present at high concentrations in human atheroma (Anand et al. 2003).

CD40 and Its Viral Mimic, LMP1

Epstein-Barr virus (EBV) is a γ-herpes virus that preferentially infects human B cells. Its successful persistence in cells is sustained by the function of several virally encoded proteins that are mimics of cellular factors critical for B cell physiology. The viral latent membrane protein 1 (LMP1) is one such protein and has been identified as the functional homologue of CD40 (Bishop and Hostager 2001). Important similarities exist between CD40 and LMP1 including the fact that signaling through either molecule leads to activation, proliferation, and survival of B cells. This functional identity reflects the ability of the intracellular domains of both LMP1 and CD40 to bind TRAF molecules and activate overlapping signaling pathways (Fig. 5). There are, however, recognized differences in the TRAF binding patterns of LMP1 and CD40 that suggest corresponding differences in select functional responses. Whereas both LMP1 and CD40 interact with TRAFs 1, 2, 3, and 5, only CD40 binds directly to TRAF6. Also, LMP1 requires TRAF3 as a positive regulator of NF-κB activity, whereas it is a negative regulator for the same pathways in B cells. Finally, LMP1 selectively binds to the tumor necrosis factor receptor-associated death domain (TRADD) protein and receptor-interacting protein (RIP) (Kilger et al. 1998).

Other distinctions in TRAF utilization directly reflect functional differences between CD40 and LMP1. As mentioned above, CD40L engagement with CD40 on B cells results in the association of CD40 with TRAF2/3 complexes; however, TRAF2 and 3 are rapidly ubiquitinated and degraded through the proteosome (Bishop et al. 2007). This degradation step leads to the downregulation of signal transmission. LMP1-mediated TRAF binding is highly stable and the difference in stability likely accounts for the fact that LMP1 provides a stronger and more

sustained signal than CD40. However, B cells that express both LMP1 and CD40 and receive signals through CD40-CD40L show an overall dampening of responses compared to LMP1 signaling alone. A plausible explanation for this lowered response is that selective TRAF degradation that accompanies CD40 signaling reduces the effective pool of TRAF3 available for subsequent signaling by LMP1. Another difference between CD40 and LMP1 is that LMP1 is constitutively located in the lipid rafts whereas CD40 moves into lipid rafts upon CD40L contact. Finally, the most striking difference between LMP1 and CD40 is that LMP1 constitutively signals in a ligand-independent manner through the self-aggregation of its 6 transmembrane-spanning domains and CD40 requires trimerization by binding to CD40L (Bishop and Hostager 2001).

To better define functional similarities of LMP1 and CD40 signaling, mice were created that expressed LMP1 in B cells deficient for CD40. Surprisingly, only a partial restoration of CD40 activity was achieved in inducing antibody class switching to IgG1, but not GC formation or the production of high-affinity antibodies after immunization. LMP1 expression even blocked GC formation in the presence of the endogenous CD40 receptor, indicating that LMP1 had an overall negative effect on differentiation. Also, constitutively active CD40 signaling in B cells produced by a fusion protein of the transmembrane domain of LMP1 and the signaling domain of CD40 inhibited the GC reaction, suggesting that GC formation can be blocked by the constitutive activation of B cells by either LMP1 or CD40 (Bishop et al. 2007).

CD40 and Cancer

The discovery that the CD40 pathway was absolutely critical for promoting B cell proliferation and rescue from apoptosis led to experiments that tested the role of CD40 in tumorigenesis. CD40 overexpression occurs in the vast majority of hematopoietic cancers and in greater than 75 % of all epithelial cancers. Also, in many cases, CD40 and CD40L are co-expressed on the same tumor cell. Accordingly, several hematopoietic cancers, including non-Hodgkin lymphoma, chronic lymphocytic leukemia, and Burkitt lymphoma, enhance proliferation and survival through an autocrine CD40-CD40L loop that acts primarily through the constitutive activation of NF-κB (Bereznaya and Chekhun 2007). This type of process may also be active in solid tumors that are capable of co-expressing CD40 and CD40L such as breast and kidney carcinoma and melanoma, where the presence of CD40L correlates with a more aggressive malignancy and shorter patient survival than tumors lacking CD40L (Bereznaya and Chekhun 2007). CD40 signaling can also drive tumor cell migration through the PI3K and NF-κB signaling pathways. It has been demonstrated that CD40 can indirectly promote tumor growth since chronically produced CD40L in the tumor microenvironment facilitates angiogenesis through the activation of CD40 expressed by endothelial cells. Metastasis can also be enhanced by tumor-expressing CD40 interacting with CD40L expressed on activated platelets (Bereznaya and Chekhun 2007).

It is clear that specific CD40-dependent signals are capable of providing growth and survival advantages to specific hematological malignancies; however, in a number of cases, CD40-CD40L interactions can also severely inhibit tumor growth. For example, a subset of aggressive B cell lymphomas respond to CD40 ligation with sensitization to apoptosis induced by chemotherapy, CD95/Fas engagement, or serum withdrawal. Also, CD40L treatment of primary high-grade B cell lymphoma, multiple myeloma, and Burkitt lymphoma results in a marked decrease in cell proliferation both in vitro and in xenotransplanted mouse models. Additionally, deregulation of the CD40 pathway has been shown to occur in CD4+ T cells from patients with chronic lymphocytic leukemia, and these leukemic cells are capable of suppressing CD40L expression in cocultured allogeneic T cells. In contrast, CD40 ligation of low-grade B cell malignancies, such as follicular lymphoma, chronic lymphocytic leukemia, and hairy cell leukemia, often stimulates cell

proliferation, underscoring the fact that the response to CD40 can be highly dependent on the differentiation state of the tumor.

The CD40 pathway is critical for the antitumor immune response through the function of DCs that are capable of cross-presenting tumor antigens to CD8 cytotoxic T cells and priming them for activation. Maturation of the DCs is required for effective priming, and this process is controlled by the binding of CD40 on the DCs with CD40L on CD4 T cells (Bereznaya and Chekhun 2007). Mature DCs have upregulated antigen-processing and presentation pathways and migrate to the lymph nodes to activate naïve CD4 and CD8 T cells. The requirement for CD40 in DC priming provides an explanation for the impaired tumor antigen-specific CTL activation in CD40-deficient mice. These findings confirm the requirement for CD40 in antitumor immunity and highlight the potential for this pathway being a viable target for cancer immunotherapy. Notably, multiple studies have addressed this and demonstrated that expression of CD40L in tumor cells or direct activation of DCs with anti-CD40 antibodies results in long-lasting systemic antitumor immune responses mediated by CD8 T cells.

Summary

CD40-CD40L interactions regulate the activation and the differentiation of a number of different cell types into effector cells. In particular, widespread expression of CD40 and CD40L has been demonstrated under pathological conditions, suggesting that this pathway is important for immune homeostasis and that deregulation leads to catastrophic consequences. Interference with CD40-CD40L interactions through the use of blocking antibodies reveals the potential of harnessing this receptor-ligand pair for the treatment of various autoimmune diseases and cancer. Finally, future work will more clearly elucidate the cross talk between the innate and adaptive immune responses and decipher how CD40-CD40L communication is moderated by signaling pathways initiated by viral infection and/or other types of immune challenges.

Definition

CD5 (previous names for CD5 have included Leu-1, Ly-1, OKT-1, T1, and Tp67) is a surface glycoprotein found in association with both the T cell antigen receptor (TCR) and the B cell antigen receptor (BCR). After the TCR or BCR is activated, CD5 is upregulated and undergoes intracellular phosphorylation of its cytoplasmic tail, although the precise role of CD5, before or after phosphorylation, is not yet clear. The 5′-flanking region of human *CD5* is transcriptionally active in T cells; the Ets transcription factors in conjunction with other regulatory elements are responsible for constitutive and tissue-specific CD5 expression (Arman et al. 2004). The levels of expression can be fine-tuned by both T cells and B cells (Soldevila et al. 2011).

There is evidence that CD5 transmits an inhibitory signal, suppressing or fine-tuning the T cell or B cell antigen-specific immune response. CD5 is also expressed on the surface of essentially all mature T cells and on thymocytes; before a monoclonal antibody to CD3 was developed, measurement of total CD5+ cell counts was often used to enumerate T cells. CD5 is present on more than 50 % of human fetal B cells but on only approximately 3 % of adult human lymph node B cells. Originally, the presence of CD5 on

B cells (albeit at about one-tenth the density as expressed on T cells) was used as the definition of a distinct B cell subpopulation, the B1 cell. The B1 cell appears early in fetal development; expresses CD5 and IgM, but little IgD; resides along pleural and peritoneal linings; is self-renewing, with a more limited repertoire (likely due to the absence of expression of terminal deoxynucleotidyl transferase [TdT]); and produces "natural antibodies." Natural antibodies (usually IgM but also IgG and IgA) show little somatic mutation; have low affinity for polysaccharides, as well as proteins and lipids; and often cross-react with self-antigens. A large proportion of the serum IgM in unimmunized mice comes from B1 cells. The B1 cell has been thought to represent a precursor population for auto-aggressive (autoimmune) B cell clones.

A population of peritoneal CD5 (−) B cells was identified whose surface phenotype was in all other ways similar to CD5+ B1 cells. The subsequent consensus terminology has been to designate CD5 (+) B1 cells as B1a cells and CD5 (−) B1 cells as B1b cells (Baumgarth 2011). Recently, CD5 has been identified on the transitional B cell population and on a newly described population of pre-naïve B cells (Lee et al. 2009).

CD5 is involved in the apoptosis of antigen-activated B cells and in the maintenance of tolerance by anergic B cells. CD5 cross-linking induces extracellular mobilization of calcium, tyrosine phosphorylation of a number of regulatory proteins at CD5 serine, threonine, and tyrosine residues, and the elaboration of diacylglycerol (Simarro et al. 1997).

The ligand(s) for CD5 have not yet been proven, but a large number of candidates have been identified.

Structure of CD5

CD5 is a glycoprotein of molecular mass 67kDa when reduced, 58kDa when not reduced. It is a member of the type B "scavenger receptor cysteine-rich" (SRCR) superfamily, an ancient and highly conserved group that includes CD6, MARCO (macrophage receptor with collagenous structure), Mac-2, M160 (CD163), M130, and a family of molecules expressed on γδ T cells, called WC (workshop cluster)-1. In humans, CD6 is only 82kb distant from CD5 on the long arm of chromosome 11 (11q13); the exon/intron organization of the human CD5 and CD6 genes is very similar, differing only in the size of intron 1 and the number of exons encoding their cytoplasmic regions; the conserved structure of the two loci, in both mouse and human, supports the premise that the two genes resulted from duplication of a primordial gene.

The common structure of members of the SRCR superfamily is a curved six-stranded β-sheet embracing an α-helix (Sarrias et al. 2004). These are transmembrane proteins with an extracellular region of three cysteine-rich scavenger receptor domains, each domain of approximately 100 amino acid residues encoded by a single exon. The cytoplasmic domain of about 90 amino acid residues is highly conserved and has no intrinsic enzymatic activity, although it contains many potential docking sites for secondary intracellular messengers, including activation molecules: Lck, PI3K (phosphatidylinositol 3-kinase), CaMKII (Ca^{2+}/calmodulin-dependent kinase), and PKC; negative regulators, C-Cbl, RAS-GAP (Ras GTPase-activating protein), and SHP-1 (Src homology region 2 domain-containing phosphatase-1); and the prosurvival molecules CK2 and Akt. Lck and RAS-GAP interact with CD5 via a pseudo-ITAM (immunoreceptor tyrosine-based activation motif) region found approximately in the middle of the intracytoplasmic region of CD5; CD5 also contains a membrane-proximal pseudo-ITIM (immunoreceptor tyrosine-based inhibitory motif) which may provide SHP-1 its docking site. CD5 also mediates activation of PC-PLC (phosphatidylcholine-specific phospholipase C), resulting in the production of diacylglycerol. In summary, CD5 is an accessory molecule whose cytoplasmic tail has no intrinsic catalytic activity but whose structures assist in activating a great many further signaling molecules.

There are two known isoforms of CD5, CD5-1a (membrane bound) and CD5-1b (intracellular form), differing in exon 1. (Please note that the two isoforms of CD5, CD5-1a and CD5-1b, have nothing to do with the two types of B1 cells, B1a and B1b.) The relative (and reciprocal) expression of the B1 isoforms is regulated by IL6 in patients with systemic lupus erythematosus (SLE), due to demethylation of the CD5-E1b promoter. This differential demethylation is more notable after BCR engagement, leading the authors to speculate that the loss of the inhibitory influence of CD5 might be involved in the immunopathogenesis of SLE (Garaud et al. 2009). The levels of these two forms are determined by regulating the levels of DNA methyltransferase with immunological consequences – decreased levels of expression of CD5-1a, the cell membrane form, are associated with lowering the threshold for BCR signaling. Defects in methyltransferase have been described in patients with SLE and in the MRL/lpr mouse which develops a lupus-like syndrome; there is recent evidence suggesting that microRNA abnormalities, specifically of mi-21 and mi-148a, may drive this defect in DNA methylation (Pan et al. 2010). Youinou and Renaudineau have discussed how such a defect in DNA methyltransferase activity could predispose to the development of SLE via decreased expression of CD5-1a (Youinou and Renaudineau 2011); this phenomenon is discussed below, under disease associations.

No alternative splicing forms have been reported.

Deletion mutations of the cytoplasmic region of CD5 have shown that retention of the single membrane-proximal tyrosine (within the pseudo-ITIM) was sufficient to maintain all observed negative regulatory activities and the ability to associate with SHP-1 (Berland and Wortis 2002).

There is also a soluble form of CD5 (sCD5), resulting from proteolytic cleavage of surface CD5 after cell activation. It is not clear if this form has regulatory or immunologic activity. Soluble CD5 is found at very low levels in the serum of normal individuals and in some patients with immune and other diseases, in some studies at higher levels. Patients with Sjogren syndrome were found to have elevated levels of sCD5, interpreted by the authors as evidence of lymphocyte activation (Ramos-Casals et al. 2001). Soldavila and colleagues speculate that the soluble form may act as a decoy receptor, which could interfere with CD5 functions as a survival mechanism and perhaps alter its regulatory capacity (Soldevila et al. 2011); a chimeric construct of murine CD5, called CD5Fc, led to apoptosis of activated T cells when given to Staphylococcus enterotoxin B-treated mice. As well, CD5Fc treatment induced the elimination of activated T cells and promoted recovery from experimental autoimmune encephalomyelitis (EAE); EAE in mice lacking CD5 was less severe and delayed than in control mice (Axtell et al. 2004). Vera and colleagues demonstrated that soluble human CD5 protects mice in a zymosan-induced model of septic shock (Vera et al. 2009). Thus, sCD5 may play a regulatory role in its own regard and may hold promise as a therapeutic in certain diseases of immune overstimulation, e.g., sepsis and autoimmune disorders.

Functions of CD5

CD5 associates with both the TCR and BCR, resulting in both quantitative and qualitative influences on signaling (Raman 2002). In its interaction with both, SHP-1 association with CD5 influences and downregulates the function of the antigen receptors; for the TCR, CD5-regulated substrates include CD3ξ, ZAP-70, Syk, and phospholipase Cγl but not the Src family tyrosine kinase p56 (lck) (Bondada et al. 2000, Perez-Villar et al. 1999). In thymocytes and B1a cells, CD5 provides inhibitory signals, whereas in peripheral mature T cells, it acts as a costimulatory signal receptor; thus, the CD5 signaling pathway can be either stimulatory or inhibitory, depending on circumstances, e.g., cell type, location, and stage of development (Lozano et al. 2000). Dalloul reviews the role of CD5+ B cells as regulatory B cells (Dalloul 2009).

Contrary to CD5 (−) B2 cells, B1 cells are long-lived because of autocrine expression of interleukin-10 (IL-10). Human peripheral B1 cells produce more IL-10 than do the far larger B2, CD5 (−) population following BCR activation. IL-10 production by B2 cells can be elicited after the introduction of CD5, by activation of the IL-10 promoter with mRNA synthesis. Only the cytoplasmic domain of CD5 is necessary for this effect. CD5 also protects normal human B cells from apoptosis after BCR stimulation. Thus, Gary-Gouy and colleagues showed that CD5 supports the survival of B cells by stimulating IL-10 production and by concurrently exerting negative feedback on BCR-induced signaling events that can promote antigen-stimulation induced cell death. (Gary-Gouy et al. 2002).

A unique population of CD5+ murine splenic cells, which are also CD1d+, expresses IL-10 and is thought to have regulatory roles in suppressing inflammation and autoimmune diseases (Watanabe et al. 2010); these are now called B10 cells and fall within a heterogenous population known as B reg (B regulatory cells), some of which are CD5-. B regs make up 1–2 % of splenic B cells and 7–8 % of peritoneal B cells but are not usually found in either lymph nodes or the peripheral blood. These cells may play a role in controlling a variety of autoimmune mouse models of disease, including SLE (Watanabe et al. 2010), collagen-induced arthritis, human rheumatoid arthritis (Mauri et al. 2003), contact dermatitis (Yanaba et al. 2008), and inflammatory bowel disease (Mizoguchi et al. 2002).

Lemoine et al. found that regulation of T cell responses was induced by B cells with the phenotype CD19(hi) IgD + CD38(hi) CD24(hi) CD5(hi) following CD40-dependent cognate interaction, and this regulation was indirect, being mediated by the induction of T regs, as indicated by the appearance of Foxp3 + CD4 + CD25 + T cells. T cell proliferation and cytokine production were differentially regulated. Thus, CD40-induced B regs partially inhibited T cell proliferation following CD40 interaction without the requirement for a soluble factor, whereas modulation of Th1 differentiation resulted from CD80/CD86-dependent interactions and from IL-10 production. Thus, activation signals from T cells appear to initiate regulatory properties in B cells that then, in turn, modulate T cell responses via the induction of T regs. Regulation of T cell proliferation was defective in SLE patients but efficient in other diseases, suggesting to the authors that this might be an active participant in the immunopathogenesis of autoimmune disease and a new therapeutic target (Lemoine et al. 2011).

Of note, Mizoguchi and colleagues subsequently found that the CD5 molecule has a role in colonic homeostatic immunomodulation. CD5 is expressed on most TCRγδ splenic T cells, whereas only a few intestinal intraepithelial TCRγδ T cells express CD5 in normal or TCRβ mutant $\beta^{-/-}$ mice; in the latter mutant mice, the absence of CD5 led to a remarkable increase in the CD4+ TCRγδ T cell population, also found to be increased in triple mutant MHC $II^{-/-}$ $CD5^{-/-}$ $\beta^{-/-}$ mice. CD4+ TCRγδ T cells provide help in Mycobacterium-induced germinal center formation and express a T_h-like cytokine profile. CD5+ TCRγδ T cells suppressed CD4+ TCR γδ T cell-mediated germinal center formation, thought by the authors to be due to the elimination of this CD4+ subset. CD5+ is expressed on >30 % of TCR γδ T cells in the colonic lamina propria, in contrast to the intraepithelial γδ T cell population. The absence of CD5 also led to increased numbers of CD4+ TCR γδ T cells in the colonic lamina propria and increased susceptibility to development of chronic colitis in $\beta^{-/-}$ mice. Cell transfer studies suggested that CD5+ TCR γδ T cells selectively eliminated CD4+ TCR γδ T cells in the intestine. The CD4+ TCR γδ T cells possess immune functions similar to CD4+ TCRαβ T cells (Mizoguchi, Mizoguchi et al. 2003).

In the EAE model of multiple sclerosis, B10 and classic T reg have different effects on disease initiation and persistence. Following inoculation with myelin oligodendrocyte glycoprotein (MOG) (33–35), B10 cell numbers expanded

quickly within the spleen but not in the central nervous system, and this expansion paralleled B10 cell regulation of disease initiation. Adoptive transfer of MOG (33–35)-sensitized B10 cells into wild-type mice suppressed the initiation of EAE but had no effect on established EAE, whereas Treg numbers expanded significantly within the CNS during progression and paralleled their ability to suppress established disease. Predictably, early depletion of B10 cells enhanced EAE severity, and Treg depletion enhanced late-phase disease (Matsushita et al. 2010). As noted above, EAE in mice lacking CD5 was less severe and was delayed in onset, compared with control mice (Axtell et al. 2004); thus, cells bearing CD5 may play a complex set of roles in the initiation and maintenance of EAE.

Murine CD5+ do not require BAFF/BLyS (B cell-activating factor/B lymphocyte stimulator) in contrast to their CD5 (−) brethren, which require this positive signaling molecule. However, BAFF can induce IL-10-producing B cells with a distinct CD1d(hi)CD5(+) phenotype, mainly derived from marginal zone B cells (Yanaba et al. 2008), via induction of activated transcription factor AP-1, which then binds to the IL-10 promoter; there is reason to believe that CD5 may be involved in the generation of B10 cells (Gary-Gouy et al. 2002). In murine studies, BAFF causes an increase in the number of IL-10-producing B cells in marginal zone regions. The BAFF-induced IL-10-producing B cells possess a regulatory function both in vitro and in vivo (Yang et al. 2010). Lo-Man recently reported that innate CD5(+) B regs negatively control innate inflammation and dendritic cell (DC) functions in neonatal mice by producing large amounts of IL-10 following Toll-like receptor triggering (Lo-Man 2011). CD5+ cells are also resistant to apoptosis due to Fas and membrane-bound immunoglobulin signaling, also explaining their prolonged survival.

CD5 antagonizes TCR activation by recruiting inhibitory intracellular mediators such as SHP-1, RAS-GAP, or Cbl, as noted previously. Bamberger and colleagues found that the inhibitory effects of CD5 also may occur via a parallel pathway through phosphorylation of the negative regulatory tyrosine (Tyr(531)) of Fyn, leading to significant reduction in Fyn kinase activity and inhibition of ZAP-70 activation. This effect requires the last 23 amino acids of the cytoplasmic domain of CD5, suggesting involvement of a new CD5-interacting signaling or adaptor protein. Of note, CD5 ligation leads to a shift in its membrane distribution from the bulk fluid phase to the lipid raft environment, where it forms homodimers and associates with Fyn, Lck, and PAG. The authors suggest this relocation may inhibit membrane-proximal signaling through control of phosphorylation and activity of Fyn, possibly by interfering with the disassembly of C-terminal Src kinase (Csk)-PAG-Fyn complexes during T cell activation (Bamberger et al. 2011).

CD5 can associate with CD2, CD3, CD4, CD8, and CD21 molecules; in thymocytes, CD5 can be found in association with PTP1C (phosphotyrosine phosphatase 1C), ZAP-70, p21 phospho-ξ, and PI3K, among other intracellular signaling molecules. As noted, T cells express higher levels of surface CD5 than B cells. CD5 is upregulated on T cells upon strong activation. In the thymus, there is a correlation between CD5 expression and the strength of the interaction of the developing T cell with self-peptides.

CD5 is prominently expressed on the surface of regulatory T cells (T regs), and Ordonez-Rueda and colleagues have suggested that CD5 regulates the generation and survival of natural T regs and furthermore provides a prosurvival signal in developing thymocytes; via phosphorylation of Akt, apoptosis is avoided (Ordoñez-Rueda et al. 2009). CD5 $^{-/-}$ have an enrichment of T reg in the thymus and the periphery as a result of a combination of deletion of naive thymocytes and increased generation of T reg due to increased TCR-mediated signaling. Expression of CD5 is apparently involved in modulating the function of CD4+ CD25+ T reg function, since Dasu and colleagues

demonstrated that these cells derived in $CD5^{-/-}$ mice are more effective in suppressing in vitro proliferation CD4+ CD25- responder T cells in response to anti-CD3 stimulation than were T regs from wild-type mice; this was not related to differences in intracellular expression of Foxp3. The severity of dextran sulfate sodium-induced colitis in $CD5^{-/-}$ mice was less than seen in wild-type mice (Dasu et al. 2008). Thus, there is evidence that CD5 is involved in immunomodulation, with a role in T reg function. Furthermore, both B cells (Hippens et al. 2000) and T cells (Stamou et al. 2003) that are unresponsive to antigen-specific stimulation have increased CD5 expression.

Further evidence of a role for CD5 in immune control is found in work by Hawiger and colleagues who identified a new mechanism for the induction of tolerance when they selectively targeted immature DC with the encephalitogenic self-antigen MOG to present this antigen to T cells in vivo. These DC resulted in peripheral T cell tolerance that interfered with induction of EAE. The tolerized T cells expressed elevated levels of CD5; this tolerance could not be invoked in $CD5^{-/-}$ mice. However, the tolerized cells were not truly anergic, since they could be activated by in vitro TCR stimulation. Thus, T cell tolerization involved the induction of CD5 on the affected cells (Hawiger et al. 2004).

There is also evidence that CD5 binds to zymosan, a β-glucan-rich particle expressed on fungi. Both membrane-bound and soluble CD5 bind to a variety of fungi, although not to bacterial components. This function is also served by several other SRCR proteins, e.g., CD6, MARCO, and CD163, although CD6 binds to bacterial antigens, e.g., lipopolysaccharide. Thus, CD5 acts as a pathogen recognition receptor (PRR) of pathogen-associated molecular patterns (PAMPs), i.e., a receptor that identifies "danger" and transmits the presence of pathogens to the innate immune system (Vera et al. 2009), e.g., PAMP recognition by PRRs activates DCs, enhancing their potency as antigen-presenting cells.

Potential CD5 Ligands

Many molecules have been claimed to be ligands for CD5, although none has yet to be universally accepted as such. These molecules include CD72 (a cell surface negative regulator of B cell activation from the pro-B through the mature B cell stage, also known as Lyb-2 in mice), pg35–37, gp77–80, gp150, gp200, the framework region of IgV_H (Soldevila et al. 2011), and CD5 itself (Brown and Lacey 2010). Zymosan, β-glycans, and fungi are capable of binding to all three extracellular domains of XCD5 (Soldevila et al. 2011).

Calvo and colleagues explored possible non-lymphocyte interactions of CD5 utilizing a soluble human CD5 extracellular domain glycoprotein (rsCD5). This molecule binds to monocytes, lymphocytes, and various cell lines of lymphoid, myelomonocytic, and epithelial origin, as do sCD5 and a human CD5-Ig fusion protein. The binding of rsCD5 may involve interactions of saccharides, since it is inhibited by high molar concentrations of certain monosaccharides (Calvo et al. 1999). Thus, CD5 may provide another means by which immune cells can communicate a state of immune activation to cells of a nonimmune lineage.

Disease Associations and Mechanisms Described for CD5

CD5 is a phenotypic marker for some B cell lymphoproliferative disorders, e.g., B cell chronic lymphocytic leukemia (CLL), mantle zone lymphoma, B cell non-Hodgkin's lymphoma, hairy cell leukemia, and small cell leukemia/lymphoma (Pangalis et al. 1999). About 76 % of T cell neoplasms express CD5. It is commonly lost in cutaneous T cell lymphoma; the absence of CD5 can be used as an indicator of degree of malignancy in this condition and serves as a poor prognostic factor for T cell acute lymphoblastic leukemia. Of note, CLL cells express the membrane form of CD5, which may provide them with a survival advantage (Soldevila et al. 2011).

The CD5+ B cell population (B1a cells) is expanded in some autoimmune disorders, including rheumatoid arthritis, Sjogren syndrome, insulin-dependent diabetes mellitus, and Graves' disease. The recently described CD5+ pre-naive (intermediate) B cell population is expanded in SLE patients and may be involved in the immunopathogenesis of autoimmunity (Lee et al. 2009). Hagn and colleagues found that serum levels of IL-21 and granzyme B (GzmB; a serine protease expressed by cytotoxic T lymphocytes and natural killer cells, which rapidly induces apoptosis of cells that on their surface bear "nonself" antigens, resulting from intracellular pathogens) correlated with each other strongly in patients with SLE. CD5+ B cells isolated from these patients constitutively express GzmB. IL-21 directly induced GzmB expression and in vitro secretion by these CD5+ B cells from lupus patients and patients with other autoimmune disease, as well as from cord blood. Coincident BCR activation caused a further increase in production of GzmB. Of note, IL-21 also suppressed both the viability and expansion of these lupus CD5+ B cells. Thus, CD5+ cells may be involved in the immunopathogenesis of SLE via a GZmB-related mechanism, and IL-21 may represent a viable therapeutic target (Hagn et al. 2010).

Initial studies implicated B1 cells as being the source of autoantibodies, but more recent work, reviewed by Youinou and Renaudineau, has found that B2 cells are actually the source of most high-affinity autoantibodies. Recent work suggests that, contrary to previous thinking, CD5+ B cells may actually play an important role in preventing autoimmunity, through its suppressive effects on BCR (and perhaps TCR) activation. The membrane expression of CD5 is regulated by the balanced expression of exon 1A (E1A) and exon 1B (E1B). The full-length protein variant, encoded by *E1A-cd5*, translocates the SHP-1 phosphatase to BCR and raises its activation threshold, thus controlling autoreactive B cell responses. However, the truncated variant, encoded *by E1B-cd5*, is not expressed on the cell surface; this intracytoplasmic CD5 traps SHP1. Under normal circumstances, EIB E1B is silenced by DNA methylation. Thus, defective DNA methylation prevents the effects of SHP-1, thereby favoring autoimmunity and perhaps the development of SLE (Youinou and Renaudineau 2011).

Conclusion

At least one of the roles CD5 plays may be modulation of immune responses, with the focus on suppression of autoimmune responses, but there is also the possibility that CD5+ functions may be dangerous, in that CD5 might enhance the survival of malignant T cells, allowing them to escape elimination. IL-10-producing B10 cells may also suppress immune responses to malignancies. Thus, CD5 is implicated in salubrious and pathological immunomodulation. There is a need for a better understanding of the factors that determine the number and potency of these cells in disease states, so that manipulation of the expression and function of CD5 can be used as a therapeutic intervention (Dalloul 2009).

As noted, the soluble form of CD5 may be implicated in immunomodulatory functions, suggesting one possible therapeutic strategy. Modification of function of the membrane-bound CD5 has been suggested as another means by which to either up- or downregulate immune function on T cells and B cells, as well as on the newly described subpopulation, B10 cells. Use of sCD5 may alter both autoimmune and malignant diseases and may be useful to block messages targeted to cells of an epithelial lineage, as noted above. The interaction of IL-21 with CD5+ cells may reveal other therapeutic targets.

Definition

Cell adhesion molecules are involved in cell-cell and cell-matrix interactions and cell adhesion and migration in physiological processes and in diseases.

Introduction

Leukocytes, endothelial cells, and other cells, as well as communication of these cells by cell adhesion molecules (CAM) with each other and with the extracellular matrix, are highly involved in various physiological and immunopathological events. The most important adhesion molecules and their superfamilies will be introduced. Regarding the importance of CAMs in immunology and in clinics, this entry will concentrate on inflammation by presenting data on a prototype inflammatory disease, rheumatoid arthritis (RA).

The topics of natural immunity, tissue development, hemostasis, and other physiological conditions will not be discussed.

Adhesion Molecule Superfamilies

CAMs have been classified into integrin, selectin, immunoglobulin, and cadherin superfamilies (Springer 1990; Szekanecz et al. 1996; Agarwal and Brenner 2006).

Integrins

Integrins are αβ heterodimers. Each of the common β chains is associated with one or more α subunits (Albelda and Buck 1990; Springer 1990). Cell adhesion to the extracellular matrix (ECM) is mostly mediated by β_1 and β_3, while intercellular adhesion is facilitated through β_1 and β_2 integrins (Albelda and Buck 1990; Springer 1990; Imhof and Aurrand-Lions 2004). β_1 and β_3 integrins are expressed on endothelial cells, while β_2 integrins are leukocyte CAMs (Albelda and Buck 1990). The α_1–α_6, α_V, α_L, α_M, α_X, and β_1–β_7 integrin subunits have all been detected in the inflamed synovium (Johnson et al. 1993; Haskard 1995; Szekanecz et al. 1996; Agarwal and Brenner 2006). Only the most important integrins will be further discussed (Table 1).

Among β1 integrins, the α4β1 heterodimer, also known as very late antigen 4 (VLA-4) and clustered as CD49d/CD29, plays an important role in lymphocyte-endothelial interactions. This molecule recognizes at least two alternative ligands, such as vascular cell adhesion molecule 1 (VCAM-1), a member of the immunoglobulin superfamily of CAMs, and the CS-1 region of fibronectin. VLA-4 is present on lymphocytes and monocytes, while VCAM-1, an endothelial marker, can be induced by cytokines on a number of other cells (Albelda and Buck 1990; Springer 1990; Szekanecz et al. 1996). Regarding inflammation, the α4β1 integrin and VCAM-1 and CS-1 are expressed on various cell types within the RA synovium (Szekanecz et al. 1996; Agarwal and Brenner 2006).

Among other β_1 integrins, most members of theβ1 (VLA) family ($\alpha_{1\text{-}6}\beta_1$ dimers; CD49(a–f)/CD29) show increased expression on lymphocytes under inflammatory conditions (Johnson et al. 1993; Szekanecz et al. 1996; Agarwal and Brenner 2006). The predominant $CD4^+$ T lymphocyte subset is enriched in β_1 subunit positive ($CD29^+$) cells in the RA synovium. The expression of β_1 integrins is increased on extravascular compared to intravascular lymphocytes suggesting the upregulation of these receptors during extravasation into inflammatory sites (Johnson et al. 1993; Agarwal and Brenner 2006). Synovial lining cells also express the β_1 integrin subunit, while endothelial cells express $\alpha_1\beta_1$, $\alpha_3\beta_1$, and $\alpha_5\beta_1$ (Szekanecz et al. 1996).

All members of the β_2 (leukocyte) integrin family, namely, the lymphocyte function-associated antigen 1 (LFA-1) ($\alpha_L\beta_2$ dimer; CD11a/CD18), the Mac-1 ($\alpha_M\beta_2$; CD11b/CD18), and the p150,95 ($\alpha_X\beta_2$; CD11c/CD18) molecules, are present on neutrophils and monocytes. In contrast, only LFA-1 is present on lymphocytes. All three intercellular adhesion molecule (ICAM) ligands for LFA-1, namely, ICAM-1, ICAM-2, and ICAM-3, belong to the immunoglobulin superfamily. Mac-1 binds ICAM-1 and some non-CAM ligands. ICAM-1 is present on a number of cell types, while ICAM-2 and ICAM-3 are mostly expressed by endothelial cells and leukocytes, respectively (Albelda and Buck 1990; Springer 1990; Szekanecz et al. 1994a; Szekanecz et al. 1996). All β_2 integrins are expressed on synovial leukocytes (Haskard 1995; Szekanecz et al. 1996; Agarwal and Brenner 2006).

The β_3 integrins (gpIIb/IIIa molecule, $\alpha_{gpIIb}\beta_3$, CD41/CD61 and the vitronectin receptor, $\alpha_V\beta_3$, CD51/CD61) have been detected on macrophages, lining cells, and fibroblasts in the arthritic synovium (Johnson et al. 1993; Szekanecz et al. 1996). Among other integrins containing the α_V subunit, the fibronectin-vitronectin receptor $\alpha_V\beta_5$ is expressed by most, while $\alpha_V\beta_1$ and $\alpha_V\beta_3$ have been detected on some synovial lining cells. Their ligands, fibronectin, and vitronectin are also present in the arthritic synovial lining layer (Johnson et al. 1993; Szekanecz et al. 1996).

Another α_4 subunit-containing integrin, $\alpha_4\beta_7$, also binds to VCAM-1 and the CS-1 peptide

Cell Adhesion Molecules, Table 1 Some relevant adhesion receptor-ligand pairs in inflammation[a]

Adhesion receptors	Ligands
Integrins	
$\alpha_1\beta_1$ (VLA-1)	Laminin, collagen
$\alpha_2\beta_1$ (VLA-2)	Laminin, collagen
$\alpha_3\beta_1$ (VLA-3)	Laminin, collagen, fibronectin
$\alpha_4\beta_1$ (VLA-4)	Fibronectin, VCAM-1
$\alpha_5\beta_1$ (VLA-5)	Fibronectin
$\alpha_6\beta_1$ (VLA-6)	Laminin
$\alpha_L\beta_2$ (LFA-1, CD11a/CD18)	ICAM-1, ICAM-2, ICAM-3, JAM-A
$\alpha_M\beta_2$ (Mac-1, CD11b/CD18)	ICAM-2, iC3b
$\alpha_X\beta_2$ (CD11c/CD18)	iC3b, fibrinogen
$\alpha_E\beta_7$	E-cadherin
$\alpha_4\beta_7$	Fibronectin, VCAM-1, MadCAM-1
Immunoglobulin superfamily	
ICAM-1 (CD54)	LFA-1, Mac-1
ICAM-2	LFA-1
ICAM-3	LFA-1
VCAM-1	$\alpha_4\beta_1$, $\alpha_4\beta_7$
MadCAM-1	$\alpha_4\beta_7$, L-selectin
CD2	LFA-3
PECAM-1 (CD31)	PECAM-1, $\alpha_V\beta_3$
Selectins	
L-selectin (CD62L, LAM-1)	Sialylated carbohydrates, GlyCAM-1
E-selectin (CD62E, ELAM-1)	ESGL (sialyl-Lewis-X)
P-selectin (CD62P, PADGEM)	PSGL (sialyl-Lewis-X, other carbohydrates)
Cadherins	
E-cadherin (cadherin-1)	E-cadherin
N-cadherin (cadherin-2)	N-cadherin
Cadherin-11	Cadherin-11
Others	
CD44	Hyaluronic acid, fibronectin
Endoglin	TGF-β1, TGF-β3
JAMs	JAMs

[a]See text for abbreviations

(Albelda and Buck 1990). This integrin is present on more than 60 % of synovial lymphocytes. The $\alpha_4\beta_7$ integrin is highly expressed in tissues belonging to the mucosa-associated lymphoid tissue (MALT), such as the gut and skin, as well as the synovium. Therefore, this integrin may link arthritis to inflammatory bowel disease or psoriasis (Salmi et al. 1995).

The Immunoglobulin Superfamily of Adhesion Molecules

The immunoglobulin superfamily of CAMs is a group of transmembrane glycoproteins containing one or more immunoglobulin-like motifs of 60–100 amino acids (Albelda and Buck 1990; Springer 1990) (Table 1). VCAM-1, already mentioned above, is constitutively expressed on endothelial cells; however, its expression is upregulated by proinflammatory cytokines (Springer 1990; Szekanecz et al. 1996). ICAM-1, the counterreceptor for the β_2 integrins LFA-1 ($\alpha_L\beta_2$), Mac-1 ($\alpha_M\beta_2$), and $\alpha_X\beta_2$, is expressed on both endothelia and leukocytes (Albelda and Buck 1990; Springer 1990; Szekanecz et al. 1994a; Szekanecz et al. 1996). Among other ICAMs, ICAM-2 is constitutively expressed on endothelia

and may not be an activation marker (Szekanecz et al. 1994a). ICAM-3 is a leukocyte CAM; however, it is also present on some endothelial cells (Szekanecz et al. 1994a). All three ICAMs bind to β_2 integrins (Szekanecz et al. 1994a; Szekanecz et al. 1996). Other members of this superfamily include CD2 and LFA-3. These CAMs bind to each other (Albelda and Buck 1990; Springer 1990; Szekanecz et al. 1996). Platelet-endothelial adhesion molecule 1 (PECAM-1; CD31) mediates homotypic adhesion by binding to another PECAM-1 molecule, as well as heterotypic adhesion by recognizing the $\alpha_V\beta_3$ integrin (Springer 1990; Szekanecz et al. 1995; Szekanecz et al. 1996). PECAM-1 is a marker of endothelial activation (Springer 1990; Szekanecz et al. 1996).

As mentioned above, ICAMs serve as ligands for β_2 integrins. Under inflammatory conditions, ICAM-1 (CD54) is present on most endothelial cells, synovial lining cells, interstitial macrophages, lymphocytes, and synovial fibroblasts (Szekanecz et al. 1994a; Szekanecz et al. 1996; Agarwal and Brenner 2006). There is an increased ICAM-1 expression on HEV-like vessels in lymphocyte-rich areas compared to the "flat" endothelium of capillaries and venules in the RA synovium (Szekanecz et al. 1996). Reports showing that ICAM-2 (CD102) is equally expressed by most RA and normal synovial endothelia suggest that this CAM is not an activation antigen on endothelial cells (Szekanecz et al. 1994a). Upregulated expression of ICAM-3 (CD50) has been reported on cells of myeloid origin in the RA compared to normal synovial tissue. ICAM-3 could also be detected on about 10 % of RA synovial endothelial cells (Szekanecz et al. 1994a).

VCAM-1 is mentioned above in connection with the $\alpha_4\beta_1$ integrin. There is abundant VCAM-1 expression in the inflamed synovium, both on endothelial cells and leukocytes (Haskard 1995; Szekanecz et al. 1996; Agarwal and Brenner 2006).

Other CAMs in the immunoglobulin superfamily are expressed in inflammatory infiltrates. These adhesion pathways include the CD2/LFA-3 adhesion counterreceptors. While CD2 is a T cell marker, LFA-3 is present on endothelial and synovial lining cells, as well as macrophages and fibroblasts (Szekanecz et al. 1996; Agarwal and Brenner 2006).

PECAM-1 is abundantly expressed by most endothelial cells, and under inflammatory conditions, its expression is upregulated on synovial lining cells and interstitial macrophages (Johnson et al. 1993; Szekanecz et al. 1995; Szekanecz et al. 1996).

Interestingly, some sialylated and glycosylated CAMs, also known as tumor-associated antigens, such as members of the carcinoembryonic antigen (CD66) family also belong to the immunoglobulin superfamily. The CD66a-e molecules are structurally closely related to PECAM-1 and CD66 and, similarly to PECAM-1, exert abundant expression on myeloid cells in the inflamed synovium (Szekanecz et al. 1996; Szekanecz and Koch 2008).

Selectins

Selectins contain a lectin-like extracellular N-terminal domain, an epidermal growth factor (EGF)-like motif and two to nine moieties related to complement regulatory proteins (Albelda and Buck 1990; Patel et al. 2002) (Table 1). E-selectin and P-selectin are expressed by ECs, while L-selectin is mostly expressed by leukocytes (Patel et al. 2002). As described later, during leukocyte transendothelial migration, selectins mediate the initial tethering and rolling of leukocytes (Springer 1990; Butcher 1991; Patel et al. 2002). E-selectin is a marker for cytokine-induced endothelial activation (Patel et al. 2002). E-selectin ligand-1 (ESL-1) and P-selectin ligand-1 (PSGL-1) contain sialylated glycan motifs, such as sialyl Lewis-X (sLe^x) (Patel et al. 2002). P-selectin is constitutively present on the membrane of endothelial Weibel-Palade bodies (Patel et al. 2002). P-selectin is involved in the very early phases of leukocyte-endothelial adhesion (Butcher 1991). L-selectin serves as a lymphocyte homing receptor, where it mediates the physiological

recirculation of naive lymphocytes through specialized HEV (Springer 1990; Patel et al. 2002). However, L-selectin has also been implicated in inflammatory leukocyte recruitment (Szekanecz et al. 1996; Patel et al. 2002) (Table 1).

Selectins also play an important role in leukocyte adhesion to endothelium during the inflammatory process. There is increased endothelial expression of E-selectin (CD62E) in RA compared to non-inflamed synovial endothelial cells. E-selectin is a marker of endothelial activation in lymphocyte-rich areas. P-selectin (CD62P) is also present on arthritic synovial endothelia, while L-selectin (CD62L) is expressed by peripheral blood mononuclear cells. While other selectins can be induced upon endothelial activation, the cellular expression of L-selectin is decreased by shedding after cytokine treatment (Johnson et al. 1993; Johnson et al. 1993; Agarwal and Brenner 2006; Sarraj et al. 2006).

Cadherins

Cadherins are calcium-dependent CAMs. N-, P-, and E-cadherin are primarily involved in embryogenesis and tissue development; however, synovial fibroblast cadherin-11 has been implicated in arthritis as well (Albelda and Buck 1990; Springer 1990; Szekanecz et al. 1996; Agarwal and Brenner 2006) (Table 1).

Other Nonclassified Adhesion Receptors

The CD44 antigen has a proteoglycan-like structure; it is a receptor for hyaluronate and is expressed on activated ECs in inflammatory sites (Springer 1990; Johnson et al. 1993; Halloran et al. 1996; Szekanecz et al. 1996; Agarwal and Brenner 2006; Sarraj et al. 2006). CD44 is present on most synovial lymphocytes, as well as lining cells, leukocytes, endothelial cells, and fibroblasts. This CAM plays an important role in cellular adhesion, as well as activation in arthritis (Szekanecz et al. 1996; Agarwal and Brenner 2006; Sarraj et al. 2006) (Table 1).

Vascular adhesion protein 1 (VAP-1) was isolated from synovial endothelial cells. VAP-1 is a marker of activated endothelium, as its expression is increased in inflammation (Salmi et al. 1993).

Endoglin (CD105) has been identified as a receptor for transforming growth factor β1 TGF-β1 and TGF-β3. This molecule contains the RGD (arginine-glycine-aspartate) sequence, a motif found in a number of extracellular matrix ligands for integrins. Thus, endoglin may be involved in intercellular adhesion. Endoglin was detected on most inflamed and normal endothelial cells. In arthritis, endoglin expression is increased on synovial lining cells and macrophages (Szekanecz et al. 1996; Szekanecz and Koch 2008).

Junctional cell adhesion molecules (JAMs) are also involved in transendothelial migration of leukocytes. JAM-A and JAM-C have been implicated in adhesive events underlying inflammatory conditions, such as RA (Imhof and Aurrand-Lions 2004; Rabquer et al. 2008).

The Role of Adhesion Molecules in Leukocyte Extravasation to Inflammatory Sites

Leukocyte extravasation into the synovium and into other inflammatory sites is an active process mediated by a number of CAMs (reviewed in Jalkanen 1989; Albelda and Buck 1990; Springer 1990; Haskard 1995; Szekanecz et al. 1996; Agarwal and Brenner 2006). The inflammatory cascade of leukocyte adhesion and migration begins with the adhesion of neutrophils and mononuclear cells to endothelium (Butcher 1991; Ziff 1991; Szekanecz et al. 1996). Inflammatory vessels, such as the specialized synovial venules resembling morphology similar to high endothelial venules (HEV), are present in the arthritic synovium (Szekanecz et al. 1996; Agarwal and Brenner 2006). Leukocytes transmigrate through the vessel wall, and then they adhere to other cells in the synovium, such as synovial lining cells, interstitial macrophages, and fibroblasts (Jalkanen 1989;

Szekanecz et al. 1996; Agarwal and Brenner 2006). Thus, leukocyte ingress into the inflamed synovium may be considered as pathological leukocyte "homing" into the joints, which is a temporally and sequentially well-regulated process.

The *temporal* organization of leukocyte migration into the joint is difficult to assess in humans. In animal models, such as rat adjuvant-induced arthritis (AA), neutrophils are present in the synovium approximately 1-week post-adjuvant injection, followed by the ingress of lymphocytes and monocyte/macrophages after another 4–6 days. These events are accompanied by the temporally regulated expression of various CAMs including selectins, integrins, and CD44 (Halloran, Szekanecz et al. 1996).

The *sequential* regulation of the adhesion cascade is similar in various types of inflamed tissues. The initial adhesion of leukocytes to endothelium ("tethering" and "rolling") is mediated mainly by selectins. This is followed by leukocyte activation, as well as the upregulation and conformational changes in the expression of a number of CAMs, mainly leukocyte (β2) integrins, resulting in firm, more stable interactions. Several CAMs including integrins and CD31 may be involved in the transendothelial migration of leukocytes into the synovium; however, some aspects of these molecular mechanisms are not fully understood (Haskard 1995; Szekanecz et al. 1996; Agarwal and Brenner 2006).

The relationship between CAM expression and the preferential "homing" of lymphocytes into certain tissues (e.g., lymph nodes, spleen, MALT) is still poorly understood. No CAM is exclusively responsible for leukocyte migration into the synovium or other tissues. However, as described below, functional human and animal studies suggest that some adhesion pathways may be more important in the synovium than others (Haskard 1995; Szekanecz et al. 1996; Imhof and Aurrand-Lions 2004; Agarwal and Brenner 2006). The tissue specificity of leukocyte migration may be important for the explanation of organ involvement in various inflammatory diseases. For example, gut-derived, mucosal T cells and immunoblasts express CAM profiles characteristic for memory cells. These cells bind well to synovial, as well as gut HEV. In addition, the α4β7 integrin described above is highly expressed on both synovial and gut lymphocytes, suggesting the role of this integrin in the pathogenesis of arthritis associated with inflammatory bowel diseases. However, mucosal lymphocyte adhesion to synovial endothelium utilizes mainly α4β1-, while that to gut HEV mostly α4β7-dependent mechanisms, showing the involvement of various CAM-mediated pathways within the MALT. In general, the adhesive mechanism of lymphocyte "homing" into the synovium is similar to that into MALT rather than that into peripheral lymph nodes (Salmi et al. 1995).

Assessment of Inflammatory Cell Adhesion in Experimental Systems

The functional role of CAMs and the interactions of these molecules with inflammatory mediators have been investigated in a number of experimental systems. Cell cultures of isolated endothelial cells or fibroblasts are suitable for studies on CAM expression regulation by cytokines, while the relative importance of certain adhesion pathways can be determined by using in vitro adhesion assays. Animal models are used to characterize all these mechanisms in vivo.

Fibroblast cultures express both ICAM-1 and VCAM-1. Among proinflammatory cytokines, tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), IL-4, and interferon-γ (IFN-γ) stimulate the adhesion of leukocytes to fibroblasts. Furthermore, IL-1β, TNF-α, IFN-γ, basic fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), and granulocyte-monocyte colony-stimulating factor (GM-CSF) may induce ICAM-1, while IL-1β, IL-4, TNF-α, and IFN-γ may stimulate VCAM-1 expression on fibroblasts. Some cytokines may also stimulate LFA-3 expression on these cells (Szekanecz et al. 1996).

In endothelial cultures, ICAM-1 expression can be induced by IL-1β, TNF-α, and IFN-γ. IL-1β stimulates endothelial E-selectin

expression as well. Peripheral blood monocytes obtained from RA patients adhere well to both resting and cytokine-stimulated synovial endothelial cells, accompanied by increased monocyte β2 integrin expression (Haskard 1995; Szekanecz et al. 1996).

In vitro adhesion assays utilize leukocytes layered on endothelial cell and fibroblast cultures and frozen tissue sections ("frozen section assay") as well as culture dishes coated with extracellular matrix components. Blocking studies may be performed by introducing anti-CAM monoclonal antibodies (mAb) to these assays. The degree of adhesion inhibition reflects the relative importance of the studied CAMs in intercellular adhesion. Furthermore, as cell cultures can be activated with inflammatory mediators, cell-cytokine-CAM interactions can be investigated. For example, blocking studies using mAbs to β1 and β2 integrins clarified the role of adhesion pathways mediated by these integrins in arthritis. In the "frozen section" assay, blocking studies have shown the importance of β1 (mainly α4β1), β2 (mainly LFA-1), and α4β7 integrins; P-, E-, and L-selectins; as well as CD44 in lymphocyte adhesion to synovial HEV-like venules. Adhesion studies using dishes coated with fibronectin revealed the functional role of integrins in the adhesion of synovial lymphocytes to the extracellular matrix. T cell-fibronectin adhesion could be blocked by mAbs to α4β1 and α5β1 integrins, as well as by their respective ligands, LDV- and RGD-containing fibronectin peptides (Jalkanen 1989; Haskard 1995; Salmi et al. 1995; Agarwal and Brenner 2006).

Some aspects of CAM expression and CAM-cytokine interactions in arthritis are difficult to assess in human systems. There are a number of in vivo animal models of arthritis available. Apart from the classical rat arthritis induced by adjuvant (AIA), additional models include streptococcal wall-, type II collagen- (CIA), and proteoglycan-induced arthritis (PGIA) (Halloran, Szekanecz et al. 1996; Szekanecz et al. 1996; Sarraj et al. 2006). For example, in rat AIA, β2 integrins were detected on myeloid cells, while ICAM-1 was expressed on most endothelial cells in the arthritic synovium. CD44 also exerts variable expression in the arthritic synovium in AIA and PGIA (Halloran et al. 1996; Szekanecz et al. 1996; Sarraj et al. 2006).

Adhesion Molecules in Atherosclerosis

Atherosclerosis may be considered as an inflammatory disease (Ross 1993). In addition, accelerated atherosclerosis and increased vascular damage, as well as increased cardio- and cerebrovascular morbidity and mortality, have been associated with arthritides (Gonzalez-Gay et al. 2006; Szekanecz et al. 2007). Several adhesion molecules, including integrins, VCAM-1, ICAM-1, ICAM-3, and selectins, have been implicated in the pathogenesis of inflammatory atherosclerosis (Ross 1993; Gonzalez-Gay et al. 2006; Szekanecz et al. 2007) as well as in the pathogenesis of inflammatory aortic aneurysms (Szekanecz et al. 1994b). Furthermore, anti-TNF biologics may suppress adhesion molecule expression in the vessel wall (Gonzalez-Gay et al. 2006).

Blockade of Adhesion Molecules: A Yet Unfulfilled Dream in Anti-Inflammatory Therapy

Certainly, corticosteroids and other immunosuppressive drugs may have modulatory effects on CAM expression and inflammatory cell adhesion (Szekanecz et al. 1996; Agarwal and Brenner 2006; Gonzalez-Gay et al. 2006); however, these nonspecific therapies will not be further discussed.

Regarding specific anti-CAM targeting in humans, first an antihuman ICAM-1 antibody (enlimomab) was used to treat refractory RA. Many patients reported improvement in their status; however, repeated administration of this antibody resulted in diminished efficacy and frequent adverse events. Therefore, further development of enlimomab in RA was terminated (Szekanecz et al. 1996). Two anti-integrin

strategies, the anti-LFA-1 antibody efalizumab and the LFA-3-Ig fusion protein alefacept, have been registered for the treatment of psoriasis. Alefacept also yielded to a moderate effect in psoriatic arthritis (Menter 2009). Efalizumab has recently been withdrawn from the market due to severe side effects. Natalizumab (anti-α_4 integrin) has been registered for the treatment of multiple sclerosis and Crohn's disease. Various other anti-integrin and anti-CD44 antibodies have been tried in animal models of arthritis, but not yet in human disease (Szekanecz et al. 1996; Agarwal and Brenner 2006; Sarraj et al. 2006). The high number of CAMs and the redundancy of adhesion network and multiple regulatory pathways may account for the notion that targeting of one CAM may be technically feasible, but it often yields to disappointing results in human trials.

Chemokines: A General Definition

Chemokines are a large family of small chemotactic cytokines involved in many physiological processes, including development, angiogenesis, tissue organization, cell homing, and inflammation. Most of these functions are associated with cellular migration and directional movement in response to specific chemokine gradients. Chemokines are also important in cellular activation and cellular protection against damage. Chemokine signaling is mediated through interactions with 7-transmembrane, G protein-coupled receptors that subsequently results in the diverse functions described above. Dysregulation of chemokine secretion directly participates in the pathogenesis of many diseases, by altering inflammation, cell survival, homeostasis, resolution of injury, migration of stem or hematopoietic cells, cellular differentiation, and scar formation as well as by global regulation of the immune response. Thus, chemokines and their receptors participate in normal physiology as well as in pathologic conditions in all tissues.

Classification: Chemokines are divided into four subfamilies according to the position of two conserved cysteine (C) residues in their amino (N)-terminus: CC ligands (CCL), CXCL, CX3CL, and XC (X represents a different amino acid). Each chemokine activates specific chemokine receptors (CCR) (see summary of chemokines and their receptors in Table 1) that, depending upon the cell type that expresses the receptor, results in diverse functions, including migration, synaptic plasticity, or regeneration. Chemokine receptors belong to the superfamily of G protein-coupled receptors (GPCRs) (Onuffer and Horuk 2002). These receptors are 7-transmembrane proteins and signal mainly through G proteins. Chemokines have different target cells according to the expression of their chemokine receptors; however, in addition to this variable, tissue localization and kinetics of expression during development or inflammation also play key roles in the function of these chemokines. Their expression can be induced by various stimuli, including growth factors, inflammatory mediators, and/or cellular debris in normal and pathologic conditions (Onuffer and Horuk 2002).

Role of Chemokines During Inflammation

During inflammation, leukocyte recruitment occurs from the bone marrow and blood into the injured/inflamed tissues. This leukocyte recruitment involves leukocyte rolling, firm adhesion, and subsequent diapedesis of cells into affected tissues in response to specific chemokine gradients and the interaction of the chemokines with the appropriate chemokine receptors on the surface of the leukocytes. Most of the chemokines released during inflammation are synthesized de novo; however, some chemokines are constitutively expressed at low levels, and some are intracellularly stored in granules, for example, in endothelial cells, platelets, and cytotoxic T cells, perhaps to mediate a rapid response (Celie et al. 2009). Some of these stored chemokines include CCL1, CCL5, CCL7, CXCL1, CXCL4, CXCL5, and CXCL8. Chemokines also interact with the extracellular matrix and remain there for a long period of time attached to cells (Imberty et al. 2007; Witt and Lander 1994), including endothelial cells,

Chemokines, Table 1 Chemokines and their receptors

CC family		
New nomenclature	Old nomenclature	Receptor
CCL1	I-309	CCR8
CCL2	MCP-1, monocyte chemotactic protein-1	CCR2/CCR4
CCL3	MIP-1α, macrophage inflammatory protein-1α	CCR1/CCR5
CCL4	MIP-1β, macrophage inflammatory protein-1β	CCR5
CCL5	RANTES, regulated upon activation, normal T cells expressed and secreted	CCR5
CCL6	–	CCR1/?
CCL7	MCP-3, monocyte chemotactic protein-3	CCR1/CCR2
CCL8	MCP-2, monocyte chemotactic protein-2	CCR2/CCR3
CCL9	MIP-1β, macrophage inflammatory protein-1γ or macrophage inflammatory protein-related protein-1 (MRP-2) and CCF18; also named CCL10 (not used any more)	?
CCL10	Now is named CCL9	–
CCL11	Eotaxin-1	CCR3
CCL12	MCP-5 or Scya12	CCR2?
CCL13	MCP-4, Scya13	CCR2/CCR3
CCL14	HCC-1	CCR1
CCL15	Leukotactin-1, MIP-5, and HCC-2	CCR1/CCR3
CCL16	HCC-4 and Scya16	CCR1/CCR2/CCR5/ CCR8
CCL17	TARC	CCR4
CCL18	PARC, pulmonary and activation-regulated chemokine	CCR6
CCL19	EBl1 ligand chemokine (ELC) or macrophage inflammatory protein-3-beta (MIP-3β)	CCR7
CCL20	Macrophage inflammatory protein-3 (MIP-3A)	CCR6
CCL21	Secondary lymphoid-tissue chemokine (SLC), 6Ckine (because it has 6 conserved cysteine residues instead of 4 as other chemokines) and exodus-2	CCR7
CCL22	Scya22	CCR4
CCL23	MIP-3 and myeloid progenitor inhibitory factor 1 (MPIF-1)	CCR1/?
CCL24	Myeloid progenitor inhibitory factor 2 (MPIF-2) or eotaxin-2	CCR3/?
CCL25	TECK (thymus-expressed chemokine)	CCR9
CCL26	Eotaxin-3, MIP-4α, and thymic stroma chemokine-1	CCR3
CCL27	Cutaneous T cell-attracting chemokine (CTACK)	CCR10
CCL28	Mucosae-associated epithelial chemokine (MEC)	CCR3/CCR10
CCL29	–	Unknown
CXC family		
New nomenclature	Old nomenclature	Receptor
CXCL1	Growth-regulated protein alpha (GRO1 or α) oncogene and neutrophil-activating protein 3 (NAP-3)	CXCR2 > CXCR1
CXCL2	GROβ	CXCR2
CXCL3	GROγ and MIP2β	CXCR2
CXCL4	Platelet factor 4 (PF4)	Splice variant of CXCR3, CXCR3B
CXCL5	Neutrophil-activating peptide 78 (ENA-78)	CXCR2
CXCL6	Granulocyte chemotactic protein 2 (GCP-2)	CXCR1/CXCR2
CXCL7	NAP-2	CXCR2
CXCL8	Interleukin-8 (IL-8)	CXCR1/CXCR2

CXC family		
New nomenclature	Old nomenclature	Receptor
CXCL9	Monokine induced by gamma interferon (MIG)	CXCR3
CXCL10	Interferon gamma-induced protein 10 (IP-10) or small inducible cytokine B10	CXCR3
CXCL11	Interferon-inducible T cell alpha chemoattractant (I-TAC) or IP-9	CXCR3
CXCL12	Stromal cell-derived factor-1 (SDF-1a)	CXCR4
CXCL13	B lymphocyte chemoattractant (BCA-1)	CXCR5
CXCL14	Breast- and kidney-expressed chemokine (BRAK)	?
CXCL15	Lungkine	?
CXCL16	Scyb16	CXCR6
CXCL17	Scyb17	?
C family		
New nomenclature	Old nomenclature	Receptor
XCL1	Lymphotactin	XCR1
XCL2	Scyc2	XCR1
CX_3C family		
New nomenclature	Old nomenclature	Receptor
CX3CL1	Fractalkine	CX3CR1

?: unknown or unclear

generating microenvironments that control baseline cell homing and trafficking, or cell repulsion, termed fugetaxis (Poznansky et al. 2002; Vianello et al. 2005).

Binding of a chemokine to its receptor on the surface of a leukocyte results in activation of integrins by a $G_{\alpha i}$ protein-dependent mechanism, leading to calcium flux and activation of phosphatidylinositol 3-kinase (PI3K) and Rho GTPase pathways (Mellado et al. 2001a). This signaling facilitates cytoskeletal changes in the leukocyte, resulting in formation of cellular processes, polarization, and directional movement towards higher concentrations of chemokines. However, high concentrations of chemokines can also induce a repulsive signal (Poznansky et al. 2002; Vianello et al. 2005), though the signaling and mechanisms that mediate these diametric differences are not yet well understood.

The ability of chemokine receptors to dimerize and heterodimerize results in even more complex chemokine-chemokine receptor signaling (Mellado et al. 2001b). The aggregation of chemokine receptors, similar to cytokine receptors, can result in different signaling according to the kinetics and type of receptor activated. Activation of monomeric chemokine receptors ($<$15 s) results in activation of phospholipase, calcium, and PI3K. Activation of oligomer chemokine receptors (20–60 s) results in kinase activity (PKB, ERK, Src, and JAK), and clustering of these receptors ($>$60 s) results in arrestin-mediated internalization and desentization (Delgado et al. 2001; Thelen 2001). Chemokine receptor signaling induced by binding of specific chemokine(s) is extremely transient. This is because G_{α} subunits, after activation to hydrolyze GTP, rapidly recombine with $G_{\beta\gamma}$ subunits to form the inactive conformation that was present before chemokine activation. Additionally, receptor desensitization occurs, especially by receptor phosphorylation by G protein-coupled receptor kinases (GRK). Receptor downregulation also occurs caused by β-arrestin or adaptin-2-mediated receptor sequestration and intracellular internalization through clathrin-coated pits or caveolae and regulated by receptor phosphorylation as well (see review by Rot and von Andrian 2004). Interestingly, in lymph node endothelial cells, the protein chemokine interceptor D6 targets many CC chemokines for internalization and subsequent degradation (Rot 2010), but the role of this protein in other tissues or during disease processes has not been

examined further. The contribution of each mechanism to chemokine signaling and chemoattraction continues to be studied.

In normal and inflammatory conditions, leukocytes are chemoattracted to a specific tissue in response to chemokine gradients. First, tethering occurs to establish a weak interaction between leukocytes and the endothelium, in part mediated by selectins. The next step is rolling that slows down leukocytes and establishes a stronger EC-leukocyte interaction, partially mediated by selectins and integrins. The third step is conformational changes in the integrins and upregulation of adhesion proteins on the endothelial cell and leukocyte, resulting in a firm adhesion that is mediated by cell adhesion molecules (CAM) including ICAM-1 and VCAM-1 expressed on the endothelium and integrins VLA-4 and LFA-1 on the leukocyte (▶ Cell Adhesion Molecules). These critical interactions mediate tight adhesion and subsequent directed intravascular diapedesis between or through endothelial cells into the target tissue (see review by Roberts et al. 2010). During the normal process of diapedesis, leukocytes migrate across the endothelium by specific interactions between adhesion molecules, tight junction proteins, integrins, cytoskeletal proteins and activation of metalloproteinases, chemokines, and chemokine receptors. The coordination of these interactions results in a controlled transmigration of leukocytes across the endothelium into target tissues, with no significant changes in permeability. However, in inflammatory conditions, this controlled transmigration is dysregulated and changes in endothelial permeability and increased numbers of leukocytes transmigrating occur. Thus, changes in any component of the transmigration process result in development of several human diseases, including autoimmune processes, developmental abnormalities, cancer, and inflammation.

There are many examples of the role of chemokines in normal and pathologic conditions. Only a few will be discussed in this review to highlight the varied functions of chemokines.

Chemokines and HIV: Currently there are an estimated 33 million people infected with HIV. Despite advances in prevention, treatment, and survival, there is still a significant percentage of the population living with the virus and with HIV-related illness. HIV infects mainly cells expressing CD4 and CCR5 or CXCR4. The chemokine receptors CCR5 and CXCR4 are co-receptors for the virus, enabling HIV entry into susceptible cells. This entry into $CD4^{+}CCR5^{+}$ T cells results in ~50 % of the cells being infected and destroyed in the first 2–3 weeks postinfection (Mattapallil et al. 2005). However, other cell types such as monocyte/macrophages, dendritic cells, and a specific naïve T cell population maintain the virus without toxic consequences, establishing reservoirs that harbor the virus for long periods of time (Lafeuillade and Stevenson 2011).

The ligands for CCR5, CCL3 (MIP-1α), CCL4 (MIP-1β), or CCL5 (RANTES) are produced by many cell types, including macrophages, T cells, dendritic cells, γδ T cells, NK cells, and astrocytes, and prevent HIV and simian immunodeficiency virus (SIV) entry by competing for binding to the chemokine receptor and by downregulating surface expression of these receptors (Cocchi et al. 1995; Pinto et al. 2000). The critical role of chemokine receptors in HIV/AIDS is underscored by the finding that individuals expressing the polymorphisms for CCR5Δ32 are protected from HIV infection (Reiche et al. 2007). Compounds that block the ability of the HIV envelope to bind to chemokine receptors to reduce viral entry have been developed, and these therapies are currently in use (Choi and An 2011). However, reducing or blocking these receptors may have other consequences. For example, CXCL12 or CXCR4 knockdown mice die during embryogenesis with several hematopoietic, gastrointestinal, cardiac, vascular, and brain defects (Nagasawa et al. 1996; Zou et al. 1998). In the brain of these knockout mice, the cerebellum, hippocampal dentate gyrus, cortex, and dorsal root ganglia are defective in migration and proliferation of progenitor cells (Dziembowska et al. 2005). Thus, some concerns related to the long-term use of CXCR4-blocking agents exist, especially as HIV-infected individuals live longer.

In addition to the role of chemokine receptors in HIV entry, chemokine and chemokine receptor expression also regulate the pathogenesis of HIV disease. Data in NeuroAIDS indicates that HIV infection of leukocytes upregulates the chemokine receptor CCR2 (Eugenin et al. 2006), which facilitates the transmigration of high numbers of HIV-infected leukocytes across a tissue culture model of the blood-brain barrier (Eugenin et al. 2006). The higher expression of this chemokine receptor on HIV-infected leukocytes may enable these cells to sense lower amounts of CCL2 from the brain parenchyma and initiate their transmigration into the brain (Eugenin et al. 2006). The mechanism by which HIV regulates the expression and function of these chemokine receptors requires further investigation.

In addition, other viruses, such as pox and herpes viruses, encode chemokines and chemokine receptors in their genomes that become expressed after infection of different cells. This expression has been proposed to participate in viral replication, migration, and cellular proliferation and to attract new circulating cells to amplify infection (Lalani et al. 2000; Murphy et al. 2001). Thus, chemokine and chemokine receptors, in addition to protecting from injury, can also be hijacked by different viruses to spread infection, evade an immune response, and induce inflammation and cellular damage.

Chemokines and Cancer: Chemokines play a key role in cancer. As discussed above, the action of chemokines and their chemokine receptors is dependent in part upon the organ in which they are expressed and where the chemokine(s) is released. Metastatic cancer cells migrate to other tissues through the blood, and several chemokines and chemokine receptors have been identified that participate in this process. Expression of CXCR4 and CCR7 in breast cancer cells has been associated with metastasis to the lung and lymph node (Cabioglu et al. 2005). Melanoma cells expressing CXCR4 and CCR7 are associated with pulmonary and lymph node metastasis (Takeuchi et al. 2004). High expression of CXCR4 has been described as a prognostic marker of myelogenous leukemia, and low expression is associated with a better prognosis (Kalinkovich et al. 2006). An example of the critical role of chemokines and their receptors in cancer has been demonstrated in pancreatic cancer, where CD133+/CXCR4+ tumor cells at the edge of the tumor are the cells that determine the metastatic capacity without affecting the growth of the primary tumor (Hermann et al. 2007). In agreement, mammary tumor cells that expressed higher amounts of CXCR4 correlate with the aggressiveness of the tumor. Inhibition of the CXCR4/CXCL12 axis using compounds that block interaction with CXCR4, such as AMD3100, reduces chemotaxis of tumor cells in vitro and suppresses tumor angiogenesis and tumor growth in vivo (Liang et al. 2007). This compound is being used in ongoing clinical trials related to metastasis (Lazennec and Richmond 2010).

Although we briefly discussed data for a role of CXCR4 and CCR7 in the pathogenesis of cancer, other receptors and chemokines are also involved. CXCL1, 2, 3, 5, 6, 8, 10, and 12; CCL2, 3, and 4 and their receptors; CXCR1, 2, 4, 5, 6, 7, 9, and 10; and CCR1, 2, 4, 5, 6, 7, 9, and 10 are also involved in different stages of the malignant process (see details in Lazennec and Richmond 2010). Changes in expression of these receptors and chemokines suggest that tissue-specific chemokine gradients enable cancer cells to colonize different tissues (▶ Tumor-Infiltrating T Cells).

Chemokines in Lymphocyte Homing and Trafficking

Lymphocytes, during their development and specialization, traverse long distances, from the bone marrow and/or thymus, circulating in the blood, homing to secondary lymphoid organs. All these processes of migration, selection, and trafficking into different tissues are controlled by chemokines. In addition, chemokines regulate integrin activation that results in intracellular signaling and cell adhesion (Kim et al. 2004). Many of these effects for T cells occur in the thymus. The adult thymus can be divided into the central medulla and the peripheral cortex. The cells present in these areas can be divided into hematopoietic cells from bone marrow

origin, such as thymocytes, dendritic cells, NK cells, and macrophages; stromal cells; and mesenchymal cells. The cortex is composed of high numbers of immature thymocytes supported by a complex network of thymic epithelial cells and dendritic cells. In contrast, the medulla has fewer thymocytes, at an immature stage, supported by thymic epithelial cells and dendritic cells (see details in Dzhagalov and Phee 2012).

Thymocytes are normally in constant motion due to their patterns of differentiation, proliferation, and selection. Chemoattraction, repulsion, and adhesion to stromal cells are essential to these processes and are mediated mostly by chemokines expressed by different cell types and in different locations within the thymus. Some of the cells that regulate these changes in movement of thymocytes are dendritic cells, endothelial cells, and epithelial cells. Different chemokine gradients, including those for CCL25, CCL21, CCL19, CCL17, and CXCL12, recruit different subsets of thymocytes (see details in Dzhagalov and Phee 2012; Le Borgne et al. 2009). Thus, alterations in expression of these chemokines or their receptors result in significant changes in differentiation and selection of T cells, leading to immune deficiencies or autoimmune diseases.

Some of these critical steps mentioned above have been demonstrated by examining lymphocyte trafficking and cell-to-cell interactions required for immune activation and migration that are dependent on CCL21 and CCR7. Expression of CCR7 is increased in a subset of thymocytes following positive selection, and the ligands for CCR7 are expressed mostly in the medulla, suggesting that selected thymocytes are preferentially recruited to the medulla by a mechanism that involves CCR7 (Kurobe et al. 2006). In agreement, CCR7 transgenic thymocytes showed an increased frequency of maturation (Kurobe et al. 2006). In addition, in other tissues, CCL21 or CCR7 genetic depletion reduced migration of T cells into lymph nodes (Cyster et al. 1999) (see details of chemokine-chemokine receptors in Table 1). CXCR5 and CCR7 are essential for migration of B cells from T cell-rich zones into B cell follicles in the spleen or the Peyer's patches (Forster et al. 1999; Gatto et al. 2011). Thus, specific changes in chemokine-chemokine receptor expression in a site-specific manner control migration, differentiation, selection, and egress of subsets of lymphocytes, suggesting that any alterations in these processes mediated by chemokines and chemokine receptors could result in immunodeficiency and/or autoimmune disease.

Conclusion

Chemokines and their receptors are essential for normal development, cellular homing, immune surveillance, regeneration, and cellular and tissue plasticity, as well as for inflammation, cellular damage, and disease. These ligand-receptor interactions are mainly mediated by the specific localization of the ligand (chemokine) and its receptor on different cells and tissues. These interactions, ligand-receptor, are tightly controlled; however, during disease pathogenesis, dysregulation of either one results in exacerbation or lack of resolution of injury. In addition, some infectious agents, such as HIV, use specific chemokine receptors to enable entry into susceptible cells, which suggests that pathogens evolved to use this important communication system to survive within a host. Other pathogens also alter the secretion of chemokines to impair and evade immune or inflammatory responses. Understanding the regulation of chemokines and their receptors should enable the design of more effective therapies to target disease processes.

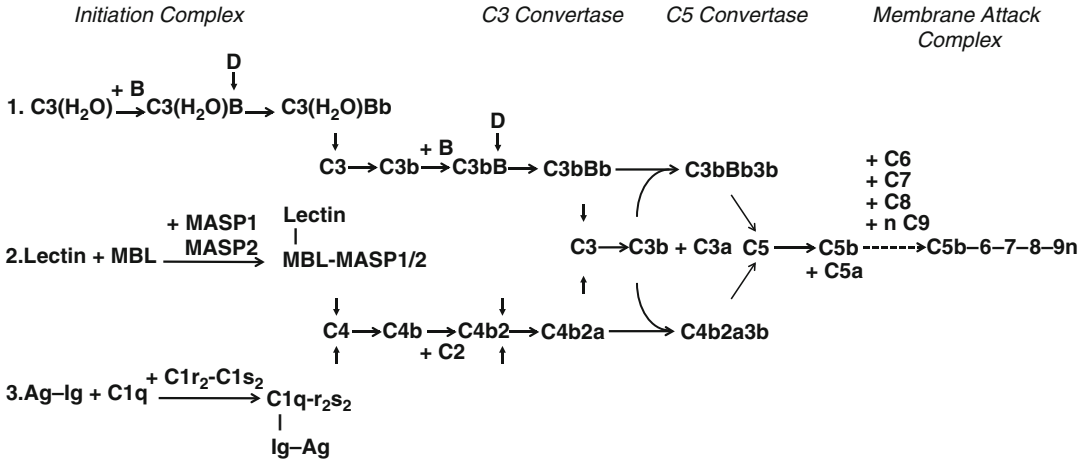
Definition

The complement system is a primary immune effector mechanism for the humoral immune response. The complement system consists of effector proteins, regulators, and receptors. There are three pathways that trigger cascades of activation through proteolysis of zymogens present in the circulation. These pathways converge at the activation of complement C3 and C5 and progress to the formation of the membrane attack complexes (MACs) on target membranes. Anaphylatoxins C3a and C5a are generated during the activation process. The cascades of complement system are regulated and adjusted according to the type of initiators, and the microenvironment in which complement activation is occurring. Proteins of the complement system cooperate and coordinate to differentiate among invading microbes, immune complexes, apoptotic cells, cellular debris, and physiologic host cells (Law and Reid 1995; Ricklin et al. 2010; Walport 2001a, b).

Pathways of Complement Activation

Three distinct pathways are engaged in the initiation of complement activation (Fig. 1). The classical pathway was discovered first,



Complement in Rheumatic Diseases, Fig. 1 The three activation pathways of the complement system, drawn according to evolution and physiologic sequences. Pathway 1 is known as the alternative pathway. It is activated through a tick-over mechanism because of continuous hydrolysis of the thioester bond in C3, which enables the formation with factor B, a weak C3 convertase. Pathway 2 is known as the MBL or lectin pathway. It is initiated through the binding of mannan-binding lectin (MBL) or ficolin to arrays of simple sugar molecules in glycosylated antigens on microbes. This is a pattern recognition mechanism characteristic of the innate immune system. Pathway 3 is initiated through the binding of specific antibodies IgM or IgG to antigens. It is an effector arm of the humoral adaptive immune system. Each activation pathway engages the formation of a multi-molecular initiation complex, followed by the assembly of a C3 convertase and a C5 convertase for activations of C3 and C5, respectively, and culminates in the formation of membrane attack complexes (MACs) on the target membrane. Anaphylatoxins C3a and C5a are produced during the activation process. For brevity, by-products generated during the activation of C4, C2, and factor B are not shown. *Vertical arrows* show activation of component proteins through cleavage by serine proteinases. A *dotted horizontal arrow* denotes multiple steps are involved in the formation of the membrane attack complex

historically, but it is the youngest in evolutionary terms. It is a key effector for the humoral adaptive immune response. In 1895, Jules Bordet demonstrated the presence of an inborn and heat-labile serum factor that was necessary to assist or "complement" antibodies in killing bacterial targets. It is now known that such inborn "complement factor" consists of more than 50 proteins. Nine different complement components named as numerals C1 to C9 – in the order of discovery – exist as zymogens, or inactive, mature secretory proteins in the blood circulation. The formation of antibody-antigen complexes exposes binding sites for C1q on Fc-regions of immunoglobulins, triggering the assembly and activation of the multi-molecular C1 complex, C1q-$C1r_2$-$C1s_2$ (Pathway 3, Fig. 1). Activated C1s in the C1 complex is a serine proteinase, which activates C4 and C2. The larger products of the enzyme digests, C4b and C2a, respectively, assemble to form the classical pathway C3 convertase (abbreviated C4b2a). The C4b subunit binds to the activator surface covalently through the carbonyl group of the glutamine-994 residue (Q994) from its newly exposed thioester bond after activation. The C2a subunit (in the C3 convertase) is a serine proteinase that cleaves C3 to C3a and C3b. Similar to C4b, C3b also consists of a highly reactive thioester bond that binds covalently to nearby membranes, or else it is hydrolyzed. The association of C3b with C4b2a changes the multi-molecular enzyme to the C5 convertase (abbreviated C4b2a3b). The C5 convertase cleaves C5 to C5a and C5b. C5b binds to target membranes through hydrophobic interaction, exposing binding sites for C6 and then C7. The C5b-7 complex then inserts to the lipid bilayers of the cell membrane and attracts the binding of C8. C5b-7 and C5b-8 complexes can partially lyse the target cells (i.e., are sub-lytic), thereby causing leakage of cytoplasm. On microbial cell

surfaces, C5b-8 initiate polymerization of multiple molecules of C9, forming membrane attack complexes (MACs). The MAC creates pores in the target membranes, which induces cell lysis, loss of cytoplasm, and osmotic shock.

During the activation process, two potent anaphylatoxins are generated by C3 and C5 convertases, C3a and C5a, respectively (Zhou 2012). Interactions of C3a and/or C5a with their corresponding receptors on granulocytes stimulate discharge of granules that have vasoactive, toxic, and bacteriocidal properties. In addition, C5a is a strong chemoattractant. It stimulates migrations of neutrophils to the site of complement activation. Thus, complement activation is linked to inflammatory response.

In the mid-1950s, Pillemer observed that complement activation could occur in the absence of a specific antibody. The existence of such an "*alternative*" pathway of activation was challenged, but confirmed more than two decades later. Specific protein factors involved in this alternative pathway are named in alphabets, such as factor B, factor D, factor H, and P (properdin). This pathway is initiated by a "tick-over" mechanism, by which a small proportion of complement C3 in the circulation is constantly hydrolyzed at slow rate by water to form $C3(H_2O)$. $C3(H_2O)$ may weakly associate with factor B. Serine proteinase factor D cleaves factor B, releasing Ba from the complex. $C3(H_2O)Bb$ is a weak C3 convertase that cleaves C3 to C3b and C3a (Pathway 1, Fig. 1). Most C3b generated in this way is inactivated by hydrolysis of the internal thioester bond. However, if the C3b is attached to a microbial or "protected" surface, factor B will associate with it and become activated by factor D, forming C3bBb. C3bBb is a powerful alternative pathway C3 convertase, which activates C3 to generate C3b and C3a. The binding of properdin to C3bBb on a microbial (or protected) surface will further stabilize the convertase and enhance its activity. The freshly produced C3b molecules associate with factor B, leading to the generation of more C3 convertase. This perpetuates and amplifies complement activation enormously.

Some C3b associates with C3bBb to form C3bBbC3b, which becomes the alternative pathway C5 convertase. C5 convertase cleaves C5 to C5b and C5a. Similar to the classical pathway, C6 and then C7 bind to C5b. The C5b-7 complex inserts into the foreign membrane, followed by the binding of C8, and the assembly of C9 to form the membrane attack complex. The alternative pathway actually represents an ancient mechanism of innate immune defense. The tick-over mechanism of complement activation enables a continuous surveillance for the host, executing the first line of defense against foreign invaders.

One strategy for organisms to achieve species-specific diversities is by modification of biomolecules such as polysaccharides, glycolipids, and glycoproteins with different complexities of sugars. Typically, carbohydrate moieties on glycoproteins among vertebrates consist of complex sugars with secondary modifications (biantennary type) and ending with sialic acids. By contrast, the carbohydrate moieties in prokaryotes consist of simpler polymers of saccharides such as mannose. Pattern recognition of biomolecules is a universal theme of innate immunity.

Another ancient pathway of complement activation is initiated by the binding of pattern recognition molecules, mannan-binding lectin (MBL) or ficolins, to bacterial membranes that express arrays of simple carbohydrates such as mannose and N-acetylglucosamine (Jensenius 2005). Such binding triggers the assembly of MBL/MASP2 and ficolin/MASP2, or MBL/MASP1 and ficolin/MASP1 complex (Pathway 2, Fig. 1). MASP2 and MASP1 are mannose-associated serine proteinases. MASP2 associated with MBL or ficolin activates both C4 and C2; MASP1 activates C2 but not C4. As a result, C4b2a, a C3 convertase identical to that produced by the classical activation pathway, is generated. The downstream activation of C3 and C5 leads to the production of C3a and C5a, the formation of C5b-7 or C5b-8 sub-lytic complexes, and to the polymerization of C9 to form MAC on bacterial membranes. The ways to generate C3 convertase, C5 convertase, and MAC by the lectin pathway are identical to those of the classical pathway.

Thus, all three complement activation pathways pass through the focal point on the activation of C3 to C3a and C3b, and then C5a and C5b, leading to the assembly of sub-lytic or lytic complexes on target membranes, and production of two powerful anaphylatoxins, C3a and C5a (Fig. 1). All three pathways employ the same positive feedback mechanism that engages the generation of alternative pathway convertase C3bBb, irrespective of the original initiator, to boost up the activation process. Through interaction between the anaphylatoxins and their receptors, C3aR, C5aR (CD88), and/or C5L2, on myeloid cells including neutrophils, macrophages, and dendritic cells, the complement system cross-talks with other players of innate immunity to potentiate immune effector functions synergistically.

Complement Regulation

The complement system was achieved after millions of years of evolution. It progresses efficiently on microbial surfaces, but not on self-cells or host cells. To avoid activation that may deplete complement proteins in the circulation, and to protect from by-stander effects that may cause tissue injuries, there are regulators for every step of complement activation.

At the initiation of classical or lectin pathways, regulation is achieved by C1-inhibitor (C1-INH), a serine proteinase inhibitor that mimics the substrate for C1s in the C1 complex, or for MASP2 or MASP1 in the MBL/ficolin complex. C1-INH is cleaved by these enzymes and then becomes covalently bound to them, leading to the dissociation of the enzymatic subunit from the recognition subunit. In the absence of C1-INH, as observed among patients with hereditary angioedema, unchecked activation occurs, leading to depletions of complement C4 and C2, plus disruption of the coagulation and kinin systems. Additional regulators of complement initiation include sMAP and MAP-1 that compete with MASP2 and MASP1, respectively, for binding to MBL or ficolin, and CRIT that binds to the N-terminus of complement C2, thereby blocking the activation of C2. This prevents the formation of the classical/lectin pathway C3 convertase.

Regarding the assembly of the C3 convertases and the propagation of complement activation, there are two key mechanisms of regulation. The first is to compete with and dissociate the enzymatic subunit from the bimolecular convertases. Fluid phase protein C4b-binding protein (C4bp) dissociates the classical pathway convertase C4b2a. Complement factor H dissociates the alternative pathway convertase, C3bBb. Notably, the activity of C4bp and CFH involves recognition of host glycoproteins with glycosaminoglycans and sialic acids. Membrane-bound complement receptor CR1 and decay-accelerating factor DAF promote the disassembly of both classical pathway and alternative pathway C3 convertases on host cells.

The second complement regulation mechanism is factor I–mediated proteolytic cleavages of C4b and C3b. This factor-I digestion requires a cofactor for its activity, which is C4bp for C4b, complement factor H (CFH) for C3b, and CR1 or membrane cofactor protein (MCP) for C4b and C3b. The cleavage of C4b releases the soluble C4c, with the C4d fragment remaining covalently attached to the membrane. The factor I–mediated cleavage of C3b with CFH or MCP as cofactors leads to formation of iC3b. The cleavages of C3b by factor I with CR1 as a cofactor are more extensive, resulting in the formation of iC3b first, then soluble C3c plus bound C3dg. The latter may be further cleaved to C3d.

The anaphylatoxins generated by C3 and C5 convertases are regulated by carboxylpeptidase N (CPN). CPN removes the active site arginine residue at the C-terminus that inactivates anaphylatoxic activities of these peptides.

On the regulation of the sub-lytic and lytic complex, complement factor H–related protein-1 (CFHR1) binds to C5 and blocks its activation by C5 convertase. CRIg, complement receptor with immunoglobulin domains, regulates C5 convertase activity. The S-protein (vitronectin) blocks the insertion of C5b-7 to host membrane. Clusterin binds to C5b-7, C5b-8 and C5b-9 and

blocks the assembly of poly-C9. Protectin (CD59) on host membrane inhibits the assembly of polymeric C9 to form the lytic complex MAC by binding to C8 and C9.

Complement Receptors

There are at least 11 receptors for complement proteins. These receptors play important roles in mediating the physiologic functions of complement. Together with regulatory proteins, complement receptors facilitate the fine-tuning of complement activation with differential reactions and end-points toward self and non-self to achieve homeostasis. The binding of processed or modified complement ligands to their receptors promotes phagocytosis (opsonization), enables the trafficking and removal of apoptotic materials and immune complexes, potentiates inflammatory responses, and enhances adaptive immune response. Notably, the interactions of complement ligands and their receptors on different cell types may elicit different reactions.

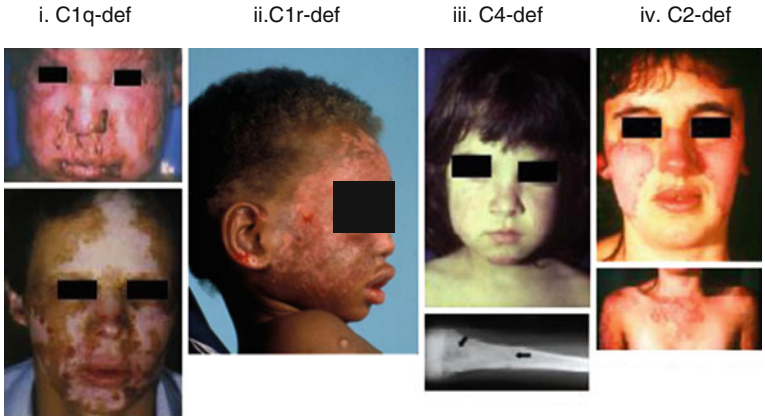
Based on the nature of ligands, complement receptors can be divided into three groups: (i) receptors for C1q and MBL, (ii) receptors for C4b and C3b and their inactivation products, and (iii) receptors for anaphylatoxins C3a and C5a.

There are three receptors that directly or indirectly bind C1q and possibly MBL. The receptor for the globular head of C1q, gC1qR appears to modulate the secretion of cytokines including IL-12 and possibly IFN-α. The other two receptors, cC1qR or calreticulin, and C1qRp or CD93, mediate phagocytosis in association with other transmembrane mediator proteins. Apoptotic cells with bound C1q are opsonized for disposal through phagocytosis by macrophages expressing C1q receptors.

There are five known receptors for C4b, C3b, and/or processed products of C3b. Complement receptor type 1 (CR1 or CD35) is a high affinity receptor for C4b, C3b, and iC3b. It is expressed on all bone marrow–derived cells including human red blood cells, lymphocytes, myeloid cells, and follicular dendritic cells of the peripheral lymphoid organs. CR1 on human erythrocytes picks up immune complexes coated with C4b, C3b, or iC3b for clearance in the liver and spleen. CR1 on neutrophils and macrophages promotes phagocytosis of antigens with C4b, C3b, and iC3b. As mentioned previously, CR1 is a cofactor for factor I–mediated proteolysis of C4b to C4c and C4d, and C3b to iC3b, C3dg and C3d. C3dg and C3d are ligands for complement receptor type 2 (CR2 or CD21). CR2 is a subunit of the tri-molecular complex, CD19-CD21-CD81, which is the co-receptor for B cell activation. The binding of either C3d- or C3dg-coated antigens or immune complexes to CR2 on B cells lowers the threshold of B cell activation and differentiation. CR2 on follicular dendritic cells serves to trap and retain antigens or immune complexes coated with C3d or C3dg in the peripheral lymphoid organs, a process important for immune memory and secondary immune response of humoral immunity (Carroll and Isenman 2012).

Complement receptors CR3 (ITGAM- or CD11b-CD18) and CR4 (ITGAX- or CD11c-CD18) belong to the β_2 integrin family. These receptors are both heterodimers, each with a distinct α-chain and a common β-chain (CD18). Besides iC3b, ligands for these receptors include intercellular adhesion molecule 1 (ICAM-1; CD54), fibrinogen and lipopolysaccharides (LPS). Both receptors are expressed on myeloid cells. They are stored in vesicles and mobilized to cytoplasmic membranes when myeloid cells are activated. In addition to promoting adhesions of myeloid cells to vascular endothelia at sites of inflammation, CR3 and CR4 are engaged in phagocytosis of iC3b-opsonized antigens. CR3 also interacts with toll-like receptors (TLR2, 4 and 9) in fine-tuning cytotoxic functions and end-points of innate immunity. Moreover, the cytoplasmic domain of CR3 provides signaling functions for glycosylphosphatidylinositol-anchored membrane proteins including Fc-γ receptor IIIb (FCGR3B or CD16b).

CRIg, the complement receptor with immunoglobulin-fold, is a receptor expressed in resident macrophages such as the Kupffer cells in the liver. This receptor binds to and mediates phagocytosis



Complement in Rheumatic Diseases, Fig. 2 Homozygous complement deficiency in human lupus. Severe cutaneous lesions are common clinical presentations in lupus patients with a complete deficiency of a classical pathway component protein. (i) A homozygous C1q-deficient male child with lupus erythematosus (LE) symptoms and cutaneous infection (*upper panel*), and with discoid LE and scarring lesions on face when he was 22 years old (*lower panel*). (ii) A homozygous C1r-deficiency male child with discoid lupus at 16 months old. This patient experienced generalized seizure, developed scissoring gait with toe walking, spasticity, and weakness of the legs. At 18 years old, he was diagnosed with class IV lupus nephritis and progressed to end-stage renal disease. (iii) A complete C4-deficient girl at 3 years old with butterfly rash and cheilitis (*upper panel*), and osteomyelitis of the femur at 10 years old (*lower panel*). This patient died at age 12 because of pulmonary infection and cardiovascular failure. (iv) A homozygous C2-deficient young woman with acute cutaneous LE. The *upper panel* shows the butterfly rash, the *lower panel* shows photosensitive lesions on sun-exposed area (Source of pictures: Yu CY et al. A Companion to Rheumatology-Systemic Lupus Erythematosus, 1st edition, Mosby Elsevier, Philadelphia, p185, 2007; Wu YL et al., Lupus 20:1126–1134, 2011)

of C3b or iC3b-opsonized particles. Therefore, CRIg is important in immunoclearance.

There are three known receptors for anaphylatoxins C3a and C5a, which are C3aR, C5aR (CD88) and C5L2 (GPR77). These receptors are characterized by the presence of seven transmembrane domains. C3aR and C5aR are G-protein coupled receptor proteins and engaged in proinflammatory signaling and effector functions upon ligations to C3a and C5a, respectively. C5L2, which binds to both C5a and C5adesArg, is independent of G-protein coupling. C5L2 is probably a decoy receptor of C5aR (Klos et al. 2013).

Genetic and Acquired Deficiencies of Classical Pathway Complement Proteins in Systemic Lupus Erythematosus (SLE)

The intricate roles of complement in rheumatic diseases are reflected by three series of observations (Atkinson and Yu 2011; Sturfelt and Truedsson 2012; Yu et al. 2007). First, homozygous genetic deficiency of any complement components specific for the classical pathway of activation (C1q, r, s, and C4) is a likely, albeit rare, cause of human SLE (Fig. 2). Second, partial or acquired deficiencies of C1q, C4 or C2 are present in numerous SLE patients. Such partial or acquired deficiencies can occur because of the presence of (i) a structural genetic variation including gene copy number variation or a polymorphism that affects the protein expression level or its functional activity, (ii) autoantibodies against C1q, (iii) a deficiency of complement C1 inhibitor leading to chronic activation and depletion of C4 and C2, or (iv) a side effect of drugs, such as from hydralazine derivatives, which inactivates the complement C4 thioester bond. Third, low levels of plasma complement C4 and/or C3 are frequently observed among SLE patients, particularly at disease diagnosis or during disease flares.

In a considerable proportion of SLE patients, serum C4 and C3 protein levels are persistently low, regardless of treatment.

Genetic Deficiency of Total C4 in Human SLE. A complete or homozygous genetic deficiency of complement C4A and C4B has been reported in 28 individuals (Atkinson and Yu 2011). Of these C4-deficient subjects, 22 (78.6 %) were diagnosed with SLE or a lupus-like disease, while 4 others had renal disease including glomerulonephritis. These C4-deficient subjects came from 19 families with different racial backgrounds, and were characterized by 16 different haplotypes of the major histocompatibility complex (MHC, also known as the HLA). Of the C4-deficient SLE patients, the female to male ratio was 1:1. Early disease onset, severe photosensitive skin rash, the presence of autoantibodies against ribonuclear protein Ro/SSA, and high titers of antinuclear antibodies (ANA) were common clinical features. Many C4-deficient patients also had severe proliferative glomerulonephritis. Almost all complete C4 deficiency patients are homozygous with identical HLA class I and class II markers from both copies of chromosome 6, possibly because of consanguineous marriages. The molecular basis of complete C4 deficiency had been determined in 15 cases. Details of the defects are shown in Fig. 3.

Copy Number Variation (CNV) of C4 Genes and Deficiency of C4A in SLE. An apparent phenotypic deficiency of complement C4A or C4B has been observed in a large proportion of SLE patients. However, the underlying causes for such phenotypes had been controversial until recently, largely because of the unawareness of common copy number variations (CNVs) and associated polymorphisms for *C4A* and *C4B* genes. Located in the central region of the HLA, among different individuals, there can be one, two, three, or four copies of *C4* genes on each chromosome 6. As a result, there is a continuous variation in the gene copy number (GCN) of C4 genes from 2 to 8 in a diploid genome among different individuals (Fig. 4). The multiplication of a *C4* gene is always concurrent with three neighboring genes. This phenomenon is dubbed RCCX modular duplications. Each RCCX module consists of a gene fragment corresponding to the 3′ end RP (also known as *STK19*), an intact *C4* gene, an intact steroid *CYP21* gene, and another gene fragment corresponding to the 3′ end of tenascin *TNX*. Each *C4* gene in the RCCX module either codes for an acidic C4A protein or a basic C4B protein. Each *C4* gene can either be a long gene of 20.6 kb or a short gene of 14.2 kb, in size. The long gene is due to the integration of an ancient retrovirus HERV-K(C4) of 6.36 kb into the ninth intron of the *C4* gene (Fig. 3).

A comprehensive study has been performed in the USA to rigorously investigate the complement *C4* genetic diversities in SLE of European decent and race-matched controls. The primary study population included 1,241 European-Americans with 233 SLE patients and 356 first-degree relatives, plus 517 unrelated healthy controls (Yang et al. 2007). Long-range mapping technique using pulsed field gel electrophoresis was employed to resolve large DNA fragments containing all RCCX modules or the number of *C4* genes present in each haplotype. Regular genomic restriction fragment length polymorphisms were performed to decipher the fine details of RCCX constituent genes. The C4 protein phenotypes were elucidated by immunofixation of EDTA-plasma, immunoblotting analyses using monoclonal antibodies to determine the Rodgers and Chido blood group antigens associated with C4A or C4B proteins, and radial immunodiffusion to determine the plasma C4 protein concentrations (Chung et al. 2005). In this particular study population, the gene copy numbers of total *C4* varied from 2 to 6, *C4A* from 0 to 5, and *C4B* from 0 to 4. Their corresponding median copy numbers were 4, 2, and 2, respectively. In comparison to healthy controls, SLE patients had their total *C4* and *C4A*, but not *C4B*, gene copy number groups shifted to the lower copy number side (Fig. 4).

Among female SLE patients, 9.3 % had only two copies of *C4* genes, and 6.5 % had a homozygous deficiency of *C4A*, compared to 1.5 % and 1.3 %, respectively, in healthy controls. Among the subjects with only two copies of *C4* genes,

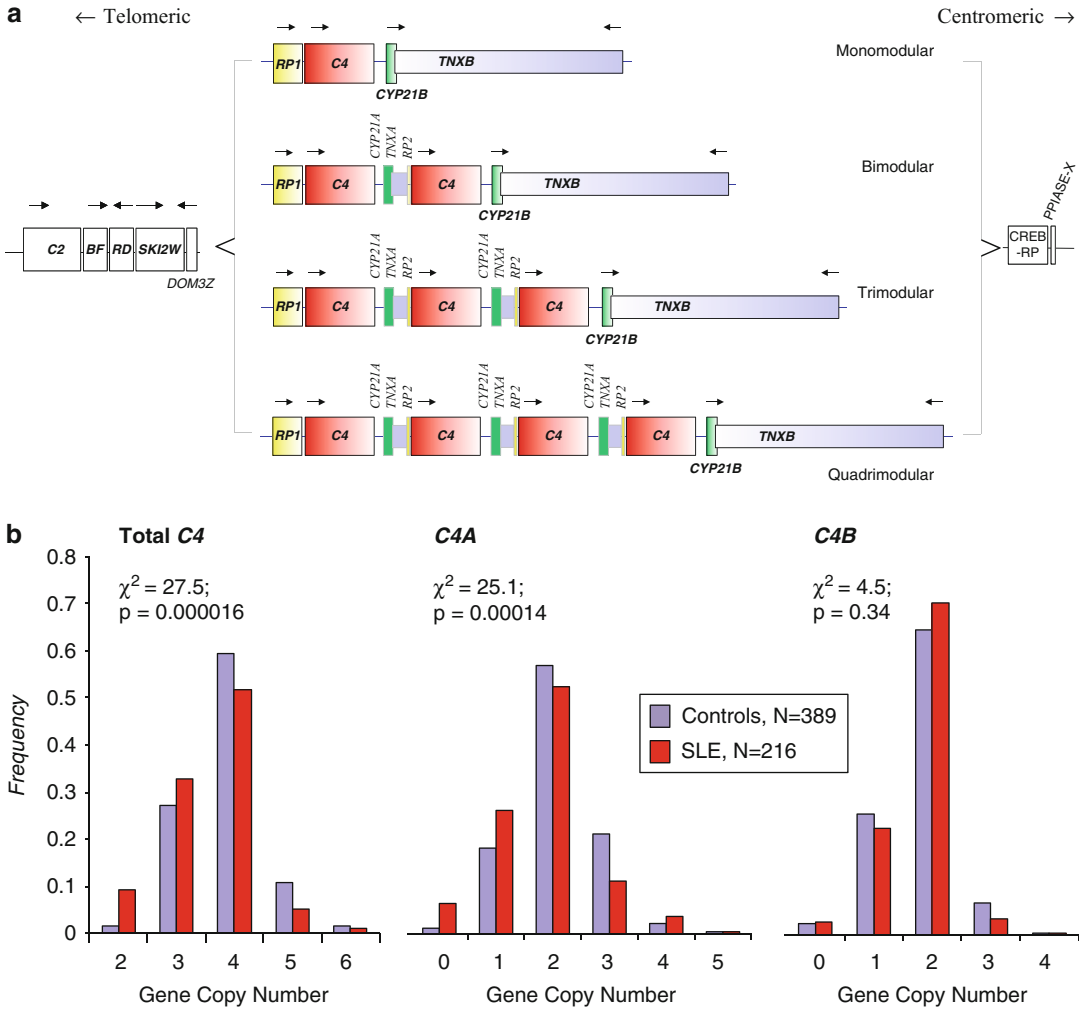
Complement in Rheumatic Diseases, Fig. 3 Molecular basis of complete C4 deficiency. A total of 28 subjects are known to have complete C4 deficiency. Among them, the molecular bases for the non-expression of C4 proteins in 15 subjects have been determined. These subjects were from eight different HLA haplotypes. Molecular defects in the mutant *C4* genes include nonsense mutations caused by point mutations, mini-deletions and mini-insertions in the coding regions, and point mutations at intron/exon splice junctions. *Filled black boxes* are the 41 exons in each *C4* gene. HERV-K (C4) is an endogenous retrovirus inserted into the intron 9 of long *C4* genes (Source: Wu YL et al., Genes and Immunity 10:433–445, 2009)

a great majority of them had no *C4A* genes; a small proportion of subjects had one copy of *C4A* and one copy of *C4B*, or with two copies of *C4A* and no *C4B*. The odds for SLE disease risk (or odds ratio, OR) for a subject with only two copies of *C4* genes in a diploid genome are 6.5 times greater than those with three or more copies of *C4* genes. Among the subjects with no *C4A* genes, the odds for SLE disease risk are 5.7 times greater than those with one or more copies of *C4A* genes. In other words, *very* low gene copy number (GCN) of total *C4* (GCN = 2), or



Complement in Rheumatic Diseases, Fig. 4 Copy number variation (CNV) of complement *C4* genes in SLE and controls. (**a**) RCCX modular variations. The *C4* gene is located in the class III region of the HLA on chromosome 6p21.3. On each chromosome 6, there can be one to four copies of *C4* gene. The duplication of a *C4* gene is concurrent with its three neighboring genes *RP* (*STK19*), *CYP21* and *TNX*. Thus, the phenomenon is known as RCCX duplication. Each *C4* gene codes either for an acidic C4A protein or a basic C4B protein. (**b**) Comparisons of total *C4*, *C4A*, and *C4B* gene copy numbers in SLE and controls. SLE patients show significantly lower copy numbers of total *C4* and *C4A* (Modified from Atkinson JP and Yu CY, In Systemic Lupus Erythematosus, 6th Edition, Lahita R, Tsokos G, Buyon J and Koike T eds, Academic Press, Amsterdam, pp21-45, 2011)

a homozygous deficiency of *C4A* (GCN = 0), is a large effect size (strong) genetic risk factor for human SLE.

Parallel increases in frequencies of heterozygous C4A deficiency (GCN = 1), and moderately low copy number of total C4 (GCN = 3), were observed in the SLE population. However, their effect size or impact on disease risk is substantially lower. Specifically, the frequency of subjects with a single copy of *C4A* was 26.4 % in SLE and 18.2 % in controls (OR = 1.6); the frequency of subjects with moderately low copy number of total *C4* was 32.9 % in patients and 27.0 % in controls (OR = 1.3). On the contrary, human subjects with high copy numbers of total *C4* or *C4A* genes were protected

against SLE disease risk (total *C4*, ≥5 copies: 6.0 % in patients, 12.0 % in controls; OR = 0.47; *C4A*, ≥3 copies: 15.3 % in patients, 23.8 % in controls; OR = 0.57) (Yang et al. 2007). In an independent study of SLE in Han-Chinese, significantly lower gene copy number of C4A and total C4 genes were observed in the SLE cases than matched controls (Lv et al. 2012).

Secondary or Acquired Deficiency of C4 and Susceptibility to SLE. Inherited or acquired deficiency of the complement C1 inhibitor is associated with an increased frequency of autoimmunity, especially SLE (Agnello 1986). With a deficiency of the C1 inhibitor, C1 cleaves, in an unchecked fashion, its natural substrates, C4 and C2, causing a chronic marked reduction in their blood levels. In most patients with C1 inhibitor deficiency, C4 and C2 concentrations are continuously reduced such that it simulates a C4-deficient and a C2-deficient state.

Therapeutic agents hydralazine and isoniazid may also induce SLE through inhibition of C4 function. The concentrations of hydralazine and isoniazid that inhibited the activity of C4 by 50 % were in the range of those obtained during therapy. Related to this observation was the finding of an increased frequency of C4A null alleles, which already predisposes a subject to higher risk of autoimmunity, in hydralazine-induced SLE patients (Sim et al. 1984).

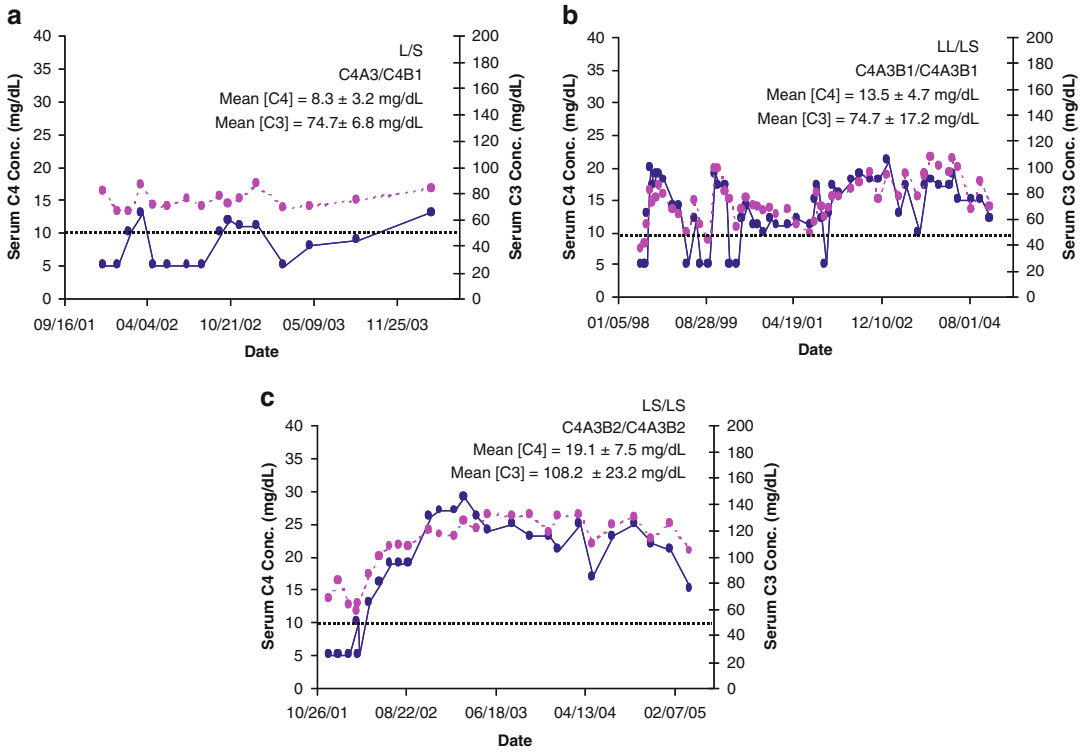
C4 Protein Concentrations in Serum and C4 Cleavage Products on Blood Cells. SLE patients are often characterized by occasionally or persistently low serum or plasma levels of complement C4 and/or C3. Through multiple logistic regression analyses, several parameters that determine serum or plasma C4 protein concentrations have been identified. The *C4* gene copy number, the copy number of short *C4* genes, and the body-mass index are positively associated with increased C4 protein concentrations. The presence of SLE is negatively associated with C4 protein levels. In some, but not all, of such patients, complement C3 and C4 levels are biomarkers for lupus disease activity – low serum levels of C3 and/or C4 correlate with a flare while normal C3/C4 levels tend to correspond with a disease remission.

Longitudinal studies of serum complement protein levels in SLE patients reveal different expression profiles (Fig. 5) (Wu et al. 2006). In one group of patients, persistently low C4 and C3 protein levels were detected, and many of these patients had a low copy number of *C4* genes. The second group of patients was marked by frequent fluctuations of C4 and C3 protein levels and SLE disease activity. The third group of patients was characterized by occasionally low C4 and C3 levels, particularly at the time of disease diagnosis, but their levels often returned to normal. Most patients in the second and third group had the median or higher copy numbers of total *C4* or *C4A*, and the C4 and C3 protein concentrations roughly parallel the SLE disease activities.

Another way to observe the consumption of C4 in SLE is by the presence of degradation product C4d attached to red blood cells, reticulocytes, and platelets (Liu et al. 2009). This chronic activation of C4 can be monitored by flow cytometry of peripheral blood samples using antibodies against C4d. It is suggested that levels of RBC-C4d reflect complement activation in the past 60 days, the levels of reticulocyte-C4d reflect during the past 2–3 days, and platelet-C4d levels reflect complement activation during the past 5 to 10 days.

Genetic Deficiency of C1q. The a, b, and c chains of human C1q are encoded by three different genes closely linked on chromosome 1p34-1p36. A total of 42 human subjects have been identified with a genetic deficiency of C1q. Among them, 39 (92.9 %) developed a syndrome related to SLE. The female to male ratio in C1q-deficient SLE was close to 1:1. The median age disease onset was 6 years old (range: 6 months to 42 years old).

C1q-deficient SLE patients were characterized by skin rash (86 %) (Fig. 2), glomerulonephritis (GN) (38 %), and central nervous system (CNS) involvement (17 %). For autoantibodies, the prevalence of ANA was only 70.6 % (24/34), anti-dsDNA was 20.8 %, and anti-ENA (extractable nuclear antigens including Sm, RNP, Ro, and/or La) was 62.5 % (15/24). At least one-third of the C1q-deficient patients were inflicted with recurrent bacterial infections



Complement in Rheumatic Diseases, Fig. 5 Typical C4 and C3 serial protein profiles in human SLE patients. Serum C4 and C3 protein levels tend to go up and down together in many SLE patients. In the first group of patients (*panel A*), levels of C4 and C3 are chronically low. In some patients, even if C3 levels rise to normal range, C4 levels remain low. This group of patients is characterized by low copy number of C4 genes. The second group of patients has frequent fluctuations of C3 and C4 (*panel B*). This group of patients has active disease, and low C3 and low C4 roughly correlate with disease activity. In the third group of patients, C4 and C3 protein levels stay in the normal range most of the time, except at the time of diagnosis and during a disease relapse. These patients tend to have relatively inactive disease. The second and third groups of patient have normal gene copy number of total *C4* but may have a heterozygous deficiency of *C4A* (Source: Wu YL et al. Adv Exp Med Biol 586:227–247, 2006)

including otitis media, meningitides, and pneumonia. Four C1q-deficient patients died of septicemia in early childhood. Some patients also developed diffuse monilia and aphthous lesions in the mouth and toenail deformity secondary to moniliasis.

There are two major causes for a hereditary C1q deficiency. The first is a nonsense mutation resulting in a failure to synthesize the C1q protein, which accounts for ~60 % of cases. Such nonsense mutations occur at codons 6 or 41 and frame-shift mutations from codon 43 that culminate to a stop codon at residue 108 of the C-chain; a stop codon for residue 150 of the B-chain; and a stop codon for residue 186 of the A-chain. The second cause of C1q deficiency is the synthesis of a low molecular weight, nonfunctional C1q, which accounts for ~40 % of the cases. Low molecular weight C1q can be caused by missense mutations that disrupt the collagen motifs in C1q and interfere with the formation of higher order structure of C1q. A normal C1q consists of 18-polypeptides intertwined to form a tulip-like structure with six globular heads and a collagen-like tail (Lu et al. 2008).

Hereditary and Acquired Hypocomplementemia of C1q. In addition to the coding mutations leading to the absence of C1q protein biosynthesis or a production of nonfunctional

C1q protein, it was observed that a silent single nucleotide polymorphism at codon 70 (GGG→GGA) of the *C1QA* gene was associated with decreased levels of C1q in patients with subacute cutaneous lupus erythematosus. Whether the SNP at codon 70 is engaged in the regulation of gene transcription has not been clarified.

Distinct from inborn factors leading to low levels of C1q production, acquired hypocomplementemia of C1q due to an increased protein consumption is frequently observed in SLE patients or other autoimmune conditions, including hypocomplementary urticarial vasculitis syndrome, cryoglobulinemia, and severe combined immunodeficiency syndromes. The major underlying cause is the presence of autoantibodies against C1q. C1q autoantibodies are present in roughly one-third of SLE patients, particularly among those with renal diseases and high disease activities.

Genetic Deficiency of C1r or C1s. Deficiencies in subcomponents of the C1 complex, C1r and/or C1s, were among the earliest reported linking complement deficiency with human SLE. The genes for human *C1s* and *C1r* are located on chromosome 12p11.31. These two genes are configured in a tail-to-tail orientation with their 3′ ends separated by 9.5 kb. The human *C1s* gene spans 10.5 kb with 12 exons coding for a precursor protein of 688 amino acids, which includes a leader peptide of 15 amino acids. The human *C1r* gene probably also consists of 12 exons.

A total of 20 cases of C1r and/or C1s deficiencies (12 cases of C1r deficiency from 8 families; 8 cases of C1s deficiency from 5 families) have been documented so far. Among these subjects, all but three were inflicted with recurrent bacterial, viral, or fungal infections. Thirteen C1r-/C1s-deficient subjects developed SLE or a lupus-like disease (65 %). The female to male ratio among C1r-/C1s-deficient subjects with SLE was 1.5 to 1. It is noteworthy that several "non-SLE" C1r- or C1s-deficient subjects were identified because of severe infections but died at young age and were therefore not available for follow-up examinations of autoimmune disease status.

Most C1r-/C1s-deficient patients were characterized with severe cutaneous lesions. Eight patients had renal disease due to lupus nephritis (40 %) (Fig. 2). Relatively low prevalence of ANA (59.4 %) was found. Among the C1r-deficient patients, there was consistent reduction in the serum protein levels of C1s to ~30 % of its normal levels, but highly *elevated* protein levels of complement C4, C2, and C1 inhibitor (200–400 % of the normal ranges), and unaffected expression level of C1q. A similar phenomenon was observable among C1s deficient patients: greatly reduced serum levels of C1r, elevated levels of C4, and steady levels of C1q. Such presentations underscore the interdependence of C1r and C1s in sustaining a stable tetrameric structure that would otherwise be susceptible to high turnover rate. A deficiency of C1r or C1s incapacitates the formation of the C1 complex and the ensuing activation of the classical activation pathway. An impairment of C1r or C1s therefore greatly reduces the consumption of C4 and C2 and the engagement of C1 inhibitor in regulating the formation of C1 complex, resulting in unusually high levels of these proteins in the circulation.

The molecular defects leading to C1r or C1s deficiency have been determined in four patients. Among them are a homozygous C to T mutation in exon 10 of the *C1r* resulting in a R380X nonsense mutation, a 4-bp deletion in exon 10 of *C1s* that created frame-shift mutations and formation of a premature stop codon, and two different nonsense mutations at codon 534 or codon 608 in exon 12 of *C1s*.

Complement C2 Deficiency and Susceptibility to SLE. Complement C2 deficiency occurs with an estimated prevalence of 1/20,000 in individuals of northern European descent. Complete C2 deficiency accounts for <1 % of SLE patients. C2-deficienct SLE patients tend to have early childhood onset but a milder disease process, with prominent photosensitive dermatologic manifestations, speckled autoantibodies that are common for the Ro (SSA) antigen, and a familial history of SLE (Fig. 2). Anti-DNA antibody tests were mostly negative. Severe kidney diseases were relatively rare among C2-deficient patients.

The association of C2 deficiency with human SLE is considerably different from that observed for C4 or C1 component protein deficiencies. First, the prevalence of SLE among C2-deficienct subjects is only between 10 % and 30 %. In other words, the effect size of C2 deficiency on SLE is substantially lower than that of C4 or C1 deficiencies. Second, the female predominance of SLE in C2-deficienct approaches that observed in the general SLE cases. Third, the severity of disease is not distinct from that of the general lupus population.

There are two mechanisms leading to complement C2 deficiency. Type 1 C2 deficiency is caused by nonsense mutations leading to the absence of C2 protein biosynthesis. The predominant form of Type 1 deficiency is present in the HLA *A10 (A25), B18, DRB1*15 (DR2), BFS, C2Q0, C4A4, C4B2*, haplotype. The defect is caused by a 28-bp deletion that removes 9-bp from the 3′ end of exon 6 and 19-bp from the 5′ end of intron 6, leading to a skipping of exon 6 in the *C2* transcript and generation of a premature stop codon. The second form of Type 1 C2 deficiency is due to a 2-bp deletion in exon 2 that leads to a nonsense mutation, as observed in HLA *A3, B35, DR4, BFF, C2Q0, C4A3A2*.

About 10 % of C2 deficiency belongs to the Type 2 deficiency, in which the C2 protein is synthesized but not secreted. The molecular defects were found to be missense mutations leading to the following changes: C111Y, S189F, and G444R. It is unclear how these missense mutations block the secretion of C2.

Genetic Deficiency of Classical Pathway Complement Proteins in Human and Murine Lupus

The prevalence of SLE among subjects with a genetic deficiency of complement C4 or component proteins (C1q, r, s) of the C1 complex (65–93 %) is higher than that observed among monozygotic twins (24–58 %) (Tsao and Wu 2007). The common features among complement-deficient SLE are the early age of disease onset, the roughly equal prevalence in males and females, the presence of anti-Ro/SSA, and severe cutaneous disease (Lipsker and Hauptmann 2010). These data suggest a causal role of complement deficiency in SLE. Although linked in the same activation pathway that is triggered by the binding of antibodies to antigens, these classical pathway complement proteins are *independent* in the protection against SLE disease susceptibility, as a deficiency in any of these four complement proteins is strongly linked to lupus disease susceptibility. The molecular defects leading to a genetic deficiency of C1q, C1r, C1s, or C4 are mostly *private* mutations detectable in probands and their close relative (s), but rarely in the general SLE population. Such a phenomenon is in keeping with the theory of "rare genetic variants with very large effect size in common diseases" (McClellan and King 2010).

The overwhelming roles of classical pathway complement protein deficiency in SLE pathogenesis have been tested in mouse models with genetic ablations of complement genes (Holers 2000; Pickering et al. 2001). In permissive genetic backgrounds, C1q-deficient or C4-deficient mice showed enhanced lupus phenotypes. Lupus disease onset was generally earlier. Antinuclear antibody titers were higher. There were also higher frequencies of DNA antibodies, and more pronounced glomerulonephritis. It is of interest to note that mice deficient in factor B, C2, or C3 did not develop or show enhanced spontaneous SLE phenotypes under any genetic background tested. It is also noteworthy that a spontaneous lupus disease phenotype in C4-knockout or C1q-knockout mice was strain dependent. Unlike the great degree of association between C4 deficiency or C1q deficiency and human SLE from multiple independent families and different racial backgrounds, a pronounced lupus phenotype was not observed in mice of most genetic backgrounds with C4 deficiency or C1q deficiency, except in those with lupus-prone backgrounds.

Two major hypotheses have been put forward to explain the engagement of complement in autoimmunity and tolerance. The first, mostly known as the waste disposal hypothesis

(Korb and Ahearn 1997; Taylor et al. 2000), is based on the roles of activated complement including C1q, C4b, and C3b in opsonizing immune complexes, foreign particles and apoptotic, necrotic, netotic, or damaged self-materials for phagocytosis and clearance from the circulation, and on solubilizing aggregates of immune complexes and reducing cryoglobulin activity. Therefore, the chance of generating autoantibodies or autoreactive T cells against self-antigens is minimized. While physiological, this hypothesis does not explain some most fundamental phenomena connected to human autoimmune diseases. Processed products of C3b including iC3b, C3dg, and C3d are highly relevant in opsonizing immune complexes and foreign particles for phagocytosis through binding to complement receptors CR1, CR3, and possibly CR4, and for B cell development through binding to CR2. However, it is C4 deficiency, and not C3 deficiency, that is strongly linked to the predisposition of SLE, both in humans and mice. While it is established that C1q binds to late apoptotic blebs and facilitates their removal through phagocytosis by macrophage or dendritic cells, MBL probably plays a similar role, but MBL deficiency does not elicit strong autoimmune defects like C1q deficiency does in humans. In addition, why a deficiency of C1r or C1s (but not MASP2 or MASP1) strongly predisposes a subject to SLE pathogenesis in the presence of normal C1q and very high C4 levels is of question.

The second hypothesis entails the observations of complement in B cell activation in animal model studies (Carroll and Isenman 2012). It has been observed that complement-coated immune complexes or antigens are trapped by follicular dendritic cells in the spleen or peripheral lymphoid system. Through germinal center reactions, antigens are presented to helper T cells, which lower the thresholds of B cell activation and promotes class-switching from low specificity and low affinity IgM to high specificity and high affinity IgG. Some complement-coated antigens are retained for long periods of time and are sampled continuously by dendritic cells in the peripheral lymphoid system. This helps explain the roles of complement in facilitating the secondary immune response and achieving immune memory. These reactions mostly engage the binding of C3b and/or C4b to CR1, C3b or iC3b to CR3 on dendritic cells and phagocytes, and C3d- or C3dg-coated antigens to CR2 on B cells. CR2 is an important co-receptor for B cell activation. It is possible that a complement-deficient or -depleted host would have prolonged or chronic antigenemia, as well as accumulation of modified or damaged self-antigens in the circulation. One probable outcome would be ectopic or impaired follicular localizations of autoantigens, leading to aberrant immune response against self-antigens. Again, this hypothesis relies on the prominent roles of C3b and its processed products on B and T cell activations. Similar to the waste disposal hypothesis, this complement in B cell activation hypothesis is unable to provide a satisfactory explanation on the differential roles of C4 deficiency and not C3 deficiency in the pathogenesis of systemic autoimmune diseases.

The classical pathway of complement activation has evolved to be a downstream effector for the adaptive humoral immune response (Fig. 1). It would be natural, and actually essential, for this effector arm to have developed a concurrent feedback mechanism to prevent or downregulate the generation of antibodies against self-antigens to achieve tolerance. Irrespective of the sequence or the hierarchy in the activation pathway, C1q, C1r, C1s, and C4 are all needed to prevent the occurrence of systemic autoimmunity against ubiquitous nuclear and cytoplasmic antigens. The emerging concept is that activated complement proteins of the classical pathway are engaged (directly or indirectly) in the regulation or the homeostasis of adaptive immunity, including the discrimination between self- and non-self-antigens.

There are multiple triggers and independent routes leading to the initiation of autoimmune rheumatic diseases. Among human subjects with an established autoimmune disease that engages autoantibodies, or with an inflammatory disease, complement activation and consumption is of concern. The generation of anaphylatoxins C3a and C5a creates an inflammatory state that

attracts and activates neutrophils and other myeloid cells to the site of complement activation. The formation of the membrane attack complex likely causes tissue damage and aggravates disease severity. Among SLE patients with an active disease or with lupus nephritis, presence of low levels of serum C4 and C3, and high levels of cell-bound C4d, is a general phenomenon. The harmful effects of complement activation are even more remarkable in rheumatoid arthritis.

Complement in Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a systemic, inflammatory, rheumatic disease affecting 0.1–1 % of the human population worldwide. RA is characterized by an inflammatory process that targets the synovium of primarily peripheral joints, leading to irreversible joint destruction and disability, plus systemic or extra-articular complications (McInnes and Schett 2011; Okroj et al. 2007). In the RA patients, there are marked infiltrations of the synovial linings with T and B cells, macrophages, and granulocytes, leading to swollen joints, destruction of cartilages, bone resorption, revascularization, and deformity.

Autoantibodies play a major role in the more severe forms of RA. The autoantibodies that are best characterized in RA are: (i) autoantibodies against citrullinated proteins (ACPA) that are both specific and sensitive, and (ii) autoantibodies against the Fc-fragment of immunoglobulins (rheumatoid factor, RF) that are sensitive but not specific. RA patients whose blood tests classified as seropositive typically express both RF and ACPA. The strongest genetic risk factor for RA is present in HLA, particularly polymorphic variants of *DRB1* genes in the class II region. More refined studies have showed that about 85 % of the seropositive RA patients have the shared epitope with amino acid sequence [(R/Q)(K/R)RAA] at position 70–74 of the HLA DR-β chain, which are mainly encoded by specific subtypes of *DRB1*04*. Seropositivity and the presence of shared epitope appear to confer increased risk of RA. In a recent study on HLA class III genes in RA, it was found that the frequency of homozygous and heterozygous deficiency of complement C4B was significantly increased in the seropositive RA patients, suggesting that C4B deficiency interacts with shared epitopes in the development of seropositive RA (Rigby et al. 2012).

Regardless of the genetic and environmental risk factors that initiate the onset of RA, it is well documented that complement proteins play important roles in the clinical phase of the disease. Complement component proteins and their proteolytic cleavage products are present in synovial fluids. Synovial fluids from RA patients contain microparticles that are likely released by apoptotic or necrotic cells. These microparticles are coated with C1q and cleavage products C3d and C4d, suggesting chronic complement activation that is likely initiated by the formation of immune complexes between RA-associated autoantibodies and autoantigens, activation of the classical pathway, and ensuing amplifications by the alternative pathway. Depressed levels of component proteins, elevated levels of complement cleavage products, and membrane attack complex C5b-9 are noted in synovial fluids from RA patients with active disease. Because of the under-expression of the terminal pathway regulatory protein CD59, the synovial membrane is particularly vulnerable to membrane attack complex–mediated damage (Okroj et al. 2007). Neutrophils and fibroblasts in synovial fluids have high expression levels of complement receptors on their membrane. Sublytic levels of C5b-9 activate synovial fibroblasts to secrete collagenases and metalloproteinases, which degrade collagens. Elevated levels of anaphylatoxins C3a and C5a in synovial fluid attract the migration of neutrophils to the inflamed joints, and activate neutrophils, macrophages, mast cells, and fibroblasts through binding to C5aR or C3aR. The secretion of inflammatory cytokines, degranulation and release of reactive oxygen species, vasoactive peptides, histamines, chemokines, proteolytic enzymes including metalloproteases collectively

contribute to joint erosion, swollen joints, and leakage of plasma proteins from micro-vessels (Okroj et al. 2007; Ricklin et al. 2010; Sturfelt and Truedsson 2012).

The relevance of complement activation in RA has been validated in animal models. Rats depleted of complement C3 through cobra venom factor were resistant to the development of collagen-induced arthritis (CIA). A variety of genetically engineered mouse strains with complement C5 deficiency or C5a-receptor deficiency were resistant to CIA, while complement C3 deficiency or factor B deficiency were either RA resistant or had a milder disease. Intriguingly, deficiencies in C1q, C4, or C6 had no effects on the progression of induced arthritis in rodent models. This phenomenon emphasizes the significance of complement activation by the alternative pathway or proteinases for the generation of anaphylatoxins C5a and C3a in the *clinical* phase of RA in animal models. Thus, applications of complement inhibitors at the level of C5 and/or C3 activations, and antagonists or blockage of C5aR and C3aR appear to be logical therapeutic approaches to treat or attenuate the disease. Indeed, there are ongoing therapeutic studies for RA in animal models using monoclonal antibodies against C5 to block C5 activation, compstatin to block C3 activation, or soluble complement receptor analog (sCR1) with complement controlling protein (CCP) domains to competitively inhibit the formation of C3 or C5 convertases. Many of these complement inhibitors appear to reduce the disease severity and halt the progression of an established disease in animal models, opening the door for potential clinical trials.

Conclusion

The complement system is activated through three distinct pathways. The alternative pathway forms the first line of defense against infections. It is initiated through a tick-over mechanism that activates complement C3 by continuous hydrolysis in the circulation. The lectin pathway engages pattern recognition by MBL and ficolins of glycosylated microbial antigens with simple sugar molecules. The classical pathway is activated by antibodies binding to antigens in adaptive humoral immune response. All three activation pathways converge on the activations of C3 and C5; the end-point of the activation cascade depends on the initiator and the microenvironment. Complement activation triggered by microbial infections culminates in the formation of membrane attack complexes to lyse the targets. Activation products of complement also serve as anaphylatoxins that activate and attract inflammatory cells, including neutrophils and macrophages to the site of complement activation. In rheumatic diseases, complement proteins play dual roles in the disease onset and pathogenesis. On the one hand, complement proteins are engaged in the prevention of autoimmunity, and a genetic deficiency of a *classical* pathway complement component proteins such as C1q, C1r, C1s, or C4 is among the strongest risk factors for systemic autoimmune disease such as SLE. Low levels of these complement proteins, which may be genetically determined or acquired, are frequently observed in SLE patients. On the other hand, complement activation is integral to tissue injuries and pathogenesis of established autoimmune disease or inflammatory disease, such as rheumatoid arthritis. There are ongoing research efforts to inhibit complement activation to ameliorate complement-mediated tissue injuries in inflammatory rheumatic diseases.

Complement Regulation in the Kidney

Daniel J. Birmingham
Division of Nephrology, Department of Internal Medicine, The Davis Heart and Lung Research Institute, Ohio State University Medical Center, Columbus, OH, USA

Definition

The complement system maintains homeostasis by achieving a balance between complement activation and complement regulation. Under normal conditions this process is tilted towards regulation through mechanisms involving specific complement regulatory proteins. Even under conditions where complement activation is beneficial, such as for clearing immune complexes and contributing to the immune response, complement control must be maintained to prevent damage to bystander tissue. This is especially important in the kidney, where many pathologies involve the complement system.

Regulation of Complement Activation

The complement system comprises proteins involved in complement pathway activation, in regulation of this activation, and in receptors that mediate many of complement's functions (Walport 2001a, b). Complement activation can proceed by three different pathways, all of which yield enzymatic complexes (C3 convertases) that cleave C3 to C3a and C3b. The three activation pathways differ in how they are initiated. The classical pathway is initiated by fixation of C1q to appropriate substrates, such as immune complexes and apoptotic debris. The lectin pathway is initiated by the binding of mannose-binding lectin (MBL) or ficolin to carbohydrates found on the surface of certain pathogens. The alternative pathway is initiated spontaneously by a hydrolyzed form of C3 ($C3_{H20}$) that is continually present in the circulation and by C3b. Thus, the alternative pathway is always poised to be activated and is usually engaged to amplify complement activation by C3b generated by any of the pathways. Under normal circumstances, complement activation is held in check by regulatory systems.

Complement regulation involves both the natural decay of the C3 convertases as well as the actions of specific complement regulators (Zipfel and Skerka 2009). Perhaps the most important of these proteins are the regulators of complement activation (RCA), a family of proteins encoded in a cluster on chromosome 1 (Hourcade et al. 1989). All of the RCA proteins bind cleaved forms of C4 and/or C3, and through this action provide two general complement regulatory functions. First, this binding accelerates the decay of the convertases, which effectively halts activation of C3 and downstream complement effects (e.g., generation of C5a and membrane attack complex (MAC)). Second, this binding provides cofactor activity for the factor I-mediated cleavage of C4b (to C4d and C4c), C3b (to C3bi), and C3bi (to C3dg and C3c), forms that can no longer participate in convertase activity. Factor I (FI) is a serine esterase with specificity for C4b, C3b, and C3bi. Through these two general functions, the RCA proteins prevent spontaneous complement activation and keep amplified complement activation in check.

There are six general types of RCA proteins, each with its own combination of function and distribution (Table 1). *C4b-binding protein* (*C4BP*) is a plasma protein that binds C4b and provides both decay acceleration activity for the classical pathway convertases and cofactor activity for the FI-mediated cleavage of C4b. *Factor H* (*FH*) is a plasma protein that binds C3b and provides both decay acceleration activity for the alternative pathway convertases and cofactor activity for the FI-mediated cleavage of C3b. There are actually seven different forms of FH from six different genes (FH, FH-like protein 1 (an alternative splice product of FH), FH-related protein 1 (FHR1), FHR2, FHR3, FHR4, and FHR5) (Rodriguez de Cordoba et al. 2004). The predominant form in the plasma is FH, and the unique physiological roles of FH-like protein

Complement Regulation in the Kidney, Table 1 The regulators of complement activation

RCA protein	Ligand	Complement regulatory function		Predominant site of activity
		Decay acceleration	Factor I cofactor	
C4BP	C4b	+	+	Fluid phase
FH	C3b	+	+	Fluid phase, membrane
MCP	C3b, C4b	–	+	Membrane (intrinsic)
DAF	C3 convertase	+	–	Membrane (intrinsic)
CR1	C3b, C4b, C3bi	+	+	Membrane (intrinsic and extrinsic)
CR2	C3bi, C3dg	–	+[a]	Membrane

[a]Cofactor activity only for cleavage of C3bi to C3dg

1 and the related FH gene products are presently unclear. *Membrane cofactor protein* (*MCP, CD46*) is a type 1 membrane protein that binds to and provides cofactor activity for the FI-mediated cleavage of both C3b and C4b. *Decay accelerating factor* (*DAF, CD55*) is a glycophosphatidylinositol (GPI)-linked membrane protein that interacts with all of the complement convertases and accelerates their decay. This interaction is unique among the RCA proteins in that it occurs through the recognition of the assembled convertase, rather than through the individual components. *The complement receptor type 1* (*CR1, CD35*) is a type 1 membrane protein that binds to and provides cofactor activity for the FI-mediated cleavage of C3b, C3bi, and C4b and accelerates the decay of all of the convertases. The sixth RCA protein, *the complement receptor type 2* (*CR2, CD21*), is a receptor for C3bi and C3dg and has demonstrated mild cofactor activity for cleavage of C3bi. However, the physiological role of CR2 is likely not as a complement regulator and will not be discussed further in this entry.

In addition to differences in how they regulate complement, the RCA proteins also differ in the tissue compartment in which they provide this function. As plasma proteins, C4BP and FH are important in regulating fluid-phase complement activation (e.g., in plasma). FH also have important complement regulatory function at specific tissue sites, through binding sites for C-reactive protein (CRP), heparin, and sialic acid. The membrane proteins MCP and DAF exert their complement regulation locally at the membrane surface, specifically on the same membrane where they are expressed ("intrinsic" function). The membrane protein CR1 exhibits both intrinsic activity and extrinsic activity, being able to regulate complement activation in the fluid phase as well as on external surfaces. The extrinsic binding of C3b, C3bi, and C4b by CR1 in the circulation that leads to complement regulation occurs mainly through erythrocyte CR1, and this binding is referred to as immune adherence (Birmingham and Hebert 2001).

Other non-RCA complement regulators also play important roles in complement regulation, including C1 inhibitor (C1INH) and CD59. C1INH is a soluble serine protease inhibitor that functions by binding activated C1r and C1s, causing their dissociation from the C1q molecule and preventing initiation of the classical pathway. CD59 is a GPI-linked membrane protein that binds to C8/C9 during the process of MAC formation, thus halting it, and in so doing protects membranes from the damaging effects of MAC.

Complement Regulation in the Kidney

All tissues are vulnerable to damage through complement activation. Under normal conditions, this damage is prevented by the action of the complement regulators in the blood and complement regulators on tissue exposed to blood. However, during appropriate complement activation by substrates such as microorganisms or immune complexes, some of the resulting complement effector proteins (e.g., MAC) can spillover and cause damage to nearby host tissue. The kidney appears to be particularly vulnerable to this type of complement-mediated damage.

As a natural filter and under high pressure and turbulence, the kidney tends to trap the types of debris that can activate complement. An example of this is the trapping of immune complexes that result following infection or the development of autoimmunity involving autoantibodies (e.g., lupus nephritis, LN). In LN, classical complement activation by immune complexes that have accumulated in the kidney tissue can initiate damage to the tissue. Alternative pathway complement activation, either amplified as a result of the initial classical pathway or directly activated through damaged tissue, perpetuates the complement-mediated damage.

Perhaps as an evolutionary response to the heightened vulnerability to complement activation, complement regulatory mechanisms exist that are specific to the kidney. For example, CR1 is expressed at high levels in glomerular podocytes (Emancipator et al. 1983). The function of glomerular podocyte CR1 is currently unproven, though this expression site likely provides complement regulation targeted to the glomerular filtration barrier, thus suppressing complement activation in the event that immune complexes become trapped at this barrier or that the filtration barrier is disrupted. In support of this, loss of podocyte CR1 commonly occurs in patients with lupus nephritis or diffuse diabetic nephropathy.

Another RCA expression pattern specific to the kidney involves DAF and MCP, the two RCA proteins that are important for intrinsic complement regulation on tissue surfaces. For DAF, normal human kidney expression is limited to the juxtaglomerular apparatus (JGA). In certain diseased kidneys, such as those from patients with LN or with hemolytic uremic syndrome (HUS)-related kidney damage, DAF expression is lost from the JGA and becomes prominent in the glomerular mesangium and interstitium and correlates with C3 deposition (Cosio et al. 1989). Normal kidney MCP expression is similar to DAF in that it is predominantly in the JGA, though weak expression also occurs at many other sites, such as basement membranes and the mesangium. In contrast to DAF, MCP expression does not change in the JGA in LN (or in membranoproliferative glomerulonephritis, membranous nephropathy (MN), and poststreptococcal acute glomerulonephritis), but its expression is greatly increased on the glomerular capillary wall and in the mesangium (Endoh et al. 1993). Similar to DAF, the levels of MCP correlate with the levels C3b/C3bi deposition. These findings suggest that DAF and MCP expression is increased in the kidney in response to complement activation during disease processes. The relevance of DAF and MCP localization within the JGA under normal healthy conditions remains unclear, though it may be part of the normal JGA response to common changes in glomerular filtration rate and renal blood flow.

Though not specifically expressed in the kidney, FH may also play a particularly important role in protecting the kidney from complement-mediated damage. As mentioned above, though often thought of as one of the circulating regulatory proteins, FH also has binding sites to heparin, sialic acid, and CRP. These binding sites may target FH to certain tissue and, in the case of the CRP binding site, may target FH to sites of tissue damage, thus targeting complement regulation in a region where complement activation may be ongoing. The importance of this has recently been recognized in studies involving the disease age-related macular degeneration (AMD). A common polymorphism in the FH gene causes a tyrosine (Y) to histidine (H) substitution at amino acid position 402, which falls in the same region of the CRP binding site. The 402H variant exhibits reduced FH binding to CRP and reduced targeted complement regulation. The 402H variant is associated with AMD and in fact imparts ~50 % risk for AMD. Together, these data suggest that the developing lesion in AMD is driven in large part by complement activation in the face of dysfunctional complement regulation by FH. A similar relationship was recently found with LN, where the 402H variant was associated with complement activation during LN flare (Birmingham et al. 2010). Thus, FH may play a significant role in complement regulation in the kidney of lupus nephritis patients during disease flare.

As discussed above, complement activation needs to be tightly regulated to protect self-tissue, even in the absence of an overt activating insult, and complement regulators provide this function. This role appears to be particularly important for general kidney health. The best evidence of this can be found in patients with dense deposit disease (DDD), also known as membranoproliferative glomerulonephritis (MPGN) type II. Patients with this disease have defects that are either related to C3NeF (~80 % of cases), which is an autoantibody to the alternative pathway C3 convertase that stabilizes the convertase, or to FH/FHR protein defects (mutations, deletions) (Smith et al. 2011). In both cases, spontaneous and prolonged alternative pathway complement activation occurs that leads to complement deposition in the renal vasculature and eventual accumulation of complement-containing dense deposits in the glomerular basement membrane (GBM). Clinical manifestations of this defect include proteinuria, hypertension, and progression to end-stage kidney disease (ESKD). Thus, the vasculature in the kidney appears to be a prime target for spontaneous complement activation due to dysfunctional complement regulation.

A similar disease has been recently described, termed complement FHR5 (CFHR5) nephropathy (Gale et al. 2010). This familial disease was discovered in two Cyprus families and was found to be associated with a variant of the FHR5 gene that exhibits reduced binding to deposited C3b. The clinical presentation included proteinuria, hematuria, and ESKD and coincided with the appearance of C3 deposition and electron-dense deposits in the capillary wall and mesangium. This is an intriguing finding from the standpoint that circulating levels are <10 % of the level of FH and suggests that FHR5 provides complement regulatory effects that are specific to the kidney.

Another form of renal disease that is directly linked to defective complement regulation is atypical HUS (aHUS), which is manifested by hemolytic anemia, thrombocytopenia, and acute renal failure from vascular thrombosis, in the absence of enteropathic infection (usually *Escherichia coli*). The majority of aHUS cases appear to be associated with deleterious mutations in the complement regulatory proteins FH, MCP, and FI, with a penetrance of about 50 % (Richards et al. 2007). Interestingly, patients with aHUS often have mutations in more than one regulatory protein, and onset of the disease is variable, suggesting this disease requires two hits, such as multiple regulatory defects or an environmental contribution (e.g., infection), for full disease onset. In the case of an environmental factor such as infection, this second hit likely initiates complement activation, which is prolonged in the absence of adequate complement regulation, resulting in complement-mediated vascular damage in the kidney. Such a scenario suggests that inefficient complement regulation may also contribute to renal vascular injury associated with typical HUS involving E. coli infections (Orth and Wurzner 2010).

Conclusions

The purpose of complement regulation is to control spontaneous complement activation and to keep appropriate complement activation in check, thus maintaining adequate complement levels and preventing complement-mediated damage to self-tissue. This is especially important to the kidney, an organ which bears the brunt of inappropriate or uncontrolled complement activation. Complement regulatory mechanisms exist that are unique to the kidney to provide enhanced protection against complement-mediated damage. Defects in these complement regulatory mechanisms can directly lead to kidney injury, and secondarily have a negative impact on kidney diseases that involve the complement system.

CTLA-4

Leonard H. Sigal
Departments of Medicine and Pediatrics, Department of Molecular Genetics and Microbiology, UMDNJ–Robert Wood Johnson Medical School, New Brunswick, NJ, USA

Synonyms

APC- antigen presenting cell; ARF- ADP-ribosylation factor; CD- clusters of differentiation; cdk- cyclin-dependent kinases; CTLA- 4 – cytotoxicT lymphocyte antigen 4; ICOS- Inducible T-cell CoStimulator; IDO - indoleamine 2, 3-dioxygenase; ITIM -immunoreceptor tyrosine-based inhibitory motif; LAT- linker of activated T cells; LAX - linker for activation of X cells; LFA-1 – lymphocyte function-associated antigen-1; MHC- major histocompatibility complex; PLD- phospholipase D; PP2A- serine/threonine phosphatase 2A; SIT - SHP2-interacting transmembrane adapter protein; SLE- Systemic Lupus Erythematosus; T reg – regulatory T cell; TCR- T cell antigen receptor; TIRC7- T cell immune response cDNA *7*; TLR- Toll-like receptor; TRIM - T-cell receptor interacting molecule; ZAP-70 -Zeta-chain-associated protein kinase 70

Definition

For antigen-induced activation of a T cell to occur, an antigen-presenting cell (APC) must provide the T cell with two signals. The first is the antigen, in the context of the major histocompatibility complex (MHC) on the surface of the APC (“a hot dog [the antigen] in a hot dog bun [the groove provided by the MHC molecules]”). The second is the costimulatory signal, classically delivered by CD80/CD86 (B7-1/B7-2; members of the immunoglobulin superfamily consisting of variable and constant domains with approximately 20 % sequence identity with each other) on the APC interacting with CD28 (another

immunoglobulin superfamily member, consisting of a disulphide bond-linked homodimer) on the surface of the T cell (Linsley et al. 1991). CD28 is constitutively expressed on the surface of T cells; the receipt of both "signal 1," antigen in the context of MHC, and "signal 2," the costimulatory signal, allows antigen-specific activation of the T cell. Absence of "signal 2" causes the T cell to be anergized. CD80/86 expression on the surface of APCs is upregulated by exposure of the APC to "danger" signals, e.g., ligands of toll-like receptors (TLRs), making the APC a more potent activator of T cells (Hertz et al. 2001).

Once optimal antigen activation occurs, there is a need for a negative signal, a means to dampen T cell activation; theoretically, the absence of this inhibitory signal could lead to excessive expansion of the T cell population, with uncontrolled lymphoproliferation and/or poorly modulated immune function, perhaps resulting in autoimmune reactivity. Thus, there is a need for a "yin" to offset the "yang" of "signal 2" provided by the binding of CD80/CD86 to CD28.

CTLA-4 (cytotoxic T lymphocyte antigen 4) was the fourth in a series of molecules identified on the surface of cytotoxic T lymphocytes, a molecule at first in search of a function, until its "yin"-like qualities were identified in the early 1990s (Noel, Boise, Thompson, 1996). And, as predicted, mice unable to express CTLA-4 were predisposed to lethal lymphoproliferative disorders.

CTLA-4 (CD152): Function and Mechanism of Action

CTLA-4 (CD152), like CD28, is a member of the immunoglobulin superfamily, a disulphide bond-linked homodimer with approximately 30 % sequence identity of its variable Ig-like chain with the analogous CD28 chain. Of note, and predictably, CTLA-4 is not expressed on resting T cells prior to or early in the process of T cell activation by the two signals from the APC. Presynthesized CTLA-4 is stored within intracellular vesicles, including the *trans*-Golgi network, overlapping with endocytic compartments and with perforin-containing secretory granules. With increasing intracellular calcium levels that follow T cell activation, CTLA-4 is upregulated on the surface of the activated T cell during cell-cycle progression, under the control of several signaling molecules, such as:

TRIM [TCR-interacting molecule], which acts as a chaperone

LAX and SIT [linker for activation of X cells and SHP2-interacting transmembrane adapter protein, respectively], either of which can substitute for TRIM

PLD and ARF-1 [phospholipase D and adenosine diphosphate-ribosylation factor-1, respectively] needed for budding of vesicles at the Golgi apparatus

TIRC7 [T cell immune response cDNA 7], which is colocalized with CTLA-4 on activated T cells and delivers an apoptotic signal to CD4+ and CD8+ T cells after it interacts with its ligand, the non-polymorphic alpha 2 domain of HLA-DR, HLA-DRα2

The short surface half-life of CTLA-4 suggests tight regulation of its surface expression. Both intracellular and cell surface CTLA-4 are focused on sites of T cell antigen receptor activation, which is to say the "immunological synapse" (Linsley, Brady, Greene, et al. 1996). Recent work shows localization of CTLA-4 to the central supramolecular synapse, where it becomes stabilized by its interaction with its ligands (CD80/86), while CD28 is excluded from interaction with CD80/86 (Yokosuka et al. 2010). Although CD80 and CD86 express only 20 % of overall amino acid identity, they both bind CD28 and CTLA-4. The latter is the high-avidity receptor for both CD80 and CD86, binding approximately 500- to 2,500-fold more avidly to CD80 and CD86 than does CD28. Thus, CTLA-4 "outcompetes" CD28 for binding with CD80/CD86; CTLA-4 then transmits an inhibitory signal to the T cell, balancing out the previously stimulatory signal of CD28 (Stamper et al. 2001).

The effects of CTLA-4 have been divided into "cell-autonomous" and "non-cell-autonomous" effects. The former represents CTLA-4

acting as an inhibitory coreceptor in T cells expressing CTLA-4, whereas the latter represents CTLA-4 on one T cell inhibiting activities or functions of other T cells. Non-cell-autonomous suppression of T cell activation may be accomplished by a regulatory population of T cells, known as Tregs; details of this phenomenon are described below.

The initial theory about how CTLA-4 delivers its inhibitory signal to the activated T cell was that CTLA-4 "outcompeted" CD28 for binding to CD80/86, resulting in a simple loss or withdrawal of the stimulation provided by CD28 signaling – this then caused the T cell to slow its activation. However, there are other reasonable explanations. Englehardt and colleagues (Englehardt et al. 2006) suggested five potential explanations:

1. As above, CTLA-4 outcompetes CD28, removing that stimulatory signal.
2. CTLA-4 delivers a negative stimulus of its own, signaling through its own intracytoplasmic tail, affecting CD28 and/or the T cell antigen receptor (TCR); this could be mediated by a number of established CTLA-4 activities, e.g., reduction of IL-2 production, decreased expression of cyclin D3, cyclin- dependent kinases (cdks) 4 and 6, or recruitment of SHP2 and serine/threonine phosphatase 2A (PP2A) to the immunoreceptor tyrosine-based inhibitory motif (ITIM) in CTLA-4's cytoplasmic tail, leading to dephosphorylation of TCR- proximal signaling proteins such as CD3ξ and ▶ LAT (linker for activated T cells), and possibly Shc, Lck, Fyn, and ZAP-70 (zeta-chain-associated protein kinase 70). CTLA-4 interferes with the formation of micro-clustering of ZAP-70, which is needed for transmission of the TCR signal (Rudd et al. 2009). Part of this negative signaling may be due to interference with the production of IL-2.
3. CTLA-4 may interfere with the integrity of the immunological synapse, by sterically interfering with tight fit, or by mechanisms described above.
4. CTLA-4 may have an effect on, or be part of, the functioning of regulatory T cells.
5. CTLA-4 may have an indirect effect by suppressing APC function, e.g., induction of indoleamine 2, 3-dioxygenase (IDO) within the APC that, by depleting local tryptophan, can inhibit T cell activation; there may be decreases in CD80/86 expression by endocytosis or trogocytosis of CTLA-4-CD80/86 complexes by Tregs; soluble CTLA-4 may inhibit access of CD28 to CD80/86.

Their study, published in 2006, shows that the effect of CTLA-4 is dependent on the presence of CD28 and supports the first two potential mechanisms (Englehardt et al. 2006). Rudd et al. described yet another mechanism: CTLA-4 interferes with the TCR signal that slows the migrating T cell, allowing it to halt and form a stable immunological synapse (Schneider et al. 2006).

Madrenas and colleagues (Madrenas et al. 2004) suggest that prior to binding CD80/86, CTLA-4 may exist in two inactive states. In one, PP2A cannot gain access to the cytoplasmic tail of CTLA-4, which is folded on the inner leaflet of the cell membrane; in the other CTLA-4 state, the cytoplasmic tail is accessible to PP2A. When CTLA-4 is colligated with the TCR, the PP2A is phosphorylated and then dissociates from the CTLA-4, unleashing its inhibitory signaling potential.

As noted by Rudd et al. in their review, CTLA-4 not only activates JNK in CD4+ T cells but it inhibits ERKs (extracellular signal-regulated kinases), thus differentially affecting various members of the greater MAPK (mitogen-activated protein kinase) family. Activation of JNK could influence Th1 over Th2 differentiation and enhance LFA-1 adhesion, among other changes (Rudd et al. 2009).

CTLA-4: Structure

CTLA-4 includes an extracellular V domain, a transmembrane domain, and a cytoplasmic tail, with the intracellular domain being similar to that of CD28, in that neither have catalytic activity. The membrane-bound isoform of CTLA-4 functions as a homodimer with a single

connecting disulfide bond, while the soluble isoform is a monomer.

Three isoforms of CTLA-4 have been identified. The full-length isoform (flCTLA-4) is expressed only on activated T cells. A form lacking the ectodomain (CTLA-4i) is expressed only on resting T cells. The third form is a soluble CTLA-4 (sCTLA-4) which lacks the transmembrane section encoded by exon 3; it is not clear to what degree sCTLA-4 is active, e.g., in modulating normal immune function and/or defending against the elaboration of an autoimmune process, although elevated levels of sCTLA-4 have been identified in patients with autoimmune diseases (Rudd et al. 2009; Park, Baek, Do, et al., 2009).

The intracellular component of CTLA-4 contains one YVKM motif capable of binding SHP2, PP2A, and/or ▶ PI3K and a single proline-rich motif which can bind SH3-containing proteins. CTLA-4 inhibits T cell responses, but there is still uncertainty about how this inhibitory signal is delivered.

CTLA-4 and Regulatory T Cells

CTLA-4 has been implicated in the maintenance of peripheral T cell tolerance, the avoidance of autoimmunity. One of the crucial processes involved in this maintenance of peace is immune suppression by a family of $CD4^+$ $CD25^+$ (IL-2 receptor α-chain) $FOXP3^+$ T cells called natural regulatory T cells, or Tregs, that inhibit T cell activation. This T cell population constitutively expresses CTLA-4 on its surface, in contradistinction to naïve T cells early in their activation by APCs; expression of CTLA-4 by Tregs increases after TCR ligation, as is the case with standard antigen-specified T responder cells. As noted, some of the actions of CTLA-4 on the Tregs constitute the "cell-non-autonomous" actions alluded to above (Wing et al. 2011).

As reviewed by Friedline et al. (2009), transfer of naive ($CD25^-$) $CD4^+$ T cells into lymphopenic hosts leads to colitis, which is blocked if $CD4^+CD25^+$ $FOXP3^+$ Treg cells are also included in the transfer. This protection from colitis is in turn blocked by injection of antibodies to CTLA-4, which supports the premise that CTLA-4 on Treg is important in this immune modulation. Friedline and colleagues recently demonstrated that regulation is mediated by CTLA-4 Treg cells; is reversible, depending on the continuous presence of these Treg cells; and does not involve "reverse inside-out" B7 signaling.

Tang and colleagues demonstrated that expression of CTLA-4 on $FOXP3^+$ Tregs in vivo is related to their rapid, perpetual homeostasis and that upregulation of CTLA-4 occurs solely on $FOXP3^+$ Tregs undergoing extensive proliferation, which can be reversed by inhibiting the CD28 pathway, with subsequent reduction in $FOXP3^+$ Treg proliferation and frequency (Tang et al. 2008). FOXP3 represses IL-2 production and that of other proinflammatory cytokines and increases the expression of both CD25 and CTLA-4. These cells also express high levels of lymphocyte function-associated antigen-1 (LFA-1), perhaps helping to explain why Tregs outcompete conventional T cells for aggregation around APCs, essentially physically preventing responder T cells access to a forming immunological synapse. CTLA-4 negatively regulates steady-state Treg homeostasis; when CTLA-4 signaling is inhibited, Treg proliferation and overall Treg frequency is enhanced.

Thus, there is evidence that CTLA-4 on the surface of Tregs is serving a homeostatic function for that population of T cells, although it almost certainly plays a direct role in the regulatory pathway by suppressing APCs (Friedline et al. 2009). CTLA-4 may also have an important role in cell survival. CTLA-4 may have the ability to reverse antigen-induced cell death in anergic T cells, perhaps by known effects on various members of the Bcl-2 protein family (Rudd et al. 2009).

A recent brief report by Ying et al. is the first demonstration that CTLA-4 has an effect on Th17 cell function. A CTLA-4 interaction with B7 inhibits Th17 cell differentiation in vitro and suppresses the development of Th17-mediated autoimmunity in vivo, utilizing an autoimmune myocarditis model (Ying et al. 2010).

CTLA-4 Polymorphisms and Linkage to Immune-Mediated Diseases/ Susceptibility to Diseases

Alternate splice variants of CTLA-4, encoding different isoforms, have been identified, as noted above. Mutations in the CTLA-4 gene have been associated with insulin-dependent diabetes mellitus, Graves' disease, Hashimoto's thyroiditis, celiac disease, ▶ systemic lupus erythematosus (SLE), thyroid-associated damage of the orbital contents ("ophthalmopathy"), ▶ primary biliary cirrhosis, and other ▶ autoimmune diseases.

Polymorphisms of the CTLA-4 gene are associated with autoimmune diseases such as autoimmune thyroid disease and multiple sclerosis, though this association is often weak. In systemic lupus erythematosus, the splice variant sCTLA-4 is found to be aberrantly produced and found in the serum of patients with active disease.

CTLA-4 variants have been implicated in immune-mediated, infectious, and malignant diseases, both as risk/susceptibility factors and as correlates of decreased risk/severity (as summarized in Sigal 2012). Some of the disease associations include:

Certain forms of CTLA-4 are protective and others connote susceptibility in Japanese patients with biliary cirrhosis.

Among many genes examined in a Chinese study, one variant of CTLA-4 represents a risk factor for breast cancer.

Polymorphisms of CTLA-4 and CD86 represent possible factors associated with risk or protection for chronic obstructive pulmonary disease in this Chinese population study.

CTLA-4 variants have been implicated in a genome-wide search for innate and adaptive immune risk factors for the development of alopecia areata, among the most prevalent of human autoimmune diseases.

CTLA-4 variants have been implicated in rheumatoid arthritis, SLE, Behcet's syndrome, and anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV). A deficiency (production or maintenance) of regulatory T cells in SLE patients may be due to variants in CTLA-4 and/or FOXP3.

In a study of Estonian and Finnish patients with type 1 diabetes mellitus, CTLA-4 but not inducible T cell costimulator (ICOS; CD278) gene variants were implicated in susceptibility to type 1 diabetes mellitus. The alleles connoting risk were more common in the Finnish controls compared with the Estonians, suggesting this gene locus might also contribute to the higher disease incidence in Finland.

CTLA-4 as a Therapeutic Target

The ability of CTLA-4 to modify T cell function has made it an obvious therapeutic target: antagonism for suppression of autoimmune responses or graft rejection and agonism to enhance immune responses to malignancy.

In the former category is the first such "costimulation modulator," abatacept (CTLA-4-Ig), consisting of the extracellular domain of CTLA-4 fused to a human IgG1 Fc backbone (hinge-CH2-CH3 domains), which had been modified to interfere with complement fixation (the purpose of the Fc component is to increase the serum half-life of the therapeutic agent). Abatacept, marketed as Orencia®, is approved for use in rheumatoid arthritis (Maxwell and Singh 2009) and juvenile idiopathic arthritis (Ruperto et al. 2008, 2010) and has been studied in psoriatic arthritis (Mease et al. 2011) and systemic lupus erythematosus (Merrill et al. 2010). A related molecule (two mutations different from abatacept) is belatacept, recently approved and marketed as Nulojix®, for use in renal transplantation as an alternative to cyclosporine (Vincenti et al. 2011). The effect of each of these drugs is to enhance CTLA-4-mediated suppression of ongoing immune responses in order to control autoimmune disorders (abatacept) and transplant graft rejection (belatacept). Although there had been speculation that abatacept might work, at least in part, by enhancing IDO in APCs, this was disproven by Davis et al. (Davis et al. 2008).

In the latter category is ipilimumab, a fully humanized IgG1 monoclonal antibody that

targets and blocks CTLA-4 on human cytotoxic cells. The result of this is to remove CTLA-4-induced suppression of these cytotoxic cells, allowing expansion of the activated clones, with a subsequent increase in antitumor activity. Previously known as MDX-010 or MDX-101, ipilimumab (Sondak et al. 2011) has been approved for use in metastatic melanoma and is now marketed as Yervoy®. Ipilimumab is still in trials for both small cell and non-small cell lung carcinoma, as well as for metastatic hormone therapy-refractory prostate cancer. Another fully human monoclonal (an IgG2) anti-CTLA-4 antibody is tremelimumab (formerly ticilimumab, CP-675,206) in trials for pancreatic, prostate, and bladder cancer; a recent study suggests this molecule has a direct impact on effector cells, rather than an indirect pathway leading through regulatory T cells (Khan et al. 2011).

Conclusion

In less than two decades, CTLA-4 has gone from a molecule in search of a purpose to one of the underpinnings of the newly described phenomenon of properly modulated "costimulation" and most recently a set of at least three successful therapeutics. As is so often the case, spontaneous "experiments of nature" have provided us with insights of how the presence of alternate forms of CTLA-4 or its absence alter normal immune function. The world of costimulation has become a bit more complex with the addition of other parallel alternate pathways to T cell activation.

Disclosure

Dr. Sigal was the medical lead at Bristol-Myers Squibb (BMS) for clinical trials of abatacept in juvenile idiopathic arthritis, psoriatic arthritis, and systemic lupus erythematosus. He is no longer employed by BMS, but owns a small amount of BMS stock.

CTLA4-Ig

Ronald L. George Jr. and E. William St. Clair
Division of Rheumatology and Immunology, Department of Medicine, Duke University Medical Center, Durham, NC, USA

Synonyms

Abatacept; Belatacept

Definition

CTLA4-Ig (abatacept) (Orencia™, Bristol-Myers Squibb) has been developed for the treatment of autoimmune disease and is approved by the US Food and Drug Administration and the European Medicines Agency for the treatment of moderately to severely active adult rheumatoid arthritis (RA) and moderately to severely active juvenile idiopathic arthritis in children 6 years of age and older.

Introduction

Soluble CTLA4-Ig binds to CD80 (B7-1) and CD86 (B7-2) on antigen-presenting cells, blocking their interaction with CD28 on T cells and inhibiting T cell activation in vivo (Linsley et al. 1992). Two closely related CTLA4-Ig molecules have been developed for the treatment of autoimmune disease and prevention of graft rejection in kidney transplantation. Abatacept (Orencia™, Bristol-Myers Squibb) has been approved by the US Food and Drug Administration and the European Medicines Agency for the treatment of moderately to severely active adult RA and moderately to severely active juvenile idiopathic arthritis in children 6 years of age and older. Abatacept consists of the extracellular domain of human CTLA4 linked to the hinge, CH2, and CH3 domains of human IgG_1. In its development, four amino acid mutations were introduced into the constant regions of the IgG portion of the molecule to improve protein production and abrogate the effects of antibody-dependent cellular cytotoxicity and complement-dependent cytotoxicity.

Belatacept (Nulojix™, Bristol-Myers Squibb), a daughter molecule of abatacept, is approved for the prevention of graft rejection in kidney transplantation. Belatacept is structurally identical to abatacept except for two amino acid substitutions in the extracellular ligand-binding domain (L104→E and A29→Y) that confer fourfold and twofold greater binding avidity to CD86 and CD80, respectively, compared with its parent compound.

CTLA4

The therapeutic mechanisms of CTLA4-Ig derive from the extracellular domain of the CTLA4 molecule, an inhibitory receptor expressed on activated but not resting $CD4^+$ and $CD8^+$ T cells. CTLA4 shares two ligands, CD80 and CD86, with CD28, a homologous co-stimulatory receptor constitutively expressed on naive T cells. CD28, the most widely studied co-stimulatory receptor on T cells, plays a major role in the induction and maintenance of T cell responses. It is the second signal of the 2-signal model of T cell activation. In this model, T cell activation depends on two signals: (1) the binding of the T cell receptor (TCR) to a major histocompatibility complex (MHC)-bound antigen on the antigen-presenting cell and (2) a co-stimulatory signal such as the binding of CD28 on the T cell to CD80 and CD86 on the antigen-presenting cell. TCR engagement by the MHC-antigen complex in the absence of a second signal leads to anergy of the T cell. Thus, depending on the strength of co-stimulation, the antigen-presenting cell may either trigger immunity (both signals) or peripheral tolerance (signal 1 alone). In general, naïve T cell responses are more dependent on a strong co-stimulatory signal than memory T cell responses.

The extracellular domain of CTLA4 has complex immunoregulatory effects. Once CTLA4 is upregulated on the surface of T cells shortly after cellular activation, it binds to CD80 and CD86, which results in a potent negative signal that downregulates the T cell response (Walunas et al. 1996). CTLA4 may also inhibit T cell activation by competing directly with CD28 for binding to CD80 and CD86. It has a competitive advantage over CD28 in this context because of its higher affinity for CD80 and CD86. CTLA4 can also generate a "reverse signal" through CD80 and CD86 and trigger the production of indoleamine 2, 3-dioxygenase (IDO) (Mellor and Munn 2004). IDO is an enzyme that catalyzes the degradation of tryptophan in many different types of cells, including dendritic cells. The restricted availability of tryptophan and the increased production of its metabolites, such as kynurenine, inhibit T cell proliferation and promote T cell apoptosis. CTLA4 is also likely to be important in the control of T regulatory cells. CTLA4 is constitutively expressed at high levels on the surface of $CD4^+FoxP3^+$ T regulatory cells. Upon antigen stimulation, its engagement by CD80 and CD86 may lead to the activation of $CD4^+FoxP3^+$ T regulatory cells and their acquisition of suppressive function (Rosenblum et al. 2011).

CTLA4-Ig

Studies in mice and nonhuman primates have shown that administration of CTLA4-Ig suppresses a mixed lymphocyte reaction, prevents allograft rejection, and inhibits T cell-dependent antibody responses (Linsley et al. 1992). In addition, CTLA4-Ig treatment has been shown to ameliorate disease in a variety of autoimmune models, including murine lupus, collagen-induced arthritis, experimental autoimmune encephalomyelitis, and diabetes. In these studies, therapy with CTLA4-Ig potently suppressed antigen-specific T cell proliferation, T-dependent B cell responses, and cytokine production by virtue of its ability to block the CD28:CD80/86 co-stimulatory pathway. However, joint inflammation was not affected when abatacept was given to a SCID mouse engrafted with human rheumatoid arthritis (RA) synovial tissue, implying this agent may not act directly on the inflamed synovium in RA, but rather at a distant site, such as secondary lymphoid tissue. CTLA4-Ig treatment has also been shown in these animal models to stimulate the production of IDO by antigen-presenting cells, resulting in suppression of T cell proliferation (Grohmann et al. 2003). Since CTLA4-Ig treatment has been reported to have both positive and negative effects in mice on the $CD4^+FoxP3^+$ T regulatory cell population, its overall impact on this regulatory subset is unclear and may vary according to disease state.

Less is known about the immunoregulatory effects of CTLA4-Ig therapy in humans. The ability of abatacept to interfere with T cell priming has been demonstrated in patients with psoriasis vulgaris. In this study, abatacept treatment decreased antibody responses to a T cell-dependent neoantigen, an inhibitory effect that was reversible upon stopping the drug (Abrams et al. 1999). In a subsequent study, a single infusion of abatacept 750 mg given at −2 weeks, +2 weeks, and +8 weeks following immunization was found to have no significant effects on the antibody response to tetanus toxoid (memory T cell-dependent antigen) or pneumococcal vaccine (memory T cell-independent antigen), although geometric mean titers of anti-tetanus and anti-pneumococcal titers tended to be lower in subjects vaccinated 2 weeks after receiving abatacept than the later time point (Tay et al. 2007).

As mentioned earlier, abatacept may induce IDO and catalyze tryptophan degradation in mice, leading to suppression of T cell activation. However, attempts to confirm these effects in humans have not produced consistent results. Human dendritic cells, in particular, have not been clearly and reproducibly shown in vitro and in vivo to increase IDO expression after CTLA4-Ig treatment. In kidney transplant recipients, belatacept therapy may have effects on the regulatory T cell population where it has been shown to increase the percentage of $CD4^+CD25^+FoxP3$ T regulatory cells infiltrating the kidneys undergoing acute cellular rejection (Bluestone et al. 2008; Furuzawa-Carballeda et al. 2010).

CTLA4-Ig as Immunotherapy: Rheumatoid Arthritis

Abatacept was initially developed as an intravenous preparation for the treatment of RA. To enhance dosing flexibility, abatacept may now also be given by the subcutaneous route, which has the same efficacy as the intravenous form. Several large, randomized, controlled trials have been performed evaluating the efficacy and safety of abatacept therapy for RA. In the AIM (Abatacept in Inadequate Responders to Methotrexate) study, for example, 652 patients with active RA despite methotrexate therapy were randomly allocated to receive treatment with abatacept ($n = 433$) or placebo ($n = 219$) while they continued their methotrexate therapy. At 1 year, the American College of Rheumatology (ACR)20 response rates in the abatacept and placebo groups were 73.1 % and 39.7 %, respectively ($P < 0.001$). An ACR response, a dichotomous outcome, corresponds to a 20 %

CTLA4-Ig, Table 1 Phase III clinical trials of abatacept therapy for adults with RA

Phase III study	N = number of subjects	Duration	Clinical efficacy endpoints	
			ACR 50 response	DAS28 remission (<2.6)
AGREE	509	1 year	Abatacept + MTX versus MTX + placebo (57.4 % vs. 42.3 %; $p < 0.001$)	Abatacept + MTX versus MTX + placebo (41.4 % vs. 23.3 %; $p < 0.001$)
AIM	652	1 year	Abatacept + MTX versus MTX + placebo (48.3 % for abatacept vs. 18.2 %; $p < 0.001$)	Abatacept + MTX versus MTX + placebo (23.8 % vs. 1.9 %; $p < 0.001$)
ATTAIN[a]	391	6 months	Abatacept versus placebo (20.3 % vs. 3.8 % ; $p < 0.001$)	Abatacept versus placebo (10.0 % vs. 0.8 %; $p > 0.001$)
ATTEST	431	6 months	Abatacept + MTX versus MTX + placebo (40.4 % vs. 20.0 %; $p < 0.001$)	Abatacept + MTX versus MTX + placebo (11.3 % vs. 2.9 %)

[a]Background oral disease-modifying antirheumatic drugs (DMARDS): methotrexate, azathioprine, penicillamine, gold, hydroxychloroquine, chloroquine, leflunomide, sulfasalazine.

or 50 % (i.e., ACR20, ACR50) improvement in a core set of 7 clinical and laboratory variables used to measure disease activity that includes the tender and swollen joint count, physician's assessment of disease activity, patient's assessment of disease activity, patient's assessment of pain, patient's assessment of physical function, and serum levels of an acute-phase reactant (C-reactive protein [CRP] or erythrocyte sedimentation rate [ESR]). Clinical remission, as defined by the Disease Activity Scale (DAS) 28, was observed in 23.8 % of the abatacept group but only 1.9 % of the placebo group (Kremer et al. 2006). The DAS 28 is a continuous score that also measures disease activity and is based on the number of tender and swollen joints (total of 28 joints), a patient's global health assessment, and serum level of acute-phase reactant (CRP or ESR). Patients taking the combination of abatacept and methotrexate showed about one-half the rate of radiographic progression of joint damage as those receiving placebo and methotrexate. Another randomized, placebo-controlled, clinical trial (AGREE) subsequently found that abatacept was also efficacious therapy for patients with early RA (Westhovens et al. 2009). Early RA was defined in this trial as disease of less than 2 years and included only those patients with a positive test for rheumatoid factor and/or anti-CCP antibodies or joint erosions on their radiographs. In this study, patients with limited or no previous exposure to methotrexate therapy (the usual first-line treatment for RA) were randomly allocated to receive treatment with abatacept and methotrexate or methotrexate alone. The patients receiving the combination of abatacept and methotrexate achieved a DAS28 remission in 41.4 % of cases as opposed to 23.3 % of patients receiving methotrexate alone ($p < 0.001$). Compared to the methotrexate-only group, the abatacept plus methotrexate combination also showed less radiographic progression of disease. Such combination therapy may be an option for patients with early RA and poor prognostic factors.

Three-year data from the AIM trial also provided valuable information about the long-term safety of abatacept therapy for RA (Kremer et al. 2011). By the third year of the AIM trial, 359 (83 %) of the original 433 patients receiving abatacept and 175 (80 %) of the 219 receiving placebo had remained in the study and were available for assessment. The most common adverse

event was infection with an incidence rate of 70.8 per 100 patient-years; the incidence rate for serious infection was 3.2 per 100 patient-years. Ten deaths occurred in the cumulative period and were primarily related to infection. The overall incidence ratio for malignancy was comparable with the rate of malignancy in patients with RA that are treated with conventional therapy. Other safety studies have shown that infection rates are higher when abatacept is combined with a biologic DMARD (e.g., etanercept, adalimumab, infliximab) as opposed to a traditional DMARD such as methotrexate. Therefore, abatacept is not combined with another biologic DMARD in routine clinical practice.

Abatacept is also effective for the treatment of juvenile idiopathic arthritis (JIA). For example, in a double-blind randomized controlled withdrawal trial, abatacept was found to be a safe and clinically effective therapy for JIA that produced tangible life benefits to children with this disease (Ruperto et al. 2008).

CTLA4-Ig Therapy for Type I Diabetes

Type I diabetes (DM1) results from the destruction of the insulin-producing islet cells of the pancreas by an immune-mediated, chronic inflammatory process. Although DM1 may be managed by insulin replacement therapy, its course may be associated with both short- and long-term complications. Therapies aimed at arresting islet cell destruction, such as those targeting CD3 and CD20, have seen only limited success thus far in clinical trials. Since T cells are believed to be central to the pathogenesis of DM1, abatacept has also been investigated as a possible treatment for this autoimmune disease. To this end, a phase II randomized, placebo-controlled trial of abatacept has been recently completed in patients with recent-onset type 1 diabetes showing abatacept therapy to be associated with a significantly higher geometric area under the curve (AUC) of the stimulated C-peptide level at 2 years compared with the placebo group (Orban et al. 2011). The serum level of C-peptide reflects the amount of residual insulin secretion by the pancreas. Treatment with abatacept delayed the reduction in stimulated C-peptide levels by 9.6 months compared with the placebo group; however, the initial benefit of the abatacept infusion was observed mainly in the first 6 months as the subsequent decline in stimulated serum C-peptide levels paralleled that of the placebo group. These observations are consistent with a "window of opportunity" during the early stages of DM1 when the chronic inflammatory response in the pancreatic islets may be inhibited to reverse the inexorable decline in β-cell function.

CTLA4-Ig for Transplantation

In nonhuman primate transplant models, abatacept was found to be relatively ineffective for preventing the rejection of a transplanted organ because it did not completely block co-stimulation mediated by CD80 and CD86. To overcome this shortcoming, Bristol-Meyers Squibb developed belatacept from the parent abatacept molecule through a mutagenesis and screening strategy that conferred it with more potent immunosuppressive properties. Belatacept produces a tenfold greater inhibition of T cell activation in vitro than abatacept.

Unlike abatacept, belatacept was effective in a nonhuman primate model where in combination with standard immunosuppressive therapy prolonged the survival of renal allografts compared to a standard cyclosporine-based regimen. Because it was effective in primates, the drug was then studied further in human trials. The Belatacept Evaluation of Nephroprotection and Efficacy as First-line Immunosuppression Trial (BENEFIT), a phase III randomized, controlled trial, tested the efficacy and safety of belatacept for the prevention of graft rejection in 527 patients who had received a living donor or deceased donor kidney (Vincenti et al. 2010). All of the patients received induction therapy with basiliximab and maintenance therapy with mycophenolate mofetil and corticosteroids. Patients were randomized into three groups: more intensive (MI) belatacept, less intensive (LI)

belatacept, and cyclosporine (CsA). The co-primary endpoints were patient/graft survival, composite renal impairment, and incidence of acute rejection at 12 month. The patients receiving the MI and LI regimens had 95 % and 97 % patient/graft survival, respectively, compared with 93 % graft survival in the patients treated with CsA. The composite renal impairment endpoint was also significantly better in both of the belatacept treatment groups compared to the cyclosporine-treated patients. While belatacept therapy was associated with a higher rate of acute rejection than CsA therapy (MI 22 %; LI: 17: CsA 7 %), it led to less chronic allograft nephropathy (MI: 18 %; LI: 24 %; CsA: 32 %).

The other large phase III study was termed BENEFIT-EXT for extended criteria donors and included patients that had received a kidney transplant from a donor defined as greater than 60 years old or greater than 50 years old with at least two risk factors such as stroke, hypertension, or serum creatinine greater than 1.5 mg/dL (Durrbach et al. 2010). The study design was otherwise the same as that of the BENEFIT trial. Both belatacept groups were non-inferior to cyclosporine based on the co-primary endpoint at 12 months of patient/graft survival and superior to CsA with respect to the co-primary endpoint of composite renal impairment. In contrast to the results from BENEFIT, this study did not find any significant differences between the three treatment groups in the incidence of acute rejection (MI: 18 %; LI: 18 %; CsA 14 %).

Based on these two phase III studies, it appears that substituting belatacept for a calcineurin inhibitor for the prevention of kidney allograft rejection may lead to an improved glomerular filtration rate, lower blood pressure, and improved lipid profile. The finding of a greater incidence of acute rejection in patients treated with belatacept as opposed to CsA in BENEFIT raises important questions about the efficacy of co-stimulatory blockade in this situation. However, the cellular rejections in the belatacept groups tended to be milder than the CsA group, allaying some of this concern. A possible explanation for these milder cellular rejections may relate to the belatacept-related expansion of $FoxP3^+$ T regulatory cells in the grafts. It has also been recognized that belatacept may promote the development of posttransplant lymphoproliferative disease (PTLD). The risk for this complication may be minimized by excluding patients without serologic evidence of prior Epstein-Barr virus infection and avoiding lymphocyte-depleting agents in the setting of acute rejection. Belatacept is currently approved for the prophylaxis of organ rejection in adult patients who are seropositive for previous Epstein-Barr virus infection receiving a kidney transplant in combination with basiliximab, mycophenolate mofetil, and corticosteroids. Its use has not been established for the prevention of rejection in patients with other transplanted organs or tissues.

Conclusion

In summary, CTLA4-Ig represents a novel approach to immunosuppressive therapy by targeting a specific co-stimulatory pathway involved in T cell activation. Abatacept is approved for the treatment of RA and JIA, providing direct evidence for an important role of T cells in the pathogenesis of these diseases. Much more will be learned from further studies investigating its clinical efficacy and safety in other settings, such as type 1 diabetes, lupus, and psoriatic arthritis. In transplant medicine, belatacept is a promising alternative to CsA for prevention of kidney allograft rejection. Future studies inhibiting this pathway in humans will be necessary to improve our understanding of the mechanisms of CTLA4-Ig in vivo and its relevance for fine-tuning the balance between immunity (autoimmunity) and regulation for therapeutic gain.

Cutaneous manifestations of vasculitis

Definition

The vasculitides or vasculitis is characterized by inflammation of and reactive damage to blood vessel walls.

Cutaneous Vasculitis

Classification of the vasculitides has been a challenging process. Traditionally, the vasculitides have been categorized based on the dominant size or type of the vessels most commonly affected by a given disease. The initial classification scheme suggested by Zeek in 1952 did not include several forms of vasculitis. The most widely accepted current classification schemes, including the American College of Rheumatology (ACR) classification criteria introduced in 1990 and the subsequent revisions in the Chapel Hill Consensus Conference (CHCC) in 1994, do not address all forms of primary vasculitis. Also, small-vessel disease and skin involvement may occur in many of the proposed groups, making the schemes less practical. The classification of vasculitis syndromes continues to evolve. The association with antineutrophil cytoplasmic antibodies (ANCA) and the concept of ANCA-associated vasculitis (AAV) have been recently added to proposed classification schemes including a new consensus algorithm.

Cutaneous vasculitis is a broad clinical entity. Many forms of vasculitis can affect the skin because of the large number of vessels in the dermis and subcutaneous tissue. Cutaneous vasculitis may be a primary process or may occur secondary to other disease processes such as infection, noninfectious inflammation due to a drug or systemic autoimmune disease, and malignancy. Infections and drug reactions are the most common etiologies of cutaneous vasculitis and account for 23 and 20 % of cases, respectively. Hepatitis C virus, hepatitis B virus, HIV, cytomegalovirus, parvovirus B19, varicella zoster virus, streptococcus, Staphylococcus aureus, neisseria, and rickettsia are the most common infectious causes of cutaneous vasculitis. Penicillins, cephalosporins, sulfonamides, thiazides, allopurinol, phenytoin, tumor necrosis factor (TNF) inhibitors, rituximab, and cocaine are among the most common triggers of drug-induced cutaneous vasculitis. Type II antibody-mediated and type III immune-complex-mediated hypersensitivity are the most common pathogenic mechanisms of cutaneous vasculitis.

The caliber of the vessels primarily involved determines the clinical morphology of cutaneous lesions. For example, small-vessel disease (capillaries, postcapillary venules, and nonmuscular arterioles <50 μm in the superficial and mid-dermis) causes palpable purpura, urticarial lesions, and superficial ulcers. Cutaneous small-vessel vasculitis (CSVV), urticarial vasculitis, cryoglobulinemic vasculitis, and Henoch-Schonlein purpura (HSP) are the most common small-vessel vasculitides. Medium-sized disease (50–150 μm vessels with muscular walls in the deep dermis and subcutis) causes subcutaneous nodules, nodular and deep ulcers, livedo reticularis (presenting as a red-blue, reticulated vascular network) and livedo racemosa (presenting as an irregular, branched, vascular pattern), purpura, and necrosis. The most common medium-vessel vasculitis is polyarteritis nodosa (PAN).

Other cutaneous lesions such as petechiae, patches, necrotic plaques, bullous lesions, and splinter hemorrhages may also be observed. Some vasculitides including microscopic polyangiitis, granulomatosis with polyangiitis (Wegener's) (GPA), and Churg-Strauss syndrome (CSS) can involve both small- and medium-sized vessels. The focus of this entry is small-vessel vasculitis, cutaneous manifestations of other types of vasculitides (e.g., PAN), and other systemic autoimmune disease or neoplasms that can manifest as cutaneous vasculitis (Table 1 and 2).

An appropriate diagnostic evaluation can guide laboratory work-up and therapy in cutaneous vasculitis. The initial approach should include a thorough history and physical examination focusing on new medications, symptoms of infection, and timing of the development of vasculitis. All patients should be questioned regarding symptoms that suggest systemic involvement such as fever, chills, fatigue, night sweats, weight loss, abdominal pain, melena, arthralgia, myalgia, muscle weakness, discoloration of the urine, hemoptysis, cough, dyspnea, wheezing, and paresthesias. Symptoms of viral hepatitis and systemic autoimmune disease should also be assessed.

Cutaneous Vasculitis, Table 1 Cutaneous manifestations in different types of cutaneous vasculitis

Types of cutaneous vasculitis	Cutaneous manifestations
Small-vessel vasculitides	
Cutaneous small-vessel vasculitis	Most common: palpable purpura, urticarial papules
	Less common: petechiae, vesiculobullous lesions, shallow ulcers, mucosal shallow ulcers
Cryoglobulinemic vasculitis	Most common: palpable purpura
	Less common: ecchymoses, papules, nodules, hemorrhagic crusts, ulcers, livedo reticularis, livedo racemosa, urticarial papules, infarcts, mucosal lesions
Urticarial vasculitis	Most common: urticarial papules, palpable purpura
	Less common: petechiae, livedo reticularis, erythema-multiforme, bullous lesions
Henoch-Schonlein purpura	Most common: palpable purpura, urticarial papules
	Less common: petechiae, vesiculobullous lesions, shallow ulcers, ecchymoses, macules, papules
Erythema elevatum diutinum	Most common: papules, nodules, plaques
	Less common: bullous lesions, ulcers, hemorrhagic lesions
Medium-vessel vasculitis	
Polyarteritis nodosa	Most common: nodules, deep ulcers, livedo **reticularis**
	Less common: bullous eruptions, palpable purpura, infarction and gangrene of the fingers and toes, livedo racemosa, large ulcers
Mixed (small and medium)-vessel vasculitides	
Granulomatosis with polyangiitis (Wegener's)	Most common: palpable purpura, deep ulcers with corrugated borders, nodules
	Less common: papulonecrotic lesions, oropharyngeal ulcers, livedo racemosa, urticaria, livedo reticularis, vesicles, infarcts, splinter hemorrhages
Churg-Strauss syndrome	Most common: palpable purpura, nodules
	Less common: ulcers, macules, papules, petechiae, ecchymoses, papulonecrotic lesions, urticaria, livedo racemosa, infarcts, livedo reticularis

Skin biopsy is an important part of the evaluation of all suspected cases of cutaneous vasculitis. Also, direct immunofluorescence (DIF) should generally be performed to identify immunoglobulin and complement deposits within the skin, particularly to determine if IgA is the predominant immunoglobulin, as seen with HSP. The DIF biopsies should be done on early lesions, preferably before 24 h. The ideal time for skin biopsy for routine histology is between 24 and 48 h after the development of the lesion. Prior to 24 h, fibrinoid necrosis may not yet be present and beyond 48 h, the inflammatory infiltrate begins to be replaced by macrophages and lymphocytes.

The type of skin biopsy affects the size of vessels available for pathological evaluation. Punch biopsies at least 4 mm in diameter are recommended for evaluation of skin lesions suggestive of involvement of vessels in the superficial to mid-dermis (palpable purpura and urticarial lesions). Deeper punch biopsies are recommended for the evaluation of skin lesions suggestive of involvement of vessels in the mid-dermis to subcutaneous tissue (subcutaneous nodules, nodular and deep ulcers, and livedo racemosa). Shave biopsies are not recommended since they are not helpful in the evaluation of the vessels in the mid- and deep dermis.

The location of biopsy is also important. Biopsies can be taken from any site of palpable purpura or petechiae. Biopsies of livedo racemosa should be taken from the pale center of an erythematous periphery. In ulcerations, biopsy should be performed from the edge of the ulcer. Biopsies of livedo reticularis are not recommended since they often show nonspecific histopathologic findings. The initial laboratory work-up should include complete blood count with differential, blood urea nitrogen (BUN), creatinine, liver function tests, and urinalysis

Cutaneous Vasculitis, Table 2 Diagnostic pearls and differential diagnosis in different types of cutaneous vasculitis

Types of cutaneous vasculitis	Diagnostic pearls	Differential diagnosis
Small-vessel vasculitides		• **Macular purpura (trauma, chronic sun exposure, glucocorticoid therapy, anticoagulant therapy)** • Noninfectious **inflammatory disorders** (drug eruptions, stasis dermatitis) • **Pigmented purpuric dermatoses** • **Arthropod bites** • **Meningococcemia** • Rickettsial and viral infections (postherpetic eruptions) • **Platelet deficiencies or dysfunction** • Ascorbic acid (vitamin C) deficiency • **Cholesterol or septic emboli** • **Hypercoagulable and thrombotic disorders** (antiphospholipid syndrome) • Amyloidosis • Atrophie blanche • Purpura fulminans • Strongyloidiasis • Cutaneous vasculitis secondary to other systemic autoimmune disease • Sarcoidosis • Superficial thrombophlebitis • Inflammatory bowel disease • Cutaneous lymphomas • Lichenoid dermatoses
Cutaneous small-vessel vasculitis	• No systemic disease (may present with fatigue or mild constitutional symptoms) • Raised, nonblanchable purpuric lesions affecting the dependent sites, such as lower extremities and back • IgM, IgA, IgG, C3 in the vessel wall on skin biopsy	
Cryoglobulinemic vasculitis	• Constitutional symptoms • Raised, nonblanchable purpuric lesions affecting the dependent sites, such as lower extremities and back • Polyneuropathy (axonal sensorimotor) • Renal disease • Presence of cryoglobulins • HCV antibody or HCV RNA-positive • IgM in the vessel wall on skin biopsy	
Urticarial vasculitis	• Constitutional symptoms • Painful urticarial papules persisting more than 24 h • Angioedema/abdominal pain • Raynaud's phenomenon • Arthralgias/arthritis • Renal disease • COPD/asthma • Hypocomplementemia (in hypocomplementemic urticarial vasculitis subtype) • C3, IgG, fibrin in the vessel wall on skin biopsy	
Henoch-Schonlein purpura	• Constitutional symptoms • Raised, nonblanchable purpuric lesions affecting the dependent sites, such as lower extremities and back • Abdominal pain • Arthralgias/arthritis • Renal disease • IgA in the vessel wall on skin biopsy	
Erythema elevatum diutinum	• No systemic involvement • Symmetrical, violaceous, red, or brown, firm, smooth papules, nodules, or plaques over the extensor surfaces of the extremities, particularly joints. • The lesions tend to increase in the number and size with time • Peripheral keratitis	
Medium-vessel vasculitis		• Infective endocarditis • Mycotic aneurysm • Hepatitis B or C infection • HIV • **Hypercoagulable and thrombotic disorders** (antiphospholipid syndrome) • **Cholesterol or septic emboli** • Small-vessel vasculitides • Granulomatosis with polyangiitis (Wegener's)
Polyarteritis nodosa	• Constitutional symptoms • Tender painful subcutaneous nodules, deep ulcers, and livedo **reticularis** • Peripheral neuropathy (mononeuritis multiplex) • ANCA negative	

(*continued*)

Cutaneous Vasculitis, Table 2 (continued)

Types of cutaneous vasculitis	Diagnostic pearls	Differential diagnosis
Mixed (small and medium)-vessel vasculitides		• Polyarteritis nodosa • Churg-Strauss syndrome • Microscopic polyangiitis • Anti-glomerular basement membrane disease • Small-vessel vasculitides • Chronic eosinophilic pneumonia • Aspirin-exacerbated respiratory disease • Allergic bronchopulmonary aspergillosis
Granulomatosis with polyangiitis (Wegener's)	• Constitutional symptoms • Raised, nonblanchable purpuric lesions affecting the dependent sites, such as lower extremities and back; deep ulcers with corrugated borders, nodules • Presence of circulating PR3-ANCA (C-ANCA) • Granulomatous inflammation on nasal biopsy • Pauci-immune necrotizing glomerulonephritis	
Churg-Strauss syndrome	• Constitutional symptoms • Raised, nonblanchable purpuric lesions affecting the dependent sites, such as lower extremities and back; nodules • Presence of asthma/rhinosinusitis/allergies • Eosinophilic pneumonia/eosinophilic gastroenteritis • Peripheral neuropathy (mononeuritis multiplex) • Clinical signs of heart failure and cardiac rhythm abnormalities • Presence of prominent eosinophilia ($\geq$ 1,500 cells/microL and/or $>$ 10 % eosinophils on differential leukocyte count) • Presence of circulating p-ANCA with anti-MPO specificity	

(including thorough examination of the urinary sediment for cellular casts). When the etiology of biopsy-proven cutaneous vasculitis is unclear, other relevant testing can be performed such as hepatitis B and C serologies, complement levels (CH50, C3, and C4), ANCA, cryoglobulins, HIV, rheumatoid factor, ANA, anti-dsDNA, anti-Smith, anti-Ro, anti-La, and anti-RNP antibodies. Chest x-ray is recommended in patients with pulmonary symptoms (Hunder et al. 1990; Jennette et al. 1994; Jennette and Falk 1997; Stone and Nousari 2001; Fiorentino 2003; Carlson and Chen 2006; Grzeszkiewicz and Fiorentino 2006; Carlson et al. 2006; Xu et al. 2009; Carlson 2010).

Small-Vessel Vasculitides

Type III immune-complex-mediated hypersensitivity plays an important role in small-vessel vasculitides since C5b-9, the terminal components of the complement cascade, are detected in most of these conditions (Black 1999; Ramos-Casals et al. 2000).

Common cutaneous manifestations of small-vessel vasculitis include palpable purpura and urticarial lesions (Fig. 1). The skin lesions primarily affect the dependent sites, such as lower extremities and back, due to increased hydrostatic pressure. Palpable purpura results from extravasation of red blood cells from the vessel lumen into the dermis and superficial perivascular neutrophilic infiltrates. Therefore, they do not blanch upon pressure. Palpable purpura can be asymptomatic, pruritic, or with a burning pain and resolves with residual postinflammatory hyperpigmentation. Urticarial lesions are thought to result from a type III immune-complex-mediated hypersensitivity reaction. Urticarial lesions due to vasculitis last longer than 24 h. They may be associated with

Cutaneous Vasculitis, Fig. 1 Palpable purpura is the most common cutaneous manifestation of small-vessel vasculitis. It can be associated with shallow ulcers

a burning sensation. The urticarial lesions of vasculitis typically resolve with postinflammatory hyperpigmentation (Hautmann et al. 1999).

The major histopathologic features of small-vessel vasculitis include the presence of inflammatory infiltrates in and/or around blood vessel walls, disruption and/or destruction of vessel walls by the inflammatory infiltrate, fibrin deposition within the vessel wall or lumen (fibrinoid necrosis).

Cutaneous Small-Vessel Vasculitis (CSVV) (Previously Termed Hypersensitivity Vasculitis)

The term "hypersensitivity vasculitis" (HV), first introduced by Zeek in 1950, is a confusing term that has been used to include several types of small-vessel vasculitis, including those triggered by a known antigen such as a drug. The ACR classification system recognizes HV; however, their criteria do not distinguish between HV and other small-vessel vasculitis such as HSP which could be of prognostic value. The term "cutaneous leukocytoclastic angiitis" was then suggested in the CHCC classification criteria. This term has its limitation, however, with the term angiitis inappropriately broad and the term "leukocytoclastic" a histopathologic term indicating the presence of polymorphonuclear leukocytes (neutrophils) and fibrinoid necrosis within and around the vessel wall. Therefore, the term "cutaneous leukocytoclastic vasculitis" most appropriately refers to neutrophilic small-vessel vasculitis.

Cutaneous small-vessel vasculitis (CSVV) is a better term that has been used to refer to vasculitis involving the small blood vessels in the skin including neutrophilic, lymphocytic, and granulomatous vasculitides. By definition, patients with CSVV have isolated skin involvement and no systemic disease. An alternative term that has been used is "cutaneous necrotizing venulitis."

CSVV primarily involves the postcapillary venules in the dermis and usually presents with palpable purpura. A single crop of skin lesions can erupt simultaneously that proceeds through morbilliform stage and evolve to palpable purpura over few hours. In severe cases, CSVV may impact the deeper dermal postcapillary venules and therefore be associated with vesiculobullous lesions and shallow ulcers as well. Mucosal surfaces can be affected. A precipitating factor such as an infectious agent or a new medication may be identified in patients with CSVV. The diagnosis is one of exclusion. The majority of

patients with CSVV have a benign course, and the lesions usually resolve within several weeks. Recurrent disease can occur in approximately 10 % of patients. Cryoglobulinemia, arthralgia, and the absence of fever have been shown to be risk factors for recurrence.

The management of CSVV involves a work-up for potential underlying systemic disorders or an infection that could guide therapy. Conservative management including simple measures such as avoiding cold temperatures and sunlight, leg elevation, and reduction of activity is often successful. Antihistamines and nonsteroidal anti-inflammatory drugs (NSAIDs) have been used to alleviate burning and itching. Topical therapy with corticosteroid and antibiotic creams may be helpful in some patients, although there is no data to support their use. For refractory, relapsing, or extensive cases, escalating therapy may be required. Colchicine has been used for cutaneous and joint symptoms. Dapsone has also been used to alleviate cutaneous and joint manifestations. The use of colchicine or dapsone is based on anecdotal studies or small case series. Colchicine was not associated with any significant therapeutic effect in the only randomized controlled trial to date (Sais et al. 1995). Some experts recommend colchicine combined with dapsone, while others believe that colchicine should be used as a first-line and dapsone as a second-line therapy. Brief periods of high-dose oral corticosteroids or other immunosuppressive strategies may be warranted for severe systemic vasculitis. The immunosuppressive agents usually considered include methotrexate, azathioprine, mycophenolate mofetil, cyclosporine, and cyclophosphamide. Rituximab and TNF inhibitors have shown some efficacy in recent case reports (Stone and Nousari 2001; Fiorentino 2003; Carlson and Chen 2006; Grzeszkiewicz and Fiorentino 2006; Carlson et al. 2006; Xu et al. 2009; Sais et al. 1995).

Cryoglobulinemic Vasculitis (CV)

Cryoglobulinemic vasculitis (CV) is characterized by the presence of cryoglobulins and vessel wall injury. Cryoglobulins are a mix of serum immunoglobulins and complement that reversibly precipitate in the cold (under body temperature; 37 °C). Preliminary classification criteria have been proposed for CV (De Vita et al. 2011). These require validation. Cryoglobulins have been divided into three subtypes. Type I is composed of monoclonal IgM that is associated with plasma cell proliferative disorders, myeloma or Waldenstrom's macroglobulinemia. Type I usually causes a hypercoagulable state and vessel obstruction that leads to ischemic vasculopathy. Type II consists of monoclonal IgM directed against polyclonal IgG. Type III is polyclonal IgM directed against polyclonal IgG. Type II and III are termed mixed cryoglobulinemia due to the presence of more than one immunoglobulin isotype. Mixed cryoglobulinemia is most often due to hepatitis C virus infection. Other etiologies include HIV, connective tissue diseases, and lymphoproliferative disorders. Mixed cryoglobulinemia can be associated with deposition of IgM-IgG complexes in the walls of small vessels and subsequent complement activation, which results in inflammation of the vessel walls and vasculitis in 15 % of patients with circulating cryoglobulins.

The most common cutaneous manifestation and presenting feature in CV is palpable purpura, usually confined to the lower extremities. Ecchymoses, papules, and dermal nodules can also occur. Other cutaneous manifestations such as hemorrhagic crusts, ulcers, livedo reticularis, and mucosal lesions more commonly occur in type I cryoglobulinemia. Cutaneous manifestations are more common in antibody-positive HCV CV. Other major clinical manifestations of CV include arthralgia, lymphadenopathy, axonal sensorimotor polyneuropathy, hepatosplenomegaly, and renal disease. The diagnosis is made based on the history, presence of palpable purpura, hypocomplementemia, and high titers of circulating cryoglobulins. Biopsy of palpable purpuric lesions most often shows leukocytoclastic vasculitis. Direct immunofluorescence microscopy of acute lesions can detect IgM, IgG, and C3 complement deposits. HCV infection should be investigated in all patients diagnosed with CV by testing the serum or cryoprecipitate for HCV antibody or HCV RNA.

Patients with HCV-related CV should be treated for the underlying viral infection. Currently, interferon alpha, preferably pegylated, plus ribavirin should be considered for patients with normal renal function. Interferon alpha has been reported to be efficacious for HCV-negative CV as well, possibly due to its immunomodulatory effects. Combination therapy with rituximab has also been suggested to target cryoglobulin-producing B cells. In patients presenting with acute and severe disease, plasmapheresis in conjunction with corticosteroids and cyclophosphamide are indicated. The titer of cryoglobulins and complement levels do not correlate with severity of disease and cannot be used to monitor response to therapy (Ramos-Casals et al. 2000; De Vita et al. 2011).

Urticarial Vasculitis (UV)

UV is an entity consisting of urticarial eruption and histopathological evidence of leukocytoclastic vasculitis. It most commonly affects the postcapillary venules. UV is divided into normocomplementemic and hypocomplementemic (HUV) subtypes for prognostic purposes. Normocomplementemic UV is associated mild disease and is usually restricted to cutaneous sites. It is usually idiopathic but frequent associations include systemic autoimmune diseases. It can also occur in association with drugs, infections, hematologic malignancies, or exposure to UV light. UV is thought to result from the depositions of antigen-antibody complexes in the blood vessel walls which can activate the classical complement pathway, generating C3a and C5a. This causes mast cell degranulation and urticaria. The eliciting antigen is still largely unknown. In some patients, and particularly in hypocomplementemic UV, C1q autoantibodies may be present. UV is a rare disease but its exact incidence is uncertain. Approximately 5–10 % of patients with chronic urticaria have UV.

The lesions of UV can occur anywhere in the body. In contrast to simple urticaria, the UV wheals are painful with a burning quality and non-pruritic. Also the urticarial lesions in UV persist more than 24 h. The UV eruptions evolve into purpura, bruising, and postinflammatory hyperpigmentation. Other cutaneous manifestations of UV include livedo reticularis, erythema multiforme, or bullous lesions. Common systemic manifestations and associations include arthralgias, arthritis, renal disease, COPD, and asthma.

The initial approach to the patient with UV-like lesions should include a thorough history and physical examination, addressing prior and current urticarial lesions, preceding exposure to drugs or infections, and systemic symptoms. UV is considered a clinicohistopathologic entity, and a skin biopsy should always be performed. The histologic features include fragmentation of leukocytes with nuclear debris (leukocytoclasis), and fibrin deposition in and around the vessels. Immunofluorescence reveals deposits of immunoglobulins, complement, or fibrin around blood vessels.

Therapies for UV are based on small case series. Antihistamines are used for symptomatic control of pruritus. Dapsone, colchicine, pentoxifylline, hydroxychloroquine, and mycophenolate mofetil can be quite effective. Additional medications such as systemic glucocorticoids are frequently required for control of the illness and prevention of further urticarial lesions. Rituximab have also been used to treat the cutaneous disease. The management of systemic symptoms depends on the severity of the disease; referral to a physician with extensive experience in the management of vasculitides is usually recommended (Black 1999; Venzor et al. 2002).

Henoch-Schonlein Purpura (HSP)

HSP is clinically characterized by palpable purpura, arthralgia/arthritis, gastrointestinal symptoms, and renal disease. It primarily involves the postcapillary venules. HSP is primarily a childhood disease with a reported male-to-female ratio of approximately 1.5:1. HSP is thought to result from IgA deposition in the vessel walls; however, the triggering antigen and pathogenesis remain unknown. An upper respiratory tract infection usually precedes the disease. Palpable purpura is the hallmark cutaneous

manifestation of HSP and is present in almost all patients; however, the clinical manifestations may occur in any order. It typically begins with erythematous, macular, papular, or urticarial lesions which then coalesce and evolve into the symmetrically distributed crops of petechiae, palpable purpura, and ecchymoses. Occasionally, the skin can blister and ulcerate. The rash primarily affects the dependent sites, such as lower extremities and buttocks. Spread of palpable purpura above the waist has been shown to be a risk factor for renal disease.

The diagnosis is typically made clinically but can be confirmed by a skin biopsy, particularly in adult patients. Immunofluorescence microscopy often reveals IgA deposition in and around the vessel walls. Patients with HSP do not have thrombocytopenia or coagulopathy. Urinalysis should be obtained in all patients with HSP as hematuria is a typical feature; cellular casts are less common.

HSP is usually self-limited; however, in adults, it can be associated with significant renal disease and a worse prognosis compared with children. Treatment is largely supportive. NSAIDs and corticosteroids can be used for the relief of arthralgia/arthritis and gastrointestinal symptoms. IVIG, plasmapheresis, and a variety of cytotoxic agents have been used as the treatment for severe renal disease (Saulsbury 2010), but there is currently no consensus regarding indications for more aggressive treatment.

Erythema Elevatum Diutinum (EED)

EED is a rare form of small-vessel vasculitis that is limited to the skin. EED mostly affects the older adults, and there is a slight female predominance. Its cause is unknown. Though its pathogenesis is also uncertain, EED is thought to result from immune complex deposition in blood vessel walls. The onset of clinical symptoms in EED has been associated with infections (such as streptococcus and HIV), hematologic malignancies, IgA monoclonal gammopathy, connective tissue disorders, celiac sprue, and drugs. EED presents with symmetrical, violaceous, red, or brown, firm, smooth papules, nodules, or plaques over the extensor surfaces of the extremities, particularly joints. Lesions may also involve the buttocks, palms, and soles. Bullous lesions, ulcers, and hemorrhagic lesions are rare. The skin lesions in EED are mostly asymptomatic but can be painful or pruritic. The lesions tend to increase in the number and size with time. Ocular complications such as peripheral keratitis have been reported. Biopsy of early lesions typically shows leukocytoclastic vasculitis with prominent interstitial neutrophils. Biopsy of well-formed and chronic lesions may reveal prominence of eosinophils and perivascular fibrosis.

Dapsone is used as first-line therapy at doses of 50–100 mg orally each day. Topical, intralesional, or systemic glucocorticoids, chloroquine, colchicine, niacinamide, and sulfapyridine have also been used. An ophthalmology consultation should be considered (Wahl et al. 2005) to screen for ocular involvement.

Medium-Vessel Vasculitis

The most common dermatologic presentations of medium-vessel vasculitis include subcutaneous nodules, deep ulcers, and livedo reticularis. The skin lesions occur frequently in the lower extremities, primarily at dependent sites. Vasculitic nodules are typically painful and may ulcerate. Deep ulcers result from intense damage to blood vessel walls leading to reduced blood supply and ischemia. Livedo reticularis in medium-vessel vasculitis indicates interruption of blood flow in muscular arterioles in the deep dermis and subcutaneous tissue.

The major histopathologic features of medium-vessel vasculitis include inflammatory infiltrates infiltrating the muscular vessel wall and fibrin deposition within the vessel wall or lumen (with fibrinoid necrosis).

Polyarteritis Nodosa (PAN)

PAN is a systemic necrotizing vasculitis that mostly involves medium-sized muscular arteries. The incidence increases with age and the male-to-female ratio is reported to be 1.5:1. PAN is mostly idiopathic. Most cases of secondary PAN

are associated with HBV infection. The pathogenesis is not well understood but may include activation of the complement cascade (perhaps triggered by viruses) and immune complex deposition in the vessel wall. PAN usually presents with involvement of the kidneys, skin, joints, muscles, nerves, and/or gastrointestinal tract. Orchitis and coronary artery narrowing may occur in some patients. PAN spares the lung parenchyma. Cutaneous manifestations are observed in around 50 % of patients and may include painful and tender subcutaneous nodules, deep ulcers, and livedo reticularis. Bullous eruptions and palpable purpura may also be observed. Digital infarction and gangrene and large ulcers may occur in severe cases. The subcutaneous nodules in PAN follow the course of the superficial arteries in the lower extremities and may clinically mimic erythema nodosum. The nodules typically distribute in a livedoid pattern. The nodules usually resolve with atrophic, ivory-colored, retiform, stellate-shaped scars that may persist for years.

Approximately 10 % of patients with PAN present with predominately skin-related symptoms and milder systemic symptoms including fever, arthralgia, myalgia, and peripheral neuropathy (mononeuritis multiplex). These cases are considered cutaneous PAN. Cutaneous PAN is the most common form of PAN in the pediatric population. Cutaneous PAN is associated with streptococcal infection in children and has also been associated with infections by parvovirus B19, hepatitis B infection, and HIV.

Whenever possible, a biopsy should be performed to confirm the diagnosis. Histopathologically, the biopsy from active subcutaneous nodules reveals a necrotizing arteritis with focal panniculitis surrounding the affected artery. This is in contrast with other forms of panniculitis that have inflammation in the septa, fat lobules, or have a mixed histologic picture, but without vasculitis.

Cutaneous PAN has a favorable prognosis, but exacerbations and relapses may occur. Patients with evidence of recent clinical or serologic streptococcal infection (such as an elevated ASO titer) should be treated with penicillin. Patients with cutaneous PAN frequently respond to dapsone or methotrexate. NSAIDs can be used to treat pain and mild exacerbations. Prednisone, with or without immunosuppressives, may be required for more severe or refractory disease. Prostaglandins (prostacyclin [PGI2]) and calcium channel blockers (nifedipine) have been tried for cases of cutaneous PAN presenting with digital infarction (Pagnoux et al. 2010).

Mixed (Small and Medium)-Vessel Vasculitides

Granulomatosis with Polyangiitis (Wegener's) (GPA)

GPA is a necrotizing, ANCA-associated vasculitis that primarily affects small- and medium-caliber vessels. GPA predominately affects older adults, is more common among Caucasians, and affects both genders equally. Its pathogenesis remains unknown. For example, it is not known whether ANCAs have a pathogenic role in GPA. Infections, genetic factors, and environmental factors, including medications have been proposed as the triggering factors. The activation of T cells, neutrophils, endothelial cells, and B cells may play a role. GPA typically presents with constitutional symptoms including anorexia, weight loss, fever, arthralgia, and myalgia. The most common organ involvement in GPA includes the ear, nose, throat, airways, lungs, kidneys, and/or skin. In addition to constitutional symptoms (such as fever and fatigue), the most common clinical symptoms include nasal crusting, purulent/bloody nasal discharge, oropharyngeal or nasal ulcerations, sinusitis, otitis media, hoarseness, cough, dyspnea, stridor, wheezing, and hemoptysis. Cutaneous manifestations are present in about one-half of patients with GPA, with skin lesions being the presenting feature in 10 % of cases. The activity of skin lesions often parallels that of systemic disease. The most frequent cutaneous manifestation is palpable purpura in the lower extremities. These purpuric lesions may be accompanied by focal necrosis and ulcers with corrugated borders resembling pyoderma gangrenosum.

Cutaneous Vasculitis, Fig. 2 Cutaneous manifestations are present in about one-half of patients with granulomatous polyangiitis (Wegener's) and may include papulonecrotic lesions or ulcerated papules

Papulonecrotic lesions, or ulcerated papules, may be present in 10 % of cases, typically favoring the elbows. Tender subcutaneous nodules, urticaria, livedo reticularis, vesicles, and splinter hemorrhages have also been observed in GPA (Fig. 2).

The diagnosis is suggested from the clinical manifestations and from the presence of circulating ANCA directed against proteinase-3 (PR-3). The absence of circulating ANCA does not exclude the diagnosis of GPA. The diagnosis of GPA should be confirmed by biopsy at a site of active disease, including skin. Skin biopsy reveals a leukocytoclastic granulomatous vasculitis with little or no immunoglobulin and complement on immunofluorescence. Biopsy of the kidney typically reveals a segmental necrotizing glomerulonephritis, with few or no immune deposits (pauci-immune) on immunofluorescence and electron microscopy. Calculated estimated glomerular filtration rate and urinalysis should be checked in all patients with GPA; while a kidney biopsy may not be required to establish the diagnosis, it can guide treatment. Granulomatous features may be seen on nasal biopsy and are occasionally diagnostic for GPA; however, nasal biopsies in suspected GPA frequently reveal nonspecific, necrotic tissue. A chest X-ray and computed tomography (CT) scan should be performed in all patients with suspected GPA.

Patients with GPA who are ANCA negative have a more favorable prognosis. Glucocorticoids, rituximab, methotrexate, cyclophosphamide, azathioprine and plasma exchange have been used for the therapy of GPA. Therapy depends on the organs involved, as well as the severity of the disease (Hoffman et al. 1992; Seo and Stone 2004).

Churg-Strauss Syndrome (CSS)

CSS is one of the ANCA-associated vasculitides that is characterized by a small- and medium-sized vessel vasculitis in association with asthma, chronic allergic rhinosinusitis, and eosinophilia. The median age at diagnosis is about 40 years. CSS tends to affect both genders equally. The pathogenesis of CSS, including the role of ANCAs, remains uncertain. There may be a role for abnormal immune function such as heightened Th1 and Th2 lymphocyte immunity, increased eosinophil recruitment, decreased eosinophil apoptosis, elevated serum IgE, and genetic factors such as HLA class and certain interleukin-10 polymorphisms. The onset of symptoms has been associated with several asthma medications, such as the leukotriene modifying agents, inhaled glucocorticoids, and omalizumab; however, CSS developing in patients taking these drugs appears to be due to unmasking of the underlying disease with the tapering of steroids rather than a causal

Cutaneous Vasculitis, Fig. 3 A subset of patients with SLE may have cutaneous vasculitis. Cutaneous vasculitis in SLE may present as digital ulcerations, microinfarctions, or subcutaneous nodules

relationship. The lungs and the skin are the most commonly involved organs in CSS. The prominent clinical features of the prodromal phase of CSS include poorly-controlled or late-onset asthma, allergic rhinitis, nasal polyposis and recurrent sinusitis. There is peripheral blood eosinophilia and eosinophilic infiltration of multiple organs, which can cause eosinophilic pneumonia, eosinophilic gastroenteritis, clinical signs of heart failure and cardiac rhythm abnormalities and peripheral neuropathy (mononeuritis multiplex) that may occur years later during the eosinophilic phase of CSS. Systemic vasculitis and granulomatosis typically occur in the vasculitic phase of CSS. About half to two-thirds of patients with CSS have skin involvement, particularly during the vasculitic phase of CSS. The most common cutaneous manifestations of CSS include palpable purpura, and tender subcutaneous nodules that favor the extensor surfaces of the arm, but can occur on the hands and legs, and scalp as well. Other skin lesions such as macular or papular erythematous rash, petechiae, extensive ecchymosis, papulonecrotic lesions, urticarial and livedo reticularis may also be observed in CSS.

The diagnosis is suggested by the presence of asthma, rhinosinusitis, and eosinophilia ($\geq$ 1,500 cells/microL and/or $>$ 10 % eosinophils on leukocyte differential). Biopsy of involved organs, including skin, lung, or peripheral nerve, can confirm the diagnosis. The major histopathologic features include leukocytoclastic vasculitis with eosinophilic infiltration, as well as interstitial and perivascular necrotizing granulomas. ANCA is positive in 40–60 % of patients, with most patients showing a peripheral staining pattern (p-ANCA) with specificity for myeloperoxidase (MPO).

The initial therapy for mild CSS is systemic glucocorticoids. Immunosuppressive agents such as azathioprine, methotrexate, mycophenolate mofetil, or cyclophosphamide may be added in patients with more severe disease (Sinico and Bottero 2009).

Cutaneous Vasculitis Secondary to Other Systemic Autoimmune Disease

A subset of patients with SLE may have cutaneous vasculitis (Fig. 3). Cutaneous vasculitis in SLE primarily affects small arterioles and postcapillary venules, most commonly presenting as urticaria and palpable purpura. Livedo reticularis, digital tip ulcerations or microinfarctions, subcutaneous nodules, or splinter hemorrhages in the nailfolds can also be seen. Other less common manifestations

include tender, erythematous, indurated lesions on the palms and the fingertips, chilblains (tender red to reddish-blue nodules on the fingers, toes, nose, or ears that occur as a reaction to cold temperatures), and atrophie blanche (ivory-colored scars with surrounding hyperpigmentation).

A small subset of patients with rheumatoid arthritis, particularly those with long-standing disease, a high level of rheumatoid factor, erosive joint disease, and rheumatoid nodules, may have rheumatoid vasculitis. Cutaneous vasculitis is the most common manifestation of rheumatoid vasculitis. Cutaneous small-vessel vasculitis presenting with palpable purpura and nailfold infarctions, appearing as periungual macules, may occur. In addition, necrotizing vasculitis of medium-caliber arteries presenting with deep ulcers on the lower extremities, typically in the area of the medial or lateral malleoli, or digital necrosis and gangrene may develop. Benign nailfold lesions, nodules on the finger pads, livedo reticularis, or urticaria may also be observed. It is important to rule out infection and vasculopathy. If a patient with rheumatoid arthritis and leg ulcers has skin biopsies that do not show vasculitis, pyoderma gangrenosum should be considered.

Cutaneous vasculitis in Sjogren's syndrome can present with palpable purpura, urticarial lesions, ecchymoses, or small ulcerations, usually on the lower extremities. Cutaneous vasculitis in Sjogren's syndrome is associated with antibodies to the Ro/SSA antigen. Sjogren's syndrome patients with cutaneous vasculitis are more likely to develop lymphoma. Vasculitis of medium-sized vessels presenting with large ulcers may be caused by cryoglobulinemia (Fiorentino 2003).

CTL; Cytotoxic T lymphocytes; Killer T cell; Tc

Definition

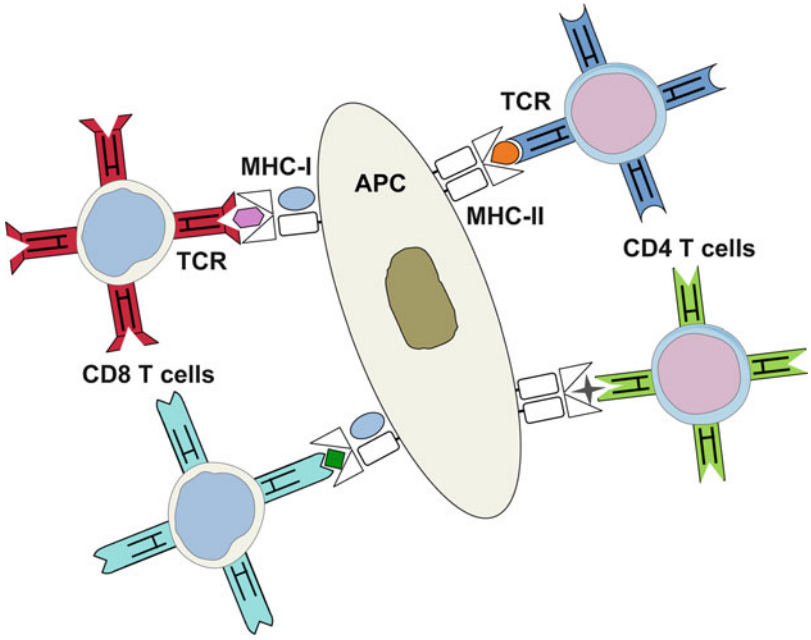
Cytotoxic T lymphocytes are specialized subsets of differentiated T cells which have the functional capability to kill target cells expressing nonself antigens. They are important components of the adaptive immune response and help control intracellular pathogens, as well as contain the development of tumors.

The Significance of Cytotoxic T Cells

Cytotoxic T lymphocytes (CTL) are a cornerstone of the adaptive immune response (Cox and Zajac 2010; Zhang and Bevan 2011). Due to their exquisite ability to detect and destroy cells presenting foreign antigens, they play a vital role in the initial control of many intracellular pathogens as well as help confer long-lived immunological protection against subsequent reinfections. Even in situations when the infection is not completely eradicated, such as during persistent chronic or latent infections, CTL function to dampen the initial burst of pathogen replication and then operate to either hold the infection at a steady state level or contain and limit the secondary spread of pathogens as they reactivate from latency. CTL responses also participate in tumor immunosurveillance and can limit the outgrowth of malignancies. CTL responses are not only induced by natural infections or as malignancies develop but are also generated in response to vaccines. Thus, CTL responses are versatile, durable, and vital for host defense.

CTL Recognition

The search and destroy functions of CTL are governed by the ability to co-recognize and respond to short peptide fragments expressed on the surface of the target cell in non-covalent association with either major histocompatibility complex (MHC) class I or MHC class II molecules (Fig. 1). CD8 T cells, which form the most prevalent population of CTL, usually



Cytotoxic T Lymphocytes, Fig. 1 *T cell recognition:* Each T cell expresses a unique, clonally distributed, TCR which governs their ability to recognize and respond to peptide-loaded MHC complexes. CD8 T cells bind to MHC class I–peptide complexes, whereas CD4 T cells recognize MHC class II–peptide complexes

recognize peptide fragments of 8–9 residues in length bound to MHC class I molecules (Neefjes et al. 2011). These antigenic peptides are most often derived from self and nonself (e.g., virus-derived) proteins which have been synthesized within the target cell and then subjected to proteolytic degradation. The antigen-processing machinery within the cell ensures that samples of these endogenous peptides associate with nascent MHC class I molecules and then localize to the cell surface for presentation to patrolling T cells. An alternative cross presentation pathway can also operate to enable peptides from exogenous proteins, which have been taken up by the target cells, to be presented by MHC class I molecules. Cytotoxic CD4 T cells are less common than CD8 CTL and their antigen-recognition properties are distinct. CD4 T cells recognize MHC class II complexes bound to peptide fragments which are generally slightly longer than those which associate with MHC class I molecules. Additionally, the peptides presented by MHC class II molecules are generally derived from exogenous antigens which have been endocytosed by specialized antigen-presenting cells (APCs) and then degraded. The resulting panels of peptides then assemble with MHC class II molecules and are presented at the cell surface. Notably, whereas MHC class I complexes are expressed by almost all cell types, the distribution of MHC class II molecules is largely confined to cells of the immune system, which limits the protective efficacy of CD4 CTL responses.

Which MHC–peptide complexes an individual T cell is capable of binding and responding to is determined by the precise sequence of the T cell's unique T cell receptor (TCR) (Bridgeman et al. 2012). The coding sequence, and thus exact structure, of the TCR is determined by a process of genetic recombination that favors diversification within the receptor regions that are most important for MHC–peptide interactions. This generates a tremendously diverse repertoire of TCRs. Nevertheless, TCRs are clonally expressed and thus an individual T cell will express a unique TCR that dictates its specific antigen and MHC recognition profile. At the population level, the lower limit of the number of T cells with nonidentical TCRs has been estimated to be 25×10^6. The actual repertoire is likely to be considerably greater, perhaps several thousandfold higher, because of additional sequence variation within the α- and β-chains which form the TCR complex

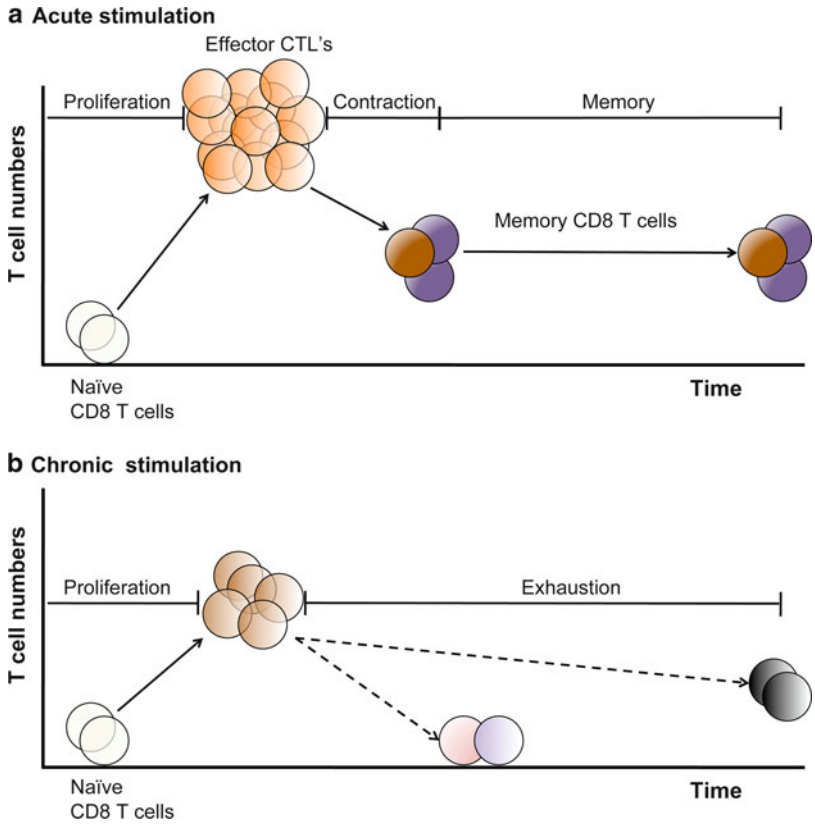
(Robins et al. 2009). This colossal inventory provides the host with a T cell pool with the potential power to detect and respond to the myriad of foreign antigens that it may encounter during its lifetime. Nevertheless, although the T cell repertoire is huge, the number of distinct naïve clones which recognize any given MHC–peptide complex is small. Estimates from murine studies have determined that there are perhaps several hundred individual T cells which express appropriate TCRs that allow them to respond to a specific peptide epitope.

Pathogens and other antigens, such as those associated with tumor development, are typically comprised of multiple epitopes which can potentially be recognized by distinct T cell clones. Nevertheless, not all epitopes are equally recognized and the magnitude, longevity, and efficacy of responses to individual epitopes varies, even if they are encoded by the same pathogen (Frelinger 2006). The hierarchical pattern of responses that emerge is determined by many factors including the properties of the antigen such as its stability, level of expression, and which cell types are presenting the antigen, as well as intrinsic T cell factors such as the avidity of the T cell for the MHC–peptide complex and the frequencies as well as activation states of the T cells which can respond to the specific antigen. The epitope hierarchy can influence the ability of CTL to control infections, as responses to individual epitopes can differ in their protective potential, and the pattern of immunodominance may change over time, during persistent infections, during recall responses, or as tumors evolve. Moreover, certain T cells may exhibit a degree of cross-reactivity which may confer beneficial additional immunological protection or cause detrimental immunopathology.

Priming the CTL Response

CTL responses are induced following an antigen-driven activation process which typically results in massive T cell expansion, their differentiation and acquisition of effector functions, and the disbursement of the cells throughout the host (Fig. 2a) (Cox and Zajac 2010; Sheridan and Lefrancois 2011). The overall response is typically comprised of CD4 helper T cells, CD8 CTL, which form the major CTL population, and under certain conditions a smaller number of CD4 CTL. Pronounced CD8 T cell responses have been detected during many infections including influenza virus, vaccinia virus, Epstein-Barr virus (EBV), yellow-fever virus, lymphocytic choriomeningitis virus (LCMV), and early following human immunodeficiency virus (HIV) infection. Moreover, it is becoming increasingly well appreciated that the vast majority of CD8 T cells detected at the peak of the response are pathogen specific (Zhang and Bevan 2011).

Usually the T cell responses are triggered in secondary lymphoid organs – the spleen and lymph nodes – as naïve T cells encounter professional APCs and recognize MHC–peptide complexes. This interaction between the T cells TCR and its cognate-presented antigen is the first signal that begins the subsequent clonal expansion and cellular differentiation; however, this initial interaction alone is insufficient to sustain the response. During infections, APCs also become activated as part of the host's innate defense mechanism, leading to the upregulation of many surface receptors including the costimulatory molecules CD80 and CD86. In order to prevent aberrant immune responses to innocuous or self-antigens, T cells must also receive costimulation via CD28 interacting with CD80 or CD86 on the APC. This second signal promotes T cell survival and a burst of interleukin (IL)-2 production. In addition, other costimulatory molecules, including many members of the tumor necrosis factor (TNF) receptor superfamily, can also influence the ensuing response. Infections with pathogens also elicit the production of other immunological warning signs including proinflammatory cytokines such as IL-12, antiviral factors such as type I interferons, and alarmins such as IL-33. All of these elements can serve as important third signals for driving the full activation of the T cell response and amplifying effector activities (Curtsinger and Mescher 2010). As the small number of naïve T cells detect antigen (signal 1),



Cytotoxic T Lymphocytes, Fig. 2 *The phases of the CTL response:* (**a**) Acute antigenic exposure, in conjunction with costimulatory signals and inflammatory cues, can drive massive proliferation and differentiation of CD8 T cells. This process ensures that an expanded pool of effector T cells form which operate to clear the inducing antigen. As the antigen is cleared, a contraction phase ensues during which most of the highly functional, terminally differentiated, T cells succumb to apoptosis. At the conclusion of the contraction phase, a pool of memory CD8 T cells remain and are represented at a greater frequency than their naïve counterparts. These memory populations can be stably maintained for years following priming and function to confer long-lived immunological protection. (**b**) Aberrant T cell responses develop under conditions of persistent antigenic stimulation, such as during chronic viral infections. Typically the burst size of the response is smaller than that observed following acute stimulation. Although the responding cells develop certain effector traits and can attain a highly activated terminally differentiated phenotype, a spectrum of functional defects can arise. As effector activities are gradually extinguished, the antigen-specific T cells may not be stably maintained

engage costimulatory molecules (signal 2), and sense certain soluble factors (signal 3), they are driven into cell cycle, proliferate vigorously, and form a highly differentiated effector pool.

During the proliferative phase of the response, the properties of the responding T cells profoundly change. The expression of adhesion molecules, as well as cytokine and chemokine receptors, shifts allowing the cells to migrate from the sites of priming in secondary lymphoid organs to other locations where they may encounter infected cells (Cox and Zajac 2010; Sheridan and Lefrancois 2011). Metabolic changes also occur which are necessary for the rapid and substantial cell division that the T cell will undergo. Importantly, the responding cells differentiate into effector cells with the ability to rapidly produce numerous cytokines as well as kill target cells. These effector activities are triggered as T cells detect and bind to their cognate MHC–peptide complexes on target cells and can be initiated by the newly differentiated

effector cell without the requirement for costimulation or third signals. The CTL population is, however, functionally heterogeneous with certain T cells more polyfunctional and capable of eliciting a broad range of effector activities, whereas other constituents of the effector pool may possess more limited functional abilities (Makedonas and Betts 2006).

Most of the CD8 T cells that are initially generated become terminally differentiated effector CTL as the response develops. If the inducing antigen is controlled, then the vast majority of these terminally differentiated T cells undergo apoptosis. Ideally the response does not completely collapse. Instead, as homeostasis is restored, a population of memory T cells remain present (Fig. 2a). Memory T cells can be maintained at remarkably stable levels and have been detected for decades following smallpox vaccination. Maintaining this memory population contributes to immunological protection against reexposure to antigen or reinfection with the pathogen. Although there are far fewer antigen-specific T cells present during the memory phase than at the peak of the response, the frequency of these cells is higher than at the onset of the priming event. Moreover, by comparison with their naïve counterparts, memory T cells are generally tuned to mount faster and more efficacious responses upon antigenic activation.

Memory T cells are distinct from their naïve and effector counterparts, and they are also diverse (Lanzavecchia and Sallusto 2005). A subset of memory cells which express lower levels of the adhesion molecule CD62L and the chemokine receptor CCR7 are referred to as effector memory cells. They are preferentially located in non-lymphoid tissues where they are immediately available to rapidly elicit effector activities, including cytokine production and cytotoxicity, in response to reexposure to antigen at these sites. They are sensitive to MHC–antigen activation but do not require professional APC or other signals in order to function. These tissue resident cells are often retained at the site of the primary infection, such as in the lung following influenza infection or the skin and dorsal root ganglion following herpes simplex virus infection, but can be more systemically distributed (Sheridan and Lefrancois 2011). A population of memory T cells, termed central memory T cells (T_{CM}), express higher levels of CD62L and CCR7 and are primarily present in secondary lymphoid organs. In some ways, T_{CM} display a less differentiated phenotype than effector memory T cells and are more prone to proliferate upon secondary stimulation. Although T_{CM} may be less efficient at deploying immediate effector activities, they can attain these traits as they begin to divide in response to antigenic activation.

The induction of robust effector responses and the development of T cell memory are usually associated with antigens that are cleared from the host, which occurs, for example, following vaccination or during acute infections. A spectrum of functional and phenotypic differences in T cell responses have been observed under conditions of antigen persistence which develop as a result of the failure to eradicate the infection or tumor (Fig. 2b) (Yi et al. 2010). The production of cytokines including interferon (IFN)-γ, TNF-α, and IL-2, as well as cytotoxic effector molecules such as perforin and granzymes, may be diminished or abolished as the T cells responding to these persistent stimuli fail to attain or lose polyfunctional traits and succumb to exhaustion. Differences in proliferative capacity and dependency on homeostatic cytokines such as IL-7 and IL-15 have also been observed, and severe functional exhaustion can culminate in the physical loss of antiviral CD8 T cells. Comparative analysis of CD8 T cell responses to viral infections which result in different levels of antigenic exposure, such as influenza virus, cytomegalovirus, EBV, hepatitis C virus, and HIV, indicates that antiviral CD8 T cells may adopt different preferred phenotypic and functional set points. This is influenced by the level and repetitiveness of the antigenic stimuli, as well as by the balance of activatory and suppressive cytokines, and also by the presence of helper and regulatory CD4 T cells.

Transcriptional Control of CTL Differentiation

The profound phenotypic and functional changes that the responding T cells undergo during the priming phase reflect modifications in gene expression which are regulated by transcription factors (Cox et al. 2011; Kallies 2008). Inflammatory cytokines such as IL-12 and IFN-γ induce expression of the transcription factor T-bet (*tbx21*), which promotes the differentiation of type I helper CD4 T cells as well as CD8 CTL responses. High levels of T-bet drive the terminal differentiation of effector CTL, which have potent cytolytic capacity but limited proliferative abilities. Notably, if CD4 T cell help is insufficient, then T-bet levels are high, which promotes effector CD8 T cell development but curbs the formation of effective memory responses. The related transcription factors FOXO1 and FOXO3 also regulate effector T cells and in the case of FOXO1, this is due to inhibition of T-bet which restricts the differentiation and expansion of the response. Lower amounts of T-bet, however, permit the formation of memory T cells, which can be maintained over time and give rise to secondary effector cells during recall responses. In mice, T-bet deficiency results in reduced effector CTL and favors the development of long-lived memory T cells. Nevertheless, some effector phenotype cells are still generated, and some cytotoxic potential is still retained as a result of compensation by another transcription factor, eomesodermin (Eomes). Eomes expression is most commonly associated with memory T cell formation, and this transcription factor is repressed by the inflammatory conditions that induce T-bet. Deletion of Eomes alone does not prevent development of an effector CTL pool; however, these cells are poorly maintained as memory cells and appear incapable of responding to secondary challenge. If both T-bet and Eomes are deleted from CD8 T cells, however, the CTL response is aberrant and infection control compromised.

In addition to T-bet and Eomes, the transcription factor B-lymphocyte-induced maturation protein (Blimp)-1 (*prdm1*) is also critical for CTL development. The absence of Blimp-1 results in poor expression of the cytolytic molecules perforin and granzyme B and poor control of viral infections. One function of Blimp-1 may be to induce greater levels of T-bet and reduce Eomes expression, thereby favoring effector CTL development. In Blimp-1-deficient T cells, *tbx21* expression is lower, and *eomes* expression is significantly higher at the mRNA level. Similar to T-bet, the level of Blimp-1 expressed in a cell is critical to determining the functional capacity of CD8 T cells. Therefore, controlling the amount of Blimp-1 expressed within a responding CTL molds that cell's ultimate fate and function.

The related transcription factors Id2 and Id3 support T cell survival and promote memory formation. Interestingly, Blimp-1 suppresses Id3, which likely helps to cement the development of terminally differentiated effector T cells at the expense of memory formation. Moreover, Bcl-6, a transcription factor associated with memory T cells, can also repress Blimp-1 expression. Overexpression of Bcl-6 drives expansion of memory T cells, and the effector cells generated under these conditions display reduced killing and granzyme B expression. As Blimp-1 and Bcl-6 are mutual repressors, this increase in Bcl-6 expression may be preventing the Blimp-1-driven differentiation of the effector response that ordinarily occurs following T cell activation.

Antigenic activation is the principle driver of the T cell response, but the levels of cytokines, which flux during the course of many infections and immune responses, also regulate the T cell transcriptional network (Cox et al. 2011). As discussed above, T-bet levels are determined in part by inflammatory cytokines such as IL-12. IL-2 signaling in CD8 T cells strongly induce the expression of Eomes and Blimp-1. Moreover, signaling through the IL-10 and IL-21 cytokine receptors activates the transcription factor STAT-3 which influences the expression of Blimp-1 and Bcl-6. Hence, the composition of the cytokine milieu affects the phenotypic and functional attributes attained by the responding T cells.

CTL Effector Mechanisms

Since CTL recognize and respond to MHC–peptide complexes expressed upon the cell surface, cell–cell contact is necessary for the elaboration of their effector activities. Thus, by comparison with antibody responses, CTL cannot confer sterilizing immunity and prevent infections by neutralizing the cell-free form of the pathogens present in circulation or other body fluids. CTL responses do, however, provide an important cellular mechanism for eliminating pathogen-infected cells or other cell types expressing nonself or tumor-associated antigens. For lytic infections, the rapidity of CTL response is critical as swift action by these cells limits the release of the pathogen and eliminates the infected cell before full replicative potential is reached. For non-lytic infections, which can parasitize the target cell without causing its destruction, CTL function to destroy these factories of pathogen production.

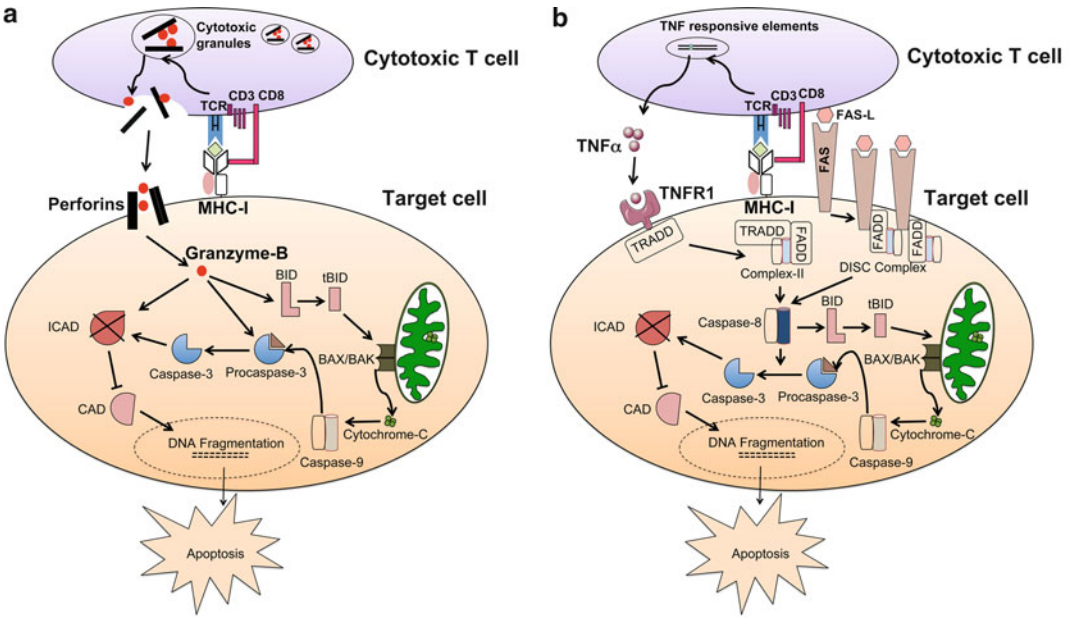
CTL functions are commonly associated with terminally differentiated effector cells which possess cytolytic functions and can also express a variety of cytokines and chemokines (Makedonas and Betts 2006). The secretion of effector cytokines and chemokines is initiated following contact of the T cell with a target cell and in the case of IFN-γ requires new protein synthesis. The production of cytokines such as IFN-γ and TNF-α by T cells can mediate the clearance of certain infections including hepatitis B virus without causing target cell death (Guidotti and Chisari 2001). Conversely, in the case of influenza infection, cytolytic effector functions can be elaborated against pulmonary epithelial cells without activating cytokine production. Such multifunctional capabilities provide a degree of flexibility and functional breadth necessary to combat diverse intracellular pathogens and tumors.

Perforin/Granzyme-Mediated Cytotoxicity

The best studied and most common mechanism of CTL-induced cell death is perforin- and granzyme-mediated cytotoxicity (Fig. 3a). As CTL gain their effector capabilities, they develop cytolytic granules which contain the pore-forming protein perforin and a variety of granzymes. As these effector CTL recognize target cells via their TCR, an immunological synapse forms between the engaged cells (Jenkins and Griffiths 2010). At the time of target cell engagement, preexisting perforin is the first to be released as marked cytoskeletal rearrangements occur within the CTL and the lytic granules migrate along microtubules toward the immunological synapse where they are discharged. This activation process can also stimulate the production of new perforin which replenishes the CTL and sustains effector capabilities.

Upon release perforin polymerizes in the target cell membrane permitting entry of granzymes which deliver the "kiss of death" to the target cell. In addition, at high concentrations, granzymes can access target cells in a perforin-independent manner. Although CTL express a variety of granzymes, the roles of granzyme B in the lytic process are most well defined (Ewen et al. 2012). Granzyme B has many molecular targets including BH3-interacting domain death agonist (BID), procaspase-3, and inhibitor of caspase-activated DNase (ICAD). Granzyme B cleaves BID into its truncated form, tBID and procaspase-3 into activated caspase-3. tBID translocates into the outer mitochondrial membrane and promotes the oligomerization of Bax and Bak, leading to membrane disruption and the release of cytochrome C into the cytosol. The cytochrome C release activates caspase-9, which further activates caspase-3, ultimately resulting in the cleavage of ICAD, which can also be directly acted upon by granzyme B, into caspase-activated DNase (CAD). Once activated, CAD then enters the nucleus causing DNA fragmentation and apoptosis.

The mechanisms of action for other granzyme molecules (A, H, K, and M) are less well understood (Ewen et al. 2012). Notably, patients with a variety of inflammatory conditions express detectable levels of soluble granzymes, which may have non-cytotoxic biological roles. It has been shown that granzyme A can elicit the production of inflammatory cytokines.



Cytotoxic T Lymphocytes, Fig. 3 *CTL killing mechanisms.* (**a**) Perforin/granzyme-mediated cytotoxicity occurs as CTL engage a target cell via their TCR, relaying a signal that releases prestored cytotoxic granules containing perforin and granzymes. Perforin forms a pore in the target cell membrane which enables the entry of granzymes. Granzyme B functions as a key inducer of apoptosis, resulting in target cell destruction. (**b**) CTL can also cause target cell apoptosis by activating the death receptor pathway via FasL–Fas interactions or by the production of TNF-α. Engagement of Fas on the target cell by FasL, which is expressed on certain populations of CTL, launches a signaling cascade via formation of the DISC complex which ultimately results in apoptosis. TNF-α, which is produced by certain CTL subsets, also causes death receptor-mediated apoptosis following binding to its receptor TNFR1 and recruiting TRADD, leading to the formation of complex II. Signaling through complex II activates downstream executioner caspases leading to cell death

In addition, granzyme A and its family member granzyme K are able to induce cell death independently of caspase activity and the release of cytochrome C from mitochondria. Granzymes A and K are also both capable of inducing the production of reactive oxygen species which can cause cell death. In addition to production of reactive oxygen species, granzyme K can also activate mitochondrial apoptosis pathways, as measured by cytochrome C release.

Throughout the killing process, the CTL must avoid autolysis and self-destruction by their own lytic granules. In order to preserve their own integrity, CTL encode the protease inhibitor-9 (in humans) or its murine ortholog, serine protease inhibitor-6, which functions to stabilize the granules within the CTL and also protects against granzyme B-mediated apoptosis (Ashton-Rickardt 2010). In addition, at the time of granule deployment, CTL release cathepsin-B which prevents perforin from attacking the effector T cell.

Death Receptor-Mediated Apoptosis

Although perforin/granzyme-dependent cytotoxicity is a principal effector mechanism, CTL can also mediate death receptor apoptosis via the Fas ligand (FasL)–Fas or TNF receptor pathways (Fig. 3b) (Smyth and Trapani 1998). The FasL–Fas pathway is initiated, as activated CTL upregulate FasL on their cell surface, usually following engagement with a target cell. The interaction between FasL on the CTL and Fas on the surface of the target cell promotes the formation of the death-inducing signaling complex (DISC), which is comprised of Fas-associated death domain (FADD), procaspase-8, and procaspase-10. Signaling through DISC results in cleavage of these

procaspases, releasing the active caspases, which in turn activate caspase-3. Caspase-3, as an executioner caspase, then cleaves ICAD, activating CAD, thus inducing DNA fragmentation and cell death. Caspase-8 also cleaves BID into tBID, which oligomerizes Bax and Bak, causing the release of cytochrome C from the mitochondria. This release of cytochrome C activates caspase-9 and elicits a downstream signaling pathway which also culminates in cell death.

TNF-α can be secreted by CTL upon antigenic stimulation and is also a mediator of cell death. TNF-α binding to TNF receptor 1 (TNFR1) on the target cell results in trimerization of the receptor complex and recruitment of TNFR-associated death domain (TRADD). FADD is also recruited forming complex II, which leads to caspase activation and induction of cell death through DISC, paralleling Fas-mediated apoptosis. TNF-α-induced cell death can also be mediated by membrane-bound TNF-α, independently of the secreted cytokine.

CTL-mediated cell death is usually a tightly regulated and exquisitely antigen-dependent process. Nevertheless, CTL can sometimes cause apoptosis in bystander cells that are not directly recognized by the effector cell. This can result from FasL present on the CTL surface engaging Fas-expressing target cells in the absence of TCR signaling. Similarly, cells expressing TNFR1 may be susceptible to bystander killing caused by membrane-bound or secreted TNF.

Evading the CTL Response

The power of CTL responses in combating pathogens is well illustrated by the various strategies which have evolved to counteract the actions of the effector response (Keckler 2007). Many pathogens encode specific molecules which interfere with antigen-processing and presentation pathways, thereby circumventing T cell recognition. In addition, an effective CTL response can exert pressure on the pathogen or tumor to select for viable genetic variants with escape mutations within antigenic epitopes. Such alterations can render the existing population of CTL ineffective if they cannot recognize or efficiently respond to the variant pathogen or tumor. Pathogens have also adopted immune evasion strategies which directly interfere with the CTL-mediated killing process. For example, certain viruses encode serpins that block caspase activation, which is critical for the cytolytic process. These molecules include one of the most potent inhibitors of caspase-mediated cell death, CrmA, encoded by cowpox virus, as well as related serpins encoded by vaccinia virus, myxoma virus, and ectromelia virus. Granzyme B is directly inhibited by CrmA, and this death pathway is also targeted by the herpes simplex virus glycoprotein J and the adenovirus-encoded L4-100K protein. Death receptor signaling is blocked by vFLIP and related molecules encoded by herpesviruses and poxviruses, which disrupt the formation and function of the DISC, impeding the induction of apoptosis. Fas-mediated cell death is blocked by the adenovirus E3 region-encoded receptor internalization and degradation complex, as well as by the myxoma virus LAP protein which reduces surface expression of this death receptor. Soluble TNF decoy receptors encoded by poxviruses also directly block the action of this cytokine.

Cytotoxic CD4 T cells

CD4 T cells are most commonly associated with helper functions which promote B cell and CD8 T cell responses and with regulatory properties which can suppress the development of pathogenic immune responses. CD4 T cells can, however, also adopt a cytotoxic phenotype, and cytolytic CD4 T cell responses have been detected following several infections including influenza virus, West Nile virus, hepatitis C virus, human cytomegalovirus, HIV, EBV, and LCMV (Marshall and Swain 2011). The effector mechanisms used by CD4 CTL mirror those used by conventional CD8 CTL. Like their CD8+ counterparts, CD4 CTL have multifunctional properties and can express cytokines including TNF-α and IFN-γ as well as cytolytic effector molecules including perforin,

granzymes, FasL, and, in humans, granulysin. CD4 CTL are detected in both lymphoid and non-lymphoid organs and may display a terminally differentiated phenotype, similar to the highly cytolytic effector CD8 CTL, (CCR7-, CD27-, CD28-, CD62L-, CD45RO+), and may express the senescence marker CD57.

CD4 CTL recognize peptide–MHC class II complexes which are primarily expressed by professional APC, but under inflammatory conditions expression can be induced on certain other cell types including fibroblasts and endothelial cells. Therefore, by comparison with CD8 T cells, which recognize broadly expressed MHC class I complexes, the more limited tissue distribution of MHC class II molecules likely limits the efficacy of the CD4 CTL response. Nevertheless, CD4 CTL may be important during EBV infection or B cell lymphocytic leukemia, as they are able to recognize and kill infected or malignant MHC II-expressing B cells. In addition, early cytolytic CD4 responses are associated with better control of HIV-1 infection and under certain circumstances CD4 CTL can also have a pathogenic role.

Immunopathology

Although CTL play a vital protective role, by clearing infections, eliminating tumors, or limiting the levels of pathogen replication, there can be detrimental consequences to these responses. Since CTL can kill target cells and produce inflammatory cytokines, they can cause tissue damage. Such immunopathology is classically described following infection of mice with the non-cytopathic virus LCMV. CD8 CTL responses are essential for the clearance of this infection. This effector response can also cause the death of the infected animal, an outcome which depends upon the route of infection, the age of the mouse, the levels of virus replication, and the tempo of the T cell response. During hepatitis B and C virus infections, virus-specific T cells infiltrate the liver, causing destruction of hepatocytes, leading to liver cirrhosis. The extent of liver injury coincides with the number of virus-specific CTL present in the liver, and pathology can be mollified by depleting hepatitis-specific CTL at the peak of the infection. This immunopathology is attributed to the cytopathic activity of the CTL, although secretion of effector cytokines and chemokines can recruit other inflammatory cells into the liver, enhancing the magnitude of tissue damage. Interestingly, during many chronic infections such as viral hepatitis or HIV, CTL lose function as they succumb to exhaustion (Yi et al. 2010). This rebalancing of the effector response may limit the ability to control the infection but also may serve as a strategy to curtail immunopathology.

Dendritic Cells in Atherosclerosis

Matthew Butcher and Elena V. Galkina
Department Microbiology and Molecular Cell Biology, Eastern Virginia Medical School, Norfolk, VA, USA

Definition

Dendritic Cells are a subset of myeloid leukocytes that play key roles in initiating and directing the adaptive immune response. Dendritic cells, which were named based on their branch-like morphology ("déndron" meaning "tree" in Greek), can be found at multiple sites of non-lymphoid tissues and within lymph nodes, and are characterized by their ability to migrate through lymphatic vessels and present antigens as professional antigen presenting cells. Dendritic cells are also detected within non-diseased and atherosclerotic aortas, but the functions of DC subsets in the development and progression of atherosclerosis are not well understood.

Historical Perspective

Dendritic cells were discovered by Ralph Steinman and Zanvil Cohn in 1973 (Steinman 2011). Initially, DCs have been described as cells that are highly mobile and, in contrast to macrophages, are weakly phagocytotic. These newly discovered cells had a large nucleus, and abundant cytoplasm, arranged in processes of different length and width. In 1978, using a mixed leukocyte reaction, it was demonstrated that DCs are potent stimulating cells that are at least 100 times more effective than other major cell subclasses in activating T cells. To date, DCs are found in various tissues of the body where they constantly communicate with a range of lymphocyte populations to serve as a bridge between the external environment and the adaptive immune system (Ueno et al. 2007). DCs capture antigens in peripheral tissues and then migrate to secondary lymphoid organs, including lymph nodes and the spleen, in order to present antigen to naïve T cells (Mempel et al. 2004). During the migration to secondary lymphoid organs, DCs also receive additional Toll-like receptor (TLR)-dependent or Nod-like receptor-dependent stimulation signals that result in DC maturation. The maturation of DCs is accompanied by the upregulation of MHC-II, the co-stimulatory molecules CD80 and CD86, and the chemokine receptor CCR7. Dendritic cells (DCs) are potent antigen-presenting cells that present various endogenous and exogenous antigens to T cells (Coquerelle and Moser 2010; Ueno et al. 2007). Antigen presentation results in either initiation of the adaptive immune response or in the induction of tolerance and the release of anti-inflammatory factors. There are 4 major categories of DCs: conventional DCs that are specialized in antigen processing and presentation; Langerhans cells; plasmacytoid DCs; and monocyte-derived DCs, which are induced in response to inflammation.

Vascular Dendritic Cells in Healthy Aortas

Dendritic cells are found within healthy human and mouse aortas (Galkina and Ley 2009; Hansson and Hermansson 2011). Human aortic DCs express $CD1a^+S\text{-}100^+lag^+$ and resemble Langerhans cells (Bobryshev 2010). These vascular-associated DCs are termed as vascular DCs. Despite the fact that some macrophages and monocytes express CD11c; the expression of the CD11c integrin is a key marker for DC identification (Geissmann et al. 2010a). Bone marrow-derived $CD11c^+CD68^+$ cells are found within the lesion-susceptible lesser curvature of the healthy aortic intima of C57BL/6 mice. This site-specific localization of intimal $CD11c^+$ cells occurs independently from circulating cholesterol levels, suggesting an important role of the microenvironment at specific anatomical locations. DCs are also found within the cardiac valve and aortic sinus of C57BL/6 mice. These aortic DCs express low levels of CD40 and are positive for CD1d, CD80, and CD86, suggesting an immature phenotype. Recent studies have also highlighted the complexity of the origins of DCs and their functions within the aorta (Bobryshev 2010; Koltsova and Ley 2011; Niessner and Weyand 2010). DCs are generated at least by two major pathways that differ in their requirement for the Flt3/Flt3L (Flt3L, fms-like tyrosine kinase 3 ligand) axis (Geissmann et al. 2010b). The development of DCs from monocyte-independent precursors is Flt-3/Flt3L-dependent, whereas the generation of DCs from monocytes is Flt3/Flt3L-independent (Geissmann et al. 2010b). A recent study demonstrated that Flt3 treatment leads to an expansion of $CD11c^+$ cells within the intima and adventitia indicating at least a partial monocyte-independent origin of some $CD11c^+$ DCs under healthy, non-atherosclerotic conditions. $CD11c^+$ cells that are located within the healthy murine aorta do not have a uniform phenotype and represent at least two major populations: $CD11c^+CD11b^+F4/80^+$ and $CD11c^+CD11b^-F4/80^-$ DCs. Additional studies have demonstrated that these two DC populations originate from different precursors. $CD11c^+CD11b^+F4/80^+CD103^-$ DCs are M-CSF-dependent and are likely derived from a common monocyte precursor, whereas $CD11c^+CD11b^-F4/80^-CD103^+$ DCs are Flt3-dependent and are derived from DC precursors (Table 1).

One of many remaining unresolved questions concerns the functions of DCs within the

Dendritic Cells in Atherosclerosis, Table 1 Vascular dendritic cell subset in atherosclerosis

Vascular DC subset	Effects on murine atherosclerosis	Marker profile
Flt-3-dependent DCs, derived from common DC precursors	Depletion of Flt-3 increases aortic plaques and Th1 cell content, but decreases Tregs in Ldlr−/− mice	CD11c+CD11b-CD103+
Flt-3 independent, M-CSF-dependent monocyte-derived DCs	Unknown	CD11c+MHC-II+CD11b+F4/80+DC-SIGN+CD103-
GM-CSF-dependent DCs	Unknown	CD11c+CD11b-CD68+MHC-II+
CCL17+ DCs	DC-derived CCL17 limits the expansion of Tregs and increases atherosclerotic plaques	CD11c+CD11b+F4/80-CCL17+
Plasmacytoid DCs	Functions are controversial. Depletion of pDCs (anti-PDCA-1 Abs) increases aortic plaques in Ldlr−/− mice, whereas pDCs-derived IFNα induces TRAIL-1-dependent VSMC apoptosis	CD11clowIFNα+CD11b-

This table describes known subsets of vascular dendritic cells and their functions during development and progression of atherosclerosis

non-diseased aortic wall. It might be possible that resident DCs provide local tolerance and regulate the balance between the active and suppressor arms of the immune response. However, recent data also suggest a potential pro-atherogenic role for several subsets of DCs in atherosclerosis. A specific subset of aortic resident DCs ($CD11c^+CD11b^-$ DCs) uptake neutral lipids in high-cholesterol diet-fed $Ldlr^{-/-}$ mice within the atherosclerosis-prone areas of the lesser curvature (Cybulsky and Jongstra-Bilen 2010). An important question concerning DC functions in atherosclerosis is whether these professional antigen-presenting cells are capable of presenting antigens within the aortic wall. Several studies using OT-I and OT-II TCR-transgenic mice (Miyagawa et al. 2010) that are specific for OT-I and OT-II OVA peptide have demonstrated that aortic $CD11c^+$ DCs are able to present OVA peptide to OT-I and OT-II T cells in vitro and in vivo. Importantly, these results correlate with experiments conducted using a model of engineered bioartificial human arteries that mimic the size and structural dimensions of human arteries. Human $CD11c^+$ DCs seeded within bioartificial arteries migrated to the intima, where they initiated an adaptive immune response, suggesting that antigen presentation by human DCs can occur in vivo (Niessner and Weyand 2010).

Dendritic Cells in Atherosclerotic Aortas

Accumulation of DC within the Aorta

Atherosclerosis-prone conditions induce significant recruitment of multiple populations of immune cells including monocytes, mast cells, neutrophils, and T cells into the aortic wall and surrounding adventitia (Galkina and Ley 2007). An increased number of $CD11c^+$ cells are found in close proximity to T cells in the zones of neovascularization within murine and human atherosclerotic plaques. DCs are detected in the shoulder regions of unstable human plaques. There are several potential mechanisms by which DCs might accumulate within the aortic wall (Ley et al. 2011). Atherosclerosis-prone conditions increase the number of peripheral blood-circulating proinflammatory monocytes that might be converted at a higher rate to aortic DCs. The direct recruitment of pre-DCs to the aorta may impact the total aortic $CD11c^+$ DC content.

The migration of monocytes and pre-DCs is directed by specific adhesion molecules and aortic chemokines, produced by endothelial and stromal cells, and subsets of leukocytes (Galkina and Ley 2007; Woollard and Geissmann 2010). P- and E-selectins play an important role in monocyte rolling along the endothelium, and combined deficiency in P- and E-selectins decreases atherosclerosis by 80 % in atherosclerosis-prone $Ldlr^{-/-}$ mice. Evidence from VCAM-1 or α_4 integrin blockade experiments suggests that VCAM-1 supports the slow rolling and tight adhesion of monocytes to the atherosclerotic endothelium. CXCL1 and CCL5, either alone or as a heterodimer with CXCL4, serve as arrest chemokines to initiate integrin activation and firm monocyte adhesion to endothelium. CXCL7 and migration inhibitory factor (MIF) also efficiently trigger monocyte arrest to the inflamed endothelium under flow conditions. CCL2 is known to be one of the key chemokines in monocyte biology. Classical $CCR2^+$ monocytes exit the bone marrow in a CCL2-dependent manner, and both CCL2 and CCL7 maintain monocyte homeostasis in circulation (Serbina and Pamer 2006). Several studies suggest that the CCL2/CCR2 axis participates in atherogenesis by the modulation of monocyte recruitment into the aorta, mostly likely via regulation of monocyte transmigration. An increase in DC content correlates with the progression of atherosclerosis with simultaneous elevation in both subsets of aortic $CD11c^+$MHC-II^+CD11b^+ Flt-3-independent DCs and $CD11c^+$MHC-II^+CD11b^- Flt3-dependent DCs in the atherosclerotic aortas of $Ldlr^{-/-}$ mice (Koltsova and Ley 2011). Increased aortic DC numbers may not be due to increased migration from peripheral circulation alone, but due to reduced emigration out of the vessel wall or increased local proliferation as well. For example, a short-term high-cholesterol diet feeding elevated local

proliferation of intimal $CD11c^+CD11b^-$MHC-II^+ DCs in the aorta of $Ldlr^{-/-}$ mice. Several lines of evidence also demonstrate defective egress of macrophages from atherosclerosis-prone aortas. Similarly, defective aortic DC egress from the aorta might be a possible reason for DC accumulation within the atherosclerotic vessel.

Possible Functions of Dendritic Cells During Atherogenesis

The accumulation of DCs within the atherosclerotic aorta induces the proinflammatory status of DCs and supports lesion progression (Koltsova and Ley 2011). Despite the attenuated ability of DCs to migrate from peripheral tissues to draining lymph nodes during atherogenesis, DCs isolated from $Ldlr^{-/-}$ or $Apoe^{-/-}$ mice efficiently induce T cell proliferation and IFNγ and TNFα production after ex vivo coculture with naïve $CD4^+$ T cells (Koltsova and Ley 2011). DCs are specialized in capturing, processing, and presenting antigen-derived peptides on major histocompatibility complex (MHC) molecules in vivo, thereby, allowing DCs to shape T cell responses in order to modulate immunity or tolerance (Steinman 2011). Several modifications of low density lipoproteins (LDL) affect the maturation and activation of DCs. Oxidized phospholipids (ox-PLs) alter DC activation and prevent their maturation through the blockade of TLR-3- and TLR-4-dependent induction of CD40, CD80, CD83, and CD86. In contrast, oxidized LDL (oxLDL) support the maturation of DCs that secrete IL-12 but not IL-10 and support both syngeneic and allogeneic T cell stimulations (Galkina and Ley 2009).

There are several potential antigens including oxLDL, beta-2 glycoprotein I (β2GPI), and heat shock proteins HSP-60 and HSP-65 that might induce the Th1-specific response during atherogenesis. Interestingly, analysis of T cell hybridomas from human apolipoprotein B100 transgenic mice that were immunized with human oxLDL revealed that T cell clones surprisingly respond to native and purified LDL apolipoprotein ApoB100, but not to oxLDL, suggesting the existence of an immune response against native LDL (Hansson and Hermansson 2011).

Direct evidence for the implication of DCs in atherosclerosis was obtained using mice that overexpress the anti-apoptotic gene hBcl-2 under a CD11c promoter (Galkina and Ley 2009; Hansson and Hermansson 2011). The content of $CD11c^{high}$MHC-II^{high} DCs was increased in DC-hBcl2 mice and was accompanied with enhanced T cell activation, elevated levels of Th1, Th17-related cytokines, and increased production of Th1-driven IgG2c antibodies, suggesting that $CD11c^+$ DCs are involved in T cell activation and Th1/Th17 helper differentiation in vivo. Interestingly, DC-hBcl2 mice also demonstrate reduced levels of plasma cholesterol. Depletion of CD11c in CD11c-diphtheria toxin receptor (DTR) (Apolipoprotein E-deficient) $Apoe^{-/-}$ transgenic mice results in elevated levels of circulating cholesterol highlighting a unique ability of DCs to modulate cholesterol levels in blood (Koltsova and Ley 2011). Further studies are necessary to provide better understanding of the mechanisms of the regulation of circulating cholesterol by DCs.

The function of multiple DC subsets in atherosclerosis is not well understood; however, several recent studies provide strong evidence for subset-specific functions of DCs. $CD11c^+CD11b^-CD103^+$ cells are Flt-3-dependent subset of DCs that induce tolerance in the steady state. Constitutive ablation of these DCs results in autoimmune disease. Flt-3 deficiency and concomitant depletion of $CD11c^+CD11b^-CD103^+$ DCs resulted in increased plaque burden within the aortic sinus and the aortic arch, and a shift toward the Th1 response at the cost of the Treg population in $Flt\text{-}3^{-/-}Ldlr^{-/-}$ mice (Choi et al. 2011). Thus, aortic $CD11c^+CD103^+$ DCs likely function as tolerogenic DCs during atherosclerosis. In contrast to $CD11c^+CD103^+$ DCs, another subset of DCs that expresses CCL17 reduces Treg expansion and supports atherogenesis. The number of Tregs decreases proportionally to the progression of atherosclerosis, but the mechanisms behind this reduction remain unclear. The discovery of suppressor $CD11c^+CD103^+$ DCs and

proinflammatory CCL17$^+$ DCs provides new understanding for the role of different DC subsets in the regulation of the immune response during atherogenesis.

There are several lines of evidence suggesting that plasmacytoid DCs (pDCs) might play a role in atherosclerosis. The hallmark of pDCs is the rapid production of high levels of type I interferon (interferon α/β, IFN) and other cytokines in response to TLR7, TLR8, and TLR9 engagement. Additionally, pDCs express low levels of CD11c and are positive for some lymphocyte antigens, including CD4, Rag-1, and CD45RA/B220 (Reizis et al. 2011). Since pDCs are weak antigen-presenting cells compared to conventional DCs, the major function of pDCs is to provide fine-tune for the balanced T helper responses via production of type I interferons. IFNα$^+$ DCs are found within atherosclerosis-prone human and mouse vessels (Koltsova and Ley 2011; Niessner and Weyand 2010). The role of pDCs in atherosclerosis is not completely understood. pDCs-derived type I IFN induces the expression of tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) on CD4$^+$ T cells that initiate VSMCs apoptosis, suggesting an important link between pDC and vascular inflammation. On the other hand, pDCs might serve as an immunogenic cell sentinel and provide suppressor functions via expression of tolerogenic enzyme indoleamine 2,3-dioxygenase (IDO), the inducible costimulator ligand (ICOS-L), and/or the programmed death 1 ligand (PD-L1), which mediates Treg development. In line with this concept, the depletion of pDCs increases the plaque burden in *Ldlr*$^{-/-}$ recipient mice with simultaneous elevated T cell proliferation and IFNγ production, suggesting a tolerogenic suppressor role (Koltsova and Ley 2011). Thus, the involvement of pDCs in atherosclerosis remains controversial and further studies are necessary to delineate the functions of pDCs in atherogenesis.

DCs and Vaccination

DCs regulate the T and B cell responses and are often targets and vectors for vaccination. It appears that DC subsets and different methods of DC activation might elicit different T cell responses. In addition to the complexity of the involvement of different DC subsets in atherosclerosis, there is also a question about the specific antigens to target. One of the first approaches to test whether vaccination might modulate atherogenesis utilized immunization of rabbits and mice with oxLDL (de Jager and Kuiper 2011). This approach resulted in attenuated atherosclerosis. Further studies using DC-based vaccination strategies have demonstrated different outcomes. The injection of bone marrow-derived DCs pulsed with oxLDL prior to lesion formation attenuated lesion formation in the brachiocephalic artery after collar placement. Multiple subcutaneous injections of bone marrow-derived DCs pulsed with malondialdehyde (MDA)-LDL or keyhole limpet hemocyanin (KLH)-loaded DCs led to an elevated plaque burden within the aortic roots. Apolipoprotein B100 (ApoB100) is a protein component of LDL, and the progression of atherosclerosis is associated with immune responses to ApoB100-derived peptides. Interestingly, immunization of mice expressing human ApoB100 in the liver with bone marrow-derived LPS maturated DCs treated with IL-10 and ApoB100 before the development of atherosclerosis reduces atherosclerosis in recipient mice after Western diet feeding. Thus, DCs with induced tolerogenic properties might be one of the promising approaches to modulate the T cell response and attenuate chronic inflammation of the aortic wall that accompanies atherogenesis (de Jager and Kuiper 2011).

Conclusion

Since the discovery of DCs within the aorta in 1995, our understanding of DC functions during the development and progression of atherosclerosis has significantly advanced. Multiple studies using gene-deficient and transgenic mice have demonstrated that atherosclerosis reduction correlates with decreased number of CD11c$^+$ DCs. Additionally, several studies have also highlighted significant heterogeneity of DC

subsets within the aorta and uncovered potential complexity of DC functions during atherogenesis. DCs have the unique capacity to discriminate between self and nonself, and are therefore well suited to regulate the delicate balance between immunity and tolerance. The identification of the factors that determine the functional activity of specific DC subsets will allow designing new approaches for atherosclerosis treatment.

Connective tissue disease; Inflammatory myopathy

Definition

Dermatomyositis is an uncommon inflammatory disease characterized by muscle weakness and a distinctive skin rash. It affects adults and children alike. In adults, dermatomyositis usually

occurs from the late 40s to early 60s; in children, the disease most often appears between 5 and 15 years of age. Dermatomyositis affects more females than males.

Introduction

Dermatomyositis (DM) is a systemic autoimmune connective tissue disease with characteristic cutaneous and muscle inflammation. It is classified as adult or juvenile idiopathic DM, amyopathic DM, or associated with internal malignancy.

Epidemiology

The incidence of dermatomyositis and polymyositis (DM/PM) is estimated at more than 5.5 cases per million. There is a female predominance with female-to-male ratio of 2:1. In patients aged 50 and above, it has a strong association with malignancy.

Pathogenesis

The precise pathogenic mechanism of DM remains uncertain. Features of superficial vasculopathy on histology suggest a capillary pathology. Clinically vasculopathy is common in childhood DM and is seen in more severe disease (Silver and Maricq 1989). Cutaneous ulceration in adults due to vasculopathy is a poor prognostic indicator (Tomb and Stephan 2002). Angiogenesis, leukocyte trafficking, and complement cascade associated genes are highly unregulated, and dendritic cells are highly enriched at the perivascular inflammatory sites. This suggests neovascularization and endothelial cell activation in both juvenile and adult DM. It is likely this close association of monocytes with endothelial cells initiates rapid dendritic cell maturation and an autoimmune response in DM (Nagaraju et al. 2006). A strong correlation with HLA-DR7 has been demonstrated (Costner and Grau 2006).

Clinical Findings

The characteristic cutaneous features of DM are the heliotrope rash and Gottron's papules. Other cutaneous findings are malar erythema, poikiloderma overexposed skin such as the extensor surfaces of the arms, the "V" of the neck, or the upper back (shawl sign), periungual telangiectasia, bullous and erosive lesions, hyperkeratosis of the lateral fingers and palms (mechanic's hands), panniculitis, urticaria, and exfoliative dermatitis. Scalp involvement in DM is often overlooked and initially misdiagnosed. Early in its course, it may mimic psoriasis, seborrheic dermatitis, or contact dermatitis. Scalp disease manifests as diffuse, confluent, atrophic, violaceous, and scaly plaques. The diagnosis of DM should be considered in both adult and pediatric patients with scaly scalp and other cutaneous and systemic signs of DM (Kasteler and Callen 1994; McDonald and Smith 1998). Peloro et al. in a retrospective study identified 16 patients under 18 years of age with juvenile DM, and 25 % of these had psoriasiform scalp dermatitis at the time of diagnosis (Peloro et al. 2001). Hypertrichosis of face and extremities is also seen in many patients with juvenile DM (Pope et al. 1994).

Kasteler and Callen in a study in 1994 showed scalp involvement in DM as a relatively common finding. In this study, 82 % patients with diagnosis of DM had scalp involvement in the form of diffuse, erythematous, scaly, atrophic, and psoriasiform dermatitis, often misdiagnosed as psoriasis or seborrheic dermatitis. Mild to moderate alopecia was noted in 43 % patients and was of a nonscarring nature. In some patients, scalp or cutaneous disease without systemic involvement of DM can be the presenting complaint. This is termed as "amyopathic DM" or "DM sine myositis." In such cases, a scalp/skin biopsy is helpful. No correlation between scalp involvement and muscle disease was noted in this study (Kasteler and Callen 1994). Another study by Tilstra JS et al. showed scalp involvement in 63 % of their patients with diagnosis of DM and 33 % patients had associated nonscarring alopecia (Tilstra et al. 2009). Nonscarring alopecia often follows a flare of the systemic disease. Lesions of DM are

frequently intensely pruritic, which is a differentiating characteristic from lupus erythematosus. Scalp pruritus can be particularly challenging to manage. Rarely, DM itself causes cicatricial alopecia, but it may frequently be associated with other connective tissue diseases like lupus which can result in cicatricial alopecia. The striking violaceous color of DM rash helps to differentiate it from the pinkish red hue of the rash seen in lupus. Also, the rash of DM is more pruritic than that of lupus.

During disease flare-up, patients can experience more hair shedding due to telogen effluvium. It is a nonscarring, diffuse hair loss in which an increased number of hairs go into resting phase (telogen phase). A hair pull test is positive (with more than six hairs out of group of 60 hairs coming out) easily with an elongated hair bulb visible to naked eye. Telogen effluvium can be due to disease activity or due to systemic medications used to treat the disease.

Diagnosis

The diagnosis of DM is suspected in patients with classic clinical findings and confirmed by a skin biopsy and serological tests. In patients with only scalp involvement, a scalp biopsy will be helpful to exclude other dermatoses. Biopsy specimen taken from scaly erythematous plaque may be indistinguishable from cutaneous lupus erythematosus. However, Crowson and Margo have suggested that microvascular pathology may enable distinction of DM from systemic lupus erythematosus (SLE) and subacute cutaneous lupus erythematosus (SCLE) (Crowson and Magro 1996).

Histopathology

Scalp biopsy shows same findings such as skin biopsy including epidermal atrophy, hyperkeratosis, follicular plugging, and vacuolar interface changes often with PAS positive irregular thickening of basement membrane zone. Subtle dermal mucin deposition and dermal edema with sparse perivascular lymphocytic infiltrate may be seen.

Immunofluorescence microscopy shows deposition of immunoglobulin at the dermo-epidermal junction, but of much less intensity than seen in lupus. Deposition of complements C5–C9 is a significant feature of DM.

Serologic Tests

Serologic tests include antinuclear antibody (ANA) testing which is positive in one-third to one-half of patients and do not correlate with disease activity (Parodi et al. 2002). Numerous myositis-specific antibodies have been recognized including Anti-Jo-1, anti Mi-2, anti-Ku, 140/155. Recently, melanoma differentiation–associated gene 5 (MDA-5) has been identified as a DM-specific auto-antigen that appears to be targeted in patients with DM and mild or absent muscle inflammation and with an increased risk of interstitial lung disease. MDA-5 has been associated with increase in scalp involvement and hair loss (Fiorentino et al. 2011).

Treatment

Cutaneous or scalp disease may remain persistent even after the myositis and systemic disease of DM are controlled with corticosteroids or immunosuppressive therapy. Daily use of broad-spectrum sunscreen with sun protective clothing must be recommended to all patients with skin or scalp disease. Anti-pruritic therapies are often necessary along with topical therapy corticosteroids or calcineurin inhibitors, such as tacrolimus or pimecrolimus. Intralesional corticosteroids (triamcinolone acetonide 10 mg/ml) every 4 weeks can reduce inflammation and pruritus.

In more severe cases, hydroxychloroquine 200–400 mg/day is effective. Chloroquine phosphate 250–500 mg/day and/or quinacrine 100 mg once or twice daily can be recommended for patients who do not respond to hydroxychloroquine.

In a study by Zieglschmid et al. and Kasteler and Callen, methotrexate at a dose of 15–35 mg/week was found to be useful for skin lesions. Other medications reported to be effective in cutaneous disease are mycophenolate mofetil, thalidomide, leflunomide, anti-estrogens, oral tacrolimus, IVIG, infliximab, sirolimus, and rituximab.

Definition

Dermatomyositis is a progressive connective tissue disorder characterized by inflammatory and degenerative changes of the muscles and skin.

Clinical Presentation

The cutaneous manifestations of dermatomyositis are arguably the most distinct and dramatic of any other autoimmune connective tissue disease. Once recognized, the clinician may establish the diagnosis even when there is histologic as well as serologic ambiguity. The unique quality of the rash is as important as its typical location pattern. Lesions typically present as patches or plaques, and all are characterized by either pink or violaceous erythema that can be with or without scale. The heliotrope eruption of the eyelids, as is typical for most of the cutaneous findings in dermatomyositis, is very distinctive and may be associated with persistent periocular edema. However, it may initially be thought to be contact dermatitis. The malar rash targets the nasolabial folds in contrast to lupus where they are spared. As rosacea does the same, initial diagnoses of rosacea are often considered in these patients. With absence of pustules, a unique type of blush rosacea does in fact occur. V-sign and Shawl sign

occur in the majority of patients which over time may lead to a poikilodermatous appearance. Linear extensor erythema often hides underlying Gottron's sign and/or papules over the extensor IP joints of the hands. The latter may be found over the elbows and knees, sometimes mimicking psoriasis. Periungual suffusion with cuticular disarray and overgrowth, and vessel "dropout" associated with a striking corkscrew pattern is found. Mechanics hand and the MDA-5 related palmar papules along the creases may also be found and initially considered as contact dermatitis or eczema. Pocket or holster sign in the vicinity of the trochanteric bursa on the lateral upper thighs is unique and often puzzling when presenting alone. Ulcerations may occur early in the MDA-5 subtype or late in association with disabling calcinosis cutis. Scalp involvement is common and described in the autoimmune hair loss section.

Amyopathic dermatomyositis (dermatomyositis sine myositis) has been shown to have the same incidence of interstitial pulmonary fibrosis as well as associated malignancy as the myositic type. A novel autoantibody to a 155-kd protein distinct from the anti-synthetases, is associated with cancer-associated dermatomyositis with or without muscle involvement.

Pathogenesis

Dermatomyositis skin disease is characterized by several pathologic findings: vacuolar interface dermatitis associated with keratinocyte (KC) injury/apoptosis; a cellular infiltrate consisting of largely T lymphocytes, dendritic cells, and macrophages located in a perivascular distribution, at the dermo-epidermal junction (DEJ), and occasionally in a peri-adnexal distribution; increased deposition of mucin in the papillary and (usually) reticular dermis; papillary dermal vascular ectasia; evidence of vasculopathy consisting of endothelial cell injury and/or vascular fibrin deposition and thrombi (Smith et al. 2009). Current data regarding the role of the immune system and environment in these pathogenic events are reviewed below.

Immune System Dysregulation

Cell Types Seen in DM Skin

Several investigators have shown that T lymphocytes (both CD4+ and CD8+) dominate the cellular infiltrate in DM skin (Caproni et al. 2004; Wenzel et al. 2006; Magro et al. 2010). In general, CD4+ lymphocytes are found primarily in a perivascular distribution, and more abundant than the CD8+ lymphocytes that are often located at the DEJ (Caproni et al. 2004; Magro et al. 2010). This has led to the postulation that keratinocyte injury might be mediated by cytotoxic lymphocytes, although this has not been shown. In addition, neutrophils and plasmacytoid dendritic cells (pDC) are commonly found in DM skin (Caproni et al. 2004; Wenzel et al. 2006; Magro et al. 2010). Interestingly, pDC are found mainly at the DEJ and perivascularly rather than in the deep dermis as is seen in cutaneous lupus (McNiff and Kaplan 2008). CD68+ cells are also found in high abundance, whereas B cells are rarely seen (Caproni et al. 2004; Dourmishev and Wollina 2006; Magro et al. 2010). Mast cells are also found in DM skin, even in skin that is uninvolved, suggesting that they may be critical in initiating DM skin disease (Caproni et al. 2004; Shrestha et al. 2010).

There are little data regarding the antigen specificity of the T lymphocytes in DM skin. The clear association of DM with MHC class II polymorphisms suggests that the adaptive T cell response is critical to disease pathogenesis (Robinson and Reed 2011). Many of them appear to be activated (as they express MHC class II and CD40L) although it is unclear if they are part of an antigen-driven response in the skin (Caproni et al. 2004; Dourmishev and Wollina 2006). T lymphocytes might be driven by upregulation of adhesion molecules such as VCAM and ICAM on the vessels, which is found in DM skin (Hausmann et al. 1996). Additionally, IFN gene products could act as chemoattractants (see below). Th1 cells appear to predominate over Th2 cells (Caproni et al. 2004; Wenzel et al. 2006; Magro et al. 2010), although the role of other Th types (e.g., Th17) has not been

investigated to date. It is tempting to speculate that the T cells are responding to many of the antigens that are known to be targeted by circulating autoantibodies in DM, although very little data currently exist regarding antigen expression in DM skin. Mi2 is known to be expressed in mouse keratinocytes, but it is unclear how this relates to DM skin (Kashiwagi et al. 2007). A recent publication demonstrated that the MDA5 antigen is expressed at high levels in DM skin (mainly in KC), although the identity of the putative cellular target(s) of this immune response in the skin is at present unknown (Zahn et al. 2011).

It has recently been shown that Treg cells are found at a decreased frequency in DM skin compared to many other inflammatory disorders (Solomon and Magro 2008; Antiga et al. 2010; Magro et al. 2010). Both FoxP3$^+$ and TGF-beta-expressing cells are found at a lower density in DM skin compared to other inflammatory disorders. This suggests that the initiation and/or propagation of T cell activation in DM skin may be in part due to defects in negative regulation of T cells.

Interferon (IFN)

As in DM muscle and peripheral blood, DM skin is characterized by overexpression of a large number of IFN-induced transcripts and proteins (Wenzel et al. 2005, 2006; Wong et al. 2012). A global transcriptional study of DM skin demonstrated that this high level of IFN-induced transcripts is seen also in cutaneous lupus and herpetic infections, and, to a lesser degree, in psoriasis (Wong et al. 2012). It has been suggested that this high IFN "signature" is characteristic of any type of interface dermatitis that is characterized by KC injury (Wenzel and Tuting 2008). Wenzel and colleagues suggest that IFN-induced proteins such as CXCL9 and CXCL10 act as chemoattractants for CXCR3-bearing lymphocytes that then mediated KC injury (Wenzel et al. 2006). Some data suggest that MxA (another IFN-induced protein) levels correlate with the number of CXCR3$^+$ cells in DM skin biopsies (Wenzel et al. 2006). In addition, IFNs are known to upregulate genes critical for immunoregulation, activate dendritic cells and natural killer cells, and mediate T cell activation and survival. Although it has been suggested that type I IFN is mediating these effects, the exact contribution of the various IFN subtypes in DM skin is not yet known. One possible source of type I IFN would be the pDC, which is a high producer of IFN-alpha. However, transcriptional data show that IFN-beta (a type I IFN) and/or IFN-gamma (type II IFN) transcript levels correlate most highly with the IFN response that is seen in DM skin (Wong et al. 2012), and DM skin has elevated levels of IFN-gamma protein (Caproni et al. 2004).

Mechanism of KC Death

The exact cause of KC injury in DM skin is unknown. Some investigators have reported close apposition of both CD8$^+$ T cells and pDC to the dying KC, suggesting a role for these two cell types (Magro et al. 2010). However, granzyme B (GrB) expression is reported to be very low in DM skin, and so, it is possible that other modes of cytotoxicity are involved (Grassi et al. 2009). Recent data suggest that the Fas/FasL mechanism might be operative (as opposed to a GrB-mediated event) (Torchia et al. 2010). Other studies suggest that KC death may be a p53-mediated apoptosis event that is associated with decreased levels of Bcl2 (Pablos et al. 1999; Dourmishev and Wollina 2006).

Vascular Injury

As in muscle, DM skin shows signs of vasculopathy. This is apparent both clinically (periungual telangiectasias, and cutaneous ulcers) and microscopically (endothelial cell swelling, ectasia, and fibrin deposition)(Crowson and Magro 1996). Although there is demonstrated pathologic rarefication of superficial vessels in DM (Crowson and Magro 1996), interestingly, there is actually clinically a gross increase in blood flow to DM skin (Dawn et al. 2007). Vasculopathy may be more pronounced in

certain DM subtypes, as patients who have antibodies to MDA5 demonstrate a clearly higher risk of cutaneous ulcers characterized by vessel damage and inflammation (Fiorentino et al. 2011; Chaisson et al. 2012). The mechanism of this vessel injury is unclear, although it is known that IFN (and its induced gene products) can induce endothelial cell injury. A recent study suggested that vasculopathy was associated with high levels of MxA expression in the endothelial cells (Magro et al. 2010). As in the muscle, DM skin is characterized by deposition of the membrane attack complex, C3d and C4d, in the vessel walls, suggesting a role for complement-mediated damage (Mascaro et al. 1995; Magro and Crowson 1997). It may be that target antigens are actually expressed in the vasculature and direct an adaptive immune response (and/or complement-mediated damage) to the vessel, but how this would relate to KC damage seen in DM is not known.

Chondroitin sulfate core protein serglycin, a known regulator of leukocyte adhesion, is significantly overexpressed in DM but not in lupus endothelial cells, and may play a role in vascular damage. Additionally, recent evidence suggests a role for angiopoietin-like protein 2 (angptl2). Angpl2 is a secreted glycoprotein with homology to the angiopoietins and may play a role in endothelial modification and inflammation through activation of NF-κB (Kim and Werth 2011). Transgenic mice expressing Angptl2 driven by a keratinocyte-specific promoter K14 (K14-Angpl2) have phenotypic and histologic similarity to DM, exhibiting heliotrope periocular rash, body rash, and increased dermal mucin (Ogata et al. 2012).

Environmental Triggers

It is postulated that DM skin disease is the result of a specific genetic interaction with an environmental response (Robinson and Reed 2011). Ultraviolet light is clearly one trigger in DM skin – DM patients have a lower threshold for UV-induced erythema (Dourmishev et al. 2004), and DM (especially anti-Mi2 positive disease) is more prevalent in areas with a higher UV index (Okada et al. 2003; Love et al. 2009). One theory is that UV induces KC injury which then results in cytokines that can activate the innate immune system and/or cause overexpression, modification, or redistribution of putative antigens, resulting in an immune response. Interestingly, UV radiation has been shown to stabilize (and thus increase epidermal levels) of the Mi2 protein, which might be a mechanism for perpetuation or initiation of an antigens-specific immune response in the skin (Burd et al. 2008).

Physical factors such as stretch have also been implicated in DM, as the inflammation is often centered over the extensor surface of joints. Werth and colleagues have shown that the glycosaminoglycans in dermal skin of DM patients contain large amounts of chondroitin-4-sulfate (C4S), a molecule with both pro- and anti-inflammatory effects (Kim and Werth 2011). Interestingly, Gottron papule lesions contain a larger relative amount of C4S than other areas, as well as increased levels of CD44v7 (a ligand for C4S) and its binding partner, osteopontin (OPN) (Kim et al. 2012). The authors show that mechanical stretch induces expression of CD44v7, and may explain localization of rash to overlying joints. They provide evidence that binding of OPN to CD44v7 induces monocyte adhesion and may provide a feed-forward mechanism for inflammation in areas of high stretch.

Discoid Lupus

Andrew G. Franks Jr.
Dermatology and Medicine (Rheumatology), Skin Lupus and Autoimmune Connective Tissue Disease Section, New York University School of Medicine, New York, NY, USA

Synonyms

Chronic cutaneous lupus; Cutaneous only lupus; Skin lupus

Definition

Discoid lupus (DLE) is a chronic, scarring skin disease characterized by clinical, histologic, and immunopathologic findings, commonly on the face over the cheeks and bridge of the nose in a "malar" or "butterfly" distribution.

Skin disease is the second most common clinical manifestation of lupus, after joint inflammation, and is divided into acute, subacute, and chronic cutaneous forms. Of the chronic cutaneous forms, discoid lupus is the most characteristic with prominence on the face, ears, and scalp.

These "discoid" or coin-shaped lesions frequently progress to permanent scars with significant effect on the quality of life in those individuals with the disease, suggesting that prevention as well as early and efficient management towards remission be the goal of the treating physician. There are variants of DLE including the hypertrophic or lichen planus overlap form as well as the palmar/plantar or acral type.

Contrary to SLE, with a female to male ratio of at least 8:1, chronic cutaneous lupus including DLE is also common in men with a female to male ratio of 6:5. The increased frequency of SLE among women has been attributed to an estrogen hormonal effect, which does not appear to play a significant role in cutaneous-only disease. This is often underrecognized and many men will not seek medical attention because of the stigma that this is a "female" disease.

There is a significant photosensitive and photoinduction component in the majority of patients with varied action spectrums. UVB is the classic action spectrum for induction of DLE, but UVA also plays a role, explaining why patients are sometimes frustrated when the standard sunscreens with limited UVA protection do not work. In addition, because UVA is present from dawn to dusk and travels through window glass, patients may be unaware of exposure. Also, the time frame between exposure and onset of lesions may be prolonged. Koebner phenomenon (Berger et al. 2012) to localized trauma does occur and also relates to thermal injury. Recently, the role of smoking as well as compliance to medications has been explored with regard to resistance to treatment.

Patients with DLE usually do not fulfill four or more of the criteria used to classify SLE and serologic abnormalities are not common (Vasquez et al. 2012). However, since DLE may occur in patients with SLE and some patients (<5 %) with DLE progress to SLE, a positive ANA when done by the IFA method may be identified and when of moderate to high titer may indicate the potential for extracutaneous disease (Chong et al. 2012). The "protective" effect of DLE regarding severe renal disease was recently reviewed (Merola et al. 2011).

It is unclear whether DLE lesions are representative of the pathologic dysfunction seen in SLE in other organ systems (Lin et al. 2007). Numerous studies have focused on the role of IL-17-producing Th17 cells in SLE. Elevated IL-17 levels and increased numbers of Th17 cells in the serum/blood of SLE patients have been reported. However, recent evidence suggests that Th1, rather than Th17, cells are the predominant T cell population in DLE lesions (Jabbari et al. 2014). TNF-alpha is also increased in lesional skin of DLE patients, and stimulation of TNF-alpha leads to increased production of IFN-gamma, whose aberrant expression is associated with a number of autoimmune disorders including SLE (Nabatian et al. 2012).

Multiple susceptibility genes play a role and several candidate genes previously associated with lupus have been confirmed (Braunstein et al. 2012),

Discoid Lupus, Fig. 1 Discoid lupus erythematosus (DLE) with chronic scarring alopecia

additional lupus-associated genes and gene loci have been identified, and variants in a novel gene (ITGAM) have been explored (Järvinen et al. 2010).

The clinical features (Fig. 1) are best described as erythematosus and scaly with central atrophy associated with loss of pigment and an inflamed, darker border with follicular plugging and scale-crust. With time the lesions leave post-inflammatory pigmentary (PIH) changes and atrophy with loss of skin markings and epidermal thinning. When on the scalp, permanent hair loss (scarring alopecia) occurs and may become widespread. The lips may become involved and when long-standing an increased incidence of squamous cell carcinoma may occur (scar carcinoma). The acronym *PASTE* is useful in initial diagnosis of active lesions as follows:

P: follicular plugging
A: atrophy
S: scale
T: telangiectasias
E: erythema

The histologic features characteristically show a superficial and deep lymphocytic infiltrate in proximity to the hair follicle and other adnexal structures, a prominent PAS + staining of a thickened basement membrane, as well as vacuolar alteration of the basal cells at the interface (interface dermatitis). Mucin may be present as well within the dermis. Direct immunofluorescence of an active lesion (lupus band test of lesional skin) usually reveals positive staining of IgG at the basement membrane in a "lumpy-bumpy" pattern. IgM deposition may occur in concert with IgG but when found alone is considered less specific. Lupus band testing of non-lesional, non-light-exposed skin has been utilized as a predictor of systemic, particularly renal, disease.

Lesions tend to occur on areas of photo-exposure such as the malar area of the face and nose but with a notable sparing of the nasolabial fold. This is in contradistinction to the malar rash of dermatomyositis which targets this area. In addition, rosacea also targets the nasolabial fold and is found in association with varying degrees of pustular lesions. When the scalp is involved, there is concordance with lesions of the ear. The "V of the neck" is also a prominent area of involvement. If DLE extends below the neck and is more disseminated (generalized DLE), it is considered a "marker of transition" as the incidence of systemic disease is increased.

Treatment

The avoidance of ultraviolet exposure in both the UVB and UVA range is important in the prevention of recurrence. Patients need to be educated

with regard to sources of exposure including artificial sources such as exposed fluorescent fixtures. UVA protection efficacy from sunscreen is not uniformly available and does not relate to SPF UVB labeling. Photosensitizing foods, supplements, and medications need to be carefully reviewed. Smoking may be a factor in some patients and it is prudent to discontinue their use. Except for photosensitizing foods such as alfalfa, some artificial sweeteners, and lime, there is no specific diet that appears to have major influence on the course of the disease in the majority of patients.

Limited disease on the skin is usually treated with topical corticosteroids or calcineurin inhibitors. Fluocinonide 0.05 % cream and tacrolimus ointment 0.1 % are useful in many patients, whereas lower potency topical steroids are generally ineffective. If lesions effect the scalp, intralesional doses of triamcinolone in the range of 0.3–0.5 mg/cc may minimize permanent hair loss.

There are no medications specifically indicated for the treatment of CLE (Jessop et al. 2009). Many of the drugs utilized are approved for use in SLE, and hydroxychloroquine is an excellent example of this strategy. Most new drug studies for DLE are utilizing the CLASI (Cutaneous Lupus Erythematosus Disease Area and Severity Index) as an outcome instrument for evaluation of cutaneous lupus (Albrecht et al. 2005).

Antimalarial drugs when used singly or in combination (hydroxychloroquine with quinacrine) will maintain remission in the majority of DLE patients encountered (Costedoat-Chalumeau et al. 2013). Dosing of hydroxychloroquine or chloroquine is based on mg/kg/day to minimize ocular toxicity. Both maximum daily dose and cumulative dose need to be considered. Hydroxychloroquine maximum dosing is generally 6.5 mg/kg/day, whereas chloroquine is 3.0 mg/kg/day. Quinacrine has no such guideline because of its relative sparing of retinal toxicity.

Acitretin (50 mg/day) has been shown to be efficacious in DLE although adverse effects are more frequent than with antimalarials. Other retinoids, such as isotretinoin, have also been utilized, but these agents are classified as second-line therapies for the treatment of CLE by the American Academy of Dermatology guidelines.

R-salbutamol, a B2 adrenergic receptor agonist commonly used in the treatment of asthma, was noted to inhibit transcription of inflammatory genes and the subsequent production of interleukin (IL)-2 and interferon (INF)-gamma. Studies suggest R-salbutamol may be an effective new topical therapy alternative for DLE (Jemec et al. 2009).

Various laser modalities have been utilized both to treat active disease (Erceg et al. 2009) as well as to repair lupus scarring in patients with DLE (Franks 2004). Guidelines are preliminary but have yet to be firmly established, but this technology appears promising, particularly with the intent to repair lupus-damaged skin.

Systemic corticosteroids are generally avoided in DLE patients due to cumulative side effects as well as their non-remittive nature. Short courses to prevent scarring or as "bridge therapy" until other agents become active are certainly warranted. Doses similar to that utilized in severe poison ivy or contact dermatitis are recommended.

Dapsone in doses of 25–100 mg/day has had beneficial effect in some patients who have not responded to or are intolerant to the antimalarials. Careful monitoring is required because of the hemolysis that invariably occurs at therapeutic levels. Because of its additional effect on neutrophil chemotaxis, some neutrophil-rich bullous forms of cutaneous disease also respond to the drug.

Thalidomide has been found to improve cutaneous lupus erythematosus in 90 % of patients utilizing doses between 50 and 400 mg daily (Cuadrado et al. 2005). It is not remittive, and rebound occurs in the majority of patients within 3–6 weeks after discontinuation. The neuropathic (Bastuji-Garin et al. 2002) and thrombophilic side effects (Piette et al. 2002) need to be individually addressed, and the use of double

contraception enforced. Those patients recalcitrant to the antimalarials are best considered for the addition of thalidomide to their regimen. Lenalidomide, an analogue of thalidomide, has recently been shown to improve patients with DLE. Similar side effects were noted.

Azathioprine in low doses, 25–100 mg/day, has been utilized for many years in patients with recalcitrant disease and has been a very useful adjunctive agent. Recently, methotrexate has been reintroduced as an excellent agent for recalcitrant disease in doses of up to 25 mg/week. Subcutaneous/intramuscular administration appears to minimize adverse side effects and may increase efficacy.

Mycophenolate mofetil and mycophenolate sodium have become increasingly popular, particularly because these drugs have become popular in lupus nephritis. They are well tolerated and have a wide therapeutic window; doses ranging from 500 mg/day to 2 g per day have been effective in DLE.

Apremilast, another analogue of thalidomide, is a novel oral PDE4 enzyme inhibitor capable of blocking leukocyte production of IL-12, IL-23, TNF-a, and INF-gamma with subsequent suppression of Th1- and Th17-mediated immune responses. It was recently shown to be effective in DLE recalcitrant to conventional therapy, with minimal side effects (DeSouza et al. 2012).

Rituximab, an anti-CD20 chimeric, monoclonal antibody, originally utilized only in B cell lymphoma, has gained acceptance for a number of autoimmune diseases including rheumatoid arthritis and granulomatosis with polyangiitis (Wegener's). Its SLE off-label autoimmune dosing is 375 mg/m^2 × 2 doses, 2 weeks apart. Infusion-related side effects are frequent and onset of clinical response may be delayed. There are significant concerns about progressive multifocal leukoencephalopathy (PML) infection in SLE patients.

Belimumab is a monoclonal antibody that inhibits soluble B-lymphocyte stimulator (anti-BlyS) and improves SLE disease activity. In a recent study, 42 SLE patients were on Belimumab intravenously for at least 3 months. Of those, 23 (55 %) patients clinically responded by 3 months with marked improvement in arthritis and/or rash, including those patients with SLE who also had DLE lesions (Akanase et al. 2013). It will shortly be available by the subcutaneous route.

The TNF-alpha inhibitors are controversial because of the systemic upregulation of autoantibody production leading to induction or acceleration of systemic disease tocilizumab prevents the binding of IL-6 to membrane-bound and soluble IL-6 receptor. It is approved by the US Food and Drug Administration for rheumatoid arthritis and juvenile inflammatory arthritis refractory to other agents and was beneficial to the skin in a patient with leukocytoclastic vasculitis who also had tumid lupus, another form of chronic cutaneous disease (Makol et al. 2012). Ustekinumab is a human monoclonal antibody directed against interleukin-12 and interleukin-23 and has recently been shown to be effective in SCLE and DLE (DeSouza et al. 2012).

Discoid SLE

Qianjin Lu
Department of Dermatology, Second Xiangya Hospital, Central South University, Hunan Key Laboratory of Medical Epigenomics, Changsha, Hunan, People's Republic of China

Synonyms

Chronic cutaneous lupus erythematosus; Discoid lupus erythematosus; Lupus erythematosus chronicus discoides

Definition

Discoid lupus erythematosus (DLE) is a chronic, autoimmune, inflammatory disease of the skin characterized by coin-shaped (discoid) lesions that give rise to scarring, atrophy, alopecia, and pigment changes as they heal. These lesions often occur on sun-exposed areas such as the face, ears, and hands although any cutaneous region as well as some mucosa can be affected.

Classification

The disease can present as localized, generalized, or childhood DLE (William et al. 2011)

1. Localized DLE: Lesions are found above the neck, with favored sites including the malar areas, bridge of nose, scalp (leading to alopecia), ears, and lower lip. This form of DLE may rarely involve the mucosa of the mouth, nose, eye, or vulva.
2. Generalized DLE: Less common than the localized form, generalized DLE often affects the thorax and upper extremities in addition to the head and neck. All degrees of severity may be encountered with this form.
3. Childhood DLE: Clinical presentation and disease course in children with DLE is similar to that observed in adults. However, there is a lower frequency of photosensitivity and a higher rate of transition to systemic lupus erythematosus (SLE). In addition, the childhood form does not demonstrate female predominance.

Epidemiology

Individuals with a family history of DLE or other autoimmune conditions are at an increased risk of acquiring the disease (Lawrence et al. 1987). Female predominance is observed in DLE, with a 2:1 female to male ratio. It may occur at any age, but most commonly affects individuals between 20 and 40 years of age. According to studies in the United States, DLE is more prevalent in African-American populations than in other ethnic groups (Molina et al. 1997). Other risk factors for developing DLE include exposure to ultraviolet (UV) light and cigarette smoking (Miot et al. 2005).

Etiopathogenesis

The etiology of DLE is incompletely understood, but it is generally believed to be caused by a genetic predisposition triggered by environmental factors. In DLE, a dysfunctional immune system produces autoantibodies that attack healthy skin tissue, resulting in inflammation and eruption of a rash.

Genetic factors: Members of the human major histocompatibility complex gene family have been implicated in the susceptibility and development of DLE (López-Tello et al. 2007).

Environmental factors: UV radiation is known to stimulate the expression of nuclear and cytoplasmic antigens like Ro/SSA on the surface of keratinocytes. These antigens are then targeted by circulating anti-Ro/SSA antibodies, leading to antibody-dependent cellular cytotoxicity and ultimately skin damage (LeFeber et al. 1984; Norris et al. 1997). UV irradiation can also upregulate Gadd45a expression and induce DNA methylation, and UV light can trigger lupus flares (Li et al. 2010). Smoking is also highly associated with the development of DLE, as it activates autoimmune lymphocytic activity, thus promoting inflammation. In addition, hormonal factors such as long-term exposure to estrogen can also lead to the development of DLE (Meier et al. 1998), which helps explain the higher prevalence of the disease in women. Drugs such as voriconazole, fluorouracil, and certain NSAIDs have been reported to induce DLE in individuals with predisposing genetic factors (Denning and Griffiths 2001).

Clinical Features

Classic DLE lesions are characterized by their red, raised, and coin-shaped (discoid) appearance. Lesions tend to start healing from the center with atrophy, scarring, hypopigmentation, and telangiectasia commonly occurring on sun-exposed areas of the face and scalp (Fig. 1).

Initial lesions consist of erythematous macules or plaques that later develop into follicular scales and crusts. There is little or no associated pain or pruritus. The lesions gradually expand, producing areas of peripheral inflammation and hyperpigmentation, leaving a central region of scarring with hypopigmentation and telangiectasia. Scalp lesions may lead to changes in hair pigment and even permanent alopecia if scarring occurs due to delayed treatment.

Discoid SLE, Fig. 1 A 68-year-old Chinese man presenting with generalized discoid lupus erythematosus involving the face and thorax. Typical lesions appear red, raised, and coin shaped, with central atrophy and scarring. Large, atypically shaped lesions result from merging of the smaller, typical discoid lesions. Mucosal lesions affecting the lips are also evident. The healed lesions have given rise to hypopigmented areas (e.g., lower chest), as well as hyperpigmentation and scarring (e.g., face) (Author took the picture himself with the permission of the patient in the Outpatient Department of Second Xiangya Hospital of Central South University)

In darker skinned individuals, late lesions appear hyperpigmented or depigmented while in lighter skinned individuals, the plaques may appear gray or exhibit little pigment change. In general, lesions leave behind scars or discolored patches after they heal.

Mucosal lesions are also common. The most frequently affected site is the mouth, predominantly on the inner cheeks and lips. They are also encountered at other sites such as the vulva (Rowell and Goodfield 1998) and nasal mucosa.

About 5–10 % of DLE patients develop SLE (Healy et al. 1995), with generalized DLE being more likely to progress into SLE than the localized type. Squamous cell carcinoma may arise in long-standing lesions of DLE.

Histopathology

Biopsy and histopathological examination are done to confirm the diagnosis of suspected DLE. Characteristic histologic findings include hyperkeratosis and follicular plugging. There is vacuolar degeneration of the epidermal basal layer and follicular epithelium, resulting in pigment incontinence. Epidermal atrophy is usually present. A patchy perivascular and periadnexal infiltrate composed mainly of lymphocytes is seen in the superficial and deep dermis. Other notable findings include thickening of the basement membrane and increased mucin deposition in the dermis (Braun-Falco et al. 2000).

The above-mentioned histologic findings are typical of and consistent with active erythematous lesions. Chronic inactive lesions are atrophic with postinflammatory pigmentation and scarring observed throughout the dermis. Inactive lesions also display damaged pilosebaceous units and have little or no inflammatory infiltrate.

Direct immunofluorescence on skin tissue from lesions that have been active for several months will be positive in about 90 % of patients. There is a granular deposition of immunoglobulin and complement at the dermoepidermal junction. Skin biopsy should always be done on well-established, active lesions.

Diagnosis

Taking a complete medical history and doing a physical examination are a fundamental first step in establishing the diagnosis of DLE (Trozak et al. 2006). The former should include a smoking history, excessive UV exposure, drug history, family history of a similar disease, and a history of exposure to estrogen-containing contraceptives, among other things. The patient should give a detailed description of the initial occurrence and evolution of the skin lesions. After

taking the history, the lesions should be examined, focusing on recognizing the typical clinical features of DLE. A biopsy is then taken in order to confirm the diagnosis. Serological tests should also be done to rule out or detect progression to SLE. The presence of antibodies such as Antinuclear Antibodies (ANAs) in high titer and/or other multi-organ system signs and symptoms are highly suggestive of lesions being a result of SLE rather than DLE. Full blood count (FBC), erythrocyte sedimentation rate (ESR), and kidney function tests should also be part of the initial work-up to exclude any systemic involvement associated with SLE. Microscopy and culture of lesion scrapings may be necessary to rule out bacterial and fungal infections.

Differential Diagnosis

Some of the main differential diagnoses for DLE include SLE, subacute cutaneous lupus erythematosus (SCLE), plaque psoriasis, rosacea, polymorphous light eruption (PMLE), actinic keratosis, and lichen planopilaris (Weber and Fritsch 2005).

SLE presents with a characteristic malar rash and affects multiple organs. Lab tests show high titers of ANA, anti-dsDNA antibodies, and anti-RNP antibodies. SCLE lesions have typical erythematous crusted margins that heal without scarring and usually spare the face, mainly affecting the upper torso, neck, and arms. Biopsy shows minimal or absent basement membrane thickening. Psoriatic lesions are papules and plaques that have a characteristic silvery white scale and are mostly seen on the scalp and extensor surfaces (knees, elbows) of the body. Psoriatic nail pitting is also a common finding. Skin biopsy findings include intra-epidermal spongiform pustules and neutrophilic microabscesses within the stratum corneum.

Rosacea is characterized by erythema and chronic flushing with other findings such as rhinophyma, rough skin, telangiectasia, and an acneiform eruption. It typically affects convex facial areas (forehead, nose, cheeks, eyelids) in fair skinned people. Skin biopsy reveals sebaceous hyperplasia, edema, telangiectasia, and a nonspecific granulomatous infiltrate. PMLE lesions develop within 24 h of sun exposure, are usually itchy, and express several clinical forms with associated urticaria. Skin biopsy shows edema in the upper dermis. Actinic keratoses are rougher, hyperkeratotic, and usually have no scales. The lesions are smaller, greater in number, and occur in older patients with evidence of chronic actinic damage on facial skin.

Lichen planopilaris is a form of lichen planus that destroys hair follicles (usually of the scalp), replacing them with scar tissue and causing permanent alopecia. Typical lichen planus lesions affecting the skin, nails, and buccal mucosa with characteristic Wickham's striae are usually present. Skin biopsy shows a band-like subepidermal infiltrate of lymphocytes involving the follicles between the infundibulum and the isthmus with sparing of the lower portion.

Laboratory Tests

In addition to a biopsy, there are other tests that can be done to establish a diagnosis of DLE. ANA are positive in a minority of patients (less than 20 %) and their presence correlates with a more active and progressive clinical disease (Callen et al. 1985). Anti-dsDNA antibodies are positive in less than 5 % of patients and may correlate with increased disease severity and a poor prognosis. Anti-Ro/SSA antibodies are positive in 1–3 % of patients.

Erythrocyte sedimentation rate (ESR) may be slightly elevated or normal, while complement levels may be low or normal.

Treatment

General measures: Some general measures are essential in the successful management of DLE. First of all, patients should avoid exposure to sunlight and use a high sun-protection factor (SPF) sunscreen daily. Patients should also avoid exposure to excessive heat, cold, or trauma. Those with a history of smoking should be

strongly encouraged to quit. All of the above-mentioned factors have been found to either induce or exacerbate DLE. In addition, maintaining a healthy diet low in red meat and dairy products and high in omega-3 fatty acids (e.g., salmon, sardines) is thought to decrease inflammation and improve overall disease status. Vitamin A supplements may also enhance the resolution of skin lesions.

Topical treatment: Potent or superpotent topical steroids are the mainstay of DLE therapy and should be applied at least twice a day. Occlusion may improve the efficiency of topical steroids and reduce treatment duration. Prolonged treatment should be avoided to reduce the risk of side effects such as skin atrophy. Topical calcineurin inhibitors like tacrolimus can also be used as second-line topical therapy.

Intralesional steroids: Intralesional triamcinolone acetonide injections can be given if lesions do not respond to topical therapy. The steroid is injected into the lesions at intervals of 4–6 weeks. The minimum possible dose should be used. Side effects include cutaneous atrophy and dyspigmentation.

Systemic treatment: Antimalarials are the first-line agents in the systemic treatment of DLE. The most commonly used preparations are hydroxychloroquine, chloroquine, and mepacrine, with hydroxychloroquine being the first line. However, high doses or prolonged treatment with hydroxychloroquine may cause adverse effects such as retinal toxicity. Patients and physicians should therefore be on the lookout for any potential side effects. Patients should be informed that it may take more than 4 weeks to note any clinical improvement. Mepacrine may be added to either hydroxychloroquine or chloroquine to improve efficacy and prevent some of the major side effects (Von Schmiedeberg et al. 2000).

Thalidomide is one of the most useful therapeutic alternatives to antimalarials, although its use has been limited due to the associated risk of teratogenicity and polyneuropathy. It is very effective and generally well tolerated if administered in low doses.

Systemic corticosteroids may be used to treat DLE, though only for a short period of time (usually less than 3 weeks) due to their long-term side effects. However, they may be added to other regimens in patients with progressive or disseminated disease, or in localized disease that does not respond to other modes of therapy. Systemic corticosteroids can also be used for initial control of severe DLE while antimalarial therapy is being initiated.

Immunosuppressive agents such as cyclosporine, methotrexate, azathioprine, and mycophenolate mofetil have been employed as steroid-sparing agents in the management of refractory DLE. Several studies have found these agents to be very effective but close monitoring is essential due to potentially severe side effects.

Some additional treatments, including the use of acitretin, efalizumab, or cryotherapy, have been found beneficial in the management of DLE.

Prognosis

The prognosis for patients with DLE is generally favorable. Nevertheless, early diagnosis and treatment are crucial to prevent the various poor outcomes of the disease. Patients who progress to SLE have a much poorer prognosis. In addition, patients with generalized DLE have a poorer prognosis than those with localized DLE., Patients with abnormal laboratory tests are also likely to have a poor outcome of disease (Millard and Rowell 1979).

Definition

Endothelial cells and inflammation: Endothelial cells line the lumen of blood and lymphatic vessels and form the interface between the vasculature and organs of the body. Endothelial activation encompasses a range of endothelial responses to inflammatory signals including changes in thromboresistance, altered vasomotor tone, and loss of barrier function. When activated, the endothelium quickly facilitates cellular trafficking. Leukocyte activation and transmigration is crucial for normal innate and adaptive immunity. The term endothelial dysfunction may be applied to states in which the endothelial cell phenotype poses a net liability to the host. The endothelial response to injury can result in vasoconstriction, vasodilatation, vascular leakage, and inflammation. Endothelial activation can transform the internal vascular surface from a nonadhesive barrier into one that recruits leukocytes, is procoagulant, and furthers the inflammatory process.

Introduction

Endothelial cells line all blood and lymphatic vessels and form the interface between the vasculature and all organs of the body. Far from inert, the endothelium forms a dynamic interface which regulates vascular tone and cellular and nutrient trafficking. It is responsible for maintaining the appropriate balance of procoagulant and anticoagulant activity. The endothelium interacts with circulating blood cells in a highly regulated manner and communicates with circulating cells based on cues received from the local environment.

Classically endothelial activation referred to the observation that endothelial cells demonstrated increased leukocyte adhesion in response to inflammatory mediators such as cytokines. The term *endothelial activation* now encompasses a range of endothelial responses to inflammatory signals. These reactions encompass a broad spectrum, including changes in thromboresistance, altered vasomotor tone, and loss of barrier function. The process of endothelial activation, inflammatory cell adhesion, and transendothelial migration requires a tightly regulated series of changes on the part of both inflammatory and endothelial cells. These changes include

morphologic cytoskeletal remodeling to optimize inflammatory cell rolling and firm adhesion.

The endothelium is critical to maintaining vascular homeostasis. Since the endothelium provides the barrier between the vasculature and each organ, endothelial dysfunction can result in deleterious effects. It is important to recognize that physiologic activation of the endothelium might be appropriate in some circumstances of cellular injury (toxins, hypoxia, laceration), in order to promote wound healing. In contrast, if the endothelial cell response is overwhelming, out of proportion to the injury, or if the stressor is severe, the endothelial response may exacerbate the injury and prove detrimental to the host. The term *endothelial dysfunction* may be applied to states in which the endothelial cell phenotype poses a net liability to the host. The endothelial response to injury can result in vasoconstriction, vasodilatation, vascular leakage, and inflammation. Endothelial activation can transform the internal vascular surface from a nonadhesive barrier into one that recruits leukocytes, is procoagulant, and furthers the inflammatory process.

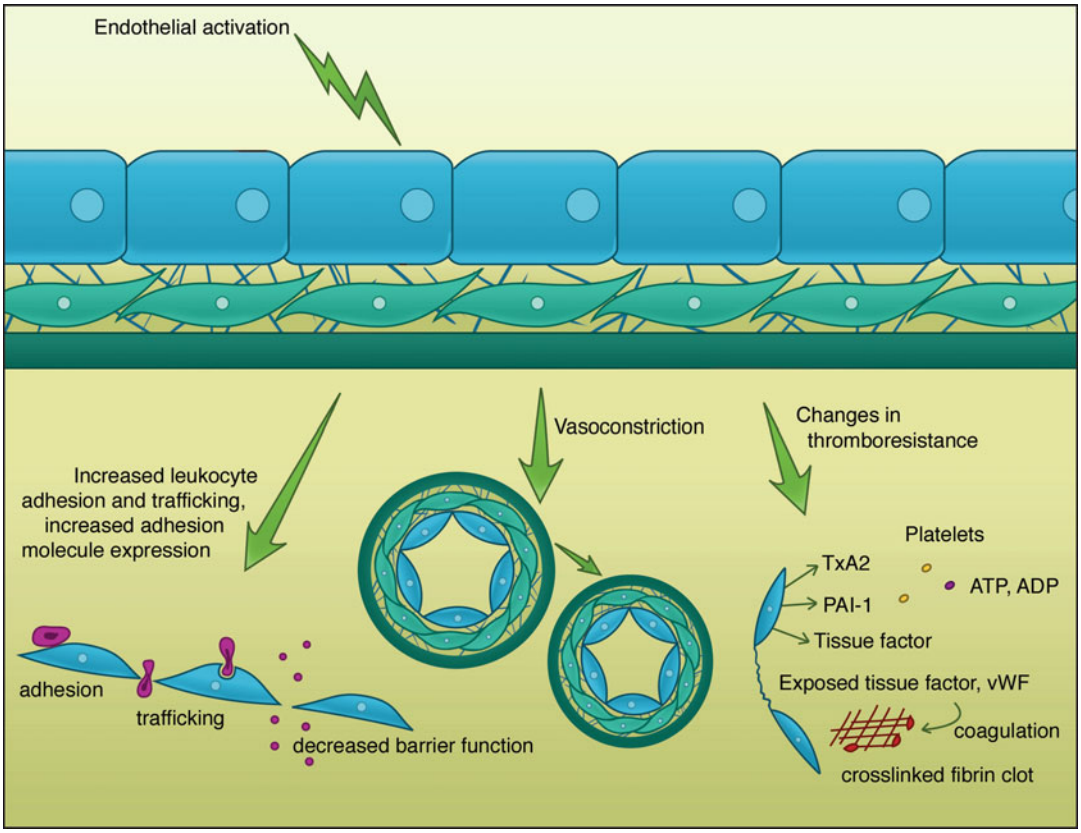
Endothelial activation can result from many stimuli. Examples include cytokine stimulation, toxins, trauma, antibodies, and ischemia. Ischemia, or the mismatch between blood supply and tissue demand, disrupts normal vascular homeostasis. Ischemia results in decreased pH, glucose, and oxygen supply. Further, ischemia hampers the tissue's ability to remove metabolic by-products. Decreased oxygen supply, or hypoxia, is common to many disease states, including pulmonary, cardiac, and peripheral arterial vascular disease. Over the course of evolution, the proximity of endothelial cells to the vascular lumen has resulted in a variety of *adaptive responses* of endothelial cells to disruptions in blood supply and composition. Undoubtedly the endothelial response to hypoxia evolved as a mechanism to prolong cellular survival despite oxygen deprivation. Among the oxygen-responsive transcription factors, early growth response protein-1 (Egr-1), nuclear factor κB (NFκB), and hypoxia-inducible factor-1α (HIF-1α) have proven to be important in mediating endothelial cell responses to hypoxia.

Endothelial activation in autoimmune disease is well described and likely contributes to the risk of early atherosclerosis in this population. Systemic inflammation, autoantibodies, and circulating immune complexes have been identified as important factors. Antiendothelial antibodies represent a heterogeneous group of autoantibodies directed against structural endothelial proteins. They are detectable in varied autoimmune and inflammatory conditions including interstitial lung disease, scleroderma, systemic lupus erythematosus (SLE), and systemic vasculitis (Narshi et al. 2011).

Barrier Function

In different vascular beds, endothelial cells take on characteristics which support the functions of the organ in which they reside. The vascular endothelium modulates the permeability of the blood vessel to solutes and fluid. In the brain, tight junctions between adjacent endothelial cells form the blood–brain barrier, vital to protecting the delicate parenchyma from toxins, metabolites, and pharmacological disturbances. In renal glomeruli, fenestrated endothelium permits filtration, whereas in the heart, non-fenestrated endothelium is present. Under basal conditions, non-fenestrated endothelium allows only restricted diffusion. *Restrictive diffusion* refers to the concept that the endothelium acts as a molecular sieve. Permeability of macromolecules is dependent upon their molecular radii as well as the particular barrier properties of the endothelium. Molecules can pass either by passive diffusion, restricted diffusion, or facilitated transport. If large gaps exist between cells (i.e., barrier function is lost), mass movement and Brownian motion are the forces which move solutes and molecules. The probability of solutes passing through the endothelium is inversely proportional to their Stokes radii. Restricted diffusion is key to maintaining protein gradients, while still allowing small solutes to move passively across the barrier via the paracellular route.

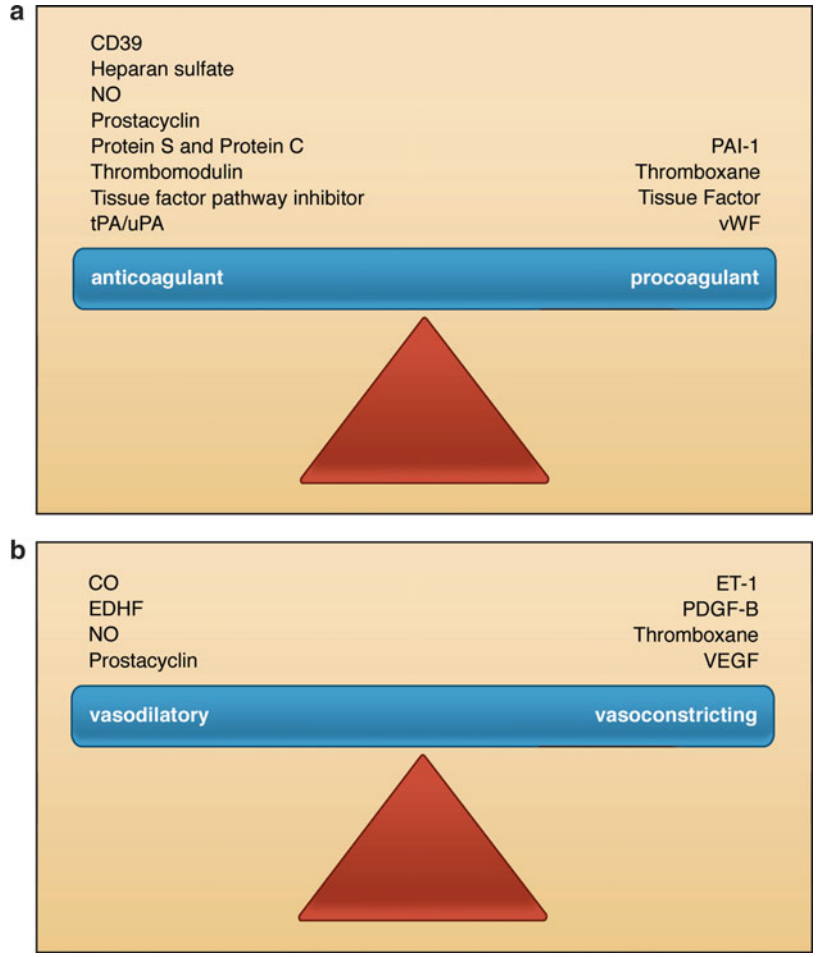
When activated, the endothelium quickly and proactively facilitates cellular trafficking (Fig. 1).



Endothelial Cells and Inflammation, Fig. 1 Endothelial cell activation results in diverse changes in the vascular environment. The endothelial cell response to injury, toxins, and inflammatory mediators includes increased leukocyte trafficking, changes in vasomotor tone, and decreased thromboresistance, to facilitate repair of injured tissue. When the endothelial cell response is disproportionate or poses a detriment to the host, this is termed endothelial dysfunction. The same endothelial cell responses may be considered adaptive or maladaptive, depending on the environmental trigger

Inflammatory mediators including thrombin, bradykinin, histamine, vascular endothelial growth factor (VEGF), interleukin (IL)-1, and tumor necrosis factor (TNF) disrupt cell-cell adhesion, causing intercellular gaps and thereby allowing unrestricted diffusion of solutes. Similarly, after exposure to hypoxia, activated endothelial cells retract, causing gaps between cells. This heralds the loss of endothelial barrier function and manifests as increased capillary leakage and interstitial edema. Solutes, proteins, and leukocytes may pass through the endothelium as diffusion becomes less restricted.

Interstitial edema as a result of increased capillary permeability after stroke contributes to infarct expansion. In septic shock, loss of barrier function and capillary leakage result in hypotension, decreased organ perfusion, organ dysfunction, and eventual death. Hypoxic stimulation of transcription factors HIF-1 and Egr-1 is known to upregulate VEGF, an inducer of increased vascular permeability (Ten and Pinsky 2002). Hypoxia-induced upregulation of Egr-1 has been shown to be detrimental in the setting of ischemic stress. For example, decreased pulmonary capillary leak and improved survival were noted after pulmonary ischemia/reperfusion in an animal model when Egr-1 was deleted from experimental animals (Yan et al. 2000). An additional consequence of loss of barrier function is exposure of the previously sequestered and highly prothrombotic subendothelial matrix,



Endothelial Cells and Inflammation, Fig. 2 Endothelial cells maintain vascular homeostasis. (**a**) Endothelial cell factors affecting coagulation, fibrinolysis, and platelet aggregation. Under basal conditions, the endothelium promotes an anticoagulant surface in diverse ways. Endothelial activation or injury tips the balance toward fibrin accumulation (*tPA* tissue plasminogen activator, *uPA* urokinase plasminogen activator, *NO* nitric oxide; *PAI-1* plasminogen activator inhibitor-1; *vWF* von Willebrand factor). (**b**) Endothelial cell influence on vasomotor tone. Endothelial cells are necessary for vasodilatory and vasoconstrictor responses (*CO* carbon monoxide, *EDHF* endothelium-derived hyperpolarizing factor, *NO* nitric oxide, *ET-1* endothelin-1, *PDGF-B* platelet-derived growth factor-B, *VEGF* vascular endothelial growth factor)

rich in tissue factor and collagen. Notably, changes in barrier function are often reversible if the initial insult is removed.

Dynamic Regulation of Coagulation, Fibrinolysis, and Platelet Aggregation

Ordinarily, the endothelium is a nonthrombotic surface which maintains blood fluidity and vascular homeostasis. This is especially remarkable when considered in light of the fact that blood exposure to nearly all other surfaces results in coagulation. The endothelium maintains its *anticoagulant surface* under basal conditions in diverse ways (Fig. 2a). The presence of heparan sulfate on the surface of the endothelial cell, which acts as a cofactor for antithrombin III, results in the inactivation of thrombin. *Thrombin*, a serine protease which is activated by factor Xa, converts fibrinogen into *fibrin* and promotes coagulation. The endothelial cell membrane surface also contains thrombomodulin. *Thrombomodulin* alters the action of thrombin, such that thrombin becomes a potent activator of protein C, which has anticoagulant properties (Ten and Pinsky 2002). Activated protein C inhibits clotting by inactivating factors Va and VIIIa. The endothelium can produce tissue and urokinase-type plasminogen activators (tPA and uPA) to promote fibrinolysis by converting plasminogen to *plasmin*, should a thrombus begin to form. Endothelial cells also produce *plasminogen activator inhibitor-1* (PAI-1). Since PAI-1 is the major regulator of tPA and uPA, a dynamic balance is struck by

the endothelium, with net fibrinolytic activity dependent upon the relative activity of these factors.

Endothelial cell release of nitric oxide (NO) inhibits platelet activation and aggregation. Endothelial cells also produce eicosanoids, lipidic biomediators including *prostaglandins* and *thromboxane*. Prostacyclin (prostaglandin I_2 or PGI_2) prevents platelet activation and is a potent vasodilator. PGI_2 and thromboxane (TXA_2) act as physiologic antagonists. TxA_2, also produced by the endothelium, activates platelet aggregation and acts as a vasoconstrictor. The balance of TXA_2 and PGI_2 effectively modulates platelet aggregation. CD39 present on the surface of endothelial cells degrades ATP and ADP, both platelet agonists, thereby attenuating platelet activation.

Activation of the endothelium tips the homeostatic balance of the cellular phenotype toward a procoagulant state (Figs. 1 and 2a). The redundancy of multiple pathways leading to the same effect highlights the importance of the role of the endothelium in orchestrating a response to cellular damage. Tipping the balance in favor of procoagulability occurs in several ways. For example, activation of the endothelium by exposure to hypoxia results in the reduction of thrombomodulin levels at the endothelial surface. As a result, a procoagulant environment is created. *Tissue factor* is a transmembrane protein which under circumstances of vascular homeostasis is not expressed on endothelial cells. Instead, tissue factor is expressed on cells in the subendothelial layers of the vasculature. Injury to the blood vessel results in endothelial denudation and exposure of the blood to tissue factor. This is a potent stimulus of the extrinsic coagulation pathway. IL-1 and TNF stimulate endothelial cells to secrete tissue factor. Exposure of subendothelial tissue factor after endothelial injury is an additional factor which promotes a local coagulable environment. Mononuclear phagocytes recruited to the vessel wall during hypoxia are a source of procoagulant tissue factor (Karimova and Pinsky 2001). Further, hypoxia induces the transcription factor Egr-1, leading to increased tissue factor gene expression in the vessel wall.

The importance of the interaction between mononuclear cells and the endothelium is also apparent when examining the suppression of the fibrinolytic axis which occurs after endothelial cell activation. *Plasminogen activator inhibitor-1* (PAI-1) is responsible for the suppression of the conversion of plasminogen to plasmin. As a consequence, increased PAI-1 expression promotes thrombus accumulation. Hypoxia has been shown to increase PAI-1 transcription and mRNA stability (Karimova and Pinsky 2001). Transcription factors early growth response gene-1 (Egr-1), hypoxia-inducible factor-1α (HIF-1α), and CCAAT/enhancer binding protein alpha (C/EBP alpha) are quickly activated in hypoxia and are responsible for transcription and expression of PAI-1 (Liao et al. 2007). Therefore, via PAI-1, hypoxia promotes thrombus accumulation by reducing its dissolution. Mononuclear cells are the predominant source of PAI-1 expression under hypoxic conditions. Hypoxia also inhibits plasminogen activator gene (tPA and uPA) expression, promoting fibrin accumulation (Pinsky et al. 1998).

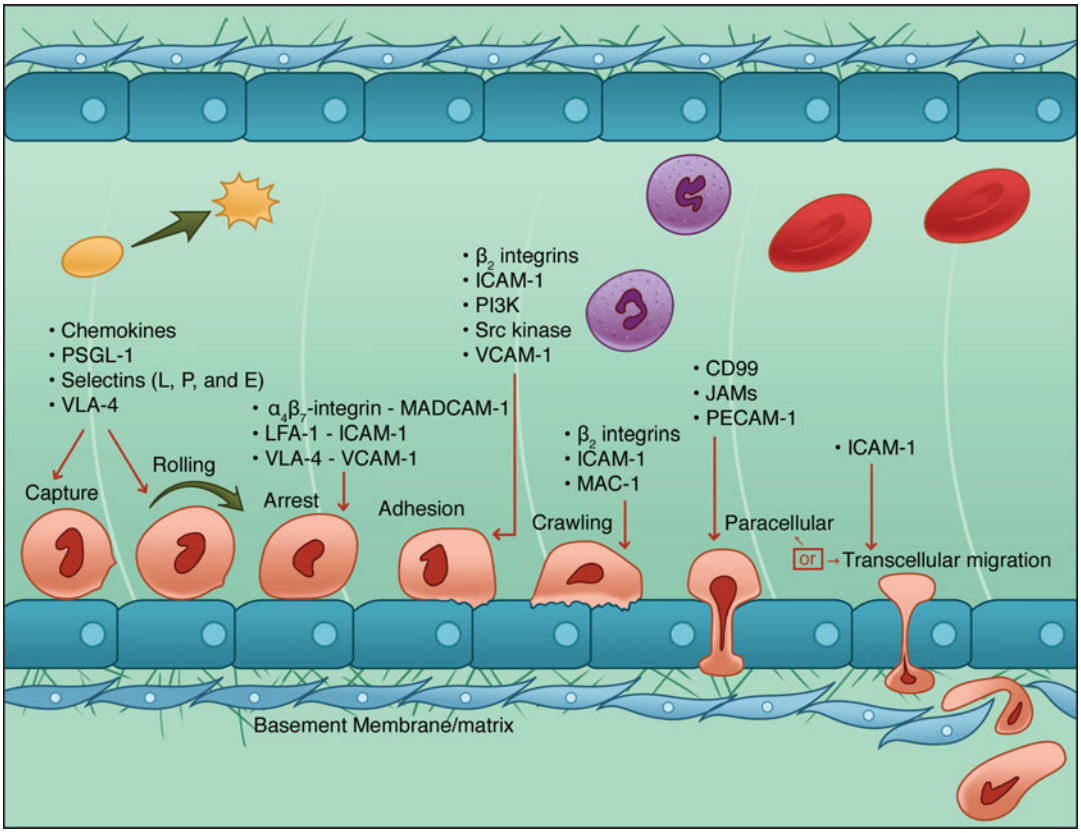
Activation of endothelial cells also drives the exocytosis of Weibel-Palade bodies (Pinsky et al. 1996). Endothelial cells contain *Weibel-Palade bodies*, intracellular organelles which store proteins including P-selectin, a leukocyte adhesion molecule, and procoagulant von Willebrand factor (vWF). Surface-immobilized vWF promotes platelet accumulation and thrombosis, by binding platelet glycoprotein receptors GP1bα and GPIIb/IIIa. Platelets home to sights of vascular injury, promoting thrombin generation and amplifying further platelet recruitment. Early in the course of systemic sclerosis, elevated vWF levels have been noted, representative of the endothelial activation and injury which occurs in this disease. In another illustration of the role of vWF, reperfusion injury is associated with increased platelet accumulation and thrombosis, in part as a consequence of precipitous decline in nitric oxide levels (Pinsky et al. 1994). This is in part due to the inhibitory effect of NO on the release of vWF from Weibel-Palade bodies under normoxic conditions (Matsushita et al. 2003).

Proinflammatory Cytokines

Cytokines are protein molecules secreted from numerous cell types, including macrophages and endothelial cells, and function to communicate signals from one cell to the next. Cytokines cause the quiescent endothelium to become activated and affect barrier function. One major group of cytokines is composed of a class of molecules, *interleukins*. Interleukin-1 (IL-1) was the first interleukin to be described, and other cytokines have since been identified that belong to the IL-1 family (Sims and Smith 2010). IL-1 is a particularly relevant target in autoimmune and chronic inflammatory diseases. It has been shown that T helper 17 cells require IL-1 signaling in order to differentiate from naïve T cells. The larger IL-1 family is composed of 11 molecules. These are IL-1α, IL-1β, IL-1Ra, IL-18, IL-33, and IL-1 F5-IL1F10. Expression levels and modes of activity differ between these highly similar interleukins. For example, IL-1β is produced by monocytes and macrophages and is able to circulate freely, whereas IL-1α is produced by a number of cells, including macrophages and endothelial cells, and is bound to the plasma membrane and tends to act locally. The two are also functionally different. For example, IL-1α is able to prime T cells during contact hypersensitivity, whereas IL-1β is involved in cell proliferation, differentiation, and apoptosis. IL-1Ra, on the other hand, can act to block the actions of IL-1α and IL-1β by binding their receptor, IL-1R1. This is an intriguing example of two countervailing forces, IL-1 and IL-1Ra, the net balance of which can either promote or inhibit inflammation. Importantly, IL-1 also influences coagulation. IL-1 induces coagulation and fibrin deposition. IL-1 induces the procoagulant cofactor tissue factor, while concomitantly blocking the protein C anticoagulant pathway and reducing thrombin-mediated protein C activation (Nawroth et al. 1986). IL-1 has also been shown (along with another cytokine, interferon-gamma or IFN-γ) to increase vascular permeability (Martin et al. 1988), thus demonstrating the integrative and critical role of cytokines for both immunologic activation and vascular endothelial function.

A subgroup of cytokines, chemotactic cytokines or chemokines, can influence the movement of leukocytes during inflammation (Fig. 3). After the innate immune response is provoked, chemokines signal the next step in progression of the response, promoting infiltration of inflammatory cells. Chemokines are classified into four families based on structural and functional differences. Of these four families, the largest is composed of the 27 identified *CC chemokines*, named for their common sequence of two adjacent cysteine residues near the amino terminus. Monocyte chemoattractant protein-1 (MCP-1) can recruit monocytes, dendritic cells, memory T cells, and basophils (Charo and Ransohoff 2006). This family of CC chemokines also includes macrophage inflammatory protein-1 (MIP-1) and RANTES (regulated upon activation, normal T cell expressed and secreted, otherwise known as CCL-5). *CXC chemokines* comprise another family of chemokines, named for an amino acid residue between the CC residue found in CC chemokines. This family of chemokines includes interleukin-8, or CXCL8, which is released by macrophages and endothelial cells and which can bind the receptors CXCR1 and CXCR2 to recruit polymorphonuclear cells as part of the innate immune response. A subfamily within the CXC chemokines is the *ELR + CXC chemokines*. These contain an ELR residue sequence (glutamate-leucine-arginine) near the N terminus and participate in wound healing and angiogenesis. Monocyte chemoattraction by chemokines involves a group of related chemokines, CCL2, 7, 8, and 13, as well as the ELR + CXC chemokines.

Other cytokines, such as interleukin-2 (IL-2), interferons, and tumor necrosis factor (TNF), have been studied as promoters of immune responses and found to play a role in autoimmune disease progression (O'Shea et al. 2002). Naïve T cells, after stimulation by an antigen, produce IL-2, which promotes clonal expansion as well as the production of other cytokines, including TNF. Within this clonal expansion, naïve T cells differentiate into one of two types. One group develops into TH1 cells under



Endothelial Cells and Inflammation, Fig. 3 Leukocyte adhesion. This cross section of a blood vessel shows the migration of a leukocyte from the capture phase along the endothelium to its complete migration past the basement membrane and smooth muscle layer. With cellular damage, activation of the endothelium, and the subsequent release of cytokines/chemokines such as IL-1β and TNF, leukocytes become activated. The activated endothelium possesses procoagulant properties, as shown by the activation of platelets. The increased expression of adhesion molecules (e.g., increased integrin-mediated binding) leads to arrest and firm adhesion of activated leukocytes. This transit across the endothelial barrier requires the involvement of molecules such as junctional adhesion molecules (e.g., JAM-A, B, C, ESAM). *PSGL-1* P-selectin glycoprotein ligand 1, *VLA-4* very late antigen 4, *LFA-1* lymphocyte function-associated antigen 1, *ICAM-1* intercellular adhesion molecule 1, *VCAM-1* vascular cell adhesion molecule 1, *MADCAM-1* mucosal vascular addressin cell adhesion molecule 1, *PI3K* phosphoinositide 3 kinase, *MAC-1* macrophage-1 antigen, *PECAM-1* platelet endothelial cell adhesion molecule, *CD99* cluster of differentiation 99 (MIC2), *JAM* junctional adhesion molecule

the control of IL-12, and the other group, TH2, under the control of IL-4. The TH1 subtype is most associated in the development of autoimmunity. For example, TH1 cells release interferon-γ (IFN-γ), resulting in elevated tissue levels of IL-4, which also modulates the TH1/TH2 balance and acts as an immune regulator, as do the cytokines IL-10 and transforming growth factor β (TGF-β). Blockade of these cytokines has resulted in increases in inflammation and autoimmunity. Cytokines also have broad effects on the endothelium. For example, TNF has been shown to increase vascular permeability in conjunction with VEGF (vascular endothelial growth factor) (Clauss et al. 2001). TNF acts in conjunction with IFN-γ to deactivate $\alpha_V\beta_3$ integrin, which is necessary for survival in angiogenic endothelial cells (Lejeune 2002).

Treatments have been developed which utilize cytokines as modulators of inflammatory diseases. For example, TNF-α, a cytokine secreted primarily from activated macrophages,

is a potent proinflammatory signal. It can stimulate the production of ELR + CXC chemokines and induces leukocyte adhesion to vascular endothelial cells. Neutralizing antibodies against TNF-α, or TNF inhibitors, are used to treat inflammatory diseases (Charo and Ransohoff 2006). Etanercept is a TNF inhibitor that is used to treat rheumatoid arthritis and is made as a fusion protein that links TNF receptor 2 to human IgG1. The soluble TNF2 receptor binds TNF competitively, and the IgG fusion element increases the serum half-life of the drug relative to other soluble receptors. Adalimumab, a human monoclonal antibody against TNF-α, is used to treat rheumatoid arthritis and Crohn's disease. Infliximab is a mouse-human chimeric antibody against TNF-α. Newer reports have revealed that the traditional view of proinflammatory cytokines (IFN-γ, IL-2, TNF) as inciters of autoimmunity and regulatory cytokines (IL-4 as protectors against autoimmunity) is too simplistic. Proinflammatory cytokines may demonstrate immunosuppressive roles; thus the idea has been introduced that the particular cytokine makeup, in concert, determines the progression of the disease state.

Cell Adhesion

The process of inflammatory cell adhesion to the vascular endothelium and eventual transendothelial migration (also termed extravasation) requires a tightly regulated series of changes on the part of both inflammatory cells and the endothelium. These changes include morphologic cytoskeletal remodeling to optimize adhesion (from rolling adhesion to firm adhesion), molecular signaling pathway activation, and redistribution and increased expression of adhesion molecules and their receptors to facilitate movement across the endothelium (Fig. 3). Movement across the endothelium can occur either between endothelial cells in a process called paracellular migration or through cells via the transcellular route. The specific process of extravasation varies between inflammatory disease states.

Activation of the endothelium leads to the upregulation of adhesion molecules that assist in inflammatory cell adhesion, such as E-selectin, ICAM-1, and VCAM-1. Endothelial cell secretion of chemokines CCL2, CCL5, CXCL10, and CX3CL1 attracts monocytes, dendritic cells (DCs), and T cells. Morphologic changes to the endothelial plasmalemma, such as the clustering of ICAM-1 and VCAM-1, as well as the directional expression of their respective receptors on the leading edge of inflammatory cells result in the generation of a molecular gradient that directs movement toward the endothelium (Nourshargh et al. 2010).

Integrins are highly involved in leukocyte recruitment, and the binding of integrins to their respective endothelial ligands is important for firm adhesion. Integrins comprise a large adhesion receptor family, and they are expressed as heterodimers with alpha and beta subunits, such as VLA-4 ($\alpha_4\beta_1$), LFA-1 ($\alpha_L\beta_2$), and Mac-1 ($\alpha_M\beta_2$). Leukocyte integrins are expressed in inactive states and undergo conformational changes upon leukocyte activation. Once adhesion is established on the vascular surface, lymphocytes begin to spread and crawl over endothelial cells through a series of morphologic changes involving cytoskeletal remodeling as well as clustering of integrins and adhesion molecules (Shulman et al. 2009). When engaged, integrins can also mediate signaling from the endothelial cell to the leukocyte in a process known as "outside-in signaling."

The upregulation of *junctional adhesion molecules* (JAMs) allows infiltrating inflammatory cells to pass across the tight junctions formed by the endothelial barrier. JAMs include a set of three closely related CTX proteins, JAM-A, JAM-B, and JAM-C, and also four other family members, ESAM, CAR, JAM-4, and JAM-L (Bradfield, ATVB 2007). The integrin LFA-1 ($\alpha_L\beta_2$) has been shown to bind JAM-A to mediate transmigration. Mice deficient in JAM-A have shown reduced leukocyte accumulation at sites of injury across a number of different injury models, including peritonitis, myocardial ischemia/reperfusion, hepatic ischemia/reperfusion,

and atherosclerotic vascular injury. The roles of JAM-B and JAM-C have also been explored; these JAMs relate with each other in multimeric interactions. JAM-B on endothelial cells binds the integrin VLA-4 and requires JAM-C expression on the infiltrating leukocyte.

Atherosclerosis is an example of a chronic inflammatory disease that illustrates various mechanisms of cellular adhesion and infiltration. In atherosclerosis, high circulating levels of low-density lipoproteins (LDL) carrying cholesterol trigger fatty plaque deposition. LDL particles accumulate subendothelially in the intima. Oxidative factors, such as reactive oxygen species, myeloperoxidases, and lipoxygenases, are released in the course of atherosclerotic progression. These factors lead to the formation of a varied group of modified LDL particles called oxidized LDL (oxLDL). The oxidation byproducts of these lipids are strong activating signals for endothelial cells and macrophages. As a result, there is an increase of inflammatory cell recruitment via an increase in adhesion molecules and cytokine release from the activated endothelium and macrophages. This type of chronic activation may be particularly important in diseases such as rheumatoid arthritis or systemic lupus erythematosus (SLE), which are associated with increased risk of atherosclerosis.

Inflammatory cells take up cholesterol through *pattern-recognition receptors* (PRR). Signaling through PRR results in upregulation of integrins (Hansson and Hermansson 2011) (Nourshargh et al. 2010). Intracellular PRRs also exist, and these are capable of aggregating into *inflammasomes*, aggregations of proteins that promote inflammatory processes such as the release of proinflammatory cytokines IL-1β and IL-18. Macrophages take up oxLDL via scavenger receptors (CD36, SRA-1, SRA-2, SR-B1, LOX-1, PSOX, MARCO), and their accrual of cholesterol then promotes the progression macrophages into foam cells that form in the core of the atherosclerotic lesion. *Toll-like receptors* (TLR) on macrophages also bind oxLDL and thus initiate signaling pathways that further promote atherosclerosis.

Leukocyte Activation

Leukocyte activation and transmigration is crucial for normal innate and adaptive immunity. During tissue injury or infection, a chemotactic gradient forms, recruiting inflammatory cells to the site of injury. An example of this is the production of monocyte chemotactic protein-1 (MCP-1), a chemoattractant protein. MCP-1 attracts monocytes, leukocytes, and dendritic cells to an injured tissue. Release of tumor necrosis factor-alpha (TNF-α) and IL-1, as well as complement activation, stimulates inflammatory cells.

Hypoxia is known to induce the endothelium to release IL-8, which plays an important role in polymorphonuclear leukocyte recruitment and activation (Oz et al. 1995).

Once at the site of injury, leukocytes first undergo rolling adhesion, mediated primarily by selectin expression on the surface of activated endothelial cells (Fig. 3). Endothelial selectins then engage their cognate ligands on the leukocyte surface, such as P-selectin glycoprotein ligand-1 (PSGL-1). This results in shape change, both of endothelial cells and leukocytes. These morphologic changes promote subsequent firm adhesion. In endothelial cells, engagement of adhesion receptors prompts the formation of docking structures around leukocytes. Docking structure formation at the apical surface of endothelial cells requires cytoskeletal scaffold rearrangement. These alterations in endothelial cell morphology complement the corresponding changes in leukocytes. As the leukocyte begins rolling along the endothelial cell surface, becoming activated, the cell transforms from a free-flowing round cell into a polarized cell with a leading edge, with adhesion molecules such as integrins clustered to facilitate transmigration. Activated endothelial cells secrete IL-1, which in turn increases expression of intercellular adhesion molecule-1 (ICAM-1), an adhesion molecule found on the surface of endothelial cells and leukocytes. This results in auto-amplification of adhesion receptor expression, leukocyte recruitment, and inflammation. Once activated, leukocytes adhere to vascular wall and

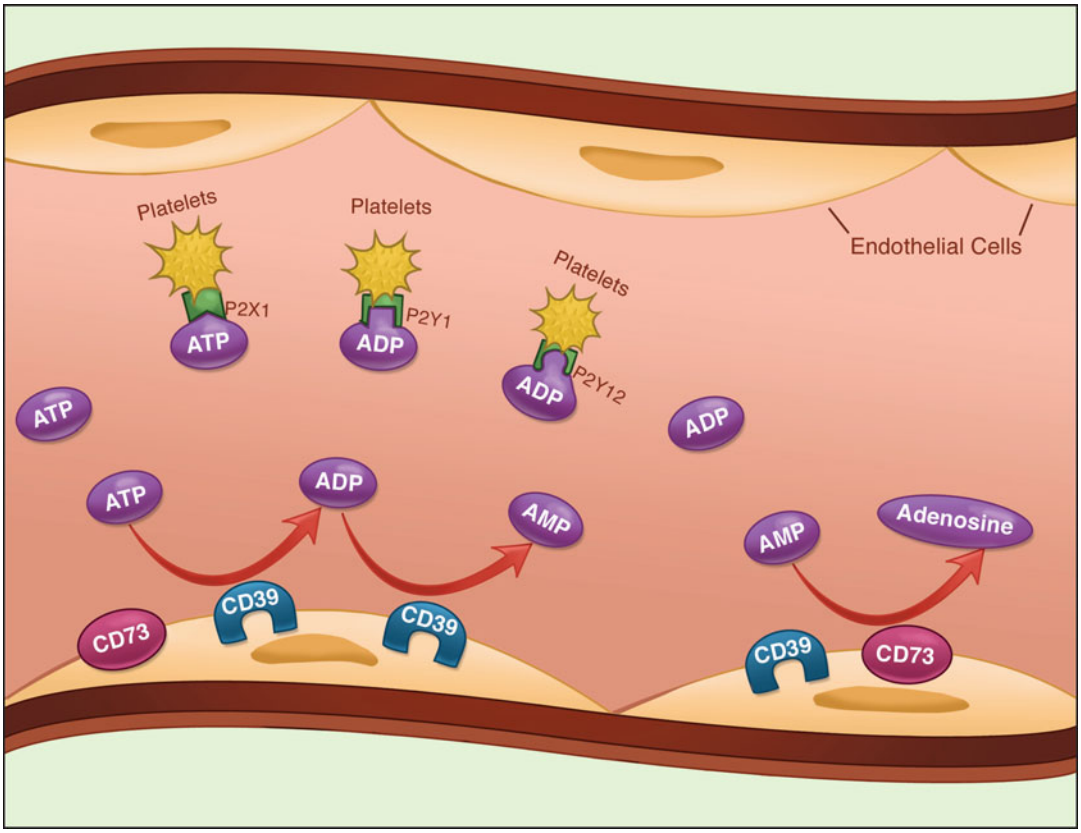
transmigrate. In the tissue, polymorphonuclear leukocytes and monocytes release cytotoxic enzymes, acids, and reactive oxygen species (Karimova and Pinsky 2001).

Reparative processes after infection, burns, or trauma depend on these events to promote removal or repair of damaged tissue. Thus, inflammation initiated by endothelial cells serves a physiologic purpose. It has been shown that distinct waves of inflammatory cell infiltration after an insult play important and differing roles in tissue repair. For example, in an animal model it was shown that after myocardial infarction, initial infiltration of a monocyte population which phenotypically exhibits phagocytic, proteolytic, and inflammatory functions occurs. This serves to remove necrotic tissue. This is followed by a monocyte population which characteristically displays attenuated inflammatory properties and promotes healing via myofibroblast accumulation and collagen deposition (Nahrendorf et al. 2007). This implies that the limitation of inflammatory cell infiltration after injury might stunt or slow wound healing.

Inflammation can become dysregulated due to positive feedback loops which result from cytokine release, adhesion molecule expression, cellular infiltration, and release of cytotoxic substances. If the insult is severe or prolonged, dysregulation of the inflammatory cascade may result in further damage to the parenchyma and endothelial cells themselves. Injured endothelial cells are themselves strong activators of the complement cascade, further leading to inflammation and injury. Some lupus patients have inherited deficiencies of C2, C4, or C1q. It has been hypothesized that this deficiency hampers the removal of circulating immune complexes and results in increased immune complex deposition, such as that which occurs in certain forms of lupus nephritis. Animal models have demonstrated that C3 deficiency protected from stroke, with a decreased brain infarct volume when compared with controls. C3-deficient mice manifested decreased granulocyte infiltration and reduced oxidative stress, highlighting the importance of C3 in brain inflammation (Mocco et al. 2006).

Dysregulated inflammation is common to many pathological conditions, from autoimmune disease to sepsis. In systemic lupus erythematosus (SLE), deposition of immune complex and complement activation are hallmarks of end-organ damage. Complement activation has been linked to the excess atherosclerosis seen in lupus, by stimulating endothelial cells and enhancing recruitment of leukocytes to the arterial wall (Narshi et al. 2011). Immune complexes stimulate endothelial cells to express VCAM-1, promoting monocyte infiltration (Narshi et al. 2011). In SLE-associated vasculitis, autoantibodies induce a proinflammatory and proadhesive endothelial cell phenotype through activation of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) transcription factor pathway (Narshi et al. 2011). Antiendothelial cell antibodies also induce upregulation of cell adhesion molecules such as E-selectin, ICAM-1, and VCAM-1 and enhance secretion of chemokines including MCP-1 and cytokines such as IL-1, IL-6, and IL-8 (Narshi et al. 2011). Antiendothelial antibodies are also thought to mediate endothelial cell apoptosis (Narshi et al. 2011).

Systemic sclerosis (SSc) is initiated by endothelial injury, and major features of this disease are the presence of mononuclear cell infiltrates and progressive structural defects in microvessels (Trojanowska 2010). SSc patients have been found to have a decrease in the expression of molecules involved in regulating endothelial cell-cell interactions, VE-cadherin and PECAM-1 (Trojanowska 2010). Decreased expression of these molecules may facilitate mononuclear cell infiltration in this disease. Friend leukemia virus integration 1 (Fli1) belongs to the Ets family of transcription factors and has an essential role in the regulation of genes encoding components of the extracellular matrix, including type I collagen. Importantly, Fli1 knockout mice show abnormal skin vasculature with many characteristics reminiscent of SSc, including a considerable decrease in the expression of molecules involved in endothelial cell-cell adhesion, VE-cadherin and PECAM1, as well as alterations in endothelial cell-pericyte



Endothelial Cells and Inflammation, Fig. 4 Ectonucleotidases limit inflammation CD39 phosphohydrolyzes extracellular ATP and ADP to AMP, and CD73 is responsible for the conversion of AMP to adenosine. ATP and ADP are released from activated platelets and from endothelial cells and other damaged cells following vascular injury. ATP binds the platelet receptor P2X1, and ADP binds the platelet receptors P2Y1and P2Y12 resulting in prothrombotic and proinflammatory effects. When adenosine binds its A3 and A2A receptors, anti-inflammatory and vasodilatory effects occur

interactions, including those involving the Tie 2 receptor (Trojanowska 2010).

In sepsis, systemic endothelial activation results in capillary leakage, hypotension, microvascular thrombosis, and tissue hypoxia. When the inflammatory response becomes dysregulated systemically, this can lead to multiorgan dysfunction and death. Augmentation of the inflammatory response in response to infection is necessary for host defense, and circulating levels of soluble adhesion molecules such as selectins, ICAM-1, and VCAM-1 are expected to increase in response to endothelial activation in infection. However, markedly elevated levels are present in those with sepsis and positively correlate with the severity of illness (Reinhart et al. 2002). The levels of these molecules have been found to be highest when severe sepsis was associated with a low probability of survival.

Of interest, self-regulation of leukocyte trafficking, moderated by leukocyte ectoenzymatic activity, may play an important role in limiting detrimental inflammation. Ectoenzymes are membrane proteins which have catalytically active sites in the extracellular environment. They are classified according to their enzymatic activities. Nucleotidases such as CD39 and CD73 are ectoenzymes involved in the extracellular metabolism of purine nucleotides including ATP (Fig. 4). They regulate inflammatory cell trafficking by modulating the levels of ATP, ADP, AMP, and adenosine at sites of

inflammation. ATP is released from dying cells at sites of injury. Binding of ATP and ADP to purinergic receptors results in prothrombotic and proinflammatory effects, while stimulation of certain adenosine receptors results in vasodilatory and anti-inflammatory effects.

In a murine model of cerebral ischemia, CD39 on monocytes and neutrophils was shown to regulate inflammatory cell sequestration into ischemic cerebral tissue, by catabolizing nucleotides released by injured cells (Hyman et al. 2009). It was shown that by this mechanism, inflammatory cells could self-regulate chemotaxis, adhesion, and transmigration. The importance of this is highlighted by the observation that cerebral infarct volumes were significantly larger in animals that did not express CD39. Cerebral infarct volumes were also shown to be larger in animals not expressing CD73, underscoring a critical role for CD73 as a modulator of brain inflammation (Petrovic-Djergovic et al. 2012). CD39 was shown to be the dominant Langerhans cell-associated ecto-NTPDase and had diverging roles in regulating inflammatory responses to environmental insults. CD39 deficiency resulted in attenuated T cell-mediated (allergic) contact hypersensitivity. In contrast, CD39-deficient animals exposed to irritant chemicals triggered rapid ATP and ADP release and demonstrated exacerbated skin inflammation in this model of irritant contact dermatitis (Mizumoto et al. 2002).

Vasomotor Tone

The endothelium plays a key role in regulating vascular tone and release of vasoactive agents. The endothelium is necessary for agents such as acetylcholine or bradykinin to cause vasorelaxation (Karimova and Pinsky 2001). Much like the endothelium maintains a nonthrombogenic surface which facilitates normal blood flow, under basal conditions, the vasoconstricting and vasodilating properties of the endothelium are in a dynamic balance (Fig. 2a). Because of the proximity of the endothelium to the underlying vascular smooth muscle, release of vasoactive signals from endothelium results in robust changes in vascular tone. Vasodilating substances released from the endothelium act in a paracrine manner. These include nitric oxide (NO), carbon monoxide (CO), prostacyclin, and endothelium-derived hyperpolarizing factor.

NO is a gaseous molecule with a short half-life in the blood stream, which serves as a key paracrine regulator of vasorelaxation. NO is synthesized from its precursor l -arginine by NO synthases. This reaction is dependent upon the presence of molecular oxygen. eNOS is the constitutive endothelial isoenzyme which produces NO. NO diffuses from endothelial cells and enters subjacent smooth muscle, where it binds guanylyl cyclase. This results in increased cGMP, which in turn mediates vasorelaxation through a reduction in intracellular calcium. NO also transcriptionally regulates the genes of vasoconstricting molecules, including endothelin-1 (ET-1) and platelet-derived growth factor-B (PDGF-B). As a result, NO both directly and indirectly regulates vasodilatation. During hypoxia, *eNOS* gene expression decreases, leading to decreased NO production by the endothelium (Karimova and Pinsky 2001). In turn, there is a decrease in guanylate cyclase activation and cGMP. In addition, during reoxygenation, NO is quenched by free radicals. This perpetuates the decrease in cGMP which occurred during the hypoxic period. NO-mediated vasodilation is impaired in many disease states, including atherosclerosis, hypertension, and diabetes.

CO is another endogenous gas that participates in vascular homeostasis. CO is produced during the breakdown of heme by the enzyme *heme oxygenase*. Hypoxia results in markedly increased expression of the inducible form of heme oxygenase, heme oxygenase-1. Similarly to NO, CO activates soluble guanylyl cyclase, albeit at a lower potency than does NO, resulting in increased cGMP. CO influences vascular tone and has noteworthy effects on hypoxia-induced transcription factors including Egr-1, as well as platelet aggregation and fibrinolysis (Karimova and Pinsky 2001; Mishra et al. 2006). The available data suggests that NO plays an important role in resting vascular tone, with CO playing

a less critical role under basal conditions. However, under conditions of hypoxia or ischemia/reperfusion, a decline in the bioavailability of NO and induction of heme oxygenase-1 may result in dominance of CO in influencing vasodilation.

Endothelium-dependent hyperpolarizing factor (EDHF) is induced by bradykinin and shear stress and, as its name implies, hyperpolarizes vascular smooth muscle. It is produced by the endothelium and dilates arteries by opening calcium-activated potassium channels. Prostacyclin is also endothelium derived and contributes to tonic coronary vasodilation. Prostacyclin is formed in vessel walls from the metabolism of arachidonic acid via cyclooxygenase.

The most potent vasoconstrictor synthesized by the endothelium is ET-1. Once released, ET-1 binds its receptor ET-A on vascular smooth muscle, increases intracellular calcium, and causes protein kinase C activation and myosin phosphorylation, leading to contraction (Karimova and Pinsky 2001). In contrast to the short-lived effects of vasodilators such as NO, constriction in response to ET-1 is prolonged. Hypoxia induces vasoconstriction and ET-1 production. It appears that under hypoxic conditions, the balance between vasodilating and vasoconstricting substances tips toward vasoconstriction (Figs. 1 and 2b). This occurs rapidly, within hours of acute hypoxia. Of note, NO and ET-1 production are mutually regulated, with NO suppressing ET-1 production. Other hypoxia-induced endothelium-released vasoconstricting substances include platelet-derived growth factor-B (PDGF-B) and vascular endothelial growth factor (VEGF). In diabetes, endothelial dysfunction contributes to increased hypertension and cardiovascular disease, in part due to increased endothelin, reduced prostacyclin activity, and abnormal NO biology (Orasanu and Plutzky 2009). Countering prostacyclin activity, thromboxane released by endothelial cells acts as a vasoconstrictor.

Growth Regulation

Endothelial proliferation is an important mechanism in angiogenesis which can be stimulated by endothelial activation. VEGF serves as a key growth factor in the regulation of ischemic angiogenesis. VEGFR-1 and VEGFR-2 are VEGF receptors expressed. On the endothelium and upregulated during hypoxia (Karimova and Pinsky 2001). Hypoxia-inducible factor-1 (HIF-1) is a transcription factor induced by hypoxia and influences the activation of the *VEGF* gene, among other genes including heme oxygenase-1 and iNOS (Karimova and Pinsky 2001). *VEGF* is also involved in vascular permeability, vasomotor tone, and regulation of fibrinolytic activity in hypoxia. Fibrin accumulates during hypoxia and serves as a matrix for subsequent angiogenesis, critical for restoration of blood flow to ischemic tissue (Karimova and Pinsky 2001). Fibroblast growth factor (FGF) and PDGF are also important growth factors. These growth factors have gained attention as therapeutic targets, both in restoring blood flow to ischemic organs and in limiting pathological angiogenesis in tumors. In systemic sclerosis, inflammatory signals resulting in endothelial activation lead to a rise in PDGF and TGF-β, triggering perivascular fibrosis.

Conclusion

The endothelium performs diverse functions and plays a critical role in maintaining vascular homeostasis. Endothelial cells perform the delicate task of balancing pro- and anticoagulant factors, inciting and tempering inflammation, and regulating cellular and molecular trafficking. In addition, the endothelium dynamically regulates vascular tone. Because of the numerous roles that the endothelium performs, endothelial activation is far reaching in its downstream effects. Endothelial activation impacts not only neighboring cells but the surrounding parenchyma as well. From an evolutionary perspective, these adaptable responses served to counter such varied insults as infection, trauma, and ischemia. On the other hand, endothelial cell activation and alterations in the basal vascular environment are a common denominator in many disease states, including those involved in atherosclerosis and

rheumatological diseases, among others. Looking toward the future, a challenge will be to develop clinical applications which fine-tune endothelial responses to injury. Clinically, targeting strategies which mimic the ideal endothelial response to injury is imperative. Development of approaches which would allow appropriate endothelial activation necessary for healing and host defense, while limiting detrimental, inappropriate activation, could have a vast impact on disease states from systemic sclerosis to atherosclerosis and stroke to sepsis.

Autoimmune diseases; Environmental triggers

Definition

Genetic, epigenetic, hormonal, and other factors, including environmental agents, contribute to the development of autoimmune disease. For the preparation of this entry, we conducted a review of recent studies regarding autoimmunity and environmental exposure using the terms: autoimmune diseases, environmental factors related to smoking, sex hormones, estrogens, infections, and autoimmune triggers.

Autoimmune diseases account for approximately 0.05–5 % of diseases in the general population (Cooper and Stroehla 2003). Incidence rates vary among the autoimmune diseases, with estimates ranging from less than one newly diagnosed case of systemic sclerosis per 100,000 person-years to more than 20 cases of adult-onset rheumatoid arthritis per 100,000 person-years. Prevalence rates range from less than 5 per 100,000 (e.g., chronic active hepatitis, uveitis) to more than 500 per 100,000 (Graves' disease, rheumatoid arthritis, thyroiditis). At least some of these diseases are thought to be related to environmental triggers. Due to the difficulty of determining specific environmental exposures, it is challenging to define a potential role for specific environmental exposures in triggering autoimmune disease. The American College of Rheumatology (ACR) proposed three ways to link a particular environmental exposure to the development of an autoimmune disease, (Miller 2011; Miller et al. 2012):

1. Through epidemiological methods, including "Hill's criteria," i.e., strength of association, consistency, specificity, temporality, biological gradient, plausibility, coherence, experiment, and analogy. These criteria further describe the potential causal link between autoimmune disease and environmental exposure as confident, likely, or unlikely (Miller et al. 2012).
2. By recognition of a new disease – This requires at least four of eight elements including at least three of five primary elements. The three primary elements should include temporal association, lack of likely alternative explanations, and at least one of the following: improvement with removal of the exposure (dechallenge), recurrence with re-exposure (rechallenge), and biologic plausibility (Miller et al. 2012). The remaining (secondary)

elements include prior reports of similar cases (analogy), dose responsiveness, and prior reports of identical cases (specificity). It was further suggested that this will be completed in four stages:
- Proposing the association
- Testing the association
- Defining criteria for the condition
- Refining criteria for the condition

3. Exposure inducing autoimmune disease in individuals – This can be tested by challenge, dechallenge, and rechallenge. If a link is suggested by challenge alone, the causation is described as possible. When a rechallenge is not possible due to the severity of the reaction, causation is considered probable. When suggested by all three (challenge, dechallenge, and rechallenge), causation is considered definite (Miller et al. 2012).

Despite the fact that there are still missing pieces of the puzzle, it is clear that the same agent can induce very different autoimmune disorders, possibly due to different genetic backgrounds, while multiple agents can produce a very similar clinical picture. The reporting of individuals who developed an autoimmune disease after a specific exposure that subsided after removal and reappeared after further exposure has added an insight on the role of many agents. These reports, together with in vitro studies, could further define the cellular players and the possible mechanisms of the suspected environmental agents involved in the induction or perpetuation of the autoimmune response.

Smoking

Cigarette smoke may trigger an autoimmune response by cellular necrosis caused by free radicals, release of pro-inflammatory cytokines, and DNA damage inducing genetic mutations, glycoprotein content inducing activation of lymphocytes, and modulation of hormones (Smyk et al. 2012). Smoking is associated with rheumatoid arthritis (RA), autoimmune thyroiditis, inflammatory bowel disease (IBD), systemic lupus erythematosus (SLE), multiple sclerosis (MS), and primary biliary cirrhosis (PBC) (Kakalacheva and Lünemann 2011; Miller 2011; Smyk et al. 2012; Moroni et al. 2012).

In a study of 241 patients with PBC, an increased odds ratio for the presence of disease was seen among smokers. In another study of 1,032 patients with PBC, similar findings were demonstrated (Smyk et al. 2012). A further association of PBC and smoking was demonstrated by a study of 2,258 patients, finding higher incidence of smokers among PBC patients (Smyk et al. 2012).

The role of smoking in the pathogenesis of multiple sclerosis (MS) was suggested by a meta-analysis of 14 studies (Kakalacheva and Lünemann 2011). Genetically susceptible individuals who smoked had a risk of developing MS that was 2.8 times higher than nonsmokers. The mechanism is unknown.

Irritants in the lung such as cigarette smoke may cause citrullination of lung proteins, triggering an autoimmune response in genetically susceptible individuals. This theory is supported by the association between RA and smoking, the presence of citrullinated proteins in the lung and in the inflamed joints of smokers with newly diagnosed RA, and positive anti-cyclic citrullinated peptide antibodies (anti-CCP) (Klareskog et al. 2011). A review of several studies demonstrated that current or past smoking increases the risk of RA, higher levels of rheumatoid factor, and increased disease severity (Pollard 2012).

In a meta-analysis, smokers have a higher risk of developing SLE compared with former or nonsmokers (Zandman-Goddard et al. 2012). Current, chronic smokers and former smokers are at a higher risk for having elevated titers of dsDNA antibodies, skin involvement, serositis, and neuropsychiatric involvement (Zandman-Goddard et al. 2012).

Hormone Replacement Therapy (HRT) and Sex Hormones

Sex hormones affect the immune system by influencing lymphocyte maturation, activation, synthesis of antibodies and cytokines, and modulating the innate and adaptive immunity components. In addition, sex hormones alter antigen-presenting cell (APC) numbers and

function, and regulation of dendritic cell differentiation (Moroni et al. 2012; Chighizola and Meroni 2012). Estrogens cause the stabilization of auto-reactive B cells via T helper 2 lymphocytes, the release of interleukins (IL), and other cytokines (Moroni et al. 2012; Chighizola and Meroni 2012).

Estrogens can also be found in the environment naturally (phytoestrogens, mycoestrogens), or industrially (xenoestrogens), in metals, plastics, detergents, surfactants, and pesticides (Chighizola and Meroni 2012). The exposure to these materials may directly affect the estrogen receptors or disturb the hormonal balance of the exposed individual (Chighizola and Meroni 2012). Several studies concerning exposure to estrogen have demonstrated effects on the immune system (Chighizola and Meroni 2012). In murine models, neonatal exposure to estrogen may cause impairment in the immune system, especially T cells (Chighizola and Meroni 2012).

Lupus is more frequent in females in the reproductive years, and in murine SLE models, estrogen administration causes an increase in titers of anti-DNA antibodies and worsening of immune complex glomerulonephritis (Moroni et al. 2012). Additional evidence is found in animal experiments showing improvement after oophorectomy and exacerbation following estrogen administration (Chighizola and Meroni 2012; Strickland et al. 2012).

In a murine animal experiment, genetically induced, susceptible lupus mice were treated with estrogen, causing the development of SLE, compared to controls that were not susceptible and had no signs of SLE (Strickland et al. 2012; Peeva and Zouali 2005). Examination of the kidneys of affected mice revealed glomerulonephritis with IgG (Strickland et al. 2012). It should be stated that the influence of estrogen was seen only in the female animals (Strickland et al. 2012).

Men with Klinefelter's syndrome (a condition associated with higher than normal estrogen levels) have an increased incidence of SLE (Chighizola and Meroni 2012).

One example of estrogen therapy associated with the development of autoimmune disease in humans was described in a man who underwent sex reassignment and later developed lupus erythematosus tumidus (Zandman-Goddard et al. 2007).

The effect of estrogen therapy in patients with PBC remains controversial. In a large, multicenter study of 1,032 patients with PBC, an association between hormone replacement therapy (HRT) and PBC was noted. However, bone loss and treatment with HRT is common among patients with PBC (Smyk et al. 2012). In another study, conflicting results were found. Of 222 patients with PBC, no association with HRT was found (Smyk et al. 2012). Estrogen therapy, including oral contraceptives, may trigger the development of lupus or a flare of the disease. However, treatment of SLE patients with HRT is relatively safe even though it may trigger mild flares. Recent research suggests that low dose estrogen oral contraceptives can be an acceptably safe option for SLE patients without antiphospholipid antibodies or overt antiphospholipid syndrome.

Infections

An association between infection and autoimmune disease is well established. A few examples are: streptococcal infection and rheumatic heart disease, hepatitis C virus with vasculitis, cryoglobulinemia and autoimmune hepatitis, enteroviruses with type 1 diabetes, Epstein–Barr virus with SLE, *Helicobacter pylori* with gastric autoimmunity, *Saccharomyces cerevisiae* with Crohn's disease, measles with multiple sclerosis and cytomegalovirus or Parvovirus B19 with systemic sclerosis (Smyk et al. 2012).

Urinary Tract Infections (UTI)

It has been demonstrated in several studies that *E. coli* can cross-react with pyruvate dehydrogenase complex (PDC)-E2 epitopes and can activate B and T cells in patients with PBC (Smyk et al. 2012). In a study of 241 patients with PBC, a high odds ratio of PBC was noted in patients with past recurrent UTI. Another study of 1,032 patients with PBC demonstrated a high incidence of recurrent UTI (Smyk et al. 2012). A study of 2,258 patients also demonstrated the association between PBC and recurrent UTI (Smyk et al. 2012).

Hepatitis Virus

In a study of 241 patients with PBC, an increased incidence of prior infection with hepatitis A was noted (Smyk et al. 2012). Several studies have demonstrated that early hepatitis A infection has a protective effect against the development of asthma. This was noted in a study of 1,600 Italian patients demonstrating a decreased likelihood of developing asthma in seropositive hepatitis A patients. The same result was found in a study of 30,000 individuals in the USA (Graham 2012).

Epstein Bar Virus (EBV)

EBV has been implicated in several autoimmune diseases, including SLE, MS, autoimmune thyroiditis (AT), RA, IBD, insulin-dependent diabetes mellitus (IDDM), Sjogren's syndrome (SjS), systemic sclerosis (SyS), myasthenia gravis, and autoimmune liver diseases (AiLD) (Rigopoulou et al. 2012). Several mechanisms are suspected to be involved in autoimmune disease associated with EBV. Among these is molecular mimicry cross-reacting with CYP2D6 and dysregulation of T-regulatory cells in genetically predisposed individuals (Rigopoulou et al. 2012).

Adolescents with EBV-associated infectious mononucleosis have a relative risk of 2.17 for developing MS according to a meta-analysis of 18 studies examining the relationship between MS and EBV (Kakalacheva and Lünemann 2011). Comparing MS patients and healthy controls, there was a significant difference in the risk of disease among those with past exposure to EBV especially in pediatric cases of MS (Kakalacheva and Lünemann 2011). A study of military personal demonstrated high EBV antibody (EBNA) titers in 69 patients with up to three times the risk for MS in such patients (Kakalacheva and Lünemann 2011). In several studies, specific EBNA-1 antibodies were found in MS patients, suggesting that an alteration in the immune system may lead to a higher risk of MS. There is limited evidence suggesting that molecular mimicry is responsible for the initiation of MS (Kakalacheva and Lünemann 2011).

AiLD includes several diseases with involvement of different cell types within the liver, including hepatocytes in autoimmune hepatitis (AIH), and cholangiocytes in PBC and primary sclerosing cholangitis (PSC) (Rigopoulou et al. 2012). In vitro studies have shown that EBV has the ability to induce B cell transformation. This may produce monoclonal autoantibodies and B cell proliferation and persistence as memory cells, even without additional stimulation (Rigopoulou et al. 2012).

The pathogenesis of AIH is unknown; however, there is some evidence of T-lymphocyte activation. AIH can be divided according to the autoantibody profile. Patients with type I AIH have antinuclear antibodies (ANA) and smooth muscle antibodies (SMA) while patients with type II disease have antibodies to liver kidney microsomal antigen type 1 (anti-LKM1) and anti-liver cytosol type 1 antibodies (anti-LC1) (Rigopoulou et al. 2012). There have been several case reports finding EBV antibodies, and EBV DNA in patients with AIH. (Rigopoulou et al. 2012). In PBC, autoantibodies target the epithelial bile ducts. Anti-mitochondrial antibodies (AMA) are pathognomonic. Patients with PBC have been found to have EBV DNA in peripheral blood cells in significantly higher amounts compared with control patients and those with other liver diseases (Rigopoulou et al. 2012). However, EBV DNA can be found in several autoimmune diseases and its presence is not specific to PBC (Rigopoulou et al. 2012).

In a study of 260 patients (120 of whom had lupus), lupus patients with evidence of prior EBV infection were more likely than those without EBV infection to have a mild form of SLE with skin and joint involvement and elevated anti-Ro antibodies. (Zandman-Goddard et al. 2009 -Ann NY Sci Acad).

Parvovirus B19

Parvovirus B19 infection can mimic autoimmune disease as it may cause rash, arthritis, and thrombocytopenia. Furthermore, it has been implicated as a trigger in patients who develop RA, SLE, and vasculitis. Direct effects on the immune system include molecular mimicry (Lunardi 2008; Miller 2011).

Human Herpes Virus 6 (HHV6)

HHV6 infects oligodendrocytes and microglia cells and its complications may include central

nervous system (CNS) involvement (Kakalacheva and Lünemann 2011). In several studies, the virus has been isolated from CNS tissue of MS patients and from MS plaques (Kakalacheva and Lünemann 2011). Further evidence of HHV6 involvement in MS is that the myelin basic protein (MBP) sequence is similar to sequences in HHV6, raising the possibility of developing MS through molecular mimicry. This is suggested by the elevated T-cell response targeting MBP and the U24 proteins of the HHV6 (Kakalacheva and Lünemann 2011).

Helminths

Parasitic infection may be protective against the development of autoimmune diseases (Zandman-Goddard and Shoenfeld 2009- Lupus). For example, there is an inverse correlation between helminthic infection and the development of SLE (Zandman-Goddard and Shoenfeld 2009-Lupus).

In studies of mouse models of MS, exposure to helminths was associated with improvement in the disease (Kakalacheva and Lünemann 2011). This was further demonstrated in a study of 12 MS patients infected with helminths who noted a decrease in disease activity and in radiographic findings; the mechanism appeared to be downregulation of pro-inflammatory cytokines. These improvements reversed after the parasitic infection was treated (Correale and Farez 2011; Zandman-Goddard and Shoenfeld 2009-Lupus). Further evidence of potentially protective effect of helminthic infection for the development of MS includes the observation that geographic regions where parasitic infestation with *T. trichiura* is common have a lower incidence of MS compared with areas where the prevalence of this parasite is low (Correale and Farez 2011).

A number of studies report that children dewormed in Vietnam and Venezuela had an increased incidence of asthma. A reverse correlation was also observed between the severity of symptoms among children with asthma and the presence of helminthic infection (Correale and Farez 2011).

The hygiene hypothesis may account, at least in part, for these observations. This hypothesis states that the decrease in exposure to microbial environmental elements plays a key role in the increase in autoimmune diseases found in developed countries (Graham 2012). For example, the theory states that due to dietary changes, altered interactions between the immune system and gut flora trigger autoimmune reactions which could include disorders such as diabetes (Graham 2012). This may be mediated by toll-like receptors as knockout mice lacking certain toll-like receptors do not develop diabetes (Graham 2012). An early exposure to hepatitis A virus is associated with protection against allergic disorders via T-cell modulation (Graham 2012). Early exposure to coxsackievirus B and rotavirus may have a protective effect for autoimmune disease development; however, due to the late exposure in developed countries, a matured immune system may react with an autoimmune reaction instead.

Increases in saponins, lectins, gliadin, and capsaicin ingestion lead to increased intestinal permeability and increased exposure to endotoxins and cross-reactive epitopes (Graham 2012). This observation is supported by studies of germ-free mouse models and the effects of bacterial exposure. Exposing these mice to intestinal flora, *Clostridium* species, and *Bacteroides fragilis* brought the induction of T-regulatory cells in the gut. Segmented filamentous bacterium, in particular, causes T helper 17 to induce an autoimmune reaction (Graham 2012). Another study suggesting the importance of exposure to infectious agents found that the microbiota of children in developing countries were highly diverse compared with children in a developed country (Graham 2012). Of note, individuals with Crohn's disease tend to have low microbiota diversity (Graham 2012).

Several studies have linked the early exposure to pathogens with the risk for developing MS. This strengthens the notion that early exposure to pathogens is required for the proper regulation of the immune system. A further decreased risk was shown in children attending day care or a household with other siblings (Conradi et al. 2011).

Influenza H1N1 Virus

Narcolepsy is caused by the loss of hypocretin/orexin neurons in the hypothalamus; this may be

the result of an autoimmune process. There is no direct evidence of autoantibodies against hypocretin cell antigens; however, antibodies against Tribbles homolog 2 (TRIB2) protein produced by the hypocretin cells have been demonstrated, which may explain the hypocretin cell damage (Han et al. 2011). In a study examining narcolepsy in children, there was a ninefold increased risk of narcolepsy following H1N1 influenza vaccination with squalene/*a*-tocopherol adjuvant (Han et al. 2011). This finding was supported by an additional study finding a 6.6-fold increased risk for narcolepsy following H1N1 vaccination (Correale and Farez 2011). In a study of 629 patients with narcolepsy, there was a sevenfold increase in narcolepsy during the year of the H1N1 outbreak and a fourfold increase among those patients who received vaccination (Han et al. 2011). There was a clear correlation between upper respiratory infection and narcolepsy onset; moreover, the diagnosis of narcolepsy was associated with infection with *Streptococcus pyogenes* and anti-streptolysin O (ASO) antibodies (Han et al. 2011). Despite these findings, a recent study showed a similar incidence of narcolepsy prior to and after the H1N1 pandemic years (Han et al. 2011).

Helicobacter pylori (H. pylori)

Individuals diagnosed with *H. pylori* infection may have an increased risk of autoimmune disease (Hasni 2012). This could be due to an effect of bacteria on the innate immune system, causing an anti-inflammatory response via the toll-like receptors and via the inhibition T helper cell proliferation (Hasni 2012). Despite this, there is evidence of autoimmunity triggered by *H. pylori* such as molecular mimicry causing the formation of autoantibodies, including IgM-rheumatoid factor, anti-single-stranded DNA antibody, and anti-phosphatidylcholine antibody (Hasni 2012).

There is also evidence associating *H. pylori* with (idiopathic thrombocytopenic purpura (ITP). Improvement in ITP patients was noticed after eradication of the bacteria, although the mechanism is unknown (Hasni 2012).

Silica and Silicone Breast Implant Surgery

Silica has been shown to interact with immune cells. Silica acts as a pro-inflammatory substance inducing the complement cascade activation, triggering the production of autoantibodies, inducing the formation of immune complexes, and deregulating the T helper/regulatory cell ratio (Smyk et al. 2012). Occupational exposure to silica has been linked to SLE, RA, vasculitis, and SyS (Miller 2011; Smyk et al. 2012).

A meta-analysis of studies found that the risk of developing SLE and RA was increased among silica-exposed individuals compared with non-exposed individuals. (Pollard 2012).

Although controversial, a number of reports have suggested a link between the development of myositis and SyS and silicone implants (Miller 2011). Slow release of silicone from the implants by migration of silicone through the capsule and into systemic circulation may increase the risk of developing an autoimmune disease. Silicone antibodies have been detected in patients with silicone implants (Lidar et al. 2012). Mice with silicone implants developed anti-ds DNA antibodies and rheumatoid factor. The same findings can be seen in women with silicone breast implants (Lidar et al. 2012). However, large epidemiological studies have found no significant association between silicone implants and the development of autoimmune disease (Lidar et al. 2012).

Solvents

Exposure to solvents is associated with SyS (Smyk et al. 2012; Pollard 2012). A meta-analysis of 11 studies examining the association between trichloroethylene solvent and SyS noted an odds ratio of 2.5 in males (Pollard 2012). Solvents may also be an occupational or recreational environmental trigger of SLE (Zandman-Goddard et al. 2012).

Vitamin D

Vitamin D deficiency is global and has a direct effect on the immune system. Autoimmune diseases associated with vitamin D deficiency include IDDM, MS, IBD, SLE, RA, and celiac disease (Smyk et al. 2012).

Epidemiologic studies have reported a lower risk of MS in countries with higher sun exposure (Kakalacheva and Lünemann 2011). Further involvement of vitamin D in MS is suggested by the finding of higher vitamin D consumption and higher exposure to sunlight in regions where MS is less common. (Kakalacheva and Lünemann 2011). In an international study of 40,000 patients with MS, prenatal sunlight exposure was associated with a decreased frequency of MS (Kakalacheva and Lünemann 2011). A study that correlated vitamin D levels and self-reported sun exposure demonstrated a decreased risk of MS in those reporting the highest sun exposure. (Kakalacheva and Lünemann 2011). Vitamin D deficiency has also been associated with relapses of MS, although in one study, no significant difference in vitamin D or its metabolites was found in patients with MS compared to the control group (Kakalacheva and Lünemann 2011). Vitamin D may have a regulatory effect on pro-inflammatory cytokines inhibiting T-cell activation and directly affecting T cells via the vitamin D receptor (Kakalacheva and Lünemann 2011).

Vitamin D has an anti-inflammatory effect through its ability to elevate the expression of T-regulatory cells and inhibit the maturation of dendritic cells (Milliken et al. 2012).

In experimental encephalitis models, in vivo vitamin D supplementation was associated with decreased auto-antigen production and an increase in T-reg cells (Milliken et al. 2012). Furthermore, in animal studies, administration of high dose vitamin D was associated with immunosuppressive effects (Milliken et al. 2012).

In the vitamin D receptor/IL-10 double knockout mouse, a severe form of IBD was noted. Furthermore, vitamin D deficiency alone leads to a more severe form of IBD in experimental models (Cantorna 2012).

Decreased levels of vitamin D are common among patients with SLE and correlate with disease severity (Hamza et al. 2011; Amital et al. 2010).

Cosmetics

Although controversial, xenobiotics (found in hair dyes and nail polish) have been linked with the development of PBC. This may be due to immune activation against self-antigens, perhaps via alteration of mitochondrial antigens (Smyk et al. 2012; Pollard 2012; Cooper et al. 2010). Anecdotes of exposure to cosmetics (whitening skin creams, lipstick, hair dyes) and the development of SLE have been described. Exposure to tanning beds may cause an exacerbation of SLE (Zandman-Goddard et al. 2012).

Metals and Toxins

Some have suggested that aluminum is a triggering factor for Crohn's disease through an interplay between aluminum and colonic bacteria (Lerner 2012). Exposure to aluminum can be from a variety of sources:

- In the soil due to changes in soil acidity (Lerner 2012),
- Occupational exposure in melting and mining industries (Lerner 2012),
- Food – Additives, purified drinking water, processed cheese, non-dairy creamers, powdered milks or food, baking powder, cake mixes, pancakes, sugars, soy-based milk products, chewing gum, rice and noodles, vending machine drinks, and icing sugar (Lerner 2012),
- Iatrogenic exposure – dialysates, phosphate, binders, antacids, intravenous solutions, urinary bladder irrigation fluids, bone and dental cements, buffered aspirins, antidiarrheal and antihemorroidal medications, vaccine adjuvants, and toothpaste (Lerner 2012).

The absorption of the aluminum in the digestive tract has been demonstrated in several studies which demonstrates aluminum presence in the pigmentation of colonic Peyer's patches and in submucosal macrophages (Lerner 2012). In animal studies, dietary aluminum is associated with bowel inflammation.

In a case report, an RA patient improved after receiving chelating therapy for suspected metal intoxication (Bamonti et al. 2011). Among patients with MS, an increased excretion of aluminum was found in a few cases (Exley et al. 2006).

A study examining a potential link between mercury exposure and autoimmune disease demonstrated a clear association between mercury

exposure from mining, and skin creams and the formation of antinuclear autoantibodies (Pollard 2012).

In mouse models of SLE, pesticides were associated with the presence of ANA. In humans, ANA positivity may be linked with prolonged exposure to pesticides (Pollard 2012). Pesticides were also associated with increased risk for RA in the analysis of the Women's Health Initiative Observational Study (Parks et al. 2011).

Although the increased incidence of IDDM is worldwide, individuals who migrate to countries with a high incidence of IDDM have an increased risk of developing the disease. This supports the suggestion that environmental factors may trigger IDDM (Howard and Lee 2012). Studies have demonstrated correlations between the incidence of IDDM and the presence of nitrate compounds, persistent organic pollutants, ozone, sulfate, and polychlorinated biphenyls. Polychlorinated biphenyls were also found in high levels among pregnant women with IDDM. Elevated titers of glutamic acid decarboxylase (GAD) antibodies were found in workers exposed to polychlorinated biphenyls (Howard and Lee 2012). Bisphenol A, phthalates, and some pesticides may also be responsible for cases of autoimmune disease; of note, the autoimmune effect may occur at doses considered below the hazard level, influencing the endocrine system in a "U" shaped dose–response curve (Howard and Lee 2012).

Oleic acid anilide (OAA) exposure can trigger an autoimmune response and autoantibody production in animal experiments. This followed descriptions of the toxic oil syndrome associated with exposure to rapeseed oil denatured with aniline in 1981 (Germolec et al. 2012).

In 1989, an exposure to L-Tryptophan caused eosinophilia-myalgia syndrome with cutaneous manifestations of SyS. Animal experiments attempting to replicate the syndrome had only partial success, suggesting additional factors play a role (Germolec et al. 2012).

Ultraviolet Light

A link between MS and UV radiation is suggested by the relationship between the prevalence of MS and the latitude gradient which demonstrates an increased risk of up to 20 times with larger distances from the equator (Pollard 2012; Simpson et al. 2011). In addition, individuals at high altitude receiving more UV radiation have a lower incidence of MS (Schwalfenberg 2012).

Narrowband UVB therapy has been shown to exert immunosuppressive effects (Milliken et al. 2012). This can be explained by the direct effects of UV light inducing T-reg cells and through effects on vitamin D (Milliken et al. 2012). This can also be demonstrated in the treatment of immune-mediated dermatoses. In a study exposing patients to UVB light, an increase in peripheral T-reg cells was noted (Milliken et al. 2012).

Exposure to different types of UV light has a variable impact on cutaneous and systemic lupus. While UVA2 and UVB can exacerbate the disease, UVA1 can be protective (de Jong et al. 2012). Not only may sunlight cause exacerbations in SLE, but fluorescent light can also cause DNA damage and trigger SLE activity. Ironically, avoidance of light causes a decrease in vitamin D which may affect disease activity as well (de Jong et al. 2012).

Drugs

There are many drugs that are suspected of causing or contributing to autoimmune disease; however, for most, there is no definitive evidence for a direct, causal role (Miller 2011).

Drug induced lupus erythematosis (DILE) is the most common autoimmune disease triggered by drug therapy. It can be induced by many different types of drugs. The exact mechanism for this is not completely understood; however, it has been shown that hydralazine causes inhibition of DNA methyltransferase, causing overexpression of T-cell immune genes, leading to lupus-like disease (Strickland et al. 2012). Therefore, in genetically predisposed individuals, factors influencing DNA methyltransferase may cause lupus-like illness. DILE is usually characterized by anti-histone autoantibodies (rather than double-stranded DNA antibodies) and a mild form of disease. More severe drug-induced lupus may be triggered by anti-TNF biologic therapy.

These patients may develop renal and central nervous system involvement and antibodies to double-stranded DNA similar to SLE rather than DILE (Zandman-Goddard et al. 2012).

Statins may have an immunosuppressive or protective effect on autoimmune disease, including RA. Patients consistently taking statins for hypercholesterolemia had a lower prevalence of RA compared to those not adhering to the treatment. A hazard ratio of 0.58 for the development of RA was found in a study of 2,11,627 patients on long-term statin treatment (Chodick et al. 2010).

Although the evidence is scant, statins may trigger a lupus-like disease (de Jong et al. 2011). Several case reports describe lupus-like disease following statin treatment; however, in a study examining the World Health Organization reports of lupus-like disease associated with statin use, only 4.3 % out of 3,362 had elevated titers of antinuclear antibodies (ANA) (de Jong et al. 2011).

Ionizing Radiation

Patients treated with radiation therapy have an increased risk of developing Graves' disease (Pollard 2012). In a study of environmental radiation exposure in regions exposed to atomic bombs or nuclear reactor catastrophes, an increased incidence of AT has been noted (Pollard 2012).

Autoimmune Syndrome Induced by Adjuvants (ASIA) Syndrome

The ASIA syndrome is a constellation of autoimmune diseases triggered by adjuvant exposure. Diagnostic criteria were suggested composed of major and minor criteria (Shoenfeld and Agmon-Levin 2011):

- Exposure to an external stimuli (infection, vaccine, silicone, adjuvant) prior to clinical manifestations,
- The appearance of typical clinical manifestations: myalgia, myositis, or muscle weakness, arthralgia and/or arthritis, chronic fatigue, nonrestorative sleep, or sleep disturbances, neurological manifestations (especially associated with demyelination), cognitive impairment, memory loss, pyrexia, dry mouth,
- Removal of inciting agent induces improvement,
- Typical biopsy of involved organs.

Minor criteria:

- The appearance of autoantibodies or antibodies directed at the suspected adjuvant,
- Other clinical manifestations (i.e., irritable bowel syndrome),
- Specific HLA (e.g., HLA DRB1, HLA DQB1)
- Evolution of the symptoms into an established autoimmune disease (e.g., MS, SjS)

To establish the diagnosis of ASIA, a patient should meet at least two major criteria or one major and two minor criteria.

ASIA syndrome includes siliconosis, macrophagic myofasciitis (MMF) syndrome, Gulf war syndrome (GWS), and post-vaccination phenomena.

Adjuvants augment the activities of dendritic cells (DCs), lymphocytes, macrophages and activate the intracellular Nalp3 inflammasome system. In animal studies, adjuvants induce lupus-like disease with lupus autoantibodies and arthritis (Shoenfeld and Agmon-Levin 2011).

Prior events of immunization and pathologic conditions are known, such as swine flu vaccine outbreak of Guillain-Barré syndrome (GBS), transverse myelitis following oral polio vaccine, arthritis following diphtheria-tetanus-pertussis (DTP) and autoimmune thrombocytopenia after measles-mumps-rubella (MMR) vaccine (Shoenfeld and Agmon-Levin 2011).

MMF syndrome was found to be the result of persistence of aluminum adjuvant at the site of inoculation months and even 8–10 years following immunization in genetically susceptible subjects (Shoenfeld and Agmon-Levin 2011).

GWS occurred following multiple vaccinations including anthrax vaccine in which aluminum hydroxide and squalene served as adjuvants. In a study of 144 Gulf war-era veterans, 95 % of overtly ill deployed GWS patients had antibodies to squalene and 100 % of GWS patients were immunized to anthrax. Of deployed veterans without signs and symptoms of GWS, none had

antibodies to squalene. Neither patients with idiopathic autoimmune disease nor healthy controls had detectable serum antibodies to squalene (Shoenfeld and Agmon-Levin 2011; Asa et al. 2000).

Siliconosis is thought to develop after exposure to silicone with symptoms of autoimmune disease without fulfilling diagnostic criteria of specific autoimmune disease (Lerner 2012; Shoenfeld and Agmon-Levin 2011).

Conclusion

- Autoimmune diseases account for approximately 0.05–5 % of diseases in the general population.
- Environmental factors play an important role in the pathogenesis in genetically susceptible individuals.
- Smoking, hormone replacement therapy, sex hormones, vitamin D deficiency, toxins, heavy metals, solvents, UV radiation, and drugs are all implicated as triggers of autoimmune disease.
- The ASIA syndrome is a new entity involving environmental agents that may trigger the development of autoimmune manifestations.

Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss Syndrome)

Augusto Vaglio and Lucio Manenti
Unit of Nephrology, University Hospital of Parma, Parma, Italy

Synonyms

Churg-Strauss syndrome; Eosinophilic vasculitis

Definition

Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome, EGPA) is a systemic small-vessel vasculitis frequently associated with asthma and eosinophilia.

Introduction

EGPA is a systemic disease characterized by asthma, eosinophilia, and vasculitic involvement of various organs or systems, particularly the respiratory tract, the heart, the skin, and the peripheral nervous system. Its main histological features include tissue eosinophilia, necrotizing vasculitis, and eosinophil-rich granulomas (Noth et al. 2003). Given the positivity of antineutrophil cytoplasmic antibodies (ANCA) in a fraction of patients and the predominant involvement of small vessels, EGPA has been grouped under the umbrella term ANCA-associated vasculitis with microscopic polyangiitis (MPA) and granulomatosis with polyangiitis (Wegener's, GPA). The etiopathogenesis of EGPA is still poorly understood, although genetic and environmental factors are likely to play a role. The diagnosis still relies on clinical and histological findings, even if new diagnostic biomarkers are emerging (Zwerina et al. 2011).

Lanham et al. 1984
1. Asthma
2. Eosinophilia $>1.5 \times 10^9$/L
3. Clinical or pathological evidence of vasculitis involving at least two organs
American College of Rheumatology 1990[a]
1. Asthma
2. Eosinophilia >10 %
3. Neuropathy (mono- or polyneuropathy)
4. Non-fixed pulmonary infiltrates
5. Paranasal sinus abnormalities
6. Extravascular eosinophil infiltration on biopsy
Chapel Hill Consensus Conference 1994
Eosinophil-rich and granulomatous inflammation involving the respiratory tract, necrotizing vasculitis affecting small to medium-sized vessels, associated with asthma and eosinophilia

[a]At least four of the six American College of Rheumatology criteria are required to classify vasculitis as Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss)

Historical Background, Definition, and Classification Criteria

In 1951, Jacob Churg and Lotte Strauss first described a syndrome characterized by "asthma, fever and eosinophilia, and [. . .]symptoms of cardiac failure, renal damage and peripheral neuropathy resulting from vascular embarrassment in various systems of organs" (Churg and Strauss 1951). The histological examination of the 13 cases (most of which were autopsy cases) described by Churg and Strauss consistently showed the presence of tissue eosinophilia, necrotizing, and granulomatous vascular lesions and extravascular granulomas.

These pathological characteristics still represent the key findings on which the diagnosis of EGPA is based. During the decades that followed the publication of Churg's and Strauss's seminal paper, several attempts were made to establish classification or diagnostic criteria for this syndrome. However, only classification criteria are currently available for EGPA. In 1984, Lanham and colleagues (Lanham et al. 1984) suggested that the presence of asthma, eosinophilia $>1.5 \times 10^9$/L, and vasculitic involvement of two or more organs (with or without histological proof) was a prerequisite for a diagnosis of EGPA (Table 1). However, no validation studies were performed for such criteria. In 1990, the American College of Rheumatology task force for the classification of vasculitis established a set of six criteria (Table 1), four of which were required in order to classify a vasculitis syndrome as EGPA (Masi et al. 1990). In 1994, the Chapel Hill consensus conference nomenclature provided mutually exclusive definitions for the classification of vasculitis and defined EGPA as a eosinophil-rich and granulomatous inflammation involving the respiratory tract, necrotizing vasculitis affecting small to medium-sized vessels, occurring in patients with asthma and eosinophilia (Jennette et al. 1994). In 2012, the revised Chapel Hill classification of vasculitis replaced the traditional term "Churg-Strauss syndrome" with the more descriptive EGPA, but did not provide further criteria for the diagnosis or the classification of the disease (Jennette et al. 2013).

Epidemiology, Genetic, and Environmental Factors

EGPA is a rare disease; its incidence in various populations ranges between 0.5 and 4.2 cases/10^6 persons per year, and its prevalence is 11–14 cases/10^6 persons. EGPA usually arises in people aged 40–60 years, the mean age at diagnosis being approximately 50 years.

No gender predominance, familial clustering, or ethnic predisposition has clearly been shown. However, the influence of genetic factors on disease susceptibility and shaping its clinical phenotype has clearly been demonstrated. Initially shown in an Italian study (Vaglio et al. 2007) and subsequently replicated in a German cohort (Wieczorek et al. 2008a), the HLA-DRB1*04 and *07 alleles and the related HLA-DRB4 gene were found to be associated with an increased susceptibility to develop EGPA; conversely, the HLA-DRB3 was protective, as its frequency was lower in EGPA patients than in healthy controls. Interestingly, the frequency of HLA-DRB4 correlated with the number of vasculitic complications of the disease (e.g., glomerulonephritis, mononeuritis multiplex, purpura) (Vaglio et al. 2007). Of note, another study (Wieczorek et al. 2008b) showed that the ANCA-negative subset of EGPA is associated with the IL10.2 haplotype of the *IL10* gene promoter, which functionally translates into increased IL-10 expression. These data support the hypothesis that the clinically distinct subgroups of EGPA may have different immunogenetic determinants.

Environmental factors have also been thought to contribute to the pathogenesis of EGPA. Occupational exposure to particulate silica has been described as a potential susceptibility factor; additionally, infections and vaccinations have been identified as possible triggers of the disease, but no specific infectious agent or type of vaccination has clearly been implicated. On the other hand, a number of studies have shown that EGPA can be precipitated by the use of certain drugs used in asthmatic patients, in particular leukotriene receptor antagonists (LTRAs) such as montelukast. Different mechanisms have been postulated to explain how LTRAs may trigger EGPA in asthmatic patients: as they may allow steroid tapering, they could unmask smoldering forms of EGPA. Alternatively, they could induce an allergic, idiosyncratic reaction. An additional view is that the development of EGPA during LTRA treatment is simply coincidental and reflects the phasic evolution of the disease through the classical allergic, eosinophilic, and vasculitic stages. The hypothesis linking LTRAs to the unmasking of subclinical disease is the most widely accepted (Hauser et al. 2008) and is also supported by the evidence that other drugs used as steroid-sparing agents in asthma (e.g., theophylline, omalizumab) have been associated with the onset of EGPA.

Pathogenesis

The pathogenetic mechanisms of EGPA are still incompletely understood, but recent studies have shown that different immune cell types are involved in the development of the disease and in mediating tissue damage.

Early reports demonstrated that $CD4^+$ T cells are activated in EGPA and that they undergo oligoclonal expansion; this is in line with the evidence of a restricted HLA repertoire and of the association with HLA class II polymorphisms. $CD4^+$ T-helper 2 (Th2) cell responses are prominent in EGPA. Peripheral $CD4^+$ T-cell lines obtained from the peripheral blood of EGPA patients are able to produce large amounts of Th2 cytokines such as IL4 and IL13, and T cells positive for the Th2 marker CD294 are abundant in EGPA tissue lesions. Additionally, the Th2 cytokine IL5 also seems to be upregulated in active EGPA; IL5 is a major survival factor for eosinophils, as it is able to induce their proliferation, activation, and to prolong their life span. However, Th1 and Th17 responses are also detectable in EGPA; peripheral $CD4^+$ T cells also produce considerable amounts of interferon-γ (IFN γ), a prototypical Th1 cytokine, and Th17 cells – capable of producing IL17A – are found at high frequencies in the peripheral blood of active patients (Vaglio et al. 2012a).

Recent evidence points to B cells and the humoral response as potential contributors to EGPA pathogenesis. The crucial role of B cells has become clear thanks to the use of the B-cell depleting antibody rituximab in several refractory cases (Vaglio et al. 2012a); although no large-scale studies have yet been published, the available reports demonstrate that B-cell depletion may induce not only disease remission but also significant reduction in eosinophil counts and in serum levels of IL5, which is essentially produced by T cells. These findings indicate that B cells may be pivotal in the immune response of EGPA and that they are capable of influencing the function of other cell types such as T cells and eosinophils. The humoral response in EGPA is also likely to be dysregulated. Autoantibodies such as ANCA are detectable in ~40 % of the patients; additionally, IgE levels are commonly high in active EGPA. Finally, a dramatic increase in serum IgG4 levels also characterizes active disease; increased IgG4 production is usually driven by Th2 (IL4, IL13) and regulatory (IL10) cytokines. Notably, IgG4 levels correlate with disease activity and with the number of organs involved (Vaglio et al. 2012b).

Eosinophils are probably the major effector cells in EGPA, as their circulating levels often parallel disease activity, and the release of their granule proteins (e.g., eosinophil basic protein, eosinophil-derived neurotoxin) may induce cell apoptosis and necrosis. Recent evidence suggests that their tissue recruitment is driven by chemokines such as eotaxin-3 (Zwerina et al. 2011), produced by endothelial and epithelial cells. Other chemokines such as CCL17, also produced by "resident" cells such as epithelial cells, can contribute to the amplification of the inflammatory lesions by inducing tissue influx of Th2 cells which, in turn, stimulate eosinophil recruitment and activation (Vaglio et al. 2012a).

Pathology

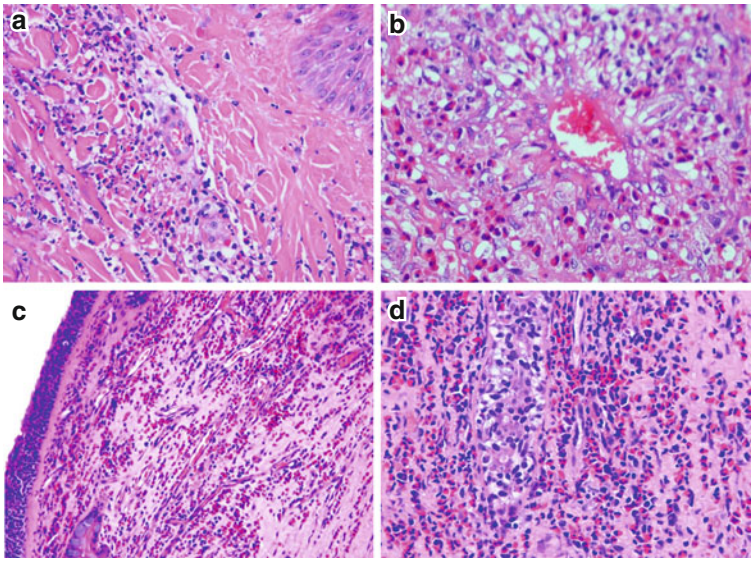
Necrotizing (granulomatous or non-granulomatous) vasculitis, extravascular granulomas, and tissue eosinophilia are the main pathological features of EGPA (Fig. 1). Vasculitis involves the small and, sometimes, medium-sized vessels and is characterized by fibrinoid necrosis and frequently by eosinophilic infiltration. Granulomas may be found within the vascular lesions, but more specific for the diagnosis of EGPA is the extravascular granuloma, which generally consists of a core of amorphous eosinophilic material (probably derived from necrotic eosinophils), surrounded by palisading lymphocytes and epithelioid and multinucleated giant cells (Vaglio et al. 2009).

In EGPA, different disease manifestations may show distinct histopathological patterns. Lung infiltrates usually encompass vasculitis, granulomas, and tissue eosinophilia; cardiomyopathy and gastrointestinal lesions are generally characterized by pronounced eosinophilic infiltration. Conversely, renal lesions usually lack eosinophilic infiltration; likewise, peripheral neuropathy is usually due to epineural vasculitis with lymphomonocytic infiltration of the vasa nervorum but eosinophil infiltration tends to be mild. Purpura and alveolar hemorrhage are also manifestation of capillaritis with few or no eosinophils. Other manifestations, such as sinusitis, bronchial involvement, or skin nodules, usually show only tissue eosinophilia with or without granulomas but lack vasculitis.

Clinical Manifestations

The clinical course of EGPA is usually reported to evolve through an allergic phase, dominated by asthma, rhinosinusitis, and other allergic manifestations; an eosinophilic phase, frequently hallmarked by lung infiltrates, cardiomyopathy, and gastroenteritis; and a vasculitic phase, characterized by organ complications due to small-vessel vasculitis, such as purpura, glomerulonephritis, and peripheral neuropathy. However, these disease phases (especially the eosinophilic and vasculitic phases) often overlap.

Asthma has been reported in 90–100 % of EGPA patients; unlike in usual bronchial asthma, in EGPA it usually arises in adulthood, has no typical seasonal exacerbations, and may precede



Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss Syndrome), Fig. 1 Representative histological pictures in Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss). (**a**) Skin biopsy showing lymphomonocytic vasculitis with moderate eosinophil infiltration; (**b**) transmural vasculitis of an intestinal submucosa blood vessel showing marked eosinophilic infiltration; (**c**) nasal polyp biopsy showing massive eosinophilic infiltration of the lamina propria with marked oedema; (**d**) biopsy of paranasal sinus mucosa showing pronounced eosinophilic infiltration around a mucin-producing gland of the lamina propria. Original magnification: x20 in **a**, **c** and **d**; x10 in **c**

the full-blown clinical picture of EGPA by many years. Notably, asthma tends to improve when the vasculitis symptoms develop (Vaglio et al. 2009). Asthma is usually accompanied by allergic rhinosinusitis with frequent polyp formation; although the histological appearance of nasal polyps in EGPA is similar to that of typical allergic nasal polyposis, nasal polyps in EGPA tend to recur after surgery if patients do not receive immunosuppression (Bacciu et al. 2008). Unlike GPA, the rhinosinusitis of EGPA does not cause bone erosions of the paranasal and nasal structures, and patients only rarely have nasal crusting or purulent-bloody nasal discharge.

Lung involvement occurs in approximately two thirds of patients with EGPA. Lung infiltrates are usually patchy, peripheral, and sometimes migratory; on high-resolution computed tomography (CT) scanning, they appear as poorly defined areas of consolidation or ground-glass opacities and are often accompanied by abnormalities resulting from bronchial wall involvement, such as bronchial wall thickening, mucous plugs, and small centrilobular nodules. EGPA limited to the respiratory tract must be distinguished from other eosinophilic lung disorders such as acute and chronic eosinophilic pneumonia and allergic bronchopulmonary aspergillosis. Both of these conditions share clinical features with EGPA, including lung infiltrates and an eosinophil-rich bronchoalveolar lavage fluid. However, acute eosinophilic pneumonia is usually a febrile illness with acute onset and sudden respiratory failure. While chronic eosinophilic pneumonia tends to begin more insidiously, both the acute and chronic forms of eosinophilic pneumonia usually lack other organ manifestations and the ANCA is usually negative. Allergic pulmonary aspergillosis may mimic EGPA forms limited to the airway tract also because it causes bronchial involvement; the isolation of Aspergillus species in the sputum or bronchoalveolar lavage fluid and the presence of Aspergillus-specific IgE in the serum are distinguishing features of this condition. Other lung manifestations in EGPA include pleural

effusion due to pleuritis or cardiomyopathy-related congestive heart failure and, rarely, alveolar hemorrhage.

Cardiac involvement is also frequent, especially if patients are screened with cardiac magnetic resonance imaging or echocardiography. Endomyocarditis is the most common pattern of cardiac involvement, but pericarditis and coronary vasculitis may also occur. EGPA-related endomyocarditis may lead to restrictive cardiomyopathy and chronic heart failure. In the eosinophilic phase of the disease, gastrointestinal involvement is also frequent; it usually presents as abdominal pain and can be complicated by gastrointestinal bleeding. The stomach and small bowel are more frequently affected, although there are some reports of involvement of the large bowel and cholecystitis. Heart and gastrointestinal involvement are predictors of poor prognosis in EGPA (Noth et al 2003).

Constitutional symptoms such as weight loss, anorexia, fatigue, and fever often herald the vasculitic or generalized phase of EGPA. Peripheral neuropathy is a cardinal feature of this disease stage, as it occurs in ~70 % of the cases; it can cause sensory and/or motor deficits and, in some cases, neuropathic pain, and more frequently involves the peroneal, tibial, ulnar, and median nerves. It is often asymmetrical, with a pattern defined as mononeuritis multiplex, and on electrophysiological studies it shows signs of axonal damage. Although rare, central nervous system (CNS) involvement may cause stroke, cranial nerve palsies, or cognitive disturbance (among other symptoms) and represents a major adverse prognostic factor.

Skin lesions, particularly purpura, also result from small-vessel vasculitis. Purpura has been reported in ~25 % of patients, and similar to that observed in other systemic vasculitis syndromes such as ANCA-associated and cryoglobulinemic vasculitis, it predominantly affects the lower limbs. Other dermatological manifestations include nodules, urticaria, livedo reticularis, and ulcers.

Renal abnormalities are found in ~25 % of the cases and range from isolated urinary abnormalities such as proteinuria and microhematuria to rapidly progressive glomerulonephritis. The histological picture is similar to that of the other ANCA-associated vasculitides, with findings of necrotizing, crescentic (i.e., with extra-capillary proliferation leading to the formation of crescents) glomerulonephritis with few or no immune deposits ("pauci-immune"). However, both histological lesions and renal manifestations in EGPA are usually much less severe than those found in GPA or MPA, and patients only rarely progress to renal failure (Sinico et al 2006). Nevertheless, proteinuria >1 g/day and serum creatinine >140 μmol/L are predictors of poor outcome in EGPA.

Laboratory Findings

Significant peripheral eosinophilia (usually >1,500 cells/μL or >10 %) is nearly always present in patients with active EGPA, except when masked by steroid therapy. Eosinophilia frequently correlates with disease activity; the reappearance of eosinophilia during remission may be an early sign of relapse. Erythrocyte sedimentation rate and/or C-reactive protein levels may also be high during active disease, although they often do not mirror disease activity. Serum IgE are high in ~80 % of the cases, but they lack specificity for common allergens. Among IgG subclasses, a dramatic increase in IgG4 levels has been found in patients with active disease. Again, the specificity of such immunoglobulins has not yet been investigated (Vaglio et al. 2012b).

ANCA always need to be tested in patients with suspected EGPA; they are positive in 35–40 % of the cases, and their immunofluorescence pattern is perinuclear (P-ANCA) in 74–90 % and cytoplasmic (C-ANCA) or mixed in the rest. P-ANCA generally correspond (using ELISA) to anti-myeloperoxidase (MPO) antibodies, while the C-ANCA pattern is generally the result of anti-proteinase 3 (PR3) antibodies; a positive ANCA in a high titer (especially when due to anti- MPO or anti-PR3 antibodies) is useful in the differential diagnosis

between EGPA and different eosinophilic conditions, including the so-called hypereosinophilic syndromes (HESs). Although no systematic studies have been conducted, it is generally accepted that most variants of the HES (including those related to chromosomal abnormalities such as the *FIP1L1-PDGFRA* fusion gene, the lymphocytic variant, chronic eosinophilic leukemia, and idiopathic HES) are ANCA-negative. However, since most EGPA patients are also ANCA-negative, the differential diagnosis between EGPA and HES is often challenging; testing serum levels of different cytokines and chemokines (e.g., sIL2R, IL5, IL6, IL8, IL10, CCL17, eotaxin-1) failed to differentiate ANCA-negative EGPA and idiopathic HES (Khoury et al. 2012). In a recent study, however, serum eotaxin-3, a eosinophil-attracting chemokine, proved a reliable diagnostic marker of active EGPA, with control groups including not only HES but also other vasculitic syndromes, secondary forms of eosinophilia, and systemic connective tissue disorders (Zwerina et al. 2011).

In EGPA, ANCAs also have a role in distinguishing clinical phenotypes of the disease. Specifically, ANCA-positive patients more frequently have peripheral neuropathy, glomerulonephritis, or purpura (which are due to small-vessel vasculitis), whereas endomyocardial involvement and lung infiltrates prevail in the ANCA-negative subset. In addition, signs of vasculitis on biopsy tend to be more frequent in ANCA-positive cases. Based on these findings, it has been hypothesized that two major subsets of EGPA exist, one ANCA-positive, in which tissue damage is mainly mediated by vasculitis, and one ANCA-negative, dominated by organ manifestations related to eosinophil tissue infiltration. This distinction is not clear-cut, however, and manifestations of the two subsets often overlap (Sinico et al. 2005; Sablé-Fourtassou et al. 2005).

Treatment and Outcome

Different immunosuppressive regimens have been proposed for the treatment of EGPA, but there is at present no consensus regarding a staged, remission-induction, and remission-maintenance approach. The prognostic profile of EGPA patients may influence therapeutic decisions. The five-factor score (FFS), the most used prognostic score for EGPA, includes five poor prognosis factors, namely, heart, gastrointestinal, and CNS involvement, creatinine >140 μmol/L, and proteinuria >1 g/24 h. Patients with one or more of these five factors are usually treated with combinations of glucocorticoids and immunosuppressants (generally cyclophosphamide for induction of remission), whereas those with a FFS $= 0$ are initially treated with glucocorticoids alone (Cohen et al. 2007). However, combinations of glucocorticoids and immunosuppressants are commonly used also for patients who have a FFS $= 0$ but bear other severe disease manifestations such as alveolitis or polyneuropathy.

In a trial of patients with no poor prognosis factors, remission was achieved using glucocorticoids alone in 90 % of patients; however, during the follow-up, 35 % of the patients relapsed and eventually required combination therapies based on azathioprine or methotrexate plus glucocorticoids (Ribi et al. 2008). In a trial of EGPA patients with FFS ≥ 1, cyclophosphamide plus prednisone was used as induction therapy, and patients were randomized to receive either 6 or 12 monthly cyclophosphamide pulses. The two regimens had similar efficacy in inducing remission, but relapses (especially minor) were more frequent in the 6-pulse group (Cohen et al. 2007).

Other traditional immunosuppressive drugs used for remission induction include methotrexate and intravenous immunoglobulins (IVIg). Methotrexate proved effective in remission induction in combination with prednisone, but relapses were frequent ($\sim$50 %) during the maintenance phase. IVIg was used in a small pilot trial together with plasma exchange, cyclophosphamide, and glucocorticoids, with good short- and long-term results (Danieli et al. 2004); however, no further trials have explored their efficacy and safety.

The duration of therapy is a matter of debate, but it is usually accepted that combination

therapies should be continued for at least 12 months. Many patients are continued even longer on low-dose glucocorticoids, which are often needed to control residual asthma.

EGPA may prove refractory to standard immunosuppressive therapy or dependent on high-dose glucocorticoids; in addition, many patients have significant toxicity or contraindications to high-dose glucocorticoids. For such cases, alternative treatments have been explored. Interferon-α, due to its ability to impair eosinophil degranulation and Th2 responses in vitro, has been used in refractory EGPA cases with positive results (Tatsis et al. 1998); however, most patients who were kept on this treatment for remission maintenance developed relapses or had to discontinue treatment because of toxicity. Recent pilot trials (Kim et al. 2010; Moosig et al. 2011) have demonstrated the efficacy of mepolizumab, a monoclonal antibody that targets IL5, the major survival factor for eosinophils. Mepolizumab was used both in refractory and glucocorticoid-dependent patients. Although it allowed significant reduction in glucocorticoid dose, relapses occurred in almost all cases upon its cessation (Moosig et al. 2011). Numerous case reports or small case series have described that rituximab, a B-cell depleting monoclonal antibody, may also be effective in refractory EGPA. In most cases rituximab induced not only disease remission but also a drop in eosinophil counts and acute-phase reactants (Cartin-Ceba et al. 2011).

The outcome of EGPA is generally good: survival rates at 1 and 5 years may be as high as 100 % and 97 %; in the trial of patients with poor-prognosis factors, 92 % were alive at the 8-year follow-up analysis. However, disease-related organ damage such as heart failure and chronic neuropathy may severely impair the quality of life of patients with EGPA. Immunosuppressive treatment can also contribute to morbidity, including an increased risk of malignancy and infection. In particular, the long-term use of glucocorticoids is often the cause of chronic, debilitating conditions such as diabetes and osteoporosis.

Chromatin remodeling

Definition

The term *Epigenetics* summarizes a group of regulatory mechanisms that affect gene expression. *Epigenetics* originates from the Greek words *επί* (*over*) and *γενετικός* (*genetics*). Epigenetic patterns of genes determine their signal- and tissue-specific expression without altering the DNA sequence. Epigenetic effects on gene expression are mediated by the reorganization of nucleosomes and chromatin fibers which affect the recruitment of transcription factors and RNA polymerases to genes. Thus, epigenetic patterns determine gene expression and are essential during cell and tissue development and differentiation. Epigenetic marks are generally variable, allowing cells and tissues to adapt to environmental changes (Brooks et al. 2010; Grolleau-Julius et al. 2010; Meda et al. 2011; Hedrich et al. 2011; Renaudineau and Youinou 2011).

Epigenetic Mechanisms in Gene Regulation

In order to exert their biological functions, transcription factors bind to their corresponding *cis*-DNA sequences within the regulatory regions

of genes. An accessible DNA structure is required for the binding of transcription factors to these regions, and an efficient way of silencing a gene is through the prevention of transcription factor binding.

CpG-DNA methylation: One way of preventing transcription factor binding is the addition of methyl groups to the 5′ carbon position of cytosine within cytosine-phosphate-guanosine (CpG-)dinucleotides. This is mediated through *DNA methyltransferases* (*DNMTs*) and can occur during cell division (DNMT1 re-methylates hemi-methylated CpGs, maintaining CpG-DNA methylation patterns) or independent of the cell cycle in the context of *de novo* methylation (DNMT3a and DNMT3b). Attenuated CpG-DNA methylation has been linked to the development of multiple diseases, including autoimmune disorders, infectious diseases, and cancer (Hedrich and Tsokos 2011; Renaudineau and Youinou 2011).

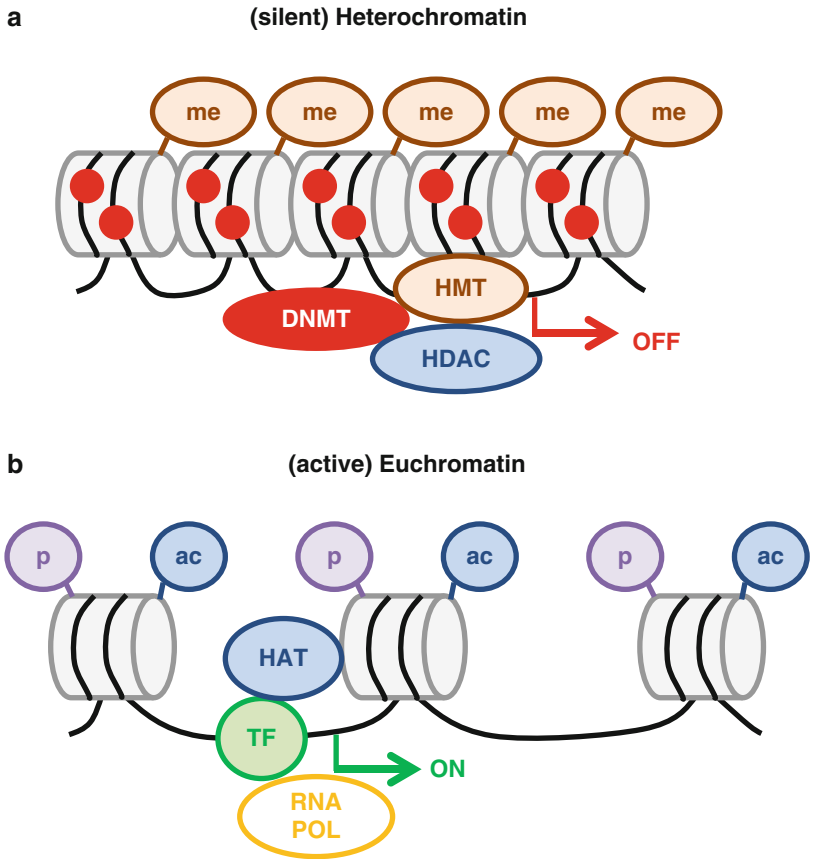
Histone modifications: Nucleosomes are the basic subunit of chromatin. A nucleosome is comprised of 146 base pairs of genomic DNA coiled around a histone octamer consisting of two copies of each of the histone proteins: H2A, H2B, H3, and H4. All histone proteins contain flexible N-terminal tails that undergo posttranslational modifications. Posttranslational histone modifications strongly impact the organization of nucleosomes, thus affecting the accessibility of DNA to transcription factors and RNA polymerases. Histone modifications include acetylation, methylation, ubiquitination, phosphorylation, sumoylation, citrullination, ADP ribosylation, and proline isomerization. Single markers and the combination of various histone modifications facilitate changes in the arrangement of nucleosomes and the resulting chromatin structure (Fig. 1) (Brooks et al. 2010; Grolleau-Julius et al. 2010; Meda et al. 2011; Hedrich and Tsokos 2011; Renaudineau and Youinou 2011).

CpG-DNA methylation and histone modifications usually follow corresponding patterns. Transcriptionally inactive (hetero-)chromatin is characterized by a high degree of CpG-DNA methylation and inactivating histone modifications, such as histone H3 lysine 9 (H3K9) and/or H3K27 tri-methylation. Active genes exhibit low levels of CpG-DNA and histone methylation, but high levels of histone acetylation (e.g., H3K9ac and H3K18ac) (Wilson et al. 2005; Brenner and Fuks 2007).

Micro RNAs (miRNAs): MiRNAs are small RNAs spanning 21 to 23 base pairs. They function as posttranscriptional regulators of gene expression. MiRNAs have been categorized as one of the three central epigenetic mechanisms in gene regulation, and miRNAs are in close relation to CpG-DNA methylation and histone modifications (Fig. 2). MiRNAs derive from larger intergenic and intronic transcripts. There is a tight correlation between the presence of intergenic transcripts and gene expression. Thus, intergenic transcription has been suggested to be at the interface of chromatin remodeling and the transcription of genes, allowing for interactions between distal regulatory elements and core promoters. RNA polymerases II or III transcribe so-called preliminary miRNAs. These preliminary RNAs are subsequently cleaved by the ribonuclease Drosha before they are exported to the cytoplasm. Dicer further processes the transcripts into mature miRNAs which form complexes with mRNA from the 3′ UTR of target genes. These interactions result in translational repression through direct mRNA cleavage or translational arrest (Thai et al. 2010; Hedrich and Tsokos 2011; Meda et al. 2011).

Immune homeostasis is maintained by a tight balance between activating and inactivating regulatory mechanisms. Changes in the epigenetic marks of single or multiple cells or tissues can contribute to autoimmune pathology on multiple levels.

Epigenetic mechanisms are involved in (1) the regulation of multiple genes, including genes encoding for cytokines, (co-)stimulatory molecules, and transcription factors, and (2) cell and tissue differentiation and lineage commitment. Furthermore, histone modifications have been documented to function as strong autoantigens and contribute to antibody production in systemic lupus erythematosus (SLE) and rheumatoid arthritis.



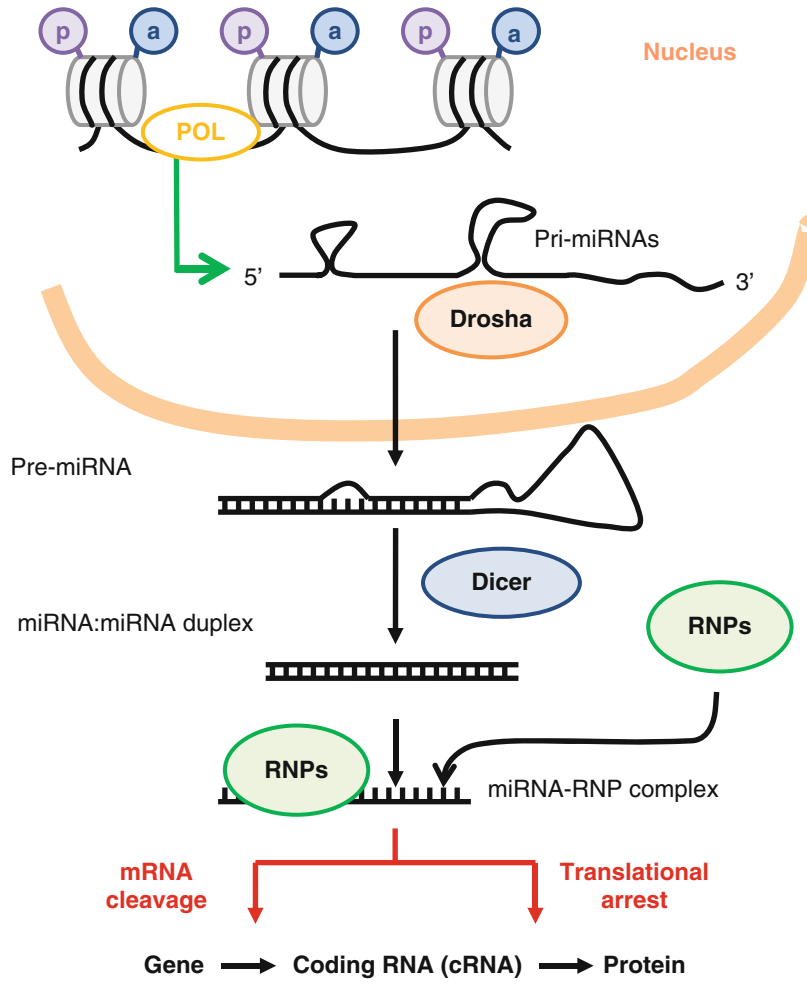
Epigenetics in Autoimmunity, Fig. 1 Nucleosome arrangement and chromatin structure in silent, transcriptionally inactive heterochromatin (**a**) and active euchromatin (**b**). Compact heterochromatin is characterized by dense packing of nucleosomes, repressive histone modifications (*brown circles*, representing histone hypermethylation), and high levels of CpG-DNA methylation (*red circles*). In these regions, recruitment of DNA methyltransferases (DNMTs), histone methyl transferases (HMTs), and histone deacetylases (HDACs) mediates a "closed" chromatin conformation. Active euchromatin is characterized by permissive histone modifications (*purple circles*, representing histone phosphorylation; *blue circles*, representing histone acetylation) and low levels of CpG-DNA methylation mediating decompaction. In these regions, transcription factors can bind to DNA motifs and recruit RNA polymerases (*yellow circle*) and additional activating epigenetic modifiers (HAT: histone acetyl transferases, blue circle) (Brenner and Fuks 2007; Hedrich et al. 2010; Wilson et al. 2005)

In the following, epigenetic mechanisms contributing to inflammation and antibody production in autoimmune diseases will be discussed.

Attenuated Epigenetic Control and Autoimmunity

Over the past years, the influence of epigenetic mechanisms on autoimmune diseases has been documented in various studies. It appears likely that epigenetic mechanisms may bridge the gap between genomic predispositions for the development of a disease and environmental factors that contribute to the pathogenesis of autoimmune disorders.

A number of immunological pathways have been demonstrated to be controlled or influenced by epigenetic mechanisms. Epigenetic mechanisms play a central role in the regulation of lymphocyte differentiation. The expression of the lineage determining *Il4* and *IFNg* genes in



Epigenetics in Autoimmunity, Fig. 2 MiRNAs are derived from noncoding transcripts of regions with "open" chromatin that are accessible to RNA polymerases (*yellow circle*). Primary transcripts (Pri-miRNAs) are processed into preliminary (pre-)miRNAs by the ribonuclease Drosha. Pre-miRNAs are transported to the cytoplasm and processed into mature miRNAs by Dicer. Mature miRNAs get incorporated into ribonuclease (RNP) complexes that exert their regulatory functions: translational arrest and mRNA cleavage (Brenner and Fuks 2007; Hedrich et al. 2010; Thai et al. 2010; Wilson et al. 2005)

T lymphocytes has been demonstrated to be under tight epigenetic control (Schoenborn et al. 2007). While the genes of naïve $CD4^+$ T lymphocytes are partially silenced, *Il4* is silenced in Th1 and *IFNg* is silenced in Th2 subsets. Similarly, the IL-10-related cytokine IL-19 is silenced in T lymphocytes through CpG-DNA methylation, while IL-19-expressing macrophages display site- and tissue-specific demethylation of several regions of the *Il19* gene (Hofmann et al. 2012). It seems likely that more genes with relevance to lymphocyte development and differentiation are under epigenetic control.

Epigenetic alterations of cytokine genes have been associated to the expression of autoimmune disease. In SLE, general ***hypomethylation of CpG-DNA*** correlates with disease activity, and several methylation-sensitive genes are over-expressed in $CD4^+$ T lymphocytes from SLE patients, including *IL4*, *IL6*, *IL10*, *IL13*, and *IL17* (Hedrich and Tsokos 2011; Rauen et al. 2011). Furthermore, a number of signaling molecules are subject to CpG-DNA hypomethylation in SLE T and B lymphocytes: *CD70/CD26L*, *CD6*, *CD11*, *CD40L/CD154* (in T cells), and *CD5* (in B cells) are over-expressed as a result of CpG-DNA hypomethylation. Interestingly, the *IL2* gene that fails to be expressed in SLE T lymphocytes is subject to epigenetic silencing through CpG-DNA and histone methylation (Renaudineau and Youinou 2011; Hedrich and Tsokos 2011). Similarly to SLE lymphocytes, rheumatoid arthritis synovial fibroblasts exhibit a hypomethylated state. Demethylated

CpG-elements within the *IL6* promoter have been demonstrated to be responsible for monocyte activation and inflammation. Hypomethylation and subsequent activation of LINE-1, a human endogenous retroviral element, has been demonstrated to contribute to the autoimmune phenotype of rheumatoid arthritis (Neidhart et al. 2000; Nile et al. 2008) (Table 1).

Histone modifications also play a role in the pathophysiology of autoimmune disorders. Thus far, histone modifications reported in SLE have been complex. Tissue-specific histone acetylation in some regions has been associated with increased disease activity, whereas histone acetylation in other regions seems to have protective effects. Increased acetylation of the *TNFα* promoter in monocytes from SLE patients is associated with increased monocyte maturation and cytokine expression (Sullivan et al. 2007; Hedrich and Tsokos 2011). Contrarily, histone acetylation of the *IL2* promoter is decreased and histone methylation is increased in T lymphocytes from SLE patients (Hedrich and Tsokos 2011). Fibroblasts from patients with rheumatoid arthritis exhibit global hyperacetylation of histone proteins. Monocytes from patients with chronic recurrent multifocal osteomyelitis fail to produce IL-10. This is associated with attenuated recruitment of the transcription factor Sp1 to the *IL10* promoter and reduced histone phosphorylation (Hofmann et al. 2011). Taken together, the involvement of histone modifications in the pathogenesis of autoimmune disorders appears certain. However, patterns are complex with areas of tissue-specific hyper- and hypo-acetylation (Table 1).

The involvement of ***miRNAs*** in various regulatory mechanisms during cell differentiation and in immune regulation embodies a huge potential for dysregulation and disease expression. However, the number of miRNAs documented to be involved in the pathogenesis of SLE and other autoimmune disorders is rather limited. The groups involved in the expression of SLE are mainly involved in the regulation of innate inflammatory responses by abnormal activation of the type I interferon pathway (miR-146a); inflammatory responses by suppressing the transcription

Epigenetics in Autoimmunity, Table 1 Selection of central epigenetic modifications in autoimmune disorders

CpG-DNA methylation	
Reduced CpG-DNA methylation	
SLE	Global hypomethylation of DNA in B and T lymphocytes
	In vivo and in vitro CpG-DNA demethylation results in SLE-like symptoms
	Altered DNA methyltransferase expression in SLE T lymphocytes
	CpG-DNA demethylation in SLE is mediated by GADD45a
	Hypomethylation and increased expression of cytokine genes: *IL4*, *IL6*, *IL10*, *IL13*, *IL17*
	Demethylation of co-stimulatory molecules: *CD6*, *CD11A*, *CD40L*, *CD70*, *CD5*
	Demethylation of perforin-1 (*PRF1*) mediates lysis of monocytes
	Demethylation and increased expression of the protein phosphatase 2A (*PP2A*)
	Demethylated DNA induces anti-DNA antibody production
	Demethylation of the human endogenous retroviral element (HERV) LINE-1
	. . . etc.
RA	Hypomethylation and increased expression of *IL6*
	In vitro demethylation of fibroblasts results in a RA-like phenotype
	Demethylation of the human endogenous retroviral element (HERV) LINE-1
MS	CpG-DNA demethylation in inflammatory white matter lesions
	Demethylation of the peptidylarginine deaminase 2 (*PAD2*) promoter:
	Attenuated proteolytic digestion of myelin and myelin instability
	Enhanced T cell responses
Increased CpG-DNA methylation	
SLE	Hypermethylation of cytokine genes in SLE T lymphocytes : *IL2*
RA	Increased methylation of the death receptor 3 (*DR3*) gene
SSc	Increased CpG-DNA methylation of the *FLI* promoter
T1D	Increased CpG-DNA methylation:
	Impaired homocysteine metabolism and tissue damage
	Impaired lymphocyte function and inflammation
Histone modifications	
Increased histone acetylation	
SLE	Globally increased histone acetylation
	Tumor necrosis factor (*TNF*) promoter:
	Increased TNF-α expression
	Increased monocyte maturation

(*continued*)

Epigenetics in Autoimmunity, Table 1 (continued)

RA	Globally increased histone acetylation
SSc	Histone deacetylase inhibitors mediate increased FL1 expression and fibrosis
	Reduced histone acetylation
SLE	Reduced acetylation of the *IL2* promoter in SLE T lymphocytes
	Increased histone deacetylase 1 (HDAC1) recruitment to the *IL2* promoter in SLE T cells
	Lupus-prone MRL/lpr mice express the histone deacetylase sirtuin-1 at increased levels
	Lupus-prone MRL/lpr mice express histone acetyltransferases p300, p300/CBP-associated factor, and HDAC7 at reduced levels
RA	Histone deacetylase inhibitors improve symptoms in murine RA models
	Histone modifications and autoantibody production
SLE	Apoptosis-related histone modifications enhance antibody production
	SLE autoantibodies react to apoptosis-related histone modifications
miRNAs	
SLE	miRNA-17 ~ 92: SLE-like symptoms in mouse model
	miRNA-125a: suppression of KLF13 and RANTES results in inflammation
	miRNA-126: interacts with DNMT1 and mediates *CD70* demethylation
	miRNA-146a: activation of type 1 interferon pathways
	miRNA-148a: direct and indirect targeting of DNMT1
	miRNA-148a: direct and indirect targeting of DNMT1
RA	miRNA-146a: activation of type 1 interferon pathways
	miRNA-155: suppression of metalloproteases in RA synovial fibroblasts
	miRNA-203: upregulated in RA synovial fibroblasts, resulting in increased IL-6 and matrix metalloprotease 1 expression
SjS	miRNA-150: upregulated in salivary glands of diabetic mice with SjS
	miRNA-574-3p and miRNA-768-3p: over-expressed in salivary glands

SLE systemic lupus erythematosus, *RA* rheumatoid arthritis, *T1D* type 1 diabetes, *MS* multiple sclerosis, *SSc* systemic sclerosis, *SjS* Sjögren's syndrome
Brooks et al. (2010), Grolleau-Julius et al. (2010), Meda et al. (2011), Hedrich and Tsokos (2011), Renaudineau and Youinou (2011), Thai et al. (2010), Hofmann et al. (2011), Rauen et al. (2011), Neidhart et al. (2000), Nile et al. (2008), Sullivan et al. (2007), Stanczyk et al. (2008), Chuang and Jones (2007), Zhao et al. (2010), Fraga et al. (2005)

factors KLF13 and RANTES (miR-125a); and CpG-DNA demethylation (miR-21, miR148a). MiR-146, miR-574, and miR-768-3p have been shown to be expressed in salivary glands and peripheral tissues from patients with Sjögren's syndrome (Brooks et al. 2010; Hedrich and Tsokos 2011). Mice that develop a rheumatoid arthritis–like syndrome exhibit miR-146a, and miR-155 expression in synovial fibroblasts. Furthermore, miR-203 was upregulated in these cells in a CpG-DNA methylation-dependent manner, resulting in increased IL-6 and matrix metalloproteinase1 expression (Stanczyk et al. 2008; Nakasa et al. 2008) (Table 1).

A strong interplay between miRNAs and other epigenetic mechanisms has been documented recently. Several of the genes regulated by mRNAs are involved in the epigenetic regulation of cellular functions. MiRNAs can influence CpG-DNA methylation through variable DNMT3a and DNMT3b expression, and DNMT1a transcript stability (Chuang and Jones 2007; Hedrich and Tsokos 2011). Overexpression of miR-126 in $CD4^+$ T lymphocytes results in the demethylation of *CD11A* and *CD70*, resulting in increased B and T lymphocyte activation (Zhao et al. 2010).

X Chromosomal Inactivation and Autoimmune Disease

The fact that females have two X chromosomes while males only have one raises the question of whether gender contributes to the female predominance in SLE (10:1), primary Sjögren's syndrome (9:1), rheumatoid arthritis (3:1), multiple sclerosis (2:1), and other autoimmune disorders (Brooks et al. 2010). The X and the Y chromosomes are believed to be derived from a common ancestor autosome. They still comprise similar genes in their pseudo-autosomal regions. Since most X-linked genes are not gender specific, they exhibit equal expression patterns in females and males. To achieve this, female mammalian organisms inactivate one X chromosome in a complicated epigenetic event, called X chromosome inactivation. X chromosome

inactivation involves all levels of epigenetic mechanisms, including CpG-DNA methylation, inactivating histone modifications (namely H3K9me2, H3K27me3, H3K20me, and reduced acetylation of H4), and miRNAs. Under physiological conditions, approximately 35 % of all genes on the short arms and 5 % of the genes on the long arms of the inactivated X chromosome are partially active. Many of these genes are also active on the Y chromosome and do not require compensation. Genes that require transcriptional control in order to avoid unbalanced expression can contribute to disease pathogenesis. This can be mediated through an abnormal number of X chromosomes (Klinefelter's syndrome: 47, XXY; Turner's syndrome: 45, X0) or incomplete X chromosomal silencing, resulting in over-expression of single genes (Brooks et al. 2010; Hedrich and Tsokos 2011).

A number of X chromosomal anomalies have been suggested to affect autoimmune disorders. Women with a complete chromosomal set of 46, XX and men with an additional X chromosome (47, XXY) develop SLE more frequently than healthy men (46, XY) (ratio 10:1). Also, an impaired X chromosomal inactivation has been documented to be associated with autoimmune disorders, including systemic sclerosis, autoimmune thyroiditis, Sjogren's syndrome, and rheumatoid arthritis. Women that lack one X chromosome (Turner's syndrome; 45, X0) develop SLE incidences that are comparable to those in men. Interestingly, fragmentation or absence of one X chromosome seems to increase the risk to develop other autoimmune disorders, such as type 1 diabetes. The loss of one X chromosome in peripheral cells, for example, is associated with primary biliary cirrhosis, autoimmune thyroiditis, but not associated with SLE (Brooks et al. 2010; Renaudineau and Youinou 2011; Hedrich and Tsokos 2011).

Age and Autoimmunity

A constantly increasing body of literature supports the hypothesis that epigenetic dysregulation contributes to the growing incidence of autoimmune disease and cancer with age (Grolleau-Julius et al. 2010), thus providing a mechanistic link between immune-senescence and autoimmune disorders. A progressive reduction of CpG-DNA methylation has been documented with growing age that appears to be proportional to life expectancy. Age-related epigenetic changes frequently accumulate in regions that contain homeobox genes (which are involved in the regulation of morphogenesis) and genes that are involved in cell differentiation (Brooks et al. 2009). Hypermethylation of tumor suppressor genes, aberrant DNMT activity that can result in loss of genomic imprinting, and chromosomal translocations in hypomethylated CpG-DNA sequences contribute to imbalances of the immune homeostasis in the elderly (Grolleau-Julius et al. 2009; Bollati et al. 2009; Brooks et al. 2009). It has been demonstrated that CpG-DNA methylation and histone H3 and H4 acetylation in PBMCs from elderly monozygotic twins diverge from younger controls, suggesting that these epigenetic variants accumulate with age (Fraga et al. 2005). In addition to age, epigenetic patterns can change in response to environmental exposure, explaining inter-individual differences in epigenetic patterns between monozygotic twins (Grolleau-Julius et al. 2010).

Recent evidence indicates the contribution of age-related changes in miRNA expression to autoimmunity and cancer (Grolleau-Julius et al. 2010). This is of special interest, since miRNAs on the one hand originate from "open" chromatin that has low degrees of CpG-DNA methylation, but can on the other hand also influence the degree of CpG-DNA methylation. Thus, it has been suggested that the involvement of the aforementioned miR-146 and miR-155 in rheumatoid arthritis is age dependent and may be indicative for further age-related disorders (Stanczyk et al. 2008).

Epigenetic Modifications and Autoantibody Production

In SLE, rheumatoid arthritis, and other autoimmune disorders, the nucleosome serves as a potent autoantigen. The presence of

nucleosome and histone-specific antibodies, as well as antigen-specific B and T lymphocytes has been demonstrated in the peripheral blood of SLE patients. Nucleosomes can be detected in the serum of SLE patients and lupus-prone mice. It has been suggested that aberrant apoptosis and impaired clearance of apoptotic material or a combination of both contribute to increased nucleosome release into the blood stream. Interestingly, autoantibodies from SLE patients show significantly enhanced activity against acetylated histones from both apoptotic cells and cells treated with HDAC inhibitors which subsequently undergo apoptosis (Table 1). Thus, it appears possible that apoptosis-induced chromatin modifications, such as histone acetylation, are an early event in the loss of self-tolerance, contributing to the development of autoimmune phenotypes (Hedrich and Tsokos 2011). At this point, it can only be speculated whether apoptosis-induced histone motifs may be a suitable substrate for future tolerizing strategies in SLE.

Mechanisms of Epigenetic Dysregulation

The underlying mechanisms leading to disturbed CpG-DNA methylation patterns and histone modifications in autoimmune diseases remain largely unknown. The addition of mitogen-activation protein kinase (MAPK) inhibitors to cultured T and B lymphocytes results in down-regulation of DNMT activity and an increased expression of methylation-sensitive genes, mimicking the pro-inflammatory phenotype of autoreactive lymphocytes. Reduced protein kinase C activity in mice and humans results in reduced MAPK and subsequently reduced DNMT1 activation, subsequently resulting in B lymphocyte expansion and the induction of pro-inflammatory cytokines (Hedrich and Tsokos 2011). Several molecules are involved in CpG-DNA demethylation of T lymphocytes from SLE patients. DNA damage inducible protein alpha (GADD45a), which is over-expressed in T lymphocytes from SLE patients, activation-inducible deaminase (AID), and the methyl-CpG binding domain 4 (MBD-4) related G:T glycosylase have been documented to contribute to CpG-DNA demethylation in B and T lymphocytes from SLE patients, thus contributing to increased gene expression and immune dysregulation (Brooks et al. 2009; Meda et al. 2011; Hedrich and Tsokos 2011; Renaudineau and Youinou 2011). Interestingly, studies investigating DNMT expression in SLE patients have produced conflicting results. This may be the result of variability in disease activity, discrepancies between DNMT mRNA and protein expression, and varying biological activity of DNMTs in the context of different genes, cells, tissues, and diseases (Hedrich and Tsokos 2011; Renaudineau and Youinou 2011) (Table 1).

The knowledge about mechanisms that contribute to pathological histone modifications in autoimmune disease is even more limited. It has been reported that the transcription factor c-AMP response element mediator (CREM)α is increased in T lymphocytes from SLE patients. CREMα is capable of recruiting HDAC1 and DNMT3a to the *IL2* gene, thus mediating epigenetic remodeling and stable silencing of the *IL2* gene. The over-expression of the histone deacetylase Sirtuin-1 in concert with reduced expression of E1A-binding protein p300, P300/CBP-associated factor, and HDAC7 in T lymphocytes from lupus-prone MRL/lpr mice suggest an involvement of these factors in the disruption of the epigenome in autoimmune disorders (Brooks et al. 2009; Meda et al. 2011; Hedrich and Tsokos 2011).

Epigenetic Patterns as Future Therapeutic Target

Given the central involvement of cell- and tissue-specific epigenetic marks in gene regulation and immune homeostasis, a reversion of pathological epigenetic patterns appears to be a promising target for future treatment. Experimental evidence

documenting the efficiency of HDAC inhibitors is growing (Hedrich and Tsokos 2011). However, HDAC inhibitors and other "epigenetic drugs" (including DNMT inhibitors, etc.) mediate genome-wide changes of histone acetylation and CpG-DNA methylation which may also result in dysregulation of previously unaffected genes. Target-directed epigenetic modifiers may reverse epigenetic changes of single genes or genomic regions. Such "intelligent" drugs may be used as future treatment of autoimmune disease and cancer; however, they remain to be discovered.

Conclusions

A constantly growing body of literature supports the central involvement of epigenetic mechanisms in immune programming and its alterations in the development of autoimmune disorders. Attenuated histone acetylation, CpG-DNA methylation, and miRNA expression, resulting in a disruption of immune homeostasis, have been linked to a number of autoimmune diseases, including SLE, Sjögren's syndrome, rheumatoid arthritis, multiple sclerosis, type 1 diabetes, and others.

However, current knowledge is limited and studies are warranted for a better understanding of epigenetic patterns and their contribution to autoimmunity. Epigenetic marks have a potential value as predictive, diagnostic, and prognostic biomarkers for multiple diseases. It is tempting to discuss epigenetic patterns as potential targets for future therapy. Still, currently available "epigenetic treatments," secondary to their global un-targeted mode of action, harbor the risk of disrupting epigenetic marks in unrelated regions, resulting in secondary pathology.

Erythema Nodosum

Sarika Ramachandran
The Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, NY, USA

Synonyms

Chronic erythema nodosum; Erythema contusiformis; Erythema nodosum (EN); Erythema nodosum migrans (EDM); Subacute migratory panniculitis of Vilanova and Piñol

Definition

Erythema nodosum (EN) is a septal panniculitis, which indicates that the inflammation in this disease occurs primarily along the fibrous septa which separate lobules of subcutaneous fat. Generally, the lesions of EN are located symmetrically over the anterior lower extremities. EN may be idiopathic or may be related to an infection, medications, sarcoidosis, inflammatory bowel disease, or other causes (Patterson 2008).

Introduction

EN, the most common type of panniculitis, was first described by Robert Willan during the eighteenth century (Patterson 2008 and Gilchrist and Patterson 2010). It is an inflammation of the fat most commonly seen symmetrically and bilaterally located over the lower legs.

Epidemiology

EN occurs in about 1–5 in every 100,000 individuals. The disease most often affects young

women; the male to female ratio is 1:6 (Schwartz and Nervi 2007). Frequently, it occurs between the second and fourth decades (Gilchrist and Patterson 2010). The highest incidence of the disease occurs between the ages of 20 and 30. The most common causes of the disease vary based on geographical location (Patterson 2008).

Pathophysiology/Immunology

EN is believed to be a type IV delayed hypersensitivity response to various antigens (Gilchrist and Patterson 2010). EN is a cutaneous response to a variety of inciting agents. It is believed that it results from the deposition of immune complexes in and near the septa located in subcutaneous fat. In some studies, patients with EN have been found to have complement activation and circulating immunocomplexes, whereas in other studies, patients were not found to have these immunocomplexes (Requena and SanchezYus 2008).

Presentation

This panniculitis presents with circular or oval tender cutaneous nodules. They are usually located symmetrically on the anterior lower legs. Lesions may also be distributed along the thighs or arms. They generally range in size from 1 to larger than 6 cm, and they usually resolve anywhere between 1 and 6 weeks after initial onset (Mana and Marcoval 2007). Episodes may last longer and recurrences are possible (Requena and SanchezYus 2008).

Lesions are usually firm, elevated, red, warm, shiny, and smooth during the initial presentation. As the lesions evolve, they flatten and leave a bruise-like appearance (erythema contusiformis). Of note, the lesions of EN do not scar or cause residual atrophy. The lesions tend to occur in crops and then slowly resolve (James et al. 2005). One to three weeks prior to the onset of cutaneous lesions, a prodrome may occur. During this period, individuals may present with muscle and joint aches, fevers, weight loss, fatigue, and cough (Schwartz and Nervi 2007). Abdominal symptoms including pain, vomiting, and diarrhea may be present. Patients may develop episcleral lesions or conjunctivitis. Less commonly, lymphadenopathy, hepatomegaly, splenomegaly, or pleuritis may occur (Requena and SanchezYus 2008). Depending on the underlying etiology, other systemic symptoms may be present as well. Patients may also develop leukocytosis and increased erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) (Schwartz and Nervi 2007).

There is a chronic variant of erythema nodosum which may be referred to as chronic EN, EN migrans, or subacute migratory panniculitis of Vilanova and Piñol. Chronic EN is less frequently seen than the acute form and is characterized by lesions that last months to years. This form may appear as a single lesion that improves but travels centrifugally. Ultimately, annular subcutaneous plaques are seen. In chronic EN, lesions affect the body in an asymmetric or unilateral manner and are not as painful as lesions in acute EN. Compared to acute EN, chronic EN is seen in older women and, with the exception of arthralgias, is generally not associated with systemic symptoms or systemic disease (James 2005).

In children and young adults, another variant of EN may occur. This form usually presents unilaterally on the palms or soles and usually occurs following physical activity (Requena and SanchezYus 2008).

Causes

EN can be idiopathic or occur secondary to a number of different etiologic factors. Broadly, these etiologic factors fall under the categories of infectious, medication-related, malignancy-related, and other miscellaneous entities (Requena and SanchezYus 2008) (Table 1).

Erythema Nodosum, Table 1 Major causes of erythema nodosum

Cause	Notes
Idiopathic	Often, a cause for EN is not found (Patterson 2008)
Infectious	**Bacteria** • In kids, streptococcal (Lancefield Group A, Streptococcus pyogenes) pharyngitis is the most common cause of EN (Gilchrist and Patterson 2010) • Bacterial gastrointestinal infections implicated in EN include Yersinia, Salmonella, Shigella, Campylobacter (James et al. 2005 and Gilchrist and Patterson 2010) **Fungal** • EN may be seen in coccidioidomycosis. When associated with EN, coccidioidomycosis is generally not disseminated (Patterson 2008) • Other less common causes include histoplasmosis and blastomycosis (Patterson 2008) **Mycobacteria** • Tuberculosis (TB) should be suspected in regions with high prevalence of the disease. However, TB is an uncommon cause of EN in areas where TB is rare (Mert et al. 2004)
Malignancy	This is usually a rarer cause, but EN can be seen in Hodgkin disease and acute myelogenous leukemia (Patterson 2008)
Sarcoidosis	EN almost always occurs during the acute phase of sarcoidosis associated with bilateral hilar lymphadenopathy, otherwise known as Löfgren's syndrome. However, occasionally, EN may occur in chronic sarcoidosis (Mana and Marcoval 2012) **Löfgren's syndrome** • This is an acute presentation of sarcoidosis and consists of EN, hilar lymphadenopathy, fevers, cough, and arthralgias (James et al. 2005). In addition, anterior uveitis, pulmonary involvement, and periarticular ankle inflammation may be seen. It is seen most often in young women from the Nordic region (Mana et al. 1999). The syndrome has a good prognosis; it is often self-limited and responsive to treatment (James et al. 2005)
Medications	Bromides Sulfonamides Oral contraceptive pills(OCP) • Although with a decrease in the hormonal content of more recent OCPs, they are becoming a rarer cause (Requena and SanchezYus 2008) Penicillin(Psychos et al. 2000)
Inflammatory bowel disease	Crohn's disease Ulcerative colitis
Behcet's disease	Behcet's disease often starts with oral ulceration and progresses to involve other mucocutaneous findings, including EN. This disease also has other systemic involvement including eyes, vessels, and digestive and nervous systems (Kaneko et al. 2011)
Pregnancy	Estrogens may be associated with the development of EN. It is often seen in the first or second trimesters of pregnancy (Mert et al. 2004)
Others	Connective tissue diseases Other infectious diseases

Diagnosis

History and clinical presentation may provide enough clues to make a diagnosis of EN. However, a skin biopsy may be diagnostic. A deep incisional biopsy or a double-punch biopsy may be necessary to capture the pathology (Gilchrist and Patterson 2010).

The histology of EN reveals a septal panniculitis. Distinguishing EN as a septal panniculitis is important as it greatly narrows the differential diagnosis and separates EN from lobular panniculitides which can sometimes have similar clinical presentations. In EN, different cells may be present, including histiocytes, lymphocytes, neutrophils, and sometimes eosinophils (Rapini 2005). The subcutaneous fat septa are thickened and are the primary location of the inflammatory infiltrate. However, the inflammatory cells may extend into the periseptal areas within the fat lobules. Early-stage EN lesions are characterized by neutrophils, edema, and hemorrhage. In long-standing lesions, multinucleated

giant cells, lymphocytes, histiocytes, granulation tissue, and fibrosis are seen (Requena and SanchezYus 2008). Immunoglobulin deposition in the vessel walls within septa has been demonstrated through direct immunofluorescence studies (Requena and SanchezYus 2008).

Preliminary investigations should consist of complete blood count including differential erythrocyte sedimentation rate, antistreptolysin O titer, urinalysis, throat culture, tuberculosis testing, and chest radiograph (Requena and SanchezYus 2008). Stool examinations and blood cultures may be obtained depending on patient presentation and history (Schwartz and Nervi 2007).

Differential Diagnosis

The differential diagnosis of EN includes other panniculitides such as lupus profundus, cold panniculitis, poststeroid panniculitis, or sclerosing panniculitis. In addition, cytophagic histiocytic panniculitis and leukemic fat infiltrates are among neoplastic entities that may mimic EN. Deep fungal, bacterial, and mycobacterial infections may mimic the presentation of EN. Other diseases that should be considered include alpha 1-antitrypsin deficiency, nodular fat necrosis, necrobiosis lipoidica, necrobiotic xanthogranuloma, scleroderma, subcutaneous granuloma, and other panniculitides (Schwartz and Nervi 2007). EN may be differentiated from these entities through clinical presentation, histological examination, and direct immunofluorescence studies.

Treatment and Management

The first approach toward treating EN is to eliminate the inciting trigger. It is important to look through the patient's history and remove possible offending medications. It is imperative to treat possible infections or malignancies. Generally, EN is self-limited so addressing symptoms is the next step. It may take up to 2 months before new EN lesions stop developing (Gilchrist and Patterson 2010).

Nonsteroidal anti-inflammatory drugs (NSAIDs) are considered first-line treatment. Therapy is started with indomethacin. Ibuprofen or naproxen may be used in patients who do not respond to indomethacin. Patients are advised to get adequate rest, elevate the legs for half an hour twice a day, and use compression stockings (Gilchrist and Patterson 2010).

Potassium iodide (KI), dispensed as saturated solution of KI (SSKI), is used to treat erythema nodosum. The mechanism is not completely understood; however, it is thought that SSKI may work by inhibiting neutrophil chemotaxis. Adults generally are started at a dose of 300 mg three times daily and titrated up to 500 mg three times daily if needed. Patients may note improvement around 14 days. Side effects include nausea, distortion of taste, hypersalivation, and irritation of the GI tract. Decreasing the dose can reduce these side effects. Patients are often encouraged to take the medication with orange juice (Gilchrist and Patterson 2010). This medication is contraindicated in pregnancy as it may cause the growth of a goiter in the fetus. Additionally, significant hypothyroidism may occur as a result of taking this medication (Requena and SanchezYus 2008).

Colchicine is another option in treating EN. It is particularly helpful in patients with Behcet's disease who develop lesions of EN. Females tend to respond to the medication more than men. Colchicine is anti-inflammatory and arrests microtubule polymerization, thereby impairing neutrophil chemotaxis. Gastrointestinal side effects are common and include diarrhea and abdominal pain. Starting colchicine at a low dose, such as 0.6 mg once daily, and increasing to twice daily as tolerated helps with these side effects. Bone marrow suppression with pancytopenia may occur with overdose (Gilchrist and Patterson 2010).

After malignancy and underlying infection have been ruled out, systemic steroid treatment may provide therapeutic benefit. In EN, systemic steroids are dosed at 1 mg per kg (Schwartz and Nervi 2007).

Local treatment of EN includes intralesional injections of triamcinolone acetonide. The

medication is injected into the center of lesions at a concentration of 5 mg/ml (Requena and SanchezYus 2008).

Conclusion

EN can occur from a number of causes. Most often it occurs idiopathically. However, if an underlying cause does exist, finding and treating the triggering disease is the first step in clearing the eruption.

Fas/Fas Ligand

Estrella García-González and Enrico Selvi
Rheumatology Unit, Department of Clinical Medicine and Immunological Sciences, University of Siena, Siena, Italy

Synonyms

Fas: CD95, Apo-1; Fasl: CD95 ligand

Definition

Fas and Fas ligand (Fasl) are transmembrane proteins that belong to the TNF receptor family and TNF family of proteins, respectively.

Fas (CD95) is expressed on many types of cells, yielding them susceptible of killing by cells expressing Fasl.

Fasl (CD95l) is expressed mainly on activated T cells. Binding of Fasl triggers apoptosis (**programmed cell death**) in the Fas-expressing cells.

Fas/Fasl: Mediators of Apoptosis

Fas is a transmembrane receptor ubiquitously expressed, in particular, in brain, heart, kidney, liver, pancreas, thymus, and lymphoid tissues. Fasl is a protein expressed mainly on membranes of activated T lymphocytes. The interaction between Fasl and the Fas receptor, triggers apoptotic signals in the cell expressing Fas (Elgert 2009a; Hotchkiss et al. 2009). The ligation of Fas by Fasl causes the activation of target cell enzymes to degrade target cell nuclear DNA with concomitant fragmentation of the target cell nucleus, leading to programmed cell death. When Fasl binds Fas, Fas trimerizes and activates its "death" domain that interacts with the "death" domains of several cytosolic proteins including FADD (Fas-associated death domain). Activation of FADD triggers the activation of a series of cysteine proteases known as caspases, resulting in apoptosis of the cell with the consequent morphological changes (reduction of cell volume, plasma membrane blebbing, condensation of chromatin, and fragmentation of DNA) (Elgert 2009a; Hotchkiss et al. 2009; Guicciardi and Gores 2009) (Fig. 1). Phosphatidylserine, normally found on the cytosolic surface of plasma membranes, is redistributed during the process of apoptosis to the extracellular surface. Phagocytic cells recognize this aberrant placement and remove the dying cells without the induction of inflammation. Cell removal is followed by a reset of the activated T lymphocytes to initiate another Fas/Fasl interaction (Elgert 2009a; Hotchkiss et al. 2009).

Fas-mediated apoptosis plays a critical role in the removal of mature autoreactive B and T lymphocytes as well as in the elimination of infected or malignant cells (Elgert 2009b, c; Crow 2003; Kay 2003).

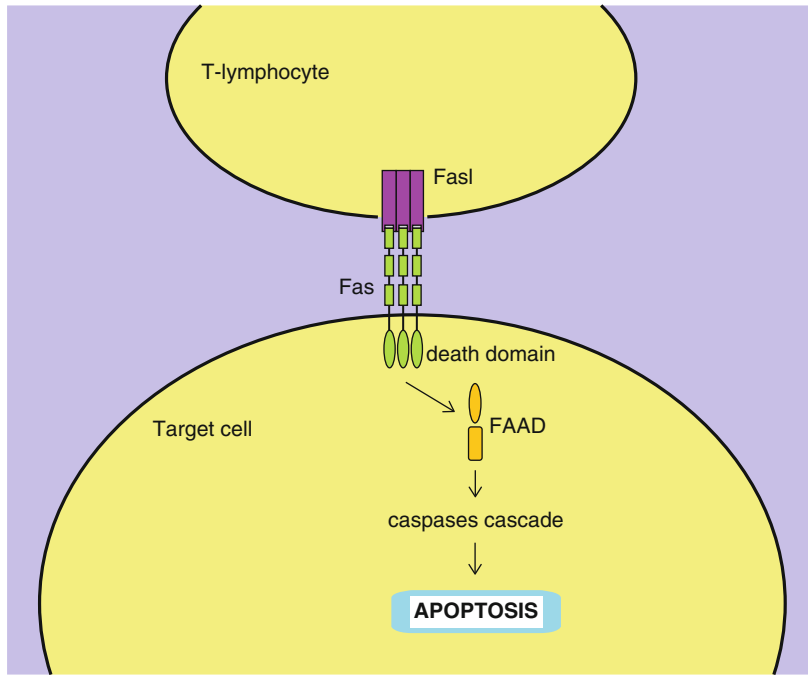
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014



Fas/Fas Ligand, Fig. 1 *Fas/Fasl apoptotic pathway*. The interaction between Fasl (expressed on T-activated lymphocyte) and the Fas receptor, expressed on target cell, triggers apoptotic signals in the cell expressing Fas. After binding of Fas by Fasl, Fas trimerizes and activates its "death" domain that interacts with the Fas-associated death domain protein (*FADD*). Therefore, activation of FADD triggers the activation of the caspases cascade, resulting in programmed cell death

Fas/Fasl: Key Role in Autoimmunity

The biological importance of Fas/Fasl interaction in the development of autoimmune diseases was established in naturally occurring mutations of either Fas or Fasl proteins in mice. The genetic lesions lead to massive T lymphocyte proliferation in lymph nodes and spleen. The mouse strain with a lesion in the gene encoding Fasl is called *gld* (general lymphoproliferative disorder). These mice do not exhibit Fas-/Fasl-induced apoptosis and therefore develop autoimmune disease early in life (Coico and Sunshine 2009). A human disease which mimics the murine model is the autoimmune lymphoproliferative syndrome (ALPS), caused by a mutation in the genes encoding Fas and Fasl. This syndrome is characterized by lymphoproliferation (lymphadenopathy, hepatosplenomegaly), several autoimmune manifestations (mainly autoimmune cytopenias), and an increased propensity to malignancy (lymphomas) (Worth et al. 2006; Teachey et al. 2010). ALPS is the first human disease which etiology has been attributed to a primary defect in apoptosis, linking lymphocyte homeostasis and the autoimmune response (Turbyville and Rao 2010; Su and Anderson 2009). Considering that abnormalities in apoptosis can increase susceptibility to autoimmunity, defects in apoptosis and the clearance of apoptotic cells have been linked to several autoimmune diseases (Elgert 2009b; Crow 2003; Viorritto et al. 2007).

Normally, in order to eliminate autoreactive T cells (mature T lymphocytes that recognize self-antigens), interaction between autoreactive T cell Fas and activated T lymphocytes Fasl induces apoptosis of the autoreactive T cells (Strasser and Pellegrini 2004). This negative regulation of T cells contributes to the elimination of T lymphocyte-activated autoreactive B cells, in the absence of presentation of the autoantigen by the autoreactive T cell (Elgert 2009b; Crow 2003; Rathmell et al. 1996). By virtue of elimination of these cells, the immune system remains safe and effective. Thus, normal Fas/Fasl function results in normal lymphocyte homeostasis and controlled autoreactivity. An alteration in Fas/Fasl structure results in impaired immune

tolerance and in uncontrolled lymphoproliferation (Turbyville and Rao 2010; Su and Anderson 2009; Hughes et al. 2008). Inadequate removal of self-reactive T lymphocytes permits the production of pathogenic autoantibodies that characterize autoimmune diseases (Crow 2003; Strasser and Pellegrini 2004; Rathmell et al. 1996).

Fas/FasL: Role in Tumor Surveillance

A critical function of the immune system is to control of malignant cell proliferation. In fact, patients with immunodeficiencies and/or autoimmune diseases are at increased risk for development of tumors. More than 50 % of neoplasms exhibit defects in apoptosis (Elgert 2009c).

The Fas/FasL proteins may be considered oncogenes, as malignancies can develop with Fas/FasL mutations. These mutations increase the capability of malignant cells to avoid immune surveillance (Elgert 2009c; Peter et al. 2005). Patients with ALPS (main sample of a disease associated with an apoptotic defect) are susceptible to malignant transformation of their lymphocytes due to high rates of cell division in the absence of normal Fas-/FasL-mediated homeostasis (Worth et al. 2006).

The evolution of tumor cells to a more malignant phenotype requires the acquisition of genetic changes that subvert apoptosis pathways and promote cancer cell survival (Elgert 2009c). It has been assumed that Fas and FasL work as tumor suppressors, since mutations that downregulate normal function of Fas have been proposed as a mechanism by which tumor cells avoid apoptosis or destruction by the immune system (Elgert 2009c). However, a single point mutation of the Fas gene can change Fas/FasL interaction from tumor suppression to tumor promotion by induction of prosurvival genes through non-apoptotic pathways. This dual role of Fas/FasL is found in advanced cancer in humans, resulting in apoptosis resistance and activation of tumorigenic pathways (Peter et al. 2005).

Fas/FasL: Biomarkers of Inflammation

Inflammatory biomarkers might help to identify specific inflammatory disturbances. Therefore, targeting specific biomarkers of inflammation might represent new therapeutic approaches (Schütz et al. 2010). Both Fas and FasL proteins exert a wide range of proinflammatory functions by inducing secretion of cytokines and chemokines (Kay 2003). Beyond activating apoptosis, the activation of the Fas "death domain" can initiate multiple non-apoptotic signaling pathways, including inflammatory responses (Hotchkiss et al. 2009; Guicciardi and Gores 2009). Furthermore, Fas/FasL increases cell removal from areas of chronic inflammation (Guicciardi and Gores 2009).

An example of the importance of Fas/FasL in inflammation is the development and progression of heart failure. Fas is expressed in cardiac myocytes, and serum concentrations of a soluble form of Fas are elevated in patients with heart failure. Furthermore, high levels of soluble Fas are associated with more severe disease, and inhibition of Fas in animal models reduces post infarction syndrome and improves survival (Braunwald 2008). Measurement of Fas/FasL soluble forms appears to be useful in risk stratification of patients with heart failure and in the screening of asymptomatic patients to identify heart failure risk. Pharmacological reduction of Fas levels may represent a new direction for treatment or prevention of heart failure (Braunwald 2008).

FcγRIIB

Falk Nimmerjahn[1,2] and Anne Bärenwaldt[2]
[1]Institute of Genetics, Department of Biology, University of Erlangen–Nürnberg, Erlangen, Germany
[2]Department of Biomedicine, University of Basel, Basel, Switzerland

Synonyms

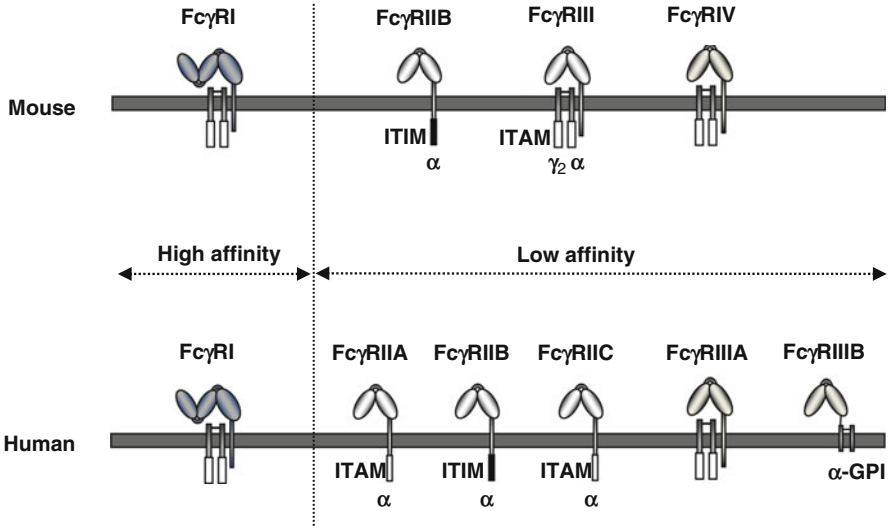
CD32B; Fc fragment of IgG low-affinity IIb receptor

Definition

FcγRIIB is a low-affinity receptor ($K_a = 10^7\ M^{-1}$) for the constant region of immunoglobulin G (IgG) and belongs to the family of Fcγ-receptors (FcγR).

Structure and Expression

The 40 kDa glycoprotein consists of two immunoglobulin-like extracellular domains, a transmembrane region and a cytoplasmic tail containing an immunoreceptor tyrosine-based inhibitory motif (ITIM) (Fig. 1). In humans and mice, two isoforms of FcγRIIB exist as a result of alternative splicing, designated FcγRIIB1 and FcγRIIB2. An insertion of 19 amino acids in humans and 47 amino acids in mice in the FcγRIIB1 isoform interrupts an amino acid motif in the cytoplasmic tail essential for endocytosis. Whereas FcγRIIB2 expression is restricted to myeloid cells, FcγRIIB1 is the main form expressed on B cells. On the majority of immune cells, including macrophages, mast cells, neutrophils, dendritic cells (DCs), and monocytes, FcγRIIB is co-expressed with activating FcγRs (FcγRI, FcγRIII, and FcγRIV in the



FcγRIIB, Fig. 1 The family of Fcγ-receptors in mouse and humans. Depicted are the members of the mouse and human FcγR family. The individual family members can be distinguished by the signals they transduce and by the affinity for IgG. FcγRIIB is a low-affinity receptor for IgG, which is characterized by an ITIM motif in its cytoplasmic domain

mouse and FcγRIA, FcγRIIA, and FcγRIIIA in humans) and thereby sets a threshold for cell activation. In contrast, FcγRIIB is the only FcγR expressed on B cells where it regulates positive signals transmitted by the B cell receptor (Ravetch and Nimmerjahn 2008).

The expression level of FcγRIIB on different B cell developmental stages varies between mice and men. In the mouse, FcγRIIB is expressed starting from the pre-B cell stage (Foy et al. 1992). In comparison to naive B cells, germinal center B cells (GC B cells) show a lower expression of FcγRIIB, whereas in plasma cells a higher expression was observed in mice (Jiang et al. 1999). In most of the human studies using isolated B cells from human blood, memory B cells show a higher expression of FcγRIIB than naive B cells (Isaak et al. 2008; Mackay et al. 2006; Tackenberg et al. 2009). For plasma cells, one study showed a lower expression of FcγRIIB compared to naive B cells (Catalan et al. 2010). On B cells from human spleen and B cells from NOD/Scid/$\gamma c^{-/-}$-deficient mice reconstituted with human CD34+ hematopoietic stem cells, memory B cells and plasmablasts had a higher expression of FcγRIIB than naive B cells, consistent with the data obtained in mice. In contrast to the mouse, however, human germinal center B cells had a higher expression of FcγRIIB than naive B cells, and the analysis of human bone marrow showed that FcγRIIB expression starts at the level of immature B cells (Baerenwaldt et al. 2011). Compared to B cells, monocytes, neutrophils, and DCs have a lower amount of FcγRIIB on the cell surface (Su et al. 2007). However, FcγRIIB expression can be modulated by several cytokines or bacterial components. Incubation of monocyte-derived DCs (moDCs) or plasmacytoid DCs with IL-4 and IL-10 was shown to up-regulate FcγRIIB expression (Su et al. 2007; Wijngaarden et al. 2004). On monocytes, IL-4 enhances FcγRIIB expression, whereas it leads to a decline of FcγRIIB on B cells (Rudge et al. 2002). In contrast to IL-4, IFN-γ treatment of monocytes, moDCs, and B cells leads to a reduced expression of FcγRIIB. TNF-α and LPS provoked

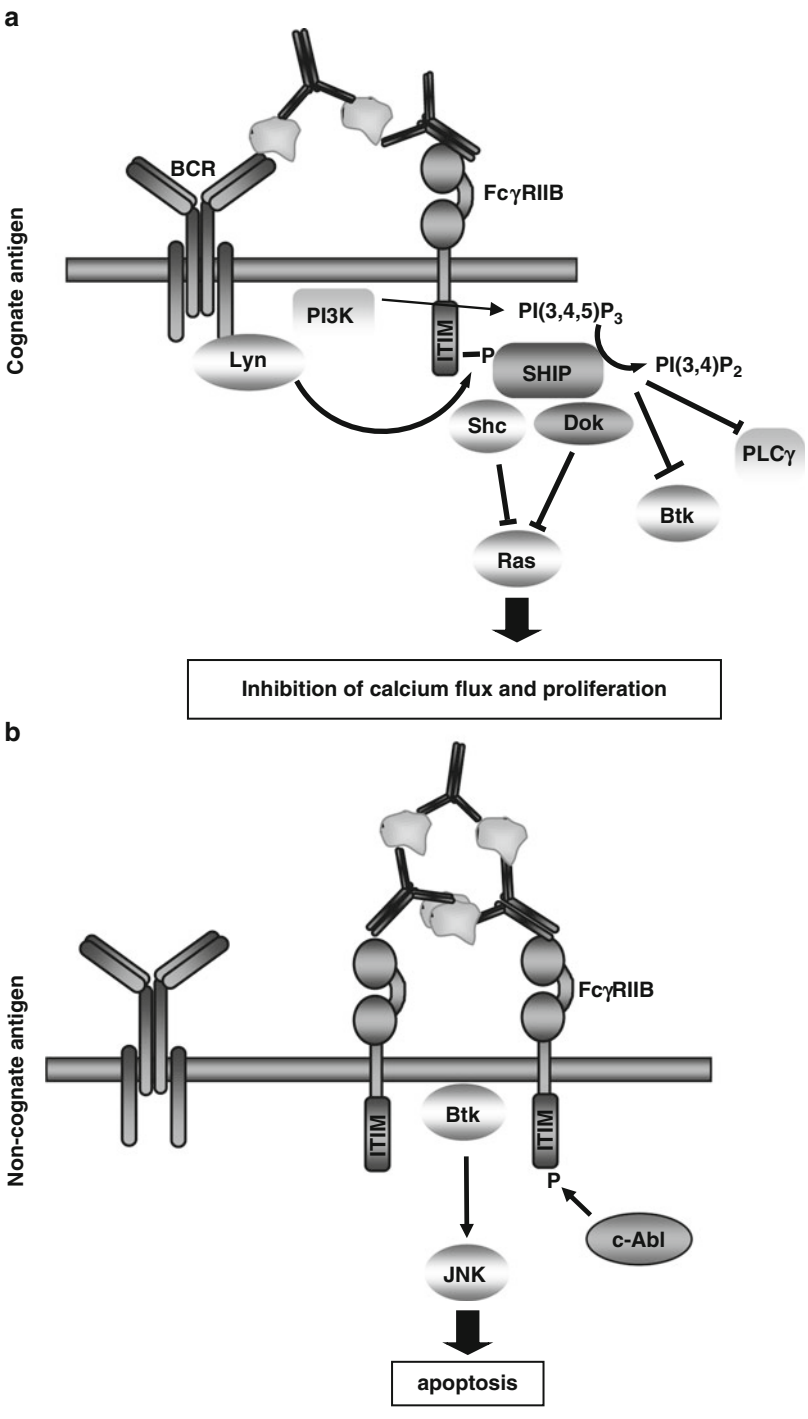
a down-modulation of FcγRIIB on moDCs (Boruchov et al. 2005). Therapeutic agents can also alter the expression of FcγRIIB. Thus, intravenous immunoglobulin (IVIg), which is used for the treatment of several autoimmune diseases, was shown to up-regulate FcγRIIB on monocytes, naive B cells, and memory B cells in humans (Tackenberg et al. 2010).

Signaling of FcγRIIB

There are two major pathways, by which FcγRIIB can transmit signals into the cell, which are either dependent or independent of the ITIM motif in the cytoplasmic tail (Fig. 2). In the ITIM-dependent pathway, immune complex binding to FcγRIIB in combination with activating signals transduced by the B cell receptor or other activating FcγRs leads to the phosphorylation of the ITIM motif by the kinase Lyn, leading to the recruitment of SRC-homology-2 domain-containing inositol polyphosphate-5-phosphatase (SHIP). This results in the dephosphorylation of phosphatidyl-inositol (3,4,5)-trisphosphate (PIP_3) which subsequently inhibits the association of Bruton's tyrosine kinase (Btk) and phospholipase C gamma (PLCγ). The outcome of this signaling pathway is the reduction of calcium influx and a diminished activation signal initiated through activating receptors. The second signaling pathway is independent of the ITIM motif and seems to be restricted to B cells. Cross-linking of FcγRIIB without co-cross-linking of the B cell receptor induces a SHIP-independent but Btk- and c-Abl-dependent signaling pathway ultimately leading to apoptosis (Tarasenko et al. 2007). This pathway is believed to be important in the germinal center reaction to delete low-affinity (and thus potentially autoreactive) B cells and to control plasma cell persistence (Xiang et al. 2007).

Modulation of Immune Cells by FcγRIIB

FcγRIIB modulates immune cells by setting a threshold for cell activation. Only if the activating signal is strong enough to overcome the inhibitory signal induced by FcγRIIB, cells can become activated. On innate immune effector cells, where FcγRIIB is co-expressed with activating FcγRs, antibody-triggered effector functions such as antigen presentation, release of cytokines, or induction of the respiratory burst are controlled by this threshold. On B cells, FcγRIIB is co-cross-linked with the B cell receptor if the antigen is presented in form of IgG immune complexes, resulting in the inhibition of B cell activation and proliferation. Modulation of B cell and innate effector cell activation by FcγRIIB was shown to be an important mechanism to limit and shut down antibody-mediated immune responses. In case of innate effector cells, FcγRIIB prevents the continuous production of inflammatory cytokines induced by cross-linking of activating FcγRs. As a result, the inflammatory response induced by the antigen can be shut down after a successful immune response (Ravetch and Nimmerjahn 2008). With respect to B cells, the threshold set by FcγRIIB is believed to be of major importance especially in the germinal center reaction. Here, B cells activated by their specific antigen undergo somatic hypermutation (SHM) to create BCRs (and later antibodies) of high affinity and narrow specificity. Since this process is driven by chance, it has to be tightly regulated to prevent the generation of autoreactive BCRs and antibodies. In the germinal center antigen is presented by follicular dendritic cells in form of immune complexes. This results in co-ligation of FcγRIIB with the BCR on antigen-specific B cells, establishing a threshold set by positive and negative signaling events. If SHM of the BCR results in a high BCR affinity for the cognate antigen, the B cell gets a strong activation signal that overcomes the negative threshold set by FcγRIIB and is positively selected (Fig. 2a). If SHM results in the loss of antigen recognition, the inhibitory signal of FcγRIIB is the only signal transmitted to the B cell leading to the induction of apoptosis (Fig. 2b). Thus, FcγRIIB-dependent elimination of B cells that lost their antigen specificity may be important to delete potentially autoreactive B cell species (Nimmerjahn and Ravetch 2010).



FcγRIIB, Fig. 2 Signaling pathways induced by FcγRIIB cross-linking. (**a**) Co-cross-linking of FcγRIIB with the B cell receptor (BCR) or activating FcγRs (not depicted) results in a Lyn-dependent phosphorylation of the ITIM motif in the cytoplasmic tail of the inhibitory FcγRIIB. This recruits SHIP to the ITIM domain, leading to the inhibition of downstream activating signaling pathways, such as the release of calcium. (**b**) Isolated triggering of the inhibitory FcγRIIB on B cells was shown to induce apoptosis in an ITIM-independent but Btk- and c-Abl-dependent manner. See text for further details

Role of FcγRIIB in Autoimmunity

Over the last years, several studies using either mouse model systems or human autoimmune patient cohorts suggest that FcγRIIB may be crucially involved in maintaining humoral tolerance. Mouse strains like BXSB, NZB, MRL, or NOD that develop spontaneous autoimmune diseases

were shown to have deletions in the promoter region of FcγRIIB leading to a diminished expression of FcγRIIB on germinal center B cells. Deletion of FcγRIIB in the mouse results in a higher susceptibility to develop spontaneous or induced autoimmunity. Thus, injection of immune complexes into FcγRIIB−/− mice results in development of glomerulonephritis or alveolitis, and immunization with collagen leads to the development of Goodpasture's syndrome and arthritis on usually non-susceptible genetic backgrounds. On the C57Bl/6 background deletion of FcγRIIB results in the spontaneous development of autoimmunity, characterized by the production of anti-DNA antibodies and the development of glomerulonephritis. Cell type-specific overexpression of FcγRIIB on B cells but not on macrophages, was able to restore self-tolerance (Brownlie et al. 2008).

In humans, two polymorphisms in the *fcgr2b* gene were associated with autoimmunity. In the Caucasian population, a promoter polymorphism was associated with systemic lupus erythematosus (SLE). The exchange of guanine to cytosine on position −386 is believed to influence the expression of FcγRIIB, but there are conflicting results if this promoter variant enhances or decreases the expression. In the Asian as well as in the Caucasian population, a polymorphism in the transmembrane region of FcγRIIB was shown to be present at a higher frequency in SLE patients compared to healthy donors. This polymorphism leads to an exchange of the isoleucine residue at position 232 (in the transmembrane domain of FcγRIIB) with a threonine residue, leading to a diminished recruitment of this receptor variant into lipid rafts upon co-cross-linking with activating receptors. Functionally this translates into a decreased inhibitory signal, an increased calcium flux, and a higher degree of cell activation (Tarasenko et al. 2007). In addition, several studies comparing cells of autoimmune patients with healthy donors support a role of FcγRIIB for human B cell tolerance. Thus, B cells from patients with different autoimmune diseases seem to have an altered expression of FcγRIIB. B cells of SLE patients (Mackay et al. 2006), patients with rheumatoid arthritis (Catalan et al. 2010), and chronic inflammatory demyelinating polyneuropathy (CIDP) (Tackenberg et al. 2009) have a reduced expression of FcγRIIB compared to healthy controls. Furthermore, the up-regulation of FcγRIIB from naive to memory B cells which can be observed in healthy individuals was absent on memory B cells of SLE and CIDP patients (Mackay et al. 2006; Tackenberg et al. 2009). Several lines of evidence suggest that FcγRIIB represents a late tolerance checkpoint during B cell development. Thus, an increased number of plasma cells, memory B cells, or GC B cells can be detected in FcγRIIB$^{-/-}$ mice, humanized mice, and in autoimmune patients (Baerenwaldt et al. 2011; Tarasenko et al. 2007). Furthermore, an increased number of autoantibody-producing cells can also be detected in FcγRIIB$^{-/-}$ mice (Fukuyama et al. 2005; Rahman et al. 2007). Additionally, it was shown that autoreactive B cells in the spleen remain at the border of the T cell zone and B cell zone and do not participate in the germinal center reaction in an FcγRIIB-dependent manner (Paul et al. 2007).

Conclusion

FcγRIIB is a low-affinity receptor for the constant region of IgG. Within the family of FcγRs, it is the only inhibitory receptor containing an ITIM motif in its cytoplasmic domain. The co-aggregation of FcγRIIB with ITAM bearing receptors, like activating FcγRs or the BCR, sets a threshold for cell activation and modulates the outcome of the resulting cellular response. In the humoral immune response, FcγRIIB is crucial for controlling the activation and proliferation of antigen-specific B cells and may represent a major checkpoint for humoral tolerance in mice and in humans. In the efferent phase of an antibody-dependent immune response, FcγRIIB modulates innate immune effector cell activation

resulting in a balanced pro-inflammatory response. New approaches influencing FcγRIIB expression on different cell types may help to treat autoimmune diseases and chronic inflammation in the future.

Definition

Fibrosis is the deposition of excess fibrous connective tissue replacing normal tissue architecture. Connective tissue cells synthesize and maintain extracellular matrix (ECM) and provide mechanical support and attachment for contiguous tissues and organs. The cells embedded within connective tissues live in specialized environments in which they experience tissue-specific chemical and mechanical signals. For all connective tissues, collagens are the principal molecular building blocks. Collagens control tissue architecture, tensile strength, and cell–matrix and matrix–matrix interactions. The ECM is the main source of collagens, other macromolecules such as proteoglycans, fibronectin, fibrillins, as well as adhesion molecules, growth factors, and other signaling molecules. Exaggerated deposition and disordered remodeling of ECM characterize the fibrotic process (Hynes 2009; Chan et al. 2010).

Fibrosis is not always pathological; the fibrotic process is a key event underlying normal wound healing and tissue repair. The level of collagen accumulation during healing is tightly regulated by a balance between synthesis and degradation. The fibroblast is the principal cell type that both synthesizes and degrades ECM components, orchestrated by chemical and biomechanical signals in endocrine, paracrine, and autocrine fashion.

Fibroblasts are mesenchymal cells identified by their location and stellate morphology, and by the absence of specific surface markers. They are found in most parenchymal tissues, especially those with prominent epithelial and microvascular components (e.g., skin, lung, liver, and kidney). Fibroblasts are important in normal development, tissue homeostasis, and wound healing. Injury and repair of most tissues begin with epithelial or endothelial damage, resulting in exudation of blood or platelet-rich plasma into extravascular spaces, leading to the formation of a fibrinous clot (provisional matrix). Fibroblasts migrate into the provisional matrix where they proliferate and produce de novo ECM components, creating a fibroblast-populated granulation tissue. Although fibroblast activation during wound healing is beneficial in rebuilding the ECM, excess collagen deposition results in pathological fibrosis and scar formation. The disordered and exaggerated deposition of ECM in affected tissues disrupts the normal architecture of the affected organs, leading to their dysfunction and ultimately failure. Therefore, fibrosis represents an uncontrolled repair process that recapitulates features of embryonic development and normal wound healing. This scenario posits that fibrosis and scarring results from failure to stop tissue remodeling rather than a specific continuing insult. Normally, the healing process is turned on and then turned off in a temporally and spatially controlled manner. In the absence of approximately timed off signals, there is an increase in cell proliferation, matrix accumulation, and remodeling, resulting in a non-resolved and intractable fibrotic scar (Wynn 2008; Rosenbloom et al. 2010; Wei et al. 2011).

It is estimated that fibrotic conditions account for up to 45 % of deaths in the developed

Fibrosis, Table 1 Selected organ-specific fibrosing conditions

• **Skin**
Hypertrophic scar
Morphea
Nephrogenic fibrosing dermatopathy (may be systemic)
Dupuytren contracture
Eosinophilic fasciitis
• **Lung**

world (Wynn 2008; Bhattacharyya et al. 2011). They encompass a wide spectrum of clinical entities, including organ-specific disorders in the skin, lung, liver, kidney, and heart, as well as multisystemic diseases such as systemic sclerosis (Table 1). Although their etiology, causative mechanisms, and underlying genetic factors are different, these conditions appear to share common feature of disordered and exaggerated deposition of ECM in affected tissues (Wynn 2008).

There are no approved anti-fibrotic therapies. Fibrosis thus represents an unmet medical need. Developing effective anti-fibrotic therapies remains a major challenge given the plethora of molecules contributing to this process, and the complex networks linking them.

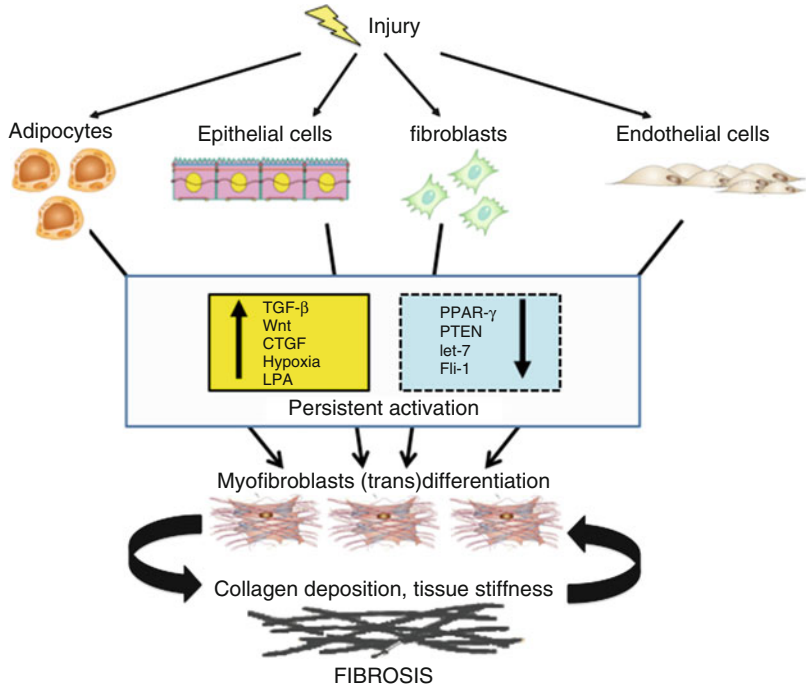
Mechanisms That Promote Fibrosis

During the fibrotic process, fibroblasts acquire a myofibroblastic phenotype. Myofibroblasts express α-smooth muscle actin (α-SMA) in stress fibers, which promotes strong force generation. During normal tissue repair, transient myofibroblast accumulation is important for restoring tissue integrity by forming a mechanically resistant scar. However, in fibrotic diseases, myofibroblasts persist in the lesion, leading to tissue deformations. The widely used molecular identifier of the myofibroblast is α-SMA. The main cues for myofibroblast differentiation and persistence are mechanical forces generated from the ECM and transforming growth factor-β (TGF-β). Tissue stiffness is increased in fibrotic organs and tissues and contributes directly to fibroblast activation (Hinz et al. 2012).

Myofibroblasts originate from resident mesenchymal fibroblasts and from circulating fibroblast-like cells (fibrocytes) derived from bone marrow stem cells. Myofibroblasts may also originate via the transdifferentiation of non-mesenchymal lineages (such as epithelial cells, pericytes, endothelial cells, and adipocytes), although the role of cellular plasticity in the pathogenesis of fibrosis remains controversial (Zeisberg and Neilson 2009; Hinz et al. in press).

Epithelial–mesenchymal transition (EMT) is important during embryogenesis and in renal, pulmonary, and liver fibrosis (Zeisberg and Neilson 2009). Endothelial–mesenchymal transition (EndoMT), characterized by loss of endothelial cell markers and acquisition of a profibrogenic phenotype, can be induced by TGF-β, hypoxia, Wnt ligands, Hedgehog, Jagged–Notch signaling, and bioactive lipids (Fig. 1) (Bhattacharyya et al. 2011; Piera-Velazquez et al. 2011).

The ubiquitously expressed and multifunctional cytokine TGF-β is recognized as a master regulator of both normal wound healing and pathological fibrosis. TGF-β regulates the growth, differentiation, survival, and function of various cell types. In the fibrotic cellular environment, the bioavailability of TGF-β is regulated both by its secretion from tissue-infiltrating macrophages and by local activation of its matrix-bound latent form. Latent TGF-β activation is mediated by cell-surface integrins such as $\alpha_v\beta_6$ on epithelial cells or fibroblasts that cause conformation changes in TGF-β resulting in liberation of the active form (Shi et al. 2011). The profibrotic cellular responses triggered by TGF-β are mediated via both canonical



Fibrosis, Fig. 1 After injury, a variety of cells can be activated including adipocytes, fibroblasts, and epithelial and endothelial cells. Elevated profibrotic signaling and/or repressed anti-fibrotic signaling leads to myofibroblasts differentiation and activation and eventually collagen deposition to restore tissue integrity. The persistence of myofibroblasts represents a deregulated and uncontrolled repair process and results in a non-resolved fibrotic wound with exaggerated deposition of collagen in affected tissues

Smad and Smad-independent signal transduction pathways involving the c-abl, ERK1/2, PI3K/AKT, FAK1, AKT, JNK, and p38. TGF-β initiates signaling through the ligand-dependent activation of a complex consisting of TGF-β receptor type I and II, and the signal is transmitted to the nucleus by Smad proteins (canonical Smad). The activated TGF-βRI directly phosphorylates cytosolic Smad2 and Smad3, which translocate to the nucleus as a heterocomplex with Smad4. Smad generally require interaction with other DNA-binding partners and coactivators such as Sp1, CREB-binding protein (CBP)/p300, and AP-1. Ligand-induced Smad signal transduction is tightly controlled by endogenous inhibitors such as Smad7, bone morphogenetic protein and activin membrane-bound inhibitor (BAMBI), and Nab-2, which are themselves regulated by TGF-β in negative feedback loops. Although pharmacological blockade of TGF-β is feasible as a strategy for controlling fibrosis, the exceptionally pleiotropic actions of TGF-β raise concerns that interfering with this essential physiological signaling molecule could result in a broad range of toxicities such as autoimmunity and defective tissue repair (Jinnin 2010; Bhattacharyya et al. 2011; Wei et al. 2011).

The Wnts are a family of poorly soluble secreted glycoproteins that regulate both cell – cell adhesion and gene transcription. Wnts have a key role in embryonic development and cell fate specification. Intracellular Wnt signaling is mediated via canonical (β-catenin-dependent) and noncanonical pathways, which engage in extensive cross talk with TGF-β signaling. The stimulation of normal fibroblasts with Wnt ligands results in β-catenin-mediated enhancement of collagen and matrix gene expressions, enhanced myofibroblast differentiation and increased cell migration. Chronic hyperactivation of β-catenin signaling in fibrosis represents aberrant recapitulation of embryologic developmental programs. It might result from Wnt-ligand-independent, constitutive β-catenin activation induced by ECM components such as fibronectin-extra domain A (EDA) and tenascin acting in a self-amplifying autocrine feedback loop (Bhattacharyya et al. 2011).

Connective tissue growth factor (CTGF), a member of the CTGF/Cyr61/NOV (CCN)

family of matricellular proteins, is induced substantially by TGF-β and is implicated in fibrogenesis. CTGF is overexpressed in most fibrotic diseases. It is thought that CTGF may, in concert with TGF-β, exert a variety of fibrotic activities although the mechanisms involved are still controversial.

Bioactive lipids are potent modulators of fibroblast function. Lysophosphatidic acid (LPA; l-acyl-2-hydroxy-*sn*-glycero-3-phosphate) is a growth-factor-like mediator acting on G-protein-coupled receptors. LPA is detectable in biological fluids including serum and saliva. Increased production of LPA in fibrotic diseases stimulates fibroblast proliferation and migration, enhances CTGF expression, induces myofibroblast transdifferentiation, and augments TGF-β signaling. Interestingly, LPA-null mice exhibit attenuated fibrotic responses.

Toll-like receptors (TLRs) are sensors of the innate immune system that allow recognition of pathogen-associated molecular patterns (PAMPs) or damage-associated molecular patterns (DAMPs), resulting in initiation of immune responses. DAMPs are generated at sites of tissue injury in response to mechanical damage, inflammation, and oxidative stress. Increased expression of TLR4 has been described in various forms of fibrosis. Fibroblast TLR signaling initiated by damage-associated endogenous TLR ligands such as fibronectin-EDA or hyaluronic acid might act as the "switch" to convert a self-limited physiological regenerative tissue repair process into an aberrant fibrotic scar.

Mechanisms That Inhibit Fibrosis

The persistence and progression of pathological fibrosis is attributed in part to the failure of intrinsic anti-fibrotic mechanisms that normally restrain fibroblast activation. An important component of innate anti-fibrotic defense is peroxisome proliferator-activated receptor gamma (PPAR-γ). Originally identified in adipose tissue, PPAR-γ is a dual-function molecule acting both as a nuclear receptor and ligand-inducible transcription factor. PPAR-γ modulates metabolic, vascular, and immune processes, and abnormal PPAR-γ function is implicated in lipodystrophy, atherosclerosis, pulmonary artery hypertension, cancer, and inflammatory diseases. Fibrosis is associated with defective expression or function of PPAR-γ in the lesional tissues (Wei et al. 2010). PPAR-γ expression in lesional tissue shows an inverse relationship with enhanced TGF-β signaling (Wei et al. 2011). Other innate anti-fibrotic mechanisms include phosphatase and tensin homolog (PTEN), Ski/Sno, and Fli-1 (Bhattacharyya et al. 2011).

miRNAs are small noncoding ribonucleic acids (RNAs) that contribute to fibroblast activation and fibrosis. Expression of miR-29, an anti-fibrotic microRNA, is markedly reduced in fibrotic tissues. Another miRNA, miR-21, is upregulated in lung, heart, and renal fibrosis and enhances fibrogenic activity. In contrast, let-7d is downregulated by TGF-β, and its loss leads to a gain of a profibrotic phenotype.

Organ-Specific Fibrosis

Pulmonary fibrosis represents a heterogeneous group of lung disorders characterized by progressive destruction of lung architecture caused by scar formation that leads to respiratory failure. Pulmonary fibrosis can be idiopathic or can develop following viral infections, bone marrow transplantation, radiotherapy, chemotherapeutic drugs, environmental toxins, and chronic inflammatory disease such as systemic sclerosis. Idiopathic pulmonary fibrosis affects more than 50,000 people in the United States and is associated with poor survival.

Despite improvements in diagnosis, pulmonary fibrosis remains refractory to treatment, and lung transplantation is the only effective treatment currently available.

Recurrent epithelial injury is considered to be the primary defect in idiopathic pulmonary fibrosis, and inflammation is variable. Ultrastructural, immunohistochemical, and bronchoalveolar lavage studies suggest alveolar type II cell injury as an early feature. The hypothesis of epithelial cell death as a driver for pulmonary fibrosis is

hampered by recent findings of mutations in the genes for surfactant proteins and genes that maintain telomere length. In addition, studies using the bleomycin model of lung injury suggest that inhibition of epithelial cell apoptosis attenuates fibrosis. While the "inflammatory" concept of pulmonary fibrosis dominated the field in the past, precise histologic definition of the disease has made it clear that inflammation in the lung is relatively slight even in the earliest phase of the disease. Furthermore, there is a lack of correlation of inflammatory markers with disease progression, and conventional immunosuppressive agents fail to arrest or reverse lung fibrosis (Homer et al. 2011; Wynn 2011).

The loss of basement membrane integrity is an important factor for aberrant lung remodeling. Interaction of epithelial cells with an abnormal ECM in the presence of active TGF-β1 leads to EMT and collagen accumulation (Wynn 2011).

Coagulation cascade activation has also been implicated as an important and early event following lung injury. The serine protease thrombin plays a major role by promoting the myofibroblast differentiation of lung fibroblasts and induction of fibrogenic cytokines and ECM proteins, contributing to progression of pulmonary fibrosis.

Liver Fibrosis

Liver architecture suffers transient changes after an acute or self-limited injury. However, if the injury is sustained, chronic inflammation and ECM accumulation persist, leading to fibrosis and cirrhosis, characterized by a distortion of the liver parenchyma and vascular architecture. Progression from liver injury to cirrhosis is generally slow, largely asymptomatic, and influenced by both genetic and environmental factors (Hernandez-Gea and Friedman 2011).

Hepatic fibrosis develops as a result of the progressive thickening of fibrotic septa and increasing cross-linking of collagen, disrupting the tightly organized liver parenchyma that provides functional and structural integrity. The hepatic ECM normally comprises less than 3 % of the relative area on a liver tissue section and approximately 0.5 % of the wet weight (Hernandez-Gea and Friedman 2011).

Hepatic scarring is a common pathway resulting from toxic, metabolic, and infectious insults. Activated hepatic stellate cells are key effectors of liver fibrosis. Following liver injury, hepatic stellate cells become activated, with loss of vitamin A droplets and acquisition of myofibroblast features (Friedman 2010; Hernandez-Gea and Friedman 2011).

PPAR-γ is expressed in unstimulated hepatic stellate cells and plays an important role in maintaining their quiescence. During liver injury, PPAR-γ expression is reduced, contributing to hepatic stellate cell activation. Other cells contributing to the fibrotic process in the liver include portal fibroblasts in biliary diseases such as ischemia and cholestasis. Fibrocytes and EMT have also been reported to play a role in liver regeneration and fibrosis (Hernandez-Gea and Friedman 2011).

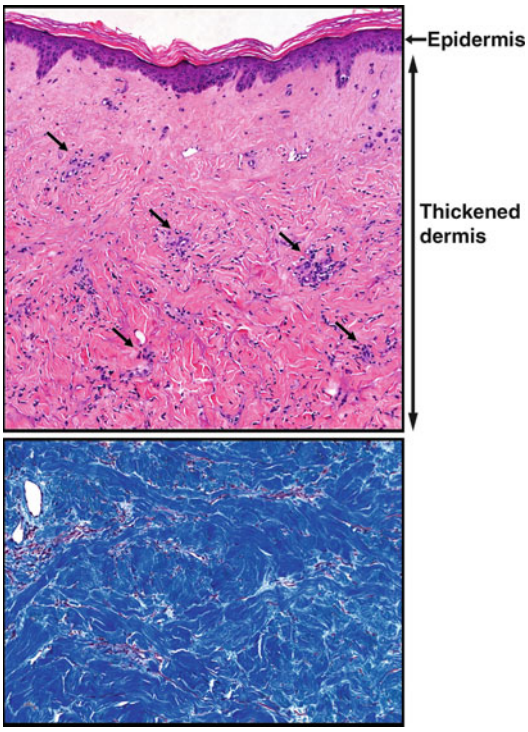
Resident hepatic macrophages called Kupffer cells participate in both progression and regression of liver fibrosis. Kupffer cells are the first point of contact for bacterial products and endotoxin (LPS) derived from the gastrointestinal tract. Through Toll-like receptor 4, the TGF-β pseudoreceptor BAMBI is downregulated in hepatic stellate cells, thereby enhancing TGF-β signaling and hepatic fibrogenesis. Interestingly, single-nucleotide polymorphisms of the *TLR* gene (D299G and T399I) associated with reduced LPS responsiveness confer a significantly reduced risk for fibrosis progression in patients with chronic hepatitis C infection (Hernandez-Gea and Friedman 2011).

Kidney Fibrosis

Renal fibrosis underlies the progression of chronic kidney disease to end-stage renal disease. Renal fibrosis results from inflammatory or immunological (pyelonephritis and lupus nephritis), obstructive (kidney stones), metabolic (diabetic nephropathy), or systemic (nephrogenic systemic fibrosis) injury ultimately progressing

to end-stage renal disease. Intrarenal hypertension and hyperfiltration, oxidative stress, angiotensin II, leptin, inflammatory cytokines, hyperinsulinemia/insulin resistance, hyperglycemia, and impaired lipid metabolism all contribute to renal fibrosis. The histologic features of renal fibrosis encompass the progressive appearance of glomerulosclerosis, tubulointerstitial fibrosis, and changes in renal vasculature (loss of glomerular and peritubular capillaries). The key events of tubulointerstitial fibrosis are initiated by mesangial cell activation and EMT of the podocytes.

Nephrogenic systemic fibrosis is a recently recognized fibrotic condition in patients with chronic renal disease. It is thought to be triggered by exposure to gadolinium, a contrast agent used for magnetic resonance imaging. Patients develop diffuse scleromyxedema-like skin lesions and less commonly, systemic manifestations with fibrosis in the lungs, myocardium, and skeletal muscles. The pathogenesis of this disorder may involve gadolinium activation of dendritic cells via TLR and accumulation of circulating fibrocytes. Chelated gadolinium directly stimulates macrophages and monocytes to release profibrotic cytokines and growth factors capable of inducing tissue fibrosis (Del Galdo et al. 2010).



Fibrosis, Fig. 2 Skin fibrosis in Scleroderma. (**a**) The papillary and reticular dermis is filled with markedly thickened collagen fibers. Lymphocytic perivascular infiltrate are present (arrows). Note loss of hair follicles and glandular structures. Hematoxylin–eosin-stained section, optical micrograph, original magnification X 100. (**b**) Thickened collagen bundles stained deep blue with Masson's trichrome stain, original magnification X 100

Systemic Sclerosis

Systemic sclerosis (SSc) is a chronic autoimmune disease with multiorgan fibrosis, associated with immune dysregulation and obliterative microvasculopathy (Fig. 2). Systemic sclerosis has multiple clinical subsets that are defined in part based on to the extent of skin involvement. It has one of the highest mortality rates among rheumatic diseases and lacks effective disease-modifying therapies. Lung involvement is the leading cause of death in patients with SSc (Bhattacharyya et al. 2011).

Although the cause of SSc is not known, its clinical and pathological manifestations are result from a complex interaction between genetic factors and environment. Genetic polymorphisms associated with SSc include genes involved in immune regulation such as BANK1, C8orf13-BLK, IL-23R, IRF5, STAT4, CD247, TBX21, and TNFSF422 as well as TGF-βRI and PPAR-Y. However, the most significant genetic association is with HLA types and defined autoantibodies (Bhattacharyya et al. 2011).

The pathogenesis of fibrosis in SSc has been investigated extensively. The "SSc fibroblast phenotype" is characterized by constitutively enhanced ECM synthesis, secretion of profibrotic cytokines and chemokines, resistance to INF-gamma and other inhibitory signals, and spontaneous generation of reactive oxygen species. The SSc fibroblast phenotype could represent a

cell-autonomous abnormality, perhaps due to epigenetic modifications, or activation in response to exogenous stimuli in the fibrotic milieu.

Fibroblasts explanted from lesional fibrotic tissue of SSc patients display phenotypic alterations that persist after several passages in vitro. One of the factors responsible for the induction and maintenance of this phenotype is autocrine TGF-β activation. Of note, SSc fibroblast characteristics can be induced in normal fibroblasts by treatment with TGF-β. Consistent with this hypothesis, SSc fibroblasts show elevated Smad3 activation and constitutive Smad interaction with the coactivator histone acetyltransferase p300/CBP. Molecules involved in intracellular signaling are abnormally expressed or constitutively activated in SSc fibroblasts in culture, including protein kinase C, Smad3, Smad7, Egr-1, p300, and c-Abl, as well as several microRNA species. Furthermore, defective expression and function of endogenous suppressors of TGF-β signaling and ECM production such as Smad7, BAMBI, and miR29 have also been demonstrated, suggesting that failure to restrain fibroblast activation may represent a fundamental defect in SSc (Jinnin 2010; Bhattacharyya et al. 2011; Wei et al. 2011).

Fibrosis Treatment

The fibrotic process causes progressive and ultimately irreversible loss of functional integrity of vital organs. Fibrosis is traditionally considered to be an intractable process, and when it affects vital organs, it is associated with high mortality. Cellular plasticity, aberrant recapitulation of embryological genetic programs, altered epigenetic modifications and miRNA regulation, and the occurrence of self-amplifying feed-forward loops driven by hypoxia, matrix stiffness, and tissue damage all contribute to uncontrolled fibroblast activation that results in an abnormal tissue repair process, progressing to intractable fibrosis.

Many potential opportunities exist for interfering with the fibrotic process, and several existing drugs approved for other indications show an anti-fibrotic effect. Ultimately, effective therapeutic strategies for fibrotic diseases will be designed to block converging fibrogenic pathways at multiple levels (Table 2).

Fibrosis, Table 2 Potential targets for anti-fibrotic therapy

Profibrotic mediators
Growth factors:
Transforming growth factor-β
CCN family
Wnt-β-catenin pathway
Integrins: $\alpha_v\beta_6$
Clotting cascade: thrombin
Bioactive lipids: lysophosphatidic acid (LPA)
Oxidative stress: reactive oxygen species (ROS)
Innate immunity: Toll-like receptors (TLR4)
Cartilage oligomeric matrix protein
Endoplasmic reticulum stress
Anti-fibrotic agonists
Type I interferon
Peroxisome proliferator-activated receptors
NF-E2-related factor 2 (Nrf-2)

Genetics of juvenile arthritis syndromes

Definition

Juvenile idiopathic arthritis (JIA) encompasses chronic childhood arthritis of unknown etiology and is manifest by diverse clinical symptoms and outcomes. Patterns of inheritance consistent with Mendelian or monogenic inheritance have not been observed in JIA. Although familial history of JIA is sparse, a familial history of autoimmunity is observed in 13–15 % of families with JIA probands, whereas only 4 % of the control families are afflicted with autoimmune disease. JIA is thought to result from interactions among genetic factors, immune mechanisms, and environmental exposures. Most of the genetic predisposition to JIA is determined by the major histocompatibility complex (MHC) loci. Multiple MHC loci are associated with the development of JIA, with specific disease subtypes being linked to specific human leukocyte antigen (HLA) alleles. In general, these associations are distinct from those in adult rheumatoid arthritis. The spectrum of non-HLA genes that may be associated with JIA is expanding rapidly, but their contribution to the risk of JIA appears to be less significant, and their effects may not be specific to JIA.

Introduction

Juvenile idiopathic arthritis encompasses chronic childhood arthritis of unknown etiology and is manifest by diverse clinical symptoms and outcomes (Petty et al. 1998). The relatively new term "*Juvenile idiopathic arthritis* (*JIA*)" has replaced the older terms "*juvenile rheumatoid arthritis*" (previously used commonly in the United States) and "*juvenile chronic arthritis*" (previously preferred in Europe). Currently, *JIA* incorporates all of what was called *juvenile rheumatoid arthritis* in the past, and also includes all other forms of "idiopathic" arthritis in childhood. Currently, six subtypes of JIA are distinguished largely on the basis of clinical and laboratory features present in the first 6 months of disease, with a seventh category reserved for individuals who cannot be unambiguously classified. Thus, patients with **persistent oligoarthritis** have cumulative involvement of fewer than five joints, whereas **extended oligoarthritis** indicates involvement of five or more joints sometime after 6 months of disease. **Polyarthritis** involves

I.R. Mackay, N.R. Rose (eds.), *Encyclopedia of Medical Immunology – Autoimmune Diseases*,
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

five or more joints within the first 6 months of disease and is subdivided by the presence or absence of rheumatoid factor (**RF-positive** or **RF-negative polyarthritis**). **Enthesitis-related arthritis** (ERA) typically affects older (>6 years) males who frequently have HLA-B27 and may have a family history of spondyloarthropathy. **Psoriatic arthritis** is usually associated with typical psoriatic skin lesions in the patients themselves or their first-degree relatives. **Systemic JIA** involves chronic arthritis and associated systemic features that may include quotidian fevers, erythematous rash, generalized lymphadenopathy, and hepatosplenomegaly. Although this new JIA classification has increased phenotypic homogeneity within some subtypes, there is still significant heterogeneity within almost each of the JIA subtypes as well as some commonalities between subtypes.

The pathogenesis and etiology of JIA are unclear. As with most autoimmune disorders (see ▶ Therapeutic Considerations in Kidney Diseases Due to Glomerulonephritis), JIA is thought to result from interactions among genetic factors, immune mechanisms, and environmental exposures. Due to high clinical heterogeneity, our understanding of the genetic factors involved in JIA has not progressed as quickly as compared with other autoimmune arthropathies, including rheumatoid arthritis and ankylosing spondylitis. The necessity to split the JIA patient population into smaller groups provides challenges for recruiting patient cohorts of adequate size with sufficient analytical power for genomic studies. In addition, the shift from the old *JRA* to the new *JIA* classification system often makes it difficult to directly compare the results between more recent and older studies.

Familial Predisposition

Patterns of inheritance consistent with Mendelian or monogenic inheritance have not been observed in JIA. The prevalence of JIA among siblings of probands is about 15–30 times greater than the population prevalence of approximately 1 in 1,000 children (Towner et al. 1983; Clemens et al. 1985). Twin studies have shown that the monozygotic twin concordance rates for JIA in general range between 25 % and 40 %. Families with multiple affected members are rare (Clemens et al. 1985; Rossen et al. 1980). In the United States, the JRA Affected Sib Pairs Research Registry in Cincinnati estimated the total number of affected sib pairs at 300 in a population of approximately 250 million (Moroldo et al. 1997, 2004). Almost 80 % of the affected pairs and 100 % of twin pairs were concordant for disease type. Furthermore, siblings were more likely to develop JIA at the same age of onset, rather than the same calendar year. Among twins, disease onset was separated by a mean of approximately 3 months.

In contrast to the sparse familial history of JIA, a familial history of autoimmunity is observed in 13–15 % of families with JIA probands, whereas only 4 % of the control families are afflicted with autoimmune disease (Prahalad et al. 2002). These observations are consistent with the idea that while some genetic associations are unique to JIA, others overlap with other autoimmune diseases.

Predisposing MHC Genes

Predisposing MHC genes are the best characterized genetic factors in JIA. Multiple HLA loci are associated with the development of JIA, with specific disease subtypes being linked to specific HLA alleles (Rossen et al. 1980; Nepom and Glass 1992). In general, these associations are distinct from those in adult rheumatoid arthritis (Stastny and Fink 1979) (see ▶ Rheumatoid Arthritis, Genetics). Genes that do not encode classic HLA proteins, but lie within the major histocompatibility complex (MHC), may also predispose to JIA.

Early-onset oligoarticular JIA – Oligoarticular JIA patients with early onset of the disease (i.e., before 6 years of age) constitute the subtype with the most distinctive HLA associations. Interestingly, this subtype of JIA has a relatively high concordance among siblings (Moroldo et al. 2004). The early reports of associations with various HLA class II DR and DP

serologic specificities including HLA-DR8 (Stastny and Fink 1979; Van Kerckhove et al. 1990), HLA-DR5 (DR11) (Glass et al. 1980; Førre et al. 1983), HLA-DR13 (Reekers et al. 1983), and HLA-DPw2 (Hoffman et al. 1986; Odum et al. 1986) have been confirmed by DNA-sequence-dependent methodologies. In oligoarticular JIA, disease susceptibility correlates with particular alleles of each serologically defined specificity, such as HLA-DRB1*0801 of DR8 and HLA-DPB1*0201 of DPw2 (Nepom and Glass 1992). Although most associations are with HLA class II, a consistent increase in risk with the HLA class I A2 allele has been reported in girls with early-onset oligoarticular JIA as well (Oen et al. 1982). In contrast to these findings, some HLA class II alleles occur with decreased frequency in this group of children, suggesting a protective effect. Examples include HLA-DR4 and HLA-DR7 (Nepom and Glass 1992).

Determination of HLA specificities using DNA-based methodologies has also better defined the genetic markers of disease outcome in early-onset oligoarticular JIA. Haplotypes carrying HLA-DRB*0801, HLA-DRB*1301, and HLA-DP*0201 alleles appear to predispose to oligoarticular JIA in general. In contrast, other alleles may contribute to the risk for other clinical manifestations. For example, HLA-DRB1*1104 predisposes to eye disease (i.e., chronic anterior uveitis) (Melin-Aldana et al. 1992), while HLA-DQA1*0101 is associated with a reduced risk of eye disease, but predisposes to evolution from oligoarticular to more aggressive polyarticular disease (van Kerckhove et al. 1991). HLA-DRB1*0101 has also been associated with polyarticular disease (Ploski et al. 1993). Whether the HLA-DQA*0101 or the HLA-DRB*0101 allele is a better marker for the haplotype is uncertain, but there are data that are compatible with either possibility.

The fact that HLA genes from four loci (HLA-A, HLA-DR/DQ, and HLA-DP) are involved in inherited predisposition to oligoarticular JIA raises the possibility that these genes make up a potential susceptibility haplotype. However, the absence of linkage disequilibrium between these three loci indicates that there are independent genetic effects. In a significant proportion of patients with early-onset pauciarticular JIA, especially those with uveitis, the development of the disease may be associated with the presence of two susceptibility alleles of either the HLA-DR or HLA-DQ loci. Interestingly, the cumulative addition of risk factors leads to increasing odds ratios. For instance, patients who are heterozygous for HLA-DR5/HLA-DR8 have a particularly increased risk for developing eye disease (Hall et al. 1986). An HLA-DP gene and the class I HLA-A2 gene also contribute, appearing as independent risk factors. Another recent study demonstrated that the number of susceptibility alleles was inversely proportional to the age of onset of JIA. Among children who carried HLA-A2, DPB1*0201, and one HLA-DR susceptibility allele, the median age of onset of oligoarticular JIA was just 2.4 years (Murray et al. 1999). Remarkably, HLA Class II gene homozygosity is not increased in the oligoarticular JIA patient population, suggesting that a dosage effect of any individual gene does not increase risk (Hall et al. 1986).

Other JIA subtypes. HLA associations with clinical forms other than early-onset oligoarticular JIA are less strong. As previously mentioned increased risk of **enthesitis-related JIA** is associated with HLA-B27 (Rachelefsky et al. 1974; Schaller et al. 1976). **Polyarticular onset, rheumatoid factor (RF)-negative JIA** has been associated with HLA-DPB1*03 (Fernandez-Viña et al. 1990). Similarly to early-onset oligoarticular JIA, JIA patients with early-onset polyarticular disease also show an association with HLA-DRB*0801. **RF-positive polyarticular JIA** has the same HLA-DR4 associations as does adult RA: HLA-DRB1*0401 and HLA-DRB1*0101 (Nepom et al. 1984). In systemic JIA, only a weak association was found with the 3 Mb interval that contains the *HLA-DRB1* and *HLA-DQA1* genes (Ombrello et al. 2011).

HLA-DR1/DR4 shared epitope hypothesis – Rheumatoid arthritis in adults is associated with the presence of the DNA sequence common to

HLA-DR1 and some HLA-DR4 specificities (Gregersen et al. 1987) (see ▶ Rheumatoid Arthritis, Genetics). However, the shared epitope hypothesis as applied to adults is not useful for oligoarticular JIA, in which HLA-DR4 is protective and HLA-DR1 haplotypes predispose to a polyarticular outcome. Similarly, patients with seronegative polyarticular JIA do not carry the appropriate epitopes. The only JIA group in which the shared epitope hypothesis may hold is in older children with polyarticular disease who are IgM RF-positive. These patients have the childhood equivalent of adult RA; they represent fewer than 10 % of all patients with JIA.

Age-specific effects – There is new evidence that some genes operative in JIA appear to have a "window-of-effect" during which time they may contribute risk of disease, but be neutral or even protective at other times (Murray et al. 1999). This appears to be particularly true in the pauciarticular groups, in which HLA-related risks clearly differ with age. For example, 50 % of children carrying at least one of the susceptibility MHC alleles have disease onset prior to their third birthday, suggesting that the period of susceptibility to early-onset pauciarticular JIA is limited to the first years of life. In contrast, HLA-B27 and DR-4 appear to be associated with the protection against early-onset pauciarticular JIA early in life, but with the increased risk for other forms of JIA later in childhood.

Predisposing Non-MHC Genes

The spectrum of non-HLA genes that may be associated with JIA is expanding rapidly. However, their contribution to the risk of JIA appears to be less significant than that of HLA genes, and their effects may not be specific to JIA. In general, the odds ratios are low, and distinguishing between founder effects (the incomplete mixing of genetically disparate populations) and associations that relate to pathogenesis has been difficult. Reproducible associations have been noted with interleukin-6, interleukin-10, and macrophage migration inhibitory factor (MIF) promoter polymorphisms (Fishman et al. 1998; Ogilvie et al. 2003; Crawley et al. 1999; Donn et al. 2001, 2002).

Several published genome-wide association studies (GWAS) in oligo- and polyarticular JIA produced compelling evidence for association with several loci also implicated in the genetics of other autoimmune diseases including adult rheumatoid arthritis. Examples include *PTPN2*, *PTPN22*,*IL2RA*, *ADAD1-IL2-IL21*, *ANGPT1*, *COG6*, *C12orf30*, and *STAT4* (Hinks et al. 2005, 2012; Thompson et al. 2004, 2012). Most of the loci have clear roles in the immune system. PTPN22 is an intracellular phosphatase that modulates cytokine signal transduction through JAK/STAT signaling pathways. PTPN2 is similar to PTPN22 and serves as a negative regulator of T cell activation. STAT4 is a transcriptional factor that mediates immune cell responses to Th1 cytokines. COG6 is a component of the conserved oligomeric Golgi complex involved in processes such as protein sorting and glycosylation. The *COG6* region has been recently associated with psoriasis. Angiopoietin-1 (ANGPT1) activates the receptor tyrosine kinase (TIE2), leading to increased expression of metalloproteinases as well as differentiation of smooth muscle and endothelial cells, generally leading to increased angiogenesis, a process that is important in the expansion of inflamed synovium in arthritis. Another recent GWAS study in oligo- and polyarticular JIA produced strong evidence for association with the chromosome 3q13 region, which includes *CD80*, a costimulatory molecule necessary for T cell activation (Hinks et al. 2012).

In summary, increasing evidence supports the concept that the occurrence of JIA and its phenotype is determined by complex genetic traits with "genetic interplay" between HLA and non-HLA predisposing alleles.

Gestational Alloimmune Liver Disease

Peter F. Whitington
Department of Pediatrics, Feinberg School of Medicine of Northwestern University, Ann and Robert H Lurie Children's Hospital of Chicago, Chicago, IL, USA

Synonyms

Neonatal hemochromatosis

Definition

Gestational alloimmune liver disease (GALD) is a unique fetal liver disease that results from maternal alloimmunity against fetal hepatocytes. Neonatal hemochromatosis (NH) is a clinical syndrome in which liver disease in the newborn is accompanied by siderosis of extrahepatic tissues in the pattern seen in hereditary hemochromatosis. NH is the phenotypic expression of severe fetal liver disease. GALD is the cause of fetal liver injury leading to nearly all instances of NH. However, GALD may also produce acute liver failure in the fetus and severe acute neonatal liver disease often with no extrahepatic siderosis.

Etiology and Pathogenesis

GALD is mediated by immunoglobulin G (IgG) as are all maternofetal alloimmune diseases (Hoftman et al. 2008). Maternal antibodies of the IgG class are actively transported across the placenta to the fetus from about the 12th week of gestation when the neonatal crystallizable fragment receptor (FcRn, the IgG chaperone) is first expressed. The principal function of this process is to provide humoral immunity for the fetus and newborn. The principle of gestational alloimmunity involves exposure of the mother to a fetal antigen that she fails to recognize as "self," which results in sensitization and production of specific reactive IgG. GALD-related alloimmunity is specifically directed at fetal hepatocyte-specific antigen. No non-hepatocyte elements in the liver appear to be injured, and tissues outside the liver are unaffected by the primary immune process. Once sensitization has occurred maternal, anti-fetal liver IgG is passed to the fetus where it binds to the liver antigen and results in immune injury of the fetal liver. The mechanism of hepatocyte injury appears to involve the fetal innate immune system. The terminal complement cascade is activated by the classical pathway and results in the formation of membrane attack complex (Pan et al. 2010). Immunohistochemical staining for complement complex C5b-9 (the neoantigen created during terminal complement cascade activation and culmination) shows nearly all hepatocytes in cases of GALD to have complement-mediated injury (Pan et al. 2010). This has become the defining feature of GALD.

Liver Pathology

GALD is defined by complement-mediated hepatocyte injury and is the only known liver disease to have this as the primary disease mechanism

(Pan et al. 2010; Whitington et al. 2011). The anatomic pathology of the liver often resembles that seen in acute and subacute liver failure in older individuals. Marked loss of hepatocyte mass is a prominent feature of most cases, and in some instances, almost no hepatocytes remain. The residual and/or regenerating hepatocytes may exhibit either giant-cell or pseudoacinar transformation with canalicular bile plugs. Fibrosis is pronounced, particularly in the lobule and around the central vein. Portal triads are spared from injury and fibrosis. Regenerative nodules may be present. Residual hepatocytes often show siderosis while Kupffer cells are spared. Inflammation is minimal. Parenchymal inflammation consists of macrophages and some neutrophils. These are the inflammatory elements of the innate immune system that are recruited by activation of the terminal complement cascade via production of complement component fragments C3a and C5a.

GALD may produce acute injury to the fetal liver and has been associated with fetal death and stillbirth (Whitington et al. 2011). The pathology in such cases shows acute hepatocyte necrosis with no collapse, no fibrosis, and no inflammation, indicating the hyperacuity of the process. Many of these cases have no siderosis of the liver or other tissues. In addition, several term newborns with acute liver failure have been found to have GALD with pathology similar to that in cases of fetal death due to GALD. It is not at all clear why some cases present with acute liver failure while others present with congenital cirrhosis.

Extrahepatic Manifestations of GALD

Extrahepatic Siderosis

Siderosis of tissues outside the liver is the defining feature of the NH phenotype (Whitington 2006; Whitington and Fleming 2008). The most consistently affected tissues are the acinar epithelium of the exocrine pancreas, myocardium, the epithelia of the thyroid follicles, and the oral mucosal ("minor salivary") glands. The spleen, lymph nodes, and bone marrow contain comparatively trivial quantities of stainable iron.

The fetal liver controls the flow of iron from the mother to the fetus just as intestinal iron absorption is controlled after birth, by sensing iron sufficiency and producing hepcidin as a regulatory feedback molecule. The efflux of iron from the placenta is dependent upon ferroportin, just as it is in the intestine and reticuloendothelial system. Hepcidin regulates ferroportin functional expression by binding to it and causing it to undergo internalization and proteosomal degradation. Liver from fetal and newborn GALD patients expresses hepcidin at a small fraction of that expressed by normal fetal and newborn liver (Bonilla et al. 2012). The liver injury-induced failure to produce adequate hepcidin to appropriately regulate placental iron flux fully explains iron overload in GALD and probably also in other fetal liver diseases leading to the NH phenotype (Zoller and Knisely 2012).

The specific distribution of iron in extrahepatic tissues in the NH phenotype requires additional explanation. These same tissues do not show siderosis in normal newborns whose plasma contains transferrin-bound iron. Thus, development of siderosis appears to be a function of excess non-transferrin-bound iron (NTBI). Examination of normal newborns for expression of uptake carriers for NTBI showed that all tissues affected by siderosis in GALD-NH expressed solute carrier family 39 (zinc transporter), member 14 (ZIP14), a known NTBI transporter (Bonilla et al. 2012). However, several tissues that expressed ZIP14 are not subject to siderosis in GALD-NH. These tissues also expressed ferroportin for export of iron. Thus, in normal newborn tissues, those expressing ZIP14 and not ferroportin are uniquely susceptible to siderosis in conditions of excess NTBI. Tissues from GALD-NH cases showed the same pattern of carrier expression and siderosis in the ZIP14-positive, ferroportin-negative tissues. It should be remembered that ferroportin is fully expressed in GALD-NH despite iron overload because of the liver's incapacity to make hepcidin. This is why reticuloendothelial cells show no siderosis in NH despite iron overload.

Angiotensinogen Deficiency-Related Renal Dysgenesis

Occasionally severely affected babies exhibit renal hypoplasia, with dysgenesis of proximal tubules and paucity of peripheral glomeruli. Correlation with the process of normal renal development dates this arrest of renal development to about 24 weeks gestation. This final stage of renal development is dependent upon liver function, specifically the synthesis of angiotensinogen. The livers and kidneys of infants with GALD-NH were studied in comparison to normal newborns dying of perinatal asphyxia to examine this process (Bonilla et al. 2010). Liver angiotensinogen expression correlated closely with the mass of hepatocytes as determined by quantitative morphometry. Hepatocyte mass and angiotensinogen gene expression were markedly reduced in GALD-NH relative to normal. Proximal tubule development was studied using quantitative morphometry of kidney sections stained by immunohistochemistry for the specific marker fumaryl acetoacetic acid hydrolase (FAH). All GALD-NH cases had a degree of dysgenesis of proximal tubules, which is a surprising finding given so few cases had been reported. Furthermore, the density of proximal tubules correlated closely with the hepatic angiotensinogen gene expression. In sum, it appears that in GALD alloimmune injury leads to reduced hepatocyte mass, which results in reduced angiotensinogen production, which in turn leads to defective renal development. Therefore, the disordered development dates fetal liver failure to the late second and early third trimester.

Clinical Findings and Diagnosis

The predominant presenting findings are those of liver failure and often multiorgan failure (Whitington and Fleming 2008). Hypoglycemia, marked coagulopathy, hypoalbuminemia and edema with or without ascites, and oliguria are prominent features. Jaundice develops during the first few days after birth. Most cases exhibit significant elevations of both conjugated and nonconjugated bilirubin, with total bilirubin levels often exceeding 30 mg/dl. Serum aminotransferase concentrations are disproportionately low for the degree of hepatic injury; indeed, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels are typically normal or low and rarely exceed 100 IU/L. Serum α-fetoprotein (AFP) levels are characteristically very high, usually 100,000–600,000 ng/ml (normal term newborn values <80,000 ng/ml). Studies of iron status often show low transferrin levels and iron saturation nearly always exceeding 95 % (Bonilla et al. 2012). The low transferrin levels probably reflect severe liver disease. Elevated serum ferritin (values >800 ng/ml) is characteristic of GALD-NH but is a nonspecific finding in neonatal liver disease.

The time of presentation extends from 18-weeks gestation to term plus 2–3 months and the mode from acute liver failure to subclinical liver disease. One of GALD's most under recognized presentations is late-second and third-trimester fetal loss. The gestational histories of women who have had a baby diagnosed with NH show that approximately one in seven pregnancies end with fetal loss. In an autopsy study, severe acute GALD has been associated with fetal death and stillbirth, presumably by causing acute liver failure in the fetus (Whitington et al. 2011). Most affected live-born babies show evidence of fetal insult (i.e., intrauterine growth restriction and oligohydramnios) and premature birth is common. Liver disease is generally apparent within hours of birth, and NH is one of the most common causes of liver failure in the neonate (Durand et al. 2001; Rodrigues et al. 2005). In occasional cases the liver disease takes a prolonged course and is manifest days to weeks after birth. There is a spectrum of disease, and some infants recover with supportive care. Indeed, it may be that some "affected" babies have no clinical disease. Twins may have disparate clinical findings, with one severely affected and the other minimally so (Ekong et al. 2005).

The approach to diagnosing GALD-NH relies mainly on diagnosing NH, since nearly all NH is due to GALD. It should be suspected in infants who manifest liver disease before or very shortly after birth. It should also be suspected in unexplained cases of stillbirth and newborn death. Demonstration of extrahepatic siderosis is

necessary to make the diagnosis of NH. Finding siderosis in the liver is not diagnostic. The normal newborn liver contains sufficient stainable iron to be confused with pathologic siderosis, although they are qualitatively different to the eyes of experienced pathologists. Furthermore, pathologic hepatic siderosis has been described in several neonatal liver diseases, usually not in combination with extrahepatic siderosis. The absence of stainable iron in the liver does not exclude the diagnosis since in many cases few if any hepatocytes remain, and hepatic siderosis in NH involves hepatocytes exclusively.

NH is often diagnosed at autopsy, where siderosis of many tissues can be demonstrated if looked for. Proper stains for iron should be performed on the tissues typically involved when autopsy is performed on any baby with liver failure or suspected liver disease and in unexplained stillbirths and newborn deaths. Demonstration of extrahepatic siderosis in living babies can be by tissue biopsy or by magnetic resonance imaging (MRI). Biopsy of the oral mucosa is a clinically useful approach to obtain glandular tissue in which to demonstrate siderosis (Knisely et al. 1988). Differences in magnetic susceptibility between iron-laden and normal tissues on T2-weighted MRI can document siderosis of various tissues, particularly the pancreas and liver (Udell et al. 2005). The diagnostic utility of these approaches has never been formally evaluated. Oral mucosal biopsy often fails because an inadequate specimen is obtained, one not containing submucosal glands. Experience suggests that adequate biopsies contain some stainable iron (any amount is abnormal) in about two-thirds of cases with autopsy diagnosis of NH, whereas MRI demonstrates abnormal iron distribution also in about two-thirds of such cases. The recommended diagnostic approach is to perform one (depending on ease and availability) and only if that is negative, do the other. There is no need to do both simultaneously. GALD can be diagnosed in the absence of NH, which is to say in the absence of extrahepatic siderosis, using immunohistochemistry for C5b-9 in liver biopsy (Whitington et al. 2011; Debray et al. 2012).

The following diagnostic approach should minimize missed diagnoses. In a newborn with liver failure or other suspicious clinical circumstances (e.g., nonimmune hydrops), an attempt should be made to demonstrate extrahepatic siderosis by oral mucosal biopsy and/or MRI. If positive, the diagnosis of NH is established. One can consider sending appropriate tests to rule out the non-GALD causes of NH at this point (i.e., bile acid synthesis defect and mitochondrial DNA depletion due to deoxyguanosine kinase (DGUOK) mutations). If negative, liver biopsy for C5b-9 staining can be considered. However, any newborn with liver failure and no identifiable other causes (e.g., perinatal herpes) should be considered to have GALD and treated accordingly (see below). Autopsy diagnosis is likewise straightforward. Stillbirths undergoing post-mortem should be examined for extrahepatic siderosis unless there is a clear cause for fetal death identified. Stillborn liver is often macerated, so a diagnosis of acute liver injury is obscured. C5b-9 staining is difficult to perform and interpret in macerated liver, so it cannot be recommended in such cases. Newborns dying of liver failure or under other suspicious circumstances and undergoing post-mortem examination should be examined for extrahepatic siderosis. Liver disease can usually be diagnosed by histopathology in these circumstances; however, the changes of acute GALD may be ascribed to post-mortem changes. Thus, in cases suspicious for GALD but with no extrahepatic siderosis, C5b-9 staining should be considered.

Prevention and Treatment

GALD shows an unusual pattern and high rate of recurrence in the progeny of affected women. After the index case there is an approximately 90 % probability that each subsequent baby born to that mother will be affected (Whitington and Kelly 2008). However, severe NH can be prevented by treatment during gestation (Whitington and Kelly 2008). The current guideline for treatment consists of intravenous immunoglobulin administered at a dose of 1 g/kg body weight (high-dose IVIG) at 14 weeks, 16 weeks, and weekly from the 18th week until the end of

gestation. Women whose most recent gestation was affected with proven NH should be treated in lieu of any other markers for high risk of recurrence. This treatment in over 100 pregnancies has resulted in >98 % success as defined by pregnancy outcome of children who are currently healthy and with no liver disease. Treatment with high-dose IVIG during gestation effectively modifies recurrent GALD so that it is not lethal to the fetus or the newborn.

Medical therapy of infants with severe GALD-NH using the combination of double-volume exchange transfusion to remove existing reactive antibody and administration of high-dose IVIG (1 g/kg) to block antibody action (i.e., interfere with complement activation) improves survival as compared to historical controls (Rand et al. 2009). Over 50 infants have been treated in this manner with approximately 80 % survival with medical therapy alone. These results may be biased by non-report of poor outcomes or treatment of infants not having NH or only mild disease, since infants have been treated around the world not on protocol and the tally relies on often spontaneous reporting by email. Yet, this appears to be an important advance in treating NH, and it can be applied in less than advanced medical environments. The recommended approach to treating NH is as follows. When presented with an infant in liver failure, if one even thinks it could be NH, a dose of IVIG should be given at once. Administration of IVIG is associated with few complications, and a single dose poses little or no risk to a newborn, no matter the disease. Then a formal evaluation can begin. If NH is proven and the infant has not shown significant clinical improvement, then exchange transfusion can be performed followed by a second dose of IVIG. Improvement in liver function may be delayed because this treatment can only reduce ongoing immune-mediated injury. These severely injured livers require regeneration and/or hepatocyte recovery before function improves. Normalization of the INR takes on average 4–6 weeks.

NH is a frequent indication for liver transplantation in the first 3 months of life (Rodrigues et al. 2005; Grabhorn et al. 2006). When performed for NH, the difficulties attendant to transplanting newborns are frequently compounded by prematurity, small size for gestational age, and multiorgan failure. The overall survival of infants receiving a liver transplant for the indication of NH is about 35 %. Furthermore, it is clear that babies with clinical liver failure due to NH can fully recover with medical therapy. So, caution is indicated when considering treating an affected baby with liver transplantation.

Giant Cell Arteritis

Dimitrios Vassilopoulos
2nd Department of Medicine, Athens University School of Medicine, Hippokration General Hospital, Athens, Greece

Synonyms

Giant cell arteritis: Temporal arteritis; Horton's disease

Definition

Giant cell arteritis (GCA): Chronic vasculitis of large and medium-sized arteries with a specific predilection for aorta and its proximal branches in individuals after the age of 50.

Definition – Criteria

Giant cell arteritis (GCA) is an idiopathic arteritis that affects predominantly large- and medium-sized arteries containing an elastic lamina layer, exclusively in individuals after the age of 50 (Salvarani et al. 2012; Borchers and Gershwin 2012; Weyand and Goronzy 2012). The most commonly affected arteries are the aorta and its proximal branches. It can involve the superficial temporal artery and occasionally the ophthalmic and posterior ciliary arteries leading to its most dreadful complication, i.e., blindness.

The American College of Rheumatology (ACR) has developed specific classification criteria for the disease in 1990 (Hunder et al. 1990). A patient should fulfill at least three of five proposed criteria in order to be classified as having GCA (age >50 years, new onset headache, tenderness or decreased palpation of temporal artery, elevated erythrocyte sedimentation rate-ESR >50 mm/h, abnormal artery biopsy).

Epidemiology

GCA is the most common form of systemic vasculitis after the age of 50; its incidence ranges as low as 1 new case/100,000/year in Turkey or African and Asian countries to 30 cases/100,000/year in Scandinavian countries (Borchers and Gershwin 2012; Weyand and Goronzy 2012). Women are affected more commonly than men (2:1).

Pathogenesis

GCA is a typical inflammatory arteritis with inflammation that involves all layers of the arterial wall, frequently leading to vascular stenosis and/or occlusion (Fig. 1) (Weyand and Goronzy 2012). The main population of infiltrating inflammatory cells consists of CD4+ T cells, macrophages, and multinucleated giant cells (which is why the disease is called giant cell arteritis) (Weyand and Goronzy 2012). These histologic features and extensive animal and human data have shown that a predominant Th1 (increased expression of interferon-γ/IFN-γ and interleukin-12/IL-12 and IL-32) and Th17 (increased expression of IL-17) response is present in the arterial wall. These cytokines together with other proinflammatory or antiangiogenic cytokines, such as IL-6, IL-1β, tumor necrosis factor, platelet-derived growth factor, free oxygen radicals, and metalloproteinases (MMP-2 and MMP-9), are responsible

for the systemic inflammatory symptoms and findings (fever, fatigue, weight loss, increased ESR and C-reactive protein – CRP), and the characteristic changes seen in the arterial wall (e.g., disruption of the internal elastic lamina, vascular occlusion).

Clinical Manifestations

The clinical manifestations of GCA depend on the site(s) of vascular involvement (Weyand and Goronzy 2012). Two types of involvement have been recognized: the cranial and the large vessel type.

The **cranial type** is the most common and is manifested by inflammation of the branches of the external carotid artery. Patients usually present with daily temporal headache (75 %) unresponsive to analgesics accompanied by scalp tenderness and jaw claudication. Involvement of the posterior ciliary or retinal arteries can lead to damage to the optic nerve and visual manifestations such as diplopia and transient or permanent loss of vision. Blindness occurs in approximately 15 % of patients with GCA during the early stages of the disease.

Large vessel arteritis involving the aorta (thoracic more than abdominal) and its branches (subclavian, axillary, lower extremity arteries) is increasingly recognized as a common manifestation of GCA (Salvarani et al. 2012). Using newer imaging techniques such as computed tomography angiography (CTA) or ^{18}F-FDG-positron emission tomography (PET) scan, subclinical involvement of large arteries is present at diagnosis in 30–70 % of cases. Clinical manifestations resulting from the formation of vascular stenoses or aneurysms are less frequent, occurring in less than 15 % of patients during the course of the disease (Weyand and Goronzy 2012; Salvarani et al. 2012).

Regardless of the site(s) of involvement (cranial and/or large vessel), almost half of the patients display systemic manifestations such as fever, weight loss, fatigue or aching, and stiffness in shoulders and hips (polymyalgia rheumatica or PMR). Fever without signs or symptoms of vascular involvement can be the only presenting symptom in a small percentage of patients with a fever of unknown origin (FUO) (Salvarani et al. 2012).

Diagnostic Assesments

Laboratory Tests

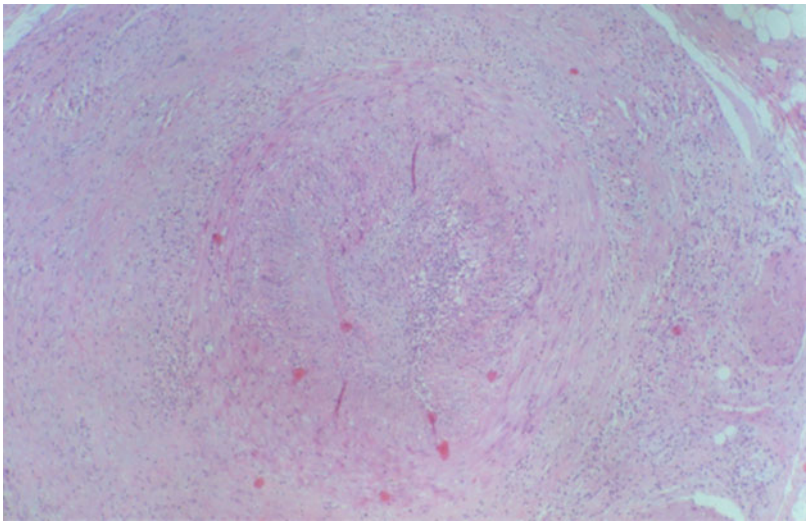
Simple markers of inflammation such as the ESR and the CRP are elevated in the majority of patients with GCA (~95 %) (Salvarani et al. 2012). Thus, a normal ESR and CRP remain the best initial tests to rule out this disease. On the other hand, it should be emphasized that in patients with typical clinical picture, a normal ESR and CRP should not exclude this diagnosis, until further workup has been performed, especially if these tests were performed while the patient was taking corticosteroids.

Temporal Artery Biopsy

Biopsy of an involved superficial temporal artery branch remains the best way to definitely establish the diagnosis of GCA (Salvarani et al. 2012; Weyand and Goronzy 2012). When an adequate size specimen is sampled (>2 cm), the biopsy is positive in 80–90 % of cranial and 40–50 % of large vessel GCA. Typical findings include a panarteritis involving the adventitia, media, and intimal layers of the artery (see Fig. 1); giant cells are present in 50 % of the cases around the elastic lamina (intima-media junction). There is currently no consensus regarding whether the initial biopsy should be unilateral or bilateral.

Imaging

A number of imaging modalities have been developed that are helpful in the diagnosis of cranial and more importantly large vessel GCA (Salvarani et al. 2012; Weyand and Goronzy 2012). These include color Doppler ultrasonography (US), magnetic resonance angiography (MRA), CTA, and ^{18}F-FDG-PET scan (Salvarani et al. 2012). US of the superficial temporal arteries has a sensitivity of 68–75 % and a specificity of 83–91 % for GCA diagnosis and could be



Giant Cell Arteritis, Fig. 1 Temporal artery biopsy of a patient with giant cell arteritis showing a panarteritis leading to occlusion of the vessel lumen

a useful tool in experienced hands to identify an abnormal artery for biopsy. MRA, CTA, and PET scan are needed for the diagnosis of large vessel GCA (aorta involvement), especially during the early stages of the disease. Their exact role in the follow-up of these patients has not been established.

Differential Diagnosis

For patients over the age of 50 presenting with the classical clinical features of cranial GCA, the diagnosis is not difficult to make. Rarely, small or medium size vasculitides or noninflammatory vasculopathies that involve the vessels surrounding the temporal artery can mimic GCA. These include ANCA-associated vasculitides (Granulomatosis with polyangiitis (Wegener's), microscopic polyangiitis (MPA), Churg-Strauss syndrome), polyarteritis nodosa, amyloidosis, or thromboangiitis obliterans (Salvarani et al. 2012). The typical histological features of the disease can easily differentiate these entities.

Large vessel vasculitis or GCA presenting only as FUO can create diagnostic difficulties since the differential diagnosis is wide and includes a number of infectious, neoplastic, and inflammatory disorders that present with nonspecific systemic manifestations (Salvarani et al. 2012). Temporal artery biopsy and appropriate imaging of aorta and its branches can aid in the correct diagnosis after other diseases have been ruled out with appropriate workup.

Treatment

The treatment of GCA (cranial or large vessel) should be started as early as possible in order to diminish the risk of blindness (Salvarani et al. 2012). This is the case even for patients without a positive temporal artery biopsy, if the clinical suspicion is sufficiently high. Despite the significant advances that have been made in the treatment of rheumatic disorders, corticosteroids remain the cornerstone of treatment. Patients are usually started with oral prednisone (40–60 mg/day) with gradual tapering of the dose that should reach 10–15 mg/day after 3 months (Mukhtyar et al. 2009; Dasgupta et al. 2010). Patients with threatened or established visual loss usually receive higher doses initially (either intravenously as pulses or by mouth). Although the majority of patients are able to discontinue steroids after approximately 2 years, relapses are frequent (40–50 %) during therapy requiring increase in the dose of steroids (Salvarani et al. 2012). Long-term therapy and high accumulating dose of steroids are associated with a number of significant side effects such as osteoporotic fractures, cataracts, infections,

hypertension, and diabetes mellitus (Salvarani et al. 2012; Weyand and Goronzy 2012).

In addition to corticosteroids, low-dose aspirin is recommended (unless contraindicated) as it may reduce the incidence of vision loss (Nesher et al. 2004).

Prophylactic anti-osteoporotic treatment is recommended for all patients treated for GCA, while there have been a number of studies assessing the role of steroid sparing agents for the treatment of GCA (Mukhtyar et al. 2009; Dasgupta et al. 2010). Among them the best studied is methotrexate with conflicting results regarding its efficacy. Newer biologic agents such as the IL-6 antagonist (tocilizumab) have shown promising results but controlled trials proving their usefulness in GCA are needed (Salvarani et al. 2012).

Gut Microbiome, Overview

Juliane Brueckner and Lloyd Mayer
Department of Immunology, Mount Sinai School of Medicine, New York, NY, USA

Synonyms

Gut microbiome; Gut microbiota; Inflammatory bowel disease; Metagenome; Probiotics

Definition

"Gut microbiome" describes the combined suite of genes of all microbiota present in the gut. It enlarges the host's gene pool 150-fold and influences health and disease. In order to illustrate the importance of the microbiome, this entry will first give an overview of its origins, normal function, and composition and, then, focus on how microbial changes affect human health. Further definitions are listed in Table 1.

Normal Gut Microbiota

In the gut, human cells are outnumbered by a vast, complex, and dynamic consortium of microorganisms, the gut microbiota (Ley et al. 2006). A refined symbiosis provides a protected habitat with constant nutrient supply for the microbes. In return the microbiota offers plenty of support in nutrient degradation and uptake where human cells alone lack the appropriate enzymes (Qin et al. 2010). Other functions influenced by the microbiota include fat metabolism, epithelial homeostasis,

Gut Microbiome, Overview, Table 1 Definitions

Gut microbiota	All microorganisms of the gut microbial community (bacteria, archaea, protozoa, fungi, viruses)
Gut microbiome	All genes present in the gut microbial community
Gut metagenome	All human and all microbial genes in the human gut combined
Microbial community	All microorganisms sharing a habitat/niche, e.g., the human gut or the colonic or ileal mucosa
Core microbiome	Set of microbial genes which can be found in most individuals of a host species; the contained genes convey important functions for the host organism
Microflora	Outdated term for microbiota ("flora" suggesting plant origin)
Probiotics	Certain microbes said to have anti-inflammatory or immune regulatory properties

angiogenesis, enteric nerve function, pathogen resistance, development, and immune homeostasis (Hill and Artis 2010). Modern sequencing techniques have shifted the focus onto microbial genes and the microbiome as a whole rather than species. Functionally, the abundance of certain genes is more important than which bacterium provides them. Besides, bacteria are known to exchange genetic information via plasmids, short loops of DNA, which can be transferred to a different bacterial cell. The terms microbiota and microbiome are often used are often used interchangeably to describe the same thing though the focus is in fact slightly different.

Composition of the Microbiota

Our knowledge of the mammal microbiome is still fairly young. Only in 1991 Weisburg et al. reported on a novel 16S rRNA approach to identify non-culturable microbial species via phylogenetic description. The gain of knowledge since has been exponential, jumping from 300 culturable species to current estimates of 1,800 genera and 15,000–36,000 species newly identified by culture-independent techniques (Weisburg et al. 1991). And still, while the size of the known microbiome has exploded, large parts of its function have yet to be deplored (Frank et al. 2007).

An important focus has been on a common microbial core, which is thought to hold the most important genes. Early reports still saw high interindividual differences (Eckburg et al. 2005; Ley et al. 2006; Frank et al. 2007). However, a recent large multicenter study using advanced deep sequencing techniques has in fact reported an important overlap: 38 % of genes as well as 18–75 of microbial species were shared among individuals, thus describing a common microbial core on the gene and the phylogenetic level (Qin et al. 2010).

However, the gut microbial community is not uniform. The microbial composition of stool is different than that on the mucosal surface. Biofilms connect different species with each other as well as with the epithelium and its overlaying mucus layer. Luminal bacteria on the other hand are considered planctonic, free floating. These varying subcommunities convey different niches for bacteria and different functions for the host (Sonnenburg et al. 2004; Eckburg et al. 2005). Upon closer look, even the gastrointestinal mucosa itself harbors varying communities. Many colonic species specialize in the degradation of fibers whereas the small intestine harbors more bacteria geared towards sugar degradation (e.g., the small intestine harbors less Bacteroidetes and Lachnospiraceae but has a higher prevalence of Streptococcaceae, Actinomycaeae, and Corynebacteriaceae (Frank et al. 2007)). However, other authors have suggested that incomplete colonic peristalsis with backflow and mixing can keep the mucus-associated microbiota relatively homogenous. While these views are not necessarily contradictory, further technologic advances and an increase in cohort size will lead to a better understanding of special niches.

Development and Ontogeny of Microbial Communities

Before birth mammals are believed to be sterile. Early colonization occurs during the first days and weeks of life more or less by chance of first contact. According studies have shown high

temporal and interindividual variation during this period. Over time, however, these preliminary communities are replaced by other microbes which are more adapted to the human gut niche. Thus, at approximately 1 year of age, broad microbial contact and food variety have shaped a typically human, adult-like microbiota that remains more or less stable. External factors influencing this process are mode of delivery, hospitalization, use of antibiotics, country of birth, prematurity, and feeding practices. A higher similarity has also been observed among relatives of several generations, suggesting a vertical inheritance ("parent-to-offspring hypothesis") (Hill and Artis 2010).

Compared to the outside world, our gut is a very selective environment. High selection pressure exists both from the host's immune system ("top-down selection") and from competing microbes ("bottom-up selection"). Phylogenetic analysis shows that almost 90 % of all gut bacteria belong to the phyla of Firmicutes (56 %) and Bacteroidetes (23 %) which in the soil and the ocean make up less than 10 % (Eckburg et al. 2005). However, although the human gut harbors a high diversity of subspecies and strains, the actual species level is rather shallow with approximately 400–500 phyla. In evolutionary terms this suggests that the initial colonization of the gut reservoir was accomplished by only a limited population of microbes that then could diversify easily ("bottleneck population and détente") (Eckburg et al. 2005; Ley et al. 2006), a bit like Darwin's finches in the Galapagos archipelago.

Gut Microbiota and Inflammatory Bowel Disease

Evidence for Microbial Involvement

The idea of microbial involvement in inflammatory bowel disease (IBD) is not new. In their 1932 landmark paper "Regional Ileitis," Crohn, Ginzburg, and Oppenheimer presented a new pathologic and clinical entity and discussed whether it might be due to "localized decrease in resistance to some bacterial invasion" (Crohn et al. 1984). Eighty years later microbial involvement is a known fact, but the mechanisms are still unclear.

Evidence for microbial involvement comes from clinical and experimental observations. Use of antibiotics can attenuate acute flares. Parts of the bowel that have been excluded from the fecal stream through surgery stay inflammation free until reconnection and consecutive microbial reexposure. In experimental settings, genetically susceptible animals such as IL-$10^{-/-}$, IL-$2^{-/-}$, or TCR$\alpha\beta^{-/-}$ mice develop IBD-like colitis within weeks of birth but remain colitis-free when raised under germ-free conditions. When germ-free animals are reconstituted with normal microbiota or a few nonpathogenic species, rapid onset of disease occurs. Remarkably, mono-association of germ-free IL-$10^{-/-}$ mice with single microbial species resulted in different phenotypes depending on the type of bacterium. For example, *Enterococcus faecalis* caused a slow but severe distal colitis with additional upper GI manifestations, whereas *E. coli* caused more rapid but moderate cecal colitis with severe reactive atypia (Kim et al. 2005). Similarly, use of different antibiotics in these animal models led to different disease activities in various segments of the colon. This observation puts additional emphasis on the following question: which microbes are present in the diseased gut?

The immune system of IBD patients also shows evidence for a specific immune response targeted against the microbiota. Increased antibody titers are reported for anti-Saccharomyces cerevisiae mannan antibodies (ASCA) and certain flagellins in Crohn's disease patients and perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) in patients with ulcerative colitis. Interestingly, ASCAs were detected in the serum of Crohn's disease patients years before clinical diagnosis (30 % seropositivity vs. 0 % in the control group) (Israeli et al. 2005). Thus, even before obvious onset of disease or in healthy relatives of IBD patients, testing for these and other seromarkers may shorten time to diagnosis and enable more rapid and effective treatment. Duchmann et al. even proposed a loss of tolerance to autologous flora as a major mechanism of disease. They reported

proliferation of lamina propria mononuclear cells in response to autologous stool sonicates in IBD patients but not healthy controls (Duchmann et al. 1995). However, these findings could not be reproduced by other groups. Still, inappropriate immunoglobulins and T cell responses against microbial proteins and cell wall components have been found in feces, mucosa, and serum. As these responses seem to be specific to a small number of enteric antigens only, they suggest that some microbes may be more involved than others (Brandwein et al. 1997).

Microbes as Causative Agents in IBD

Several microbes have been accused of actually causing IBD as an infective agent. Most importantly is Mycobacterium avium paratuberculosis (MAP), which can invade epithelial cells and persist in macrophages. However, MAP has been isolated or detected in both healthy and diseased patients, and it could well be a regular part of our gut microbiota that is often missed due to limited sequencing techniques. Another more recently described bacterium is adherent-invasive *E. coli* (AIEC), which has been found in 25–35 % of patients with CD ileitis. AIEC adheres via CEACAM6, an enterocyte surface antigen that is increased in inflammation. It is unclear whether it actually promotes disease or simply adheres more easily under inflammatory conditions.

Changes in Microbial Composition in IBD

Advances in culture-independent sequencing techniques have given rise to theories focusing on the composition of the microbiome as a whole. A loss of microbial diversity has been reported in up to 50 % for Crohn's disease and 70 % for ulcerative colitis patients. This includes a decreased diversity of the core microbiome, which carries the functionally most important genes (Willing et al. 2010), and a decrease of the metagenome of 25 % (Qin et al. 2010). Plausibly, this would be accompanied by loss of function and adaptability in the human host. To a lesser extent these effects have also been reported for other inflammatory diseases (e.g., C. difficile colitis), so specificity has to be questioned. Typical for IBD, however, seems to be a loss of group similarity: patients from IBD cohorts show less overlap than healthy subjects (Scanlan et al. 2006). This supports a multifactorial pathogenesis of IBD where different genetic backgrounds may lead to different changes in the microbiome. Also, CD microbial communities have been reported to be less stable over time. This might reflect disease activity and treatment efficacy. As abnormalities are greater during active disease than in remission (Scanlan et al. 2006).

Upon closer examination the microbial depletion takes place mainly in the phyla of Firmicutes (50-fold) and Bacteroidetes (300-fold), whereas the usually scarce Proteobacteria show an increase (Frank et al. 2007). Principal component analysis, an analysis tool which graphically compares the most prevalent components of microbial communities, has in fact repeatedly been able to determine distinct clusters of microbial composition for healthy, Crohn's disease, and ulcerative colitis patients. Interestingly, it has also been able to identify subsets of patients with correlation to abscess formation, ileal disease, young age at surgery, early recurrence, and response to specific treatments (Frank et al. 2007; Qin et al. 2010). This has been shown for both mucosal and fecal samples. It could thus be a valuable clinical tool for diagnosis and therapeutic management of patients. A gene chip for detecting the relevant bacteria has facilitated the transition to more extensive patient cohorts, reliable clinical correlation, and predictive exploitation of results. However, due to high cost, clinical application is not realistic, yet.

Balance Between Detrimental and Protective Bacterial Species

A more recent theory is that of an (un)balanced microbiome. Whereas in healthy individuals, the microbial community is thought to be in a state of in a state of balance between detrimental and protective bacterial species, overgrowth of detrimental microbes or loss of protective ones – for whatever reason – could contribute to inflammation. While microbial communities as a whole are still too complex to study, first experiments with biofilm simulation are on their way.

Gut Microbiome, Overview, Table 2 Detrimental species in IBD with observed pathomechanisms

Microbe	Phylum	Disease	Observed mechanisms
Segmented filamentous bacteria (SFB)	Spore formation, close relative to Clostridia	CD	Firm epithelial attachment
		EAE	Secretion of serum amyloid A (which activates dendritic cells and T_{H17} cells)
Enterotoxigenic *Bacteroides fragilis* (ETBF)	Bacteroidetes	CD, diarrhea	Secretion of BFT toxin (which causes actin restructuring, cell swelling, and loss of microvilli)
			Epithelial barrier damage, epithelial leakage, and microbial translocation
Bacteroides thetaiotaomicron	Bacteroidetes	CD	Paneth cell stimulation via TLR activation induces release of antimicrobial peptides, which kill Gram-positive bacteria via cell wall damage
Bacteroides vulgatus	Bacteroidetes	CD, UC	Unknown
		CD	
Bifidobacterium animalis		Experimental colitis	Elevated IL-12/23 p40 levels
Enterococcus faecalis	Firmicute, Gram-positive	CD, UC, pouchitis psoriasis	Early loss of epithelial barrier function and resistance via TLR2-mediated NFkB activation
			Stimulates TNF and IL-12p70 secretion from peritoneal macrophages
			Oligoclonal T cell expansion
Fusobacterium varium	Fusobacterium, Gram-negative, anaerobic	UC	Induces apoptosis in colonocytes
			Formation of ulcers and crypt abscesses, probably via butyric acid

Detrimental Species

Several microbes have been shown to have a detrimental effect on the host (Table 2). Segmented filamentous bacteria (SFB), spore-forming bacteria closely related to Clostridia, show firm epithelial attachment especially in the terminal ileum. Interaction with the epithelium leads to a pro-inflammatory host gene program that stimulates lamina propria DCs to induce Th17 differentiation of naïve $CD4^+$ -T cells. This mechanism has been held responsible in the observation that SFB-mono-colonized mice were protected from Citrobacter rodentium infection (Ivanov et al. 2009). However, SFB was also linked to colitis in a SCID transfer model (Stepankova et al. 2007). Thus, it seems to play a dual role in gut immune homeostasis. The likely involvement of Th17 cells in Crohn's disease and the primary location of SFB in the terminal ileum make their involvement in Crohn's disease a likely possibility.

Enterotoxigenic *Bacteroides fragilis* (ETBF) causes loss of epithelial barrier function. It expresses the enterocyte-damaging toxin BFT that damages the tight junction protein E-cadherin, followed by epithelial leakage and translocation of other microbes. The epithelial cells undergo actin restructuring leading to cell swelling and unraveling of apical membrane microvilli. Despite this damaging character, ETBF prolongs the cell life span by inhibiting apoptosis and has also been associated with cancer development (Sears 2009).

Bacteroides thetaiotaomicron has been detected in increased numbers in the mucosa of Crohn's disease patients. It stimulates Paneth cells, which then upregulate RegIIIγ (in mice) or HIP/PAP (in humans) and release antimicrobial peptides damaging the cell wall of Gram-positive bacteria (Vaishnava et al. 2008). This could be one of many reasons for the reduction of Firmicutes in IBD.

Bacteroides vulgatus can either promote or protect from colitis depending upon the host's genetic background. In an early UC model using carrageenan-fed guinea pigs, isolates from UC patients caused robust disease (Onderdonk et al. 1984). IL-$10^{-/-}$ mice, however, did not develop

Gut Microbiome, Overview, Table 3 Currently used probiotics and assumed mechanisms

Microbe	Phylum	Disease	Observed mechanisms
Faecalibacterium prausnitzii	Firmicute (Clostridium leptum group)	CD	Anti-inflammatory cytokine profile (IL-12/IFN-g decrease, IL-10 increase)
			Correction of dysbiosis
Lactobacilli	Firmicute	IBD	Reduction of bacterial adherence/translocation
		EAE	Reduction of IL-12/IFN- g, TNF, and IgG2a
		Autoimmune arthritis	IL-10-induced generation of regulatory $CD4^+$ T cells
			Correction of dysbiosis
			Resistance to pathogens (Salmonella)
Bacteroides fragilis	Bacteroidetes	Colitis	Induction of IL-10-producing $CD4^+$ T cells, possibly via $CD103^+$ dendritic cells
		EAE	Suppression of local IL-17 levels
VSL#3		Type 1 diabetes	Restoration of epithelial barrier function, bacterial adherence/translocation, and mucosal histology
		UC	DC activation and IL-10 production in $CD4^+$ Tregs
Saccharomyces boulardii		CD	Unknown
Nonpathogenic *Escherichia coli*	Proteobacterium	UC	Unknown

colitis in the presence of *B. vulgatus* mono-association. Also in IL-$2^{-/-}$mice *B. vulgatus* attenuated *E. coli*-induced colitis (Sellon et al. 1998; Waidmann et al. 2003). *Bacteroides vulgatus* may in fact show a rather typical colitogenic profile with different immunologic effects depending on host background and presence of other microbes, thus, illustrating the complexity of gut homeostasis.

Enterococcus faecalis causes severe duodenitis and distal colitis in IL-$10^{-/-}$ mice (Kim et al. 2005). Observation of oligoclonal T cell expansion suggests several antigens are involved. It also caused loss of intestinal barrier function and transepithelial resistance via a TLR2-mediated NFkB activation pathway (Steck et al. 2011). However, how these epithelial cell and adaptive immune responses are connected is still unclear.

Fusobacterium varium has been isolated from inflamed UC mucosa. Over 60 % of UC patients are seropositive for *F. varium*, and the titer correlates with disease severity and extension of involved mucosa. *F. varium* has been shown to induce apoptosis in colonic epithelial cells, and its supernatants were reported to cause ulcers, crypt abscesses, and inflammatory infiltration in mice within 24 h. The exact mechanism of these events is unknown (Ohkusa et al. 2003).

This list is by no means complete. Advances in sequencing techniques and cohort size will hopefully shed more light onto their role in IBD and give us ideas how to regulate them.

Beneficial Species

The beneficial species are listed in Table 3 and will be discussed below under Probiotics.

Gut Microbiome and Other Auto-inflammatory Diseases

The intestinal microbiota has also been associated with a series of other diseases beyond the boundaries of the gut. Most obvious is its involvement in obesity and the metabolic syndrome. The microbiota of obese people and mice shows a reduction in Bacteroidetes and increase in Firmicutes that were reversible by low calorie diet. Germ-free mice, which are generally protected from obesity, show an increase in body fat of up to 60 % in 14 days without higher food intake upon colonization with regular microbiota. Furthermore, there is

a connection between the microbiota and innate immunity. TLR5-deficient mice develop a full metabolic syndrome, which does not develop under germ-free conditions. Interestingly, microbial transfer is sufficient to transfer the disease to wild-type germ-free mice stressing the importance of the microbiome in this disease (Vijay-Kumar et al. 2010).

Type 1 diabetes mellitus also has been linked to the gut microbiota and its effect on innate immunity. Nonobese diabetic (NOD) mice insufficient in the TLR signaling molecule MyD88 show a different penetrance of disease depending on microbial colonization. Raised germ-free, these mice develop full blown disease, while no diabetes occurs under specific pathogen-free (SPF) conditions (Wen et al. 2008). Also, young children with a genetic predisposition, who later developed type 1 diabetes, showed a gradual decrease in microbial diversity before onset of disease (Giongo et al. 2011).

Similar reports have emerged for other autoimmune diseases. Various models of experimental autoimmune encephalomyelitis (EAE), arthritis, and systemic lupus erythematosus show varying penetrance and disease severity depending on microbial colonization. Germ-free EAE model mice had attenuated disease with lower dendritic cell and $CD4^+$-T cell activity and lower cytokine responses. All of which could be restored by mono-association with segmented filamentous bacteria (SFB) (Berer et al. 2011). In a model of autoimmune arthritis, SFB also restored full phenotype as well as T cell numbers and function, which were repressed under germ-free conditions (Wu et al. 2010). Interestingly, microbial colonization is pro-inflammatory in these above-mentioned disease models but anti-inflammatory in the $MyD88^{-/-}$ NOD mice. This stresses the complex regulatory effects of microbial communities and their dependence on underlying host immune defects.

According to the hygiene hypothesis, early exposure to bacteria, viruses, or fungi sets the repertoire for the immune system. A clean environment and consecutive lack of microbial contact could therefore explain a myriad of autoimmune/auto-inflammatory diseases from a Th1-driven disease (e.g., diabetes) to allergic diseases (Th2). However intriguing, this theory has been replaced. The "microbial hypothesis" postulates that an imbalance in the human microbiota, which may arise from environmental changes, could be responsible for altered immune regulation. An altered gut microbiota has been reported in asthma, food allergies, atopic eczema, and dermatitis. An overall lack of Bifidobacteria and Lactobacilli has also been associated with the development of allergies. Underlying risk factors seem to be early antibiotic use and dietary changes.

Lastly, microbes have also been linked to the pathogenesis of cancer. Mouse models reported protection from carcinogen-induced colorectal carcinoma under germ-free conditions, as well as an involvement of TLR adaptor molecule MyD88 (Uronis et al. 2009). In humans the correlation cannot clearly be drawn. Recently two independent studies have shown increased Fusobacterium spp. in colorectal tumor tissue. Fusobacterium is an invasive bacterium formerly associated with appendicitis (Kostic et al. 2011). Likewise, two species, *Neisseria elongata* and *Streptococcus mitis*, were increased in the saliva of pancreatic cancer patients. Still, a better mechanistic understanding of the relationship between microbiota, immune system, and carcinogenesis is needed before new therapeutic approaches can be established.

Probiotics

Treating a microbe-driven disease by adding regulatory microbes seems intuitively obvious. However, probiotics have been around for centuries, without much measurable success. With the new appreciation of microbial composition and growing knowledge of immune and microbial interactions, recent results are more focused and somewhat promising.

Several bacterial families and species have been examined for anti-inflammatory or regulatory properties (Table 3). Lactobacilli reduced bacterial adherence and translocation and

ameliorated mucosal histology in an IL-$10^{-/-}$ colitis model. They also partially corrected microbial dysbiosis and conveyed resistance to salmonella infection. The exact mechanism is unknown but seems to involve reduction of IL-12, IFN-γ, TNF-α, and IgG2a (Madsen et al. 1999). Lactobacilli also had beneficial effects in experimental models of multiple sclerosis and arthritis.

Bacteroides fragilis was shown to protect from experimental colitis and encephalomyelitis (EAE) via secretion of polysaccharide A (PSA). Possible mechanisms are activation of $CD103^+$ dendritic cells, induction of IL-10 producing $CD4^+$-T cells, and local IL-17 suppression (Mazmanian et al. 2008; Ochoa-Reparaz et al. 2010).

Faecalibacterium prausnitzii and an unknown metabolite induced a typical anti-inflammatory cytokine profile in experimental colitis, with low IL-12/IFN-γ and high IL-10 levels in vitro and in vivo. It not only attenuated TNBS colitis significantly but also corrected the microbial dysbiosis, thus demonstrating relevance for microbe-microbe interaction. Interestingly, systemic administration of the metabolite was equally effective suggesting a possible beneficial effect in other systemic immune disorders (Sokol et al. 2008).

VSL#3, a standardized mixture of eight live probiotics from the lactic acid bacteria group, had a restorative effect on epithelial barrier function, bacterial adherence, and translocation and mucosal histology in an IL-$10^{-/-}$ colitis model (Madsen et al. 2001). It has also been shown to ameliorate TNBS colitis and decrease insulitis, beta cell destruction, and insulin resistance in NOD mice. The involved mechanisms include inhibition of dendritic cells and increased IL-10 production in $CD4^+$ Tregs (Hart et al. 2004).

However, in human disease the effects of probiotics are not as straightforward. Most studies have been carried out in a laboratory setting. Probiotic therapy works in theory. Clinical studies, on the contrary, show mixed to poor results. A positive impact has been shown for nonpathogenic *E. coli* strain Nissle 1917. It was equivalent to mesalazine in preventing relapse in quiescent ulcerative colitis when administered rectally (Kruis et al. 2004). However, other studies have shown no effect in Crohn's disease. *Saccharomyces boulardii* increased the time of remission when administered in addition to mesalamine in Crohn's disease, but administration of VSL#3 or nonpathogenic *E. coli* had only minimal effects (Guslandi et al. 2000).

If intestinal microbiota does in fact play a major role in the pathophysiology of immune diseases, there is hope for effective, possibly physiologic, therapies. Deeper insights into the mechanisms towards an immunoregulatory environment or correction of dysbiosis may, in fact, bear valid therapeutic approaches. However, various studies have shown that strain specificity and host genetic background are important. Thus, it would be desirable to find the right bug for each genetic defect, as to avoid unintended effects in the host. Metabolites of *Faecalibacterium prausnitzii* and *Bacteroides fragilis* have been shown to work on their own in the intestine or through systemic administration, so despite discouraging results from human studies, current work on probiotic therapies may soon be productive.

Conclusions and Future Directions

The gut microbiome markedly enriches our genome and influences our whole body throughout life. Technical advances over the last two decades have increased our understanding of the microbiota and stressed its importance in both health and disease. Several immune-related disorders such as inflammatory bowel disease, diabetes, atopy, and cancer show shifts in microbial composition (dysbiosis). Combined with refined analyzing techniques, these observations have a realistic potential to be applied in clinical prognosis and therapeutic management. So far efforts to manipulate the microbiota and correct dysbiosis are still rudimentary, and promising results have been limited to animal models. However complex, our understanding of the mechanisms of host-microbe and

microbe-microbe interactions is progressing. In order to further appreciate the role of the microbiota in health and disease, technical approaches have to become more cost-effective and more easily accessible. Additionally, simulation and study of biofilms in mammals will open up a new level of host microbial research. Given the recent acquisition of new information and advancing techniques, future revelations promise to be inspiring and productive.

Hair Loss in Lupus Erythematosus

M. J. Kristine Bunagan[1], Nusrat Banka[1] and Jerry Shapiro[1,2]
[1]Department of Dermatology, University of British Columbia, Vancouver, BC, Canada
[2]The Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, NY, USA

Synonyms

Alopecia in systemic disease; Discoid scarring alopecia; Hair loss in SLE; Lupus hair loss

Definition

The clinical presentation of lupus erythematosus (LE) may be confined to cutaneous disease or may involve various internal organs. Alopecia may occur with cutaneous and/or systemic lupus erythematosus. Hair loss over the scalp may range from localized scarring type of alopecia to non-scarring hair loss.

Discoid Lupus Erythematosus

Epidemiology

According to the Gilliam classification for cutaneous LE, DLE is considered an LE-specific skin lesion under the chronic cutaneous LE (CCLE) category. It is the most common clinical presentation of CCLE and commonly affects the scalp.

In patients with DLE, the scalp may be involved in 34–60 % of cases (Wilson et al. 1992; De Berker et al. 1992) and may be the only site affected in 10 % (Sontheimer and Mccauliffe 2002). Scalp DLE can be purely cutaneous or may be associated with SLE. DLE lesions may be the first clinical manifestation of SLE in 23–28 % of cases (Sontheimer and Mccauliffe 2002; Ross et al. 2005). The age range is from 20 to 40 years with a female predilection (Ross et al. 2005). It is not common in children.

While it is considered uncommon for patients with DLE to manifest systemic disease (Vera-Recabarren et al. 2010), approximately 5–10 % of patients with DLE will progress to SLE (Parodi and Rebora 1997; Wallace 1993). Among patients with SLE, about 5 % will have DLE lesions at some point (Sontheimer and Mccauliffe 2002).

DLE may be confined locally to the head and neck area or may be generalized (disseminated) affecting areas above and below the neck. The more widespread form has greater risk of developing systemic lupus disease and higher possibility of more severe SLE manifestations (Cardinalli et al. 2000; Callen 1982). Likewise, initial localized disease becoming generalized has higher association with developing internal organ involvement.

Pathogenesis

The exact etiology of DLE remains unknown. The etiopathogenesis likely involves the interplay of multiple factors such as genetic, environmental, and immunologic regulatory mechanisms.

In DLE, scarring of the hair follicle is considered to be due to a primary process with resultant destruction of follicular units. The inflammatory infiltrates are mainly found around the bulge region, the site of the epithelial hair follicle stem cells (Harries et al. 2009; Cotsarelis 2006). Inflammation localized over the bulge area contributes greatly to the irreversible follicular damage seen in the primary scarring alopecias such as scalp DLE (Harries et al. 2009).

Lymphocytes comprise the main inflammatory cell infiltrate. The North American Hair Research Society (NAHRS) consensus scheme categorizes DLE as a primary lymphocytic cicatricial alopecia. DLE lesions have predominant T lymphocytes as mediators of immunity. There are elevated levels of CD4+ and CD8+ as well as increases in CD3+ T cells in the dermal infiltrates of DLE (Xie et al. 2011). Higher numbers of cytotoxic T lymphocytes and type 1 interferon (IFN) have been associated with scarring DLE (Wenzel et al. 2005a). In contrast, there was reduction in the regulatory cytokines, transforming growth factor (TGF) beta and interleukin (IL)-10 in patients with DLE. These immunosuppressive cytokines are involved in T cell regulation with lower levels seen in other autoimmune diseases (e.g., multiple sclerosis) (Antiga et al. 2011).

In patients with disseminated chronic DLE, there were findings of increased percentage of skin homing CD25+ CLA+ CD8+ T cells (Wenzel et al. 2005b). These cells are also seen in scarring DLE where they are found increased in the epidermis and outer root sheath of the hair follicle. Other proinflammatory cytokines upregulated in DLE include tumor necrosis factor (TNF) alpha, interleukin (IL)-2, and IFN gamma (Toro et al. 2000).

Effector mechanisms such as Fas/FasL interaction may also be involved in the pathogenesis of DLE. Macrophages with FasL expression were found around hair follicles with resultant apoptosis in follicles in DLE. Fas/FasL action could lead to destruction of hair follicles seen in scarring DLE (Nakjima et al. 1997).

There is convincing data for the role of ultraviolet (UV) light in the pathogenesis of lupus erythematosus particularly for acute and subacute cutaneous lupus erythematosus (Sontheimer and Mccauliffe 2002). However, the association of UV as a possible antigenic stimulus in the development of DLE over relatively sun-protected hair-bearing scalp is less evident.

Other environmental factors such as nonspecific cutaneous trauma (Koebner phenomenon) and smoking have been associated with the development and persistence of DLE lesions, respectively (Sticherling 2010).

Clinical Features

Scalp sites more commonly affected are the vertex followed by parietal and temporoparietal areas (Ross and Shapiro 2008).

Patients with scalp DLE may be relatively asymptomatic or may have accompanying symptoms of pruritus, pain, burning sensation, and tenderness over the affected areas (Vera-Recabarren et al. 2010).

DLE is a chronic, long-standing disease with lesions that typically start as erythematous to violaceous well-defined macules or papules with scaling. As the disease progresses, there is expansion of lesions to larger erythematous plaques with thick adherent scales extending into the ostia of the hair follicles. Removal of the adherent scale reveals an undersurface with keratotic spikes as is also seen in psoriasis, which correspond to hyperkeratosis of the follicular infundibulum (Carpet tack sign) (Ross and Shapiro 2008).

The inflammatory changes of erythema and scaling may be more prominent centrally in DLE compared to other primary cicatricial alopecias where inflammation commonly occurs over the outer margins (Mirmirani 2008).

With progressive disease, lesions become flatter with less erythema and develop depressed atrophic scarring, telangiectasia, and depigmentation. In some individuals especially those with

darker skin color, the lesions may exhibit central areas of hypopigmentation and hyperpigmentation over the periphery. Mottled dyschromia may also occur in some patients. With the development of progressive irreversible scarring alopecia, the lack of follicular ostia becomes more apparent. In some cases there may be increased curl of hair shafts (torsion due to fibrosis within hair follicle). During active disease, the pull test is positive for anagen hairs (Shapiro 2002).

Pathology

In DLE the main injury is found in the basal layer of the epidermis. DLE of the scalp shows vacuolar interface change of the follicular epithelium mainly at the infundibular level of the hair follicle with scattered epidermal dyskeratotic keratinocytes (Stefanato 2010) and superficial and deep lymphocytic inflammatory cell infiltrate around blood vessels and appendageal structures. Other features include prominent hyperkeratosis and follicular plugging. There is loss of sebaceous epithelium. The adjacent epidermis may be atrophic with pigment incontinence and the dermis has mucin deposition (Stefanato 2010; Whiting 2001).

In late disease there is epidermal and follicular BMZ thickening, perifollicular concentric lamellar fibrosis (Stefanato 2010), and interfollicular dermal fibroplasia. Diffuse scarring of the dermis with loss of elastic fibers can be apparent on Verhoeff-van Gieson stain.

Direct immunofluorescence of lesional discoid scalp skin shows IgG or IgM with C3 mainly over the epidermal and follicular basement membrane zone deposited in a thick continuous band or in a granular type of deposition (Stefanato 2010; Sperling 2003). The deposition localizes on the upper dermal collagen fibers and lamina densa of the epidermal basement membrane zone. Older lesions which are more than 3 months in duration compared to those less than a month old when examined showed higher immunoreactant positivity at the DE junction [3]. Scalp DLE with positive DIF results range from 63 % to 100 % (Sontheimer and Mccauliffe 2002; Ross and Shapiro 2008).

Differential Diagnosis

DLE of the scalp has to be differentiated from other scarring alopecias. One of the main differentials is lichen planopilaris, another primary scarring alopecia. This disease may present similarly as alopecic patches with scarring. Commonly there is perifollicular erythema and scaling in contrast to DLE where there is more diffuse erythema. Pigmentary changes are more common in DLE compared to lichen planopilaris. A biopsy may be needed to confirm the diagnosis. Other primary cicatricial alopecias such as folliculitis decalvans may present with scarring patches without papules and pustules in the chronic stage. Another differential is central centrifugal cicatricial alopecia (CCCA). This disease however occurs over the central aspect of the scalp in individuals predominantly of African descent. Typically features of erythema and dyspigmentation and follicular plugging are found in DLE but less likely in CCCA (Sontheimer and Mccauliffe 2002; Ross and Shapiro 2008).

Non-scarring Alopecia

Aside from the scarring alopecia seen in scalp DLE, there are other hair loss manifestations associated with lupus erythematosus. These hair loss features are considered nonspecific to the LE disease and are non-scarring in nature.

Patients with SLE may undergo telogen effluvium (TE) where there is excessive hair shedding diffusely affecting the entire scalp. Hair fall in TE exceeds physiologic levels, with approximately 150–300 or more hairs being shed per day. TE coincides with flares of systemic lupus whereby the disease process interrupts the hair growth cycle causing hairs to prematurely enter the telogen phase. When the acute flare of SLE subsides, hair shedding typically lessens. However, it takes a long time period (6 months to 1 year) for the hairs to grow back to previous hair density. This hair loss condition is nonspecific for LE and may occur due to other conditions (e.g., thyroid disorders, medications, postpartum, major stress, major surgery) (Trueb 2010).

Another type of hair loss which may occur with LE is termed lupus hair. Clinically, hair

strands appear dry and fragile. Affected hair shafts easily break off after exiting the surface of the scalp. Scalp sites which are commonly involved are the frontal hairline and the lateral hair margins in an ophiasis pattern. Lupus hair is a non-scarring type of alopecia associated with increased systemic activity. Hair regrowth occurs following disease control (Trueb 2010).

Patchy non-scarring alopecia may develop in severe established SLE disease. Clinically, multiple partial alopecic patches occur in various areas of the scalp. Some lesions may have mild erythema. The affected hairs are composed of telogen hairs or dystrophic anagen hairs. Dystrophic anagen effluvium results from severe illness causing transient hair matrix shutdown. In some cases there may be resultant constricted hair shafts (Pohl-Pinkus constriction). When the disease activity subsides, there is regrowth of areas with hair loss (Trueb 2010).

There have been some reports of the occurrence of alopecia areata in patients with SLE. While their association remains unclear and may be coincidental, a clinical pattern of alopecia areata may be seen. When biopsied and evaluated with H&E as well as direct immunofluorescence, typical immunologic features of lupus are found. The term "alopecia areata-like DLE" (Werth et al. 1992) has been utilized in this setting.

Course and Prognosis

Treatment of scalp DLE is usually initiated with intralesional corticosteroids (triamcinolone acetonide 10 mg/cc for a maximum volume of 2 cc every month depending on extent) and superpotent topical steroids, often in liquid or foam. In addition, systemic therapy with antimalarials is important to consider in those patients with multiple active sites, as well as with active serology. Short courses of systemic steroids may be added depending on severity of the condition in an attempt to prevent permanent scars.

Scalp DLE is considered a chronic, progressive disease. Early treatment of limited localized disease may halt the scarring process. In most cases though the disease results in progressive irreversible scarring of the scalp unless the patient is started on a remittive agent such as hydroxychloroquine. A serious sequela of chronic DLE is the risk of development of squamous cell carcinoma (scar carcinoma). Hair loss which accompanies SLE typically follows the activity of the disease with hair regrowth reversal possible upon disease control (Sontheimer and Mccauliffe 2002; Ross and Shapiro 2008).

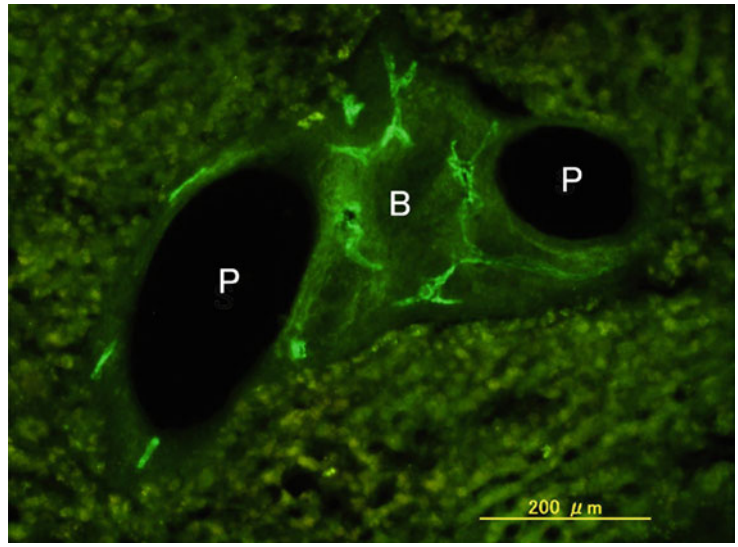
Lymph circulation of the liver

Definition (Overview)

As in other organs, the lymphatics in the liver function as a tissue drainage system and an immunological control system. The lymphatic vascular system consists of noncontractile initial lymphatics and contractile collecting lymphatics. Initial lymphatics are tubulosaccular and have many valves that allow unidirectional lymph flow. Basement membranes of the lymphatics are incomplete or absent. Reportedly, lymphatic basement membrane in human skin, digestive tract, and ovary contains laminin α4, β1, β2, γ1, type IV and XVIII collagens, and nidogen-1 (Vainionpää et al. 2007), but that in human liver remains to be studied. Lymphatic endothelial cells (LECs) show three types of intercellular contacts: end-to-end, overlapping, and interdigitated junctions. Open junctions are occasionally seen. Specialized junctional complexes, either fasciae occludentes or fasciae adherentes are seen in 65 % of the contacts. LECs are strongly attached at the anchoring filaments to the surrounding collagen and elastin fibers (Leak and Burke 1968). During expansion of the initial



Hepatic Lymphatic System,
Fig. 1 Fluorescent micrograph of the human liver showing lymphatics around the interlobular bile duct (*B*) and interlobular vein (or portal vein branch) (*P*). Immunohistochemistry to D2-40

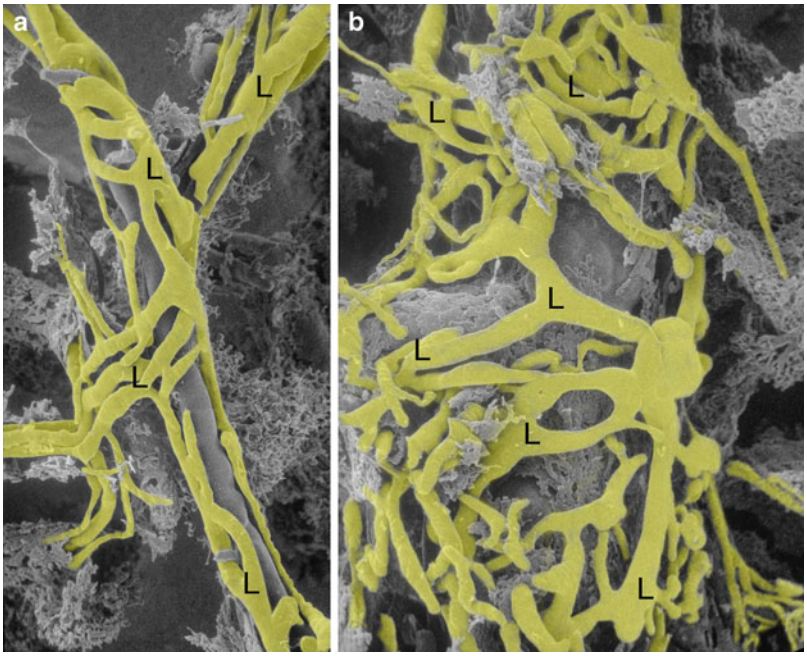
lymphatics, overlapping junctions can be opened, thus allowing fluid to flow from the interstitium into the lumen, while during compression, overlapping junctions can be closed, thereby retarding the backflow of lymph into the interstitium. Collecting lymphatics are, on the other hand, located downstream of the initial lymphatics and serve as a drainage system. Collecting lymphatics are endowed with smooth muscle cells and valves (Ohtani and Ohtani 2008b). Lymphatics in normal and cirrhotic human liver can be revealed using D2-40 (Fig. 1), a monoclonal antibody raised against a 40 kD membrane sialomucin (Breiteneder-Geleff et al. 1999). D2-40 specifically recognizes human podoplanin, which is homologous to human gp36 (Schacht et al. 2005). LYVE-1, a homolog of hyaluronan receptor CD44 (Jackson 2000), is expressed by hepatic sinusoids as well as by lymphatics (Carreira et al. 2001).

The liver produces a large volume of lymph, which is estimated to be 25–50 % of lymph flowing through the thoracic duct (Barrowman 1991). The hepatic lymph output is approximately half of the intestinal lymph output in sheep. The hepatic lymphatics fall into three categories depending on their locations: portal, sublobular, and superficial (or capsular) lymphatics (Lee 1923; Comparini 1969). It is suggested that 80 % or more of hepatic lymph drains into portal lymphatics, while the remainder drains through sublobular and capsular lymphatics (Popper and Schaffner 1957; Yoffey and Courtice 1970).

Because the liver is exposed to antigens from the gut or from the peripheral tissues, a considerable number of lymphocytes drain into the hepatic lymph nodes, which play a crucial role in immunosurveillance (Matsuno and Ezaki 2000; Xu et al. 2008). Lymphocytes and dendritic cells transmigrate from the blood into the portal tract (Matsuno and Ezaki 2000). These cells either remain in the portal tract or enter the draining lymphatics and migrate into the hepatic lymph node to contribute to the immune response. The minimal transit time of rat recirculating lymphocytes is 3–4 h in the liver and 5–8 h in the hepatic lymph nodes, in normal steady state (Xu et al. 2008).

Portal Lymphatics

Color gelatin injected into the portal vein first appears in the space of Disse; then reaches the perilobular space, i.e., the space of Mall; and finally enters portal lymphatics (Mall 1901). There are well-developed lymphatic networks around interlobular veins, arteries, and bile ducts, which extend distally as far as the terminal



Hepatic Lymphatic System, Fig. 2 Scanning electron micrographs of the corrosion cast of the rabbit liver showing lymphatic network (*L*, *yellow*) in the portal tract. The lymphatic network in the thin portal tract is composed by longitudinal vessels with transverse anastomoses (**a**). There is a dense lymphatic network in the thicker portal tract (**b**). The corrosion cast was made by retrograde injection of semipolymerized methacrylate into the bile duct

portal tract (Figs. 1 and 2). The lymphatics in the thin portal tract are composed of longitudinal vessels with transverse anastomoses (Fig. 2a). In the thicker portal tract, the lymphatics form dense networks (Fig. 2b).

The hepatic artery is responsible for 19 % of the hepatic blood flow in mice, 17 % in rats, 21 % in rabbits, 23 % in monkeys, 20 % in dogs, and 21 % in humans (Davies and Morris 1993) and primarily supplies the peribiliary plexus of the intrahepatic bile duct (Ohtani and Ohtani 2008a). Portal lymph comes from the plexus to some extent but Földi (1974) estimates that the plexus contributes less than 10 % to the total lymph output from the liver. However, 75 % of the blood in the liver comes from the portal vein, and almost all the blood of the liver flows through sinusoids. Furthermore, the protein concentration of hepatic lymph is about 80 % of the plasma protein concentrations (Yoffey and Courtice 1970). These suggest that lymph in the portal tract primarily derives from highly permeable sinusoids, i.e., hepatic sinusoids.

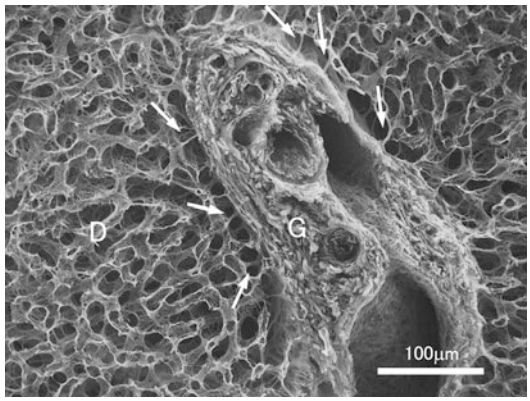
The space of Disse is continuous with the interstitial space of the portal tracts at the origin of the sinusoids (or inlet venule). There are also many channels with collagen fibers penetrating through the portal limiting plate to connect the space of Disse with the interstitial space of the portal tract (Ohtani et al. 2003). The density of the openings is approximately 1.3×10^3/mm (Ohtani et al. 2003).

The collagen fiber network in the liver has been demonstrated by NaOH maceration/scanning electron microscope technique (Ohtani 1988). There are condensations of collagen fibers in the Glisson's sheaths. Some collagen fibers in the portal tract extend along the inlet venules to continue with those in the space of Disse, while others travel independently of blood vessels through the channels with collagen fibers between the periportal limiting plate hepatocytes to connect with those in the space of Disse (Ohtani and Ohtani 2008a) (Fig. 3).

Horseradish peroxidase (HRP) injected into the blood vascular system of the rat appears in the hepatic sinusoids, in the space between limiting plate hepatocytes and in the space of Mall (Ohtani et al. 2003) (Fig. 4). This indicates that fluids in the space of Disse pass through channels between limiting plate hepatocytes to enter the space of Mall as well as through the space around the initial segment of the hepatic sinusoids (or inlet venules). Figure 5 shows pathways for

movement of fluid and cells from hepatic sinusoids to the portal lymphatics.

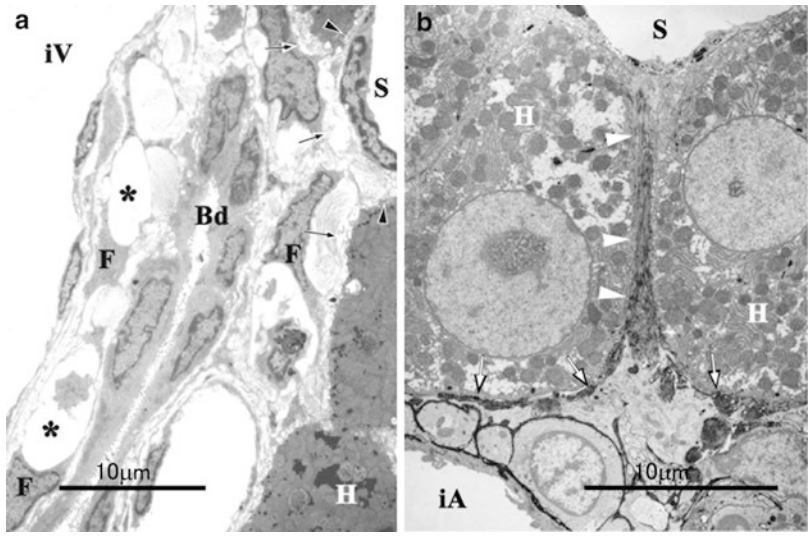
The interstitial space of the portal tract shows a porous structure partly lined with fibroblast-like cells (Fig. 4). The porous spaces frequently contain lymphocytes and/or dendritic cells. It is likely that the porous structures are prelymphatics (Ohtani et al. 2003) and serve as pathways for free cells such as lymphocytes and dendritic cells as well as fluid draining into the portal tract (Ohtani and Ohtani 2008a).



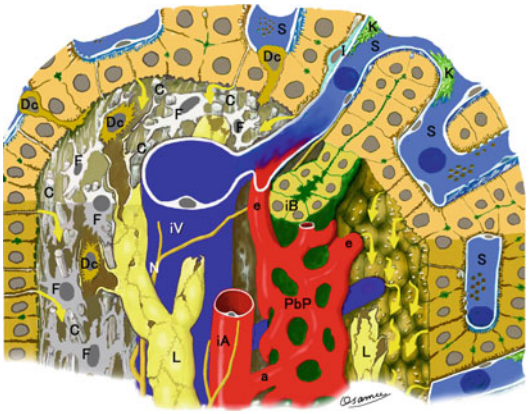
Hepatic Lymphatic System, Fig. 3 Scanning electron micrograph of collagen fiber network of the human liver. There is a condensation of collagen fibers in the Glisson's sheath (*G*). The collagen fibers in the space of Disse (*D*) form sheaths for housing the hepatic sinusoids. *Arrows* indicate collagen fibers passing through the layer of periportal limiting plate independently of blood vessels (From Ohtani 1988)

Sublobular Lymphatics

Sublobular lymphatics exist in many mammals, including rabbits, dogs, cats, and humans (Lee 1923; Yoffey and Courtice 1970), but not in smaller animals such as common tree shrews, rats, and mice. Sublobular lymphatics lead into lymphatics running along the inferior vena cava. Collagen fibers in the space of Disse are continuous with those around the central vein, which in turn increase in number toward the sublobular vein and the hepatic vein and finally continue into those around the vena cava (Ohtani and Ohtani 2008a). In addition, many collagen fibers traversing the hepatic limiting plate



Hepatic Lymphatic System, Fig. 4 Transmission electron micrographs of the intact (*A*) and HRP-injected rat liver. (**a**) *Arrowheads* indicate transition of the space of Disse at the initial segment of sinusoids (*S*) to the space of Mall (*arrows*). Processes of fibroblast-like cells (*F*) form spaces (*) that mimic lymphatic vessels, in which migrating cells (presumably dendritic cells and/or lymphocytes) can be seen. (**b**) HRP reaction products can be seen in the sinusoids (*S*), in the space of Disse, in the space (*arrowheads*) between limiting plate hepatocytes (*H*), and in the space of Mall (*arrows*). Also note collagen fibers with HRP in the space between limiting plate hepatocytes (From Ohtani et al. 2003)



Hepatic Lymphatic System, Fig. 5 A schematic representation of pathways of fluid and migrating cells such as dendritic cells (*Dc*) extending from the sinusoids (*S*) through the space of Disse, channels in the limiting plate, and interstitial space of the portal tract to portal lymphatic vessels (*L*). *Arrows* indicate the presumable flow direction. *C* collagen fibers, *iA* interlobular artery, *iV* interlobular vein, *iB* interlobular bile duct, *F* fibroblast, *I* Ito cell (or stellate cell), *K* Kupffer cell, *N* nerve, *PbP* peribiliary capillary plexus, *a* afferent vessel of PbP, *e* efferent vessel of PbP (From Ohtani et al. 2003)

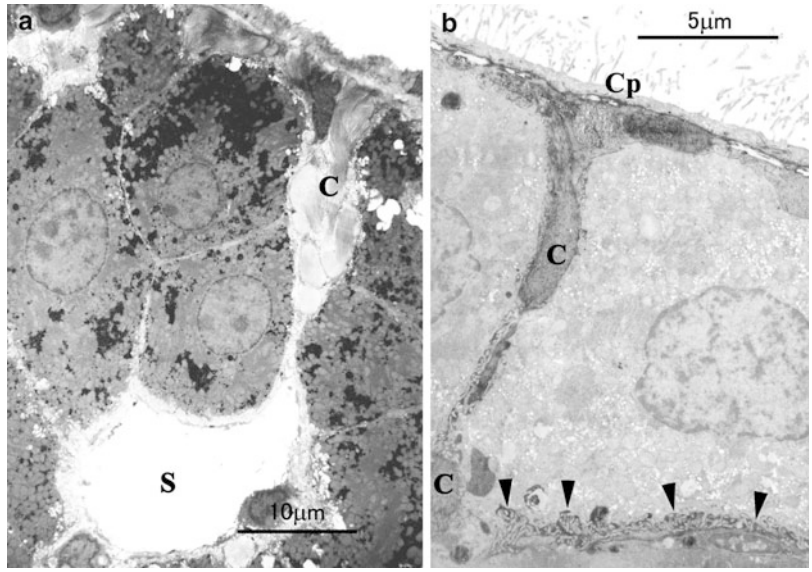
independently of blood vessels connect collagen fibers in the space of Disse with those around the sublobular veins. There are many channels with collagen fibers that pass through the limiting plate: the channels communicate the space of Disse to the sublobular interstitial space. HRP injected into the systemic vein flows along collagen fibers in the liver (Ohtani et al. 2003). In this context, it is likely that fluid in the space of Disse flows through the channels along collagen fibers traversing the hepatic limiting plate. Fluids in the space of Disse also flow through spaces along collagen fibers connecting those around sinusoids with central veins into the interstitial space of the sublobular and hepatic veins (Ohtani and Ohtani 2008a). Fluid in the interstitial space around the sublobular vein finally enters sublobular lymphatics.

Sublobular and portal lymphatics are sometimes enclosed in a common investment of connective tissue. The sharing of connective tissue of both kinds of lymphatics has been reported in rabbits, cats, dogs, and humans. In mice and rats, sublobular veins sometimes cross over interlobular veins. Liver lymph flow correlates directly with hepatic venous pressure in dogs and cats. Blood pressure of the portal vein is higher than that of the hepatic vein: normal blood pressure in the portal vein is 7 mmHg and that in the inferior vena cava is 2 mmHg. These facts suggest that some of the interstitial fluid in the portal tract may flow to the interstitial space around the sublobular veins to enter the sublobular lymphatics (Ohtani and Ohtani 2008a).

Superficial Lymphatics

According to Rusznyak and his colleagues (1967), superficial lymphatics in human liver form a very dense network, and their efferent vessels travel in several directions. Some of the lymphatics coming from the central area of the liver run in the falciform ligament toward the diaphragm; others pass downward into the lymph nodes of the porta hepatis. The lymphatics from the lateral area of the liver convexity advance in the triangular ligament toward the diaphragm and lead into the pancreaticolienal lymph nodes. The lymphatics in the coronary ligament drain into those along the inferior vena cava. The superficial lymphatics from the concave part of the liver curvature run in various directions toward their regional lymph nodes.

The space of Disse around the hepatic sinusoids close to the hepatic capsule communicates through the spaces containing collagen fibers between hepatocytes with the interstitial space of the hepatic capsule (Ohtani et al. 2003). HRP injected into the blood vascular system appears along collagen fibers running from the space of Disse through the space between hepatocytes to the interstitial space of the hepatic capsule (Fig. 6), suggesting that collagen fibers in the space of Disse are connected with those in the hepatic capsule (Ohtani et al. 2003). Thus, fluids in the hepatic sinusoids located close to the hepatic capsule can flow at least in part to the interstitial space of the hepatic capsule and finally enter the capsular lymphatics (Ohtani and Ohtani 2008a).



Hepatic Lymphatic System,
Fig. 6 Transmission electron micrographs of the intact (**a**) and HRP-injected (**b**) rat liver capsule. (**a**) Collagen fibers (*C*) running independently of blood vessels between hepatocytes connect those of the liver capsule (*Cp*) with those in the space of Disse (*arrowheads*). (**b**) HRP fills the space along the collagen fibers connecting those in the liver capsule with those in the space of Disse (From Ohtani et al. 2003)

Lymphatics in Pathological Conditions

Portal lymph flow increases in the liver with diffuse structural abnormalities such as fibrosis and cirrhosis. Lymph flows from the liver in cirrhotic rats are increased 30-fold, and hepatic lymph flows correlate well with portal venous pressure. As the hepatic sinusoids are capillarized in cirrhotic liver, the highly permeable blood-lymph barrier of the normal liver becomes markedly restrictive. The intravital fluorescent microscopy of CCl_4-induced liver fibrosis in the rat shows a strong negative correlation between the density of portal lymphatics and macromolecular trans-sinusoidal exchange. Lymphatics in the human liver also increase in size and number with the progression of chronic fibrosis and especially increase in end-stage cirrhosis necessitating transplantation.

The area of portal lymphatics increases in idiopathic portal hypertension (IPH), also known as Banti's syndrome, suggesting that the increased lymphatic area may be associated with a reduction in portal blood flow and increased lymph flow and that the latter may in turn reduce the high portal pressure in IPH.

Tumor metastasis to lymph nodes via lymphatics results in poor prognoses of patients with cancers. In human hepatocellular carcinoma (HCC) and some metastasized tumors, lymphatic vessel endothelial hyaluronan receptor (LYVE)-1- and Prox 1-positive lymphatics are abundant in the immediate vicinity of the tumors (Carreira et al. 2001). Poorly differentiated HCCs express vascular endothelial growth factor (VEGF)-C significantly stronger than well- or moderately differentiated HCCs, and the incidence of metastasis is higher in patients with VEGF-C-expressing HCC than those without. These seem to indicate that lymphangiogenesis is associated with enhanced metastasis as in other human cancer (Achen et al. 2005).

Conclusion

The hepatic lymphatic system falls into three categories depending on their location: portal, sublobular, and superficial lymphatics. The hepatic lymph primarily comes from the hepatic sinusoids, although the peribiliary capillary plexus contributes to the total hepatic lymph output to some extent (less than 10 %). Fluid filtered out of the sinusoids into the space of Disse flows through the channels traversing the limiting plate either independently of blood vessels or along blood vessels and enters the interstitial space of either the portal tract, sublobular veins, or the

hepatic capsule. Fluids and migrating cells in the interstitial space pass through prelymphatics to finally enter the lymphatics. The area of portal lymphatics increases in liver fibrosis and cirrhosis and in IPH. Lymphatics are abundant in the immediate vicinity of HCC and liver metastasis. HCC expressing VEGF-C is more liable to metastasize, indicating that lymphangiogenesis is associated with their enhanced metastasis. Little is known about the development of hepatic lymphatics in the fetal and early postnatal liver, which is a topic that warrants to be studied.

Definition

IgA nephropathy is a form of mesangioproliferative glomerulonephritis defined by the deposition of the immunoglobulin IgA within the mesangium of the glomerulus. This deposition is variably associated with mesangial hypercellularity and expansion of the mesangium.

Introduction and History

IgA nephropathy (IgAN) was first described in the 1960s by the French pathologist Jean Berger (1930–2011). He used the new technique of immunofluorescence to study renal biopsy specimens and noted that in a subset of patients with renal disease, deposits of the immunoglobulin IgA could be detected in the glomerulus. He published these findings in the seminal paper "Les dépôts intercapillaires d′IgA-IgG" in 1968 with Nicole Hinglais, an electron microscopist (Berger and Hinglais 1968). Since this time, IgAN, also known as Berger's disease, has become recognized as the commonest glomerulonephritis in countries where renal biopsy is routinely performed. Its defining feature is the finding of deposits of IgA in the glomerular mesangium. It is an important cause of chronic kidney disease with up to one-third of patients progressing to end-stage renal disease requiring dialysis or transplantation. Interestingly, there is a striking disparity between presentation, clinical course, and pathological findings.

Clinical Features

Presentation

The classic presentation of IgAN, recognized by Berger during his early studies, is of a young adult (often male) with visible hematuria coinciding with an upper respiratory tract infection (D'Amico 2004). Other mucosal infections, such as urinary or gastrointestinal infections, are also recognized triggers. Hematuria occurs within the first 48–72 h of the infection and clears within a few days. It may be associated with loin pain. Between episodes of visible hematuria, patients can have persistent non-visible hematuria. Thirty to forty percent of

I.R. Mackay, N.R. Rose (eds.), *Encyclopedia of Medical Immunology – Autoimmune Diseases*,
DOI 10.1007/978-0-387-84828-0, © Springer Science+Business Media New York 2014

cases present in this way. A further 40 % of cases are identified incidentally by the presence of non-visible hematuria or proteinuria on routine urine dipstick testing. Five percent of cases present with the nephrotic syndrome (heavy proteinuria, hypoalbuminemia, edema). A smaller proportion present with acute kidney injury or hypertension.

Diagnosis and Investigations

The diagnosis of IgAN requires a renal biopsy (▶ Indications for Biopsy in Autoimmune GN). Supplementary tests should be carried out when there is a clinical suspicion of a secondary cause of IgAN (Pouria and Barratt 2008). Common secondary causes of IgAN include:

- Henoch-SchÖnlein purpura [▶ Vasculitis: Henoch-Schönlein Purpura]
- Liver cirrhosis, in particular alcoholic liver disease
- Celiac disease
- HIV infection

Further investigations, while not specific for IgAN, include routine monitoring of kidney function and urinary protein excretion and testing for generic complications of chronic kidney disease. Patients require long-term follow-up as up to one-third of patients will show progressive decline in kidney function requiring renal replacement therapy over 20–25 years. There are currently no tests at diagnosis which can predict accurately who will develop progressive disease.

Epidemiology

Peak incidence of IgAN is in the second and third decades, with a higher prevalence in men. The highest worldwide incidence is in Southeast Asia but this may reflect different approaches to investigation of renal disease and different thresholds for renal biopsy. IgAN is uncommon in African Americans. It is recognized that there may be many more undiagnosed asymptomatic cases, particularly in countries that do not screen for urine abnormalities and do not biopsy patients with minor urinary abnormalities.

Biopsy Findings and the Oxford Classification

The presence of dominant or codominant IgA deposits in the renal mesangium is the defining feature of IgAN. This is detected in renal biopsy specimens by immunofluorescence (Fig. 1a) or immunohistochemistry. In 15 % of cases, IgA is the only deposited immunoglobulin. Other immunoglobulins are also frequently detectable (IgG in 50–70 %, IgM in 31–66 %) but their presence does not appear to correlate with clinical outcome. The complement component C3 is also commonly present. IgA deposition is diffuse and global. Light microscopy appearances are, however, highly variable and do not correlate with degree of IgA deposition. The commonest appearance is of diffuse mesangial proliferation and extracellular matrix expansion (Fig. 1b) although focal changes may alternatively be seen. Progressive disease is associated with increasing accumulation of mesangial matrix. Crescents may be present. These occur most frequently in biopsy samples taken during episodes of macroscopic hematuria but can also occur in rare presentations with acute kidney injury.

Electron microscopy shows electron dense deposits in the glomerular mesangium (Fig. 1c). Deposits in glomerular capillary walls may also be seen and these can be subepithelial or, more commonly, subendothelial. Capillary loop deposits are associated with more severe disease. Glomerular basement membrane changes are seen in a minority but especially in those with heavy proteinuria or crescents.

The Oxford Classification of IgAN, published in 2009, is an international scoring system for evaluating pathological features on renal biopsy which can predict renal prognosis, independent of clinical and laboratory parameters (Cattran et al. 2009). Four variables are independently associated with risk of developing progressive disease: mesangial cell proliferation (M), endocapillary proliferation (E), segmental glomerulosclerosis (S), and extent of tubulointerstitial atrophy/interstitial fibrosis (T).

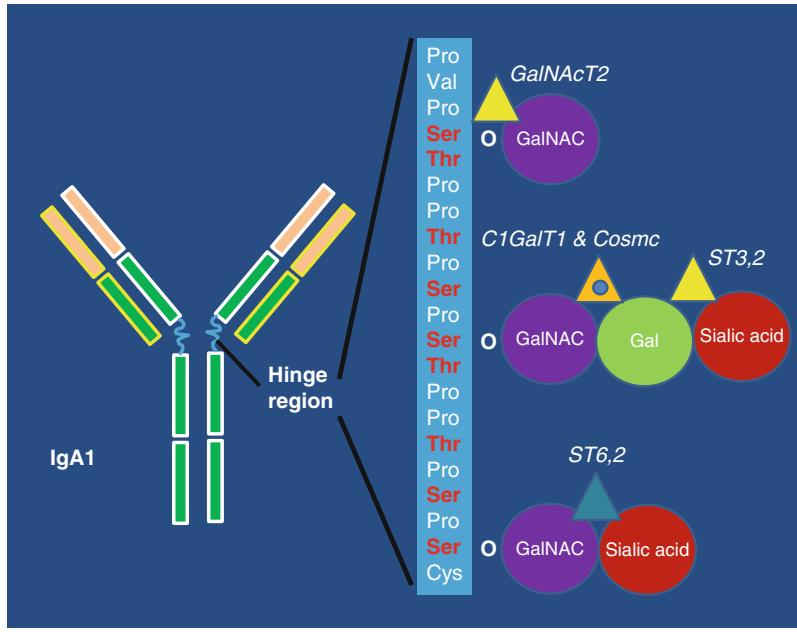
Pathogenesis

Over the past 40 years, considerable progress has been made in characterizing a number of pathogenic pathways operating in IgAN, and this has been enhanced by an increased knowledge of the IgA immune system in health (Fig. 2). However, there is still a great deal we do not understand, and in particular it remains to be established whether IgAN is a single entity, or mesangial IgA deposition is simply the final common pathway for a number of distinct renal diseases (Barratt and Feehally 2011). Differences between the human IgA immune system and that of other species mean that, although animal models of IgAN exist, the extent to which they can be used to study mesangial IgA deposition is limited.

IgA in IgA Nephropathy

In humans IgA is the most abundant antibody and is predominantly present at mucosal surfaces and in secretions such as saliva and tears where it protects against mucosal pathogens (Brandtzaeg et al. 1999). IgA is also found in the systemic circulation, albeit at low levels. In humans,

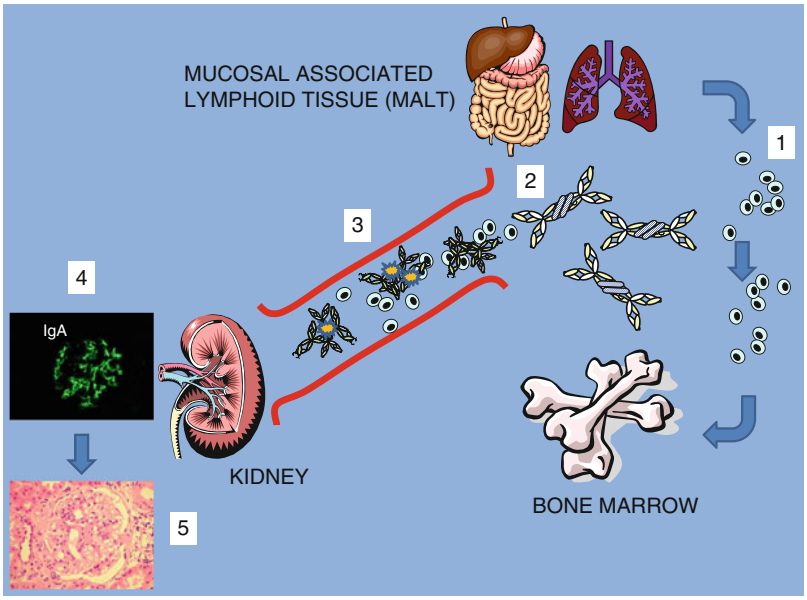


IgA Nephropathy, Fig. 2 *Proposed pathway for deposition of pathogenic IgA and renal injury*. There is a relocation of mucosa-derived polymeric IgA1 producing plasma cells from the mucosal associated lymphoid tissue (MALT) to the bone marrow (1). Mucosal-type IgA1 (polymeric, poorly galactosylated and low affinity) is secreted into the circulation (2). The stimulus for IgA secretion and the factors controlling its phenotype are unknown. Circulating IgA forms large immune complexes which include antibody-antibody complexes and complexes with the IgA Fc receptor CD89 (3). These immune complexes are prone to deposition in the renal mesangium (4). Mesangial deposition triggers the release of proinflammatory and profibrotic mediators from resident mesangial cells resulting in glomerular injury and scarring (5)

IgA exists in two isoforms, IgA1 and IgA2, which are secreted in varying ratios in a site-specific manner (Kerr 1990). IgA1 differs from IgA2 by the presence of a 17 amino acid hinge region. The hinge region is unusual in that it contains up to nine potential *O*-glycosylation sites, although current evidence would suggest that at most six of these sites can simultaneously carry *O*-glycans (Fig. 3). The IgA1 *O*-glycan chains are built-up in a step-wise fashion starting with *O*-linkage of N-acetylgalactosamine (GalNAc) to serine or threonine residues in the hinge. GalNAc may be further extended either by the addition of galactose (Gal) or sialic acid (N-acetylneuraminic acid, NeuNAc). Gal is β-1,3-linked to GalNAc by the enzyme core 1 β-1,3-galactosyltransferase (C1GalT1) and its molecular chaperone Cosmc which ensures its correct folding and stability. Alternatively, GalNAc may be sialylated in an α-2,6 linkage by the enzyme alpha-2,6-sialyltransferase. GalNAc-Gal may be further extended by sialylation of the Gal residue in an α-2,3 linkage by the enzyme alpha-2,3-sialyltransferase. Normal serum consists of a mixture of IgA1 *O*-glycoforms because of the heterogeneity afforded both by varied site occupancy and by occurrence of a mixture of GalNAc-Gal-NeuNAc structures at each of the *O*-glycosylation sites.

IgA is produced by IgA committed plasma cells. These cells reside principally in either the mucosa associated lymphoid tissue (MALT) or systemic sites such as the bone marrow. IgA has a characteristic phenotype dependent on its systemic or mucosal origin. In the systemic circulation, IgA is mostly IgA1, typically monomeric, of high affinity, and more heavily galactosylated IgA1 *O*-glycoforms predominate.

In mucosal secretions, IgA1 and IgA2 are present equally, IgA is predominantly polymeric,



IgA Nephropathy, Fig. 3 *O-glycosylation of IgA1 hinge region*. IgA1 contains a 17 amino acid hinge region which undergoes co/posttranslational modification by the addition of up to 6 *O*-glycan chains. These chains comprise *N*-acetylgalactosamine (GalNAc) in *O*-linkage with either serine or threonine residues. Galactose is β-1,3-linked to GalNAc by the enzyme Core 1 β-3-galactosyltransferase (C1GalT1) and its molecular chaperone Core 1 β-3-galactosyltransferase molecular chaperone (Cosmc) which ensures its correct folding and stability. Galactose may also be sialylated. In addition, sialic acid (*N*-acetylneuraminic acid, NeuNAc) may be attached directly to GalNAc by α-2,6 linkage which prevents further addition of galactose. *GalNAcT2* N-acetylgalactosaminyltransferase 2, *ST6,2* α-2,6-sialyltransferase II, *ST3,2* α-2,3-sialyltransferase 2

usually existing as J-chain-containing dimers, of lower affinity and poorly galactosylated IgA1 *O*-glycoforms are more common.

The IgA deposited in the kidneys in IgAN is of the IgA1 subclass and is predominantly polymeric. Another key feature of this deposited IgA is that it is enriched for poorly galactosylated IgA1 *O*-glycoforms (Allen et al. 2001). In parallel, most patients have elevated serum levels of poorly galactosylated IgA1 *O*-glycoforms, and this is thought to be the source of mesangial IgA (Moldoveanu et al. 2007). The reason for this change in the composition of circulating IgA1 *O*-glycoforms is not clear. Other serum *O*-glycosylated proteins display normal patterns of glycosylation in IgAN, suggesting any defect is specific to immunoglobulin *O*-glycosylation. Furthermore, IgD, the only other *O*-glycosylated immunoglobulin, also displays a normal pattern of *O*-glycosylation in IgAN. This suggests that changes in *O*-glycosyltransferase activity occurring after class switching from $sIgD^+$ naïve B cells are likely to be key to the changes in serum IgA1 *O*-glycoforms seen in IgAN. Current experimental work is therefore focussed on understanding the control of *O*-glycosylation during the class switch reaction and specifically in $sIgA^+$ antibody-secreting cells (ASC) and plasma cells. It is important, however, to appreciate that alteration in the composition of serum IgA1 *O*-glycoforms is neither an absolute requirement for the development of IgAN nor a ubiquitous finding in all patients. It is nevertheless the most consistent and reproducible finding in patient cohorts from North America, Europe, and Australasia.

Origins of Mesangial IgA

An increased understanding of the IgA immune system in health has shown that IgA production can be heavily influenced by the site of antigen encounter. At mucosal surfaces, antigen exposure

triggers an IgA immune response which is predominantly polymeric and low affinity. IgA responses in the systemic compartment result in monomeric high-affinity antibody production. Vaccination studies have also shown that IgA1 *O*-glycosylation varies depending on the site of antigen encounter. For instance, mucosal *Helicobacter pylori*-specific IgA1 antibodies are more likely to be poorly galactosylated compared to the IgA1 produced in response to systemic tetanus toxoid immunization. This pattern of differential *O*-glycosylation at mucosal versus systemic sites is also seen in patients with IgAN.

Many of the features of mesangial IgA are those typically seen in "mucosal-type" IgA. Overabundance of this "mucosal-type" IgA in the serum in IgAN might suggest that this IgA originates from mucosal sites. However, mucosal biopsies from patients with IgAN show significantly reduced numbers of polymeric IgA-secreting plasma cells compared with healthy subjects (Harper et al. 1994). This finding would suggest that mesangial IgA is not derived from the mucosal compartment. By comparison, increased numbers of polymeric IgA-secreting plasma cells are seen in bone marrow samples from patients with IgAN suggesting mesangial IgA is derived from systemically located $sIgA^+$ ASC and plasma cells (Harper et al. 1996). This has led to the hypothesis that in IgAN, mucosally primed $sIgA^+$ ASC relocate to systemic sites such as the bone marrow where they secrete their poorly galactosylated polymeric IgA1 directly into the circulation rather than into the submucosa for passage across the mucosal epithelium. In addition, the systemic microenvironment is likely to be very different from the MALT these plasma cells would normally inhabit, and it is possible that these plasma cells also receive cytokine signals promoting undergalactosylation of IgA1.

It is contended that one of the most likely mechanisms for this displacement is mishoming of mucosal $sIgA^+$ ASC to systemic sites. While there is emerging evidence of altered homing of B and T lymphocyte subsets in IgAN, much more work needs to be undertaken to fully evaluate this hypothesis.

Poorly Galactosylated IgA1 *O*-Glycoforms and IgA-Containing Immune Complex Formation

IgAN is being increasingly recognized as an immune complex deposition disease, although the trigger for immune complex formation is not known (Novak et al. 2008). Circulating immune complexes predominantly comprise polymeric IgA1 and immune complexes rich in poorly galactosylated polymeric IgA1 are believed to be both the source of mesangial IgA and the trigger for mesangial cell activation and induction of glomerular injury. IgA immune complexes containing poorly galactosylated IgA1 have been shown in vitro to bind to mesangial cells with high affinity and trigger mesangial cell proliferation and a proinflammatory and profibrotic phenotypic transformation similar to that seen in vivo. Understanding the reasons for IgA immune complex formation in IgAN is therefore of particular interest.

Poorly galactosylated IgA1 molecules have an increased tendency both to self-aggregate and form complexes with IgG antibodies. The absence of Gal appears to lead to exposure of hinge region epitopes that are normally sequestered, including terminal and sialylated GalNAc residues. There is now clear evidence that these epitopes, and particularly exposed GalNAc, are recognized by IgG and IgA1 antibodies with anti-glycan specificities (Suzuki et al. 2009). Furthermore, binding of glycan-specific IgG from patients with IgAN to poorly galactosylated IgA1 directly results in IgA-IC formation.

The IgA Fc receptor, CD89, has also been implicated in the development of circulating IgA immune complexes in IgAN (Boyd and Barratt 2010). CD89 is expressed by myeloid cells and two soluble receptor isoforms have been demonstrated to exist in vivo. The larger 50–70 kDa isoform has only been detected in patients with IgAN and has been demonstrated in IgA immune complexes in the circulation although not in the kidney. The smaller isoform is 30 kDa and, when complexed with IgA1, has been shown to protect against progressive renal disease, possibly through inhibition of immune complex formation. The role of CD89 in immune complex formation requires further investigation.

The Role of the Innate Immune System in IgA Nephropathy

There is accumulating evidence that in IgAN the innate immune system may play a significant role in driving pathogenic IgA production and immune complex formation. Toll-like receptors (TLR) play key roles in innate immunity to microbial pathogens via recognition of a diverse range of pathogen-associated molecular patterns (PAMPs). Of the 15 TLR thus far described, there is emerging evidence for contributions by TLR-4, TLR-9, and TLR-10 to the pathogenesis of IgAN.

Perhaps the two most intriguing observations to date are, firstly, that binding to B cell TLR leads to polyclonal activation of B cells, class switching, and immunoglobulin production. IgA secretion by mucosal lamina propria and tonsillar B cells is increased after TLR-9 stimulation implying that mucosal B cells can recognize PAMPs and secrete IgA in a T cell independent manner (Blaas et al. 2009). Secondly, ligation of B cell TLR-4 by bacterial LPS induces methylation of the Cosmc gene, leading to reduced activity of C1GalT1 and undergalactosylation of IgA1 (Qin et al. 2008). Whether B cell TLR-4 expression is increased in IgAN is not known; however, this in vitro data provides early evidence that mucosal pathogens might be able to influence the *O*-glycosylation of IgA antibodies.

Mechanisms of Glomerular Injury and Tubulointerstitial Scarring

What are the major pathogenic consequences of IgA deposition on mesangial cell, podocyte, and proximal tubular cell function in IgAN? The recently published Oxford Classification of IgA Nephropathy identified four key pathological consequences of IgA deposition that independently determine the risk of developing progressive renal disease: mesangial cell proliferation (M), endocapillary proliferation (E), segmental glomerulosclerosis (S), and tubulointerstitial scarring (T). There is increasing evidence, predominantly from in vitro models, that IgA immune complexes promote mesangial cell activation, resulting in proliferation (M) and release of proinflammatory and profibrotic mediators. These mediators, along with the direct effects of exposure to IgA immune complexes, cause podocyte injury, a process fundamental to segmental glomerular scarring (S) and proximal tubule cell activation, which drives tubulointerstitial scarring (T). Genetic factors are likely to play an important role in modulating all of these processes.

Genetics of IgAN

IgAN usually occurs sporadically; familial cases are rare. Multiple attempts have been made to establish a genetic basis for the disease both in familial cohorts and sporadic IgAN, although to date, little headway has been made in identifying the genes involved. There is, however, now evidence in several ethnic backgrounds to suggest that genetic factors heavily influence the composition of circulating IgA *O*-glycoforms in the serum (Gharavi et al. 2008). From these studies, it has also become apparent that first degree unaffected relatives of patients with IgAN often also have high levels of poorly galactosylated IgA1, supporting the hypothesis that changes in the composition of serum IgA1 *O*-glycoforms is only one part of a "multiple-hit" pathogenic process.

Several susceptibility loci have been identified from genome-wide association studies (GWAS) and one region that has gained particular interest is the major histocompatibility complex (MHC) (Feehally et al. 2010). Polymorphisms within the MHC have been associated with several autoimmune diseases, and an association in IgAN is consistent with an autoimmune component to IgAN, perhaps through production of autoantibodies with specificity for the poorly galactosylated IgA1 hinge region.

Treatment

No specific treatment for IgAN exists. An incomplete understanding of the pathological mechanisms causing pathogenic IgA production and mesangial deposition combined with the heterogeneity of observed pathological findings and clinical presentations has hindered attempts to find common targets for medical therapies.

Treatment strategies are therefore generic and aimed at ameliorating the downstream consequences of immune system activation and renal inflammation. In common with other causes of chronic kidney disease, management of patients with IgAN also involves treatment of secondary complications and in particular cardiovascular risk reduction (▶ Proteinuric Kidney Diseases: Importance of Blood Pressure Control).

Those with preserved renal function, non-visible hematuria, and <0.5 g/24 h proteinuria require no specific therapy. In patients with proteinuria >0.5 g/24 h, renin-angiotensin blockade has been shown to slow progression of IgAN. In those with ongoing proteinuria, despite maximal renin-angiotensin blockade, and continuing decline in renal function, there may be a role for immunosuppression. Published data in this patient group is, however, inconclusive and no clear guidance exists as to which agents should be used (Floege and Eitner 2010). Targeting immunosuppressive therapy to those patients exhibiting a pronounced inflammatory glomerular response may be more effective than treating patients whose renal biopsy shows predominantly fibrotic histological features. Such a strategy would optimize treatment benefits while limiting adverse effects of drugs which commonly have significant side effects. The recent publication of the Oxford Classification of IgAN which delineates specific pathological features associated with outcome may enable investigators to tailor treatment to patients based on degree of active glomerular injury.

Immunosuppression

The efficacy of corticosteroids in IgAN has been tested in several studies. Overall results have been equivocal and reports showing positive outcomes have been criticized for inadequate trial design and the presence of multiple confounding factors. The risks of high-dose corticosteroid use must also be considered. Similarly, studies examining the use of other immunosuppressive agents including azathioprine, cyclophosphamide, and mycophenolate mofetil have been inconclusive. There are large randomized controlled trials in progress in 2011 and hopefully the results when available will lead to a clearer understanding of the role of immunosuppression in the treatment of IgAN.

Fish Oil

The use of fish oil in IgAN has been advocated, although the evidence for benefit is again limited. Fish oil contains omega-3 fatty acids which have anti-inflammatory benefits, and while their use appears to be safe, it is limited by gastrointestinal side effects and fishy odor to breath and perspiration.

Tonsillectomy

The lymphoid tonsils contain an abundance of B cells and have been proposed to be a source of pathogenic IgA in IgAN. In patients where tonsillitis provokes visible hematuria, tonsillectomy has been shown to reduce episodes. There is conflicting evidence, however, as to whether tonsillectomy improves long-term renal prognosis, and given the significant morbidity associated with tonsillectomy, further clear evidence is needed before its use is embedded in standard clinical practice.

Rapidly Progressive Glomerulonephritis

In the small proportion of patients presenting with rapid loss of renal function and crescentic glomerulonephritis due to IgAN, treatment is in common with other forms of crescentic glomerulonephritis: high-dose corticosteroids, cyclophosphamide, and sometimes use of plasma exchange. However, the evidence base for this practice is limited and renal outcome is typically poor.

Renal Transplant

Patients with end-stage renal disease due to IgAN may be considered for transplantation. Recurrent IgA deposition is very common in transplanted kidneys; however, it rarely causes allograft failure (Floege 2004). At 5 years there is a 5 % risk of graft failure due to disease recurrence. In those who have lost a first graft due to recurrence, there is a 25 % risk of loss of subsequent grafts. No specific immunosuppression regimen has been shown to prevent IgA deposition and disease recurrence in IgAN.

Interestingly, when kidneys with subclinical IgA deposition have inadvertently been transplanted into patients without IgAN, deposited IgA immune complexes have cleared on rebiopsy. This supports the notion that mesangial IgA is derived from a circulating pool of pathogenic IgA and that the kidney has an ability to clear IgA deposits if given the opportunity.

Conclusion

IgAN is an important cause of renal disease which leads to end-stage renal failure requiring dialysis or kidney transplantation in a significant proportion of patients. Pathological features are disparate and the extent of IgA deposition does not correlate with degree of renal injury or clinical features. Additionally, despite extensive research into the disease, no unifying pathogenic mechanism can explain all the observed features. It is possible that several different pathways lead to the common finding of IgA in the renal mesangium, and specific combinations of risk factors influence disease progression and outcome.

Synonyms

Non-A, non-B hepatitis (prior to 1989)

Definition

First identified in 1989, the hepatitis C virus (HCV) is the prototypical member of the Hepacivirus genus of the *Flaviviridae* family. HCV is a 9.6 kb positive-sense single-stranded RNA virus, which encodes a polyprotein cleaved to derive three structural and seven nonstructural proteins, as well as a frameshift protein. Despite its genetic and structural simplicity, the hepatitis C virus has nevertheless evolved remarkable capacity for persistent infection, with 70–80 % of affected individuals developing chronic infection. An estimated 170 million individuals are infected with HCV worldwide, with some 38,000 new infections occurring per year in the USA alone; there is no effective vaccine available against the virus. Cirrhosis occurs in approximately 20 % of persistently infected individuals, and up to 2.5 % develops hepatocellular carcinoma. The associated morbidity and mortality constitutes a major health burden globally; HCV-related liver disease is now the leading indication for liver transplantation in many countries (Bowen and Walker 2005a; Bowen et al. 2009) (▶ Liver Transplantation for Chronic Viral Hepatitis).

Introduction

Well-orchestrated responses mediated by innate, humoral, and cellular immune responses likely determine the outcome of HCV infection. A sizeable body of evidence indicates that both innate immunity and HCV-specific T cell immune responses are critical to control and clear HCV infection in the minority of individuals that resolve acute infection, while the role of HCV-specific antibodies remains unclear. Persisting HCV-specific T cell responses in the setting of chronic infection may, however, play a role in mediating ongoing hepatocellular injury associated with the eventual development of cirrhosis and its resultant complications.

Innate Immunity to HCV

Innate immunity is a critical component of the immune response to viral infections, both in terms of antiviral mechanisms within the infected cell and cellular mediators of the innate immune response such as NK cells and plasmacytoid dendritic cells (pDCs) (▶ Innate Immune cells in the Liver). Available evidence would suggest that HCV also elicits significant innate immune responses, which contribute to control of viral replication.

HCV is known to stimulate cellular pathogen-associated molecular pattern (PAMP) receptors (Gale and Foy 2005). Although HCV appears to have evolved mechanisms that subvert intracellular signaling via these molecules, as will be discussed below, interferon stimulated genes (ISGs) have nevertheless been shown to be upregulated in HCV-infected livers, both in acute and in chronic infection (Bowen et al. 2009). Both type I (IFN α and β) and type III (IFN-λ) interferons, produced as a component of innate immune responses, have been demonstrated to inhibit HCV replication in vitro (Chung et al. 2001; Marcello et al. 2006); consistent with this in vitro data, IFN-α has long been a central component of HCV antiviral therapy. Genetic evidence also points to an important role for innate immunity in HCV infection, with polymorphisms upstream of the IL28B (IFN-λ3) gene

correlating with both responses to IFN-α therapy, and with spontaneous clearance of viral infection (Shackel et al. 2010). Recent work in this field indicates that reduced likelihood of viral clearance in those individuals with certain variants in this genomic region may be associated with production of a newly described variant IFN-λ, IFNL4 (Prokunina-Olsson et al. 2013), potentially via reduction of response to type I and other type III interferons.

In addition to production of antiviral cytokines by infected cells, pDCs, the major source of type I IFNs, are able to produce these cytokines in response to HCV infection. This appears to be independent of their infection by HCV (Takahashi et al. 2010) and may be mediated via transfer of viral RNA from infected cells via endosomes, leading to triggering of toll-like receptor 7 (TLR7) (Dreux et al. 2012). pDCs have also been shown to produce type III IFN in response to HCV RNA in vitro (Stone et al. 2013). However, the role of pDCs in the control of HCV replication and resolution of acute infection remains to be determined.

NK cells both possess important direct antiviral functions via cytotoxicity and the production of antiviral cytokines, as well as by performing an important role in recruiting cells of the adaptive immune system to the infected liver (▶ Innate Immune cells in the Liver). Genetic evidence suggests a significant role for NK cells in resolution of HCV infection: expression of the inhibitory NK cell molecule killer immunoglobulin-like receptor (KIR) 2DL3 along with its ligand HLA-C group 1 is associated with increased likelihood of HCV clearance, potentially mediated via decreased NK cell inhibition mediated by this receptor combination (Bowen et al. 2009). A role for NK cells in HCV immunity is also suggested by data indicating that intravenous drug users repeatedly exposed to HCV who remain uninfected had a higher proportion of circulating mature NK cells than those exposed individuals who subsequently became infected (Golden-Mason et al. 2010). Similarly, a recently published report has described both NK and NKT cell activation in healthcare workers exposed to HCV who did not develop infection, indicating activation of the innate immune system by exposure to the virus, and a potential role for these cell populations in control of infection (Werner et al. 2013).

Humoral Immunity to HCV

Antibodies to HCV can develop as early as 6 weeks postinfection, although seroconversion more commonly occurs around 10–12 weeks postexposure. The antibody response to HCV is polyclonal and multi-specific. Both structural and nonstructural proteins are targeted (Bowen et al. 2009).

The role of the anti-HCV antibody response to HCV in controlling and resolving infection remains unclear. Early evidence indicated that changes in viral envelope sequences at the time of antibody seroconversion were associated with viral clearance, while stable viral quasispecies were associated with viral clearance (Farci et al. 2000). This data suggested that antibody responses play a role in HCV clearance and that escape from these responses is associated with viral persistence. The lack of in vitro models to study neutralizing antibody response to HCV hampered further studies until the development of recombinant HCV pseudoparticle systems. However, work using HCV pseudoparticles has led to variable conclusions. The majority of initial studies using HCV pseudoparticles found neutralizing antibodies to be rare in the setting of resolving acute infection, more often occurring in chronic infections, although this was not universally observed (Bowen et al. 2009). However, these studies involved the use of HCV pseudoparticles generated from prototypical viruses; in a study in which homologous viral pseudoparticles were utilized, clearance of infection was found to be associated with the development of neutralizing antibodies (Pestka et al. 2007).

Although the role of neutralizing antibodies in control of HCV infection remains unclear, it is apparent that at least in some circumstances, antibody responses are dispensable to viral clearance. Spontaneous clearance of HCV in the setting of hypogammaglobulinemia has been described

(Christie et al. 1997). HCV clearance has been demonstrated in chimpanzees in the absence of the development of a detectable antibody response, and in humans, viral clearance can occur in the absence of antibodies to structural proteins (Bowen and Walker 2005a). Furthermore, T cell responses have been described in likely exposed individuals who apparently cleared the virus without seroconverting or who did not mount antibody responses to structural proteins. In addition, preexisting antibodies do not provide protection from reinfection (Bowen et al. 2009).

Adaptive Cellular Immunity to HCV in Acute Infection

Effective HCV-specific cellular immune responses are critical for viral clearance. Failure to develop an HCV-specific CD4 T cell response is associated with viral persistence. In contrast, clearance of HCV during the initial acute infection is associated with a vigorous, broad CD4 T cell response (Bowen and Walker 2005a), with the initial presence and then loss of these responses also being associated with the development of chronic infection (Bowen and Walker 2005a; Schulze Zur Wiesch et al. 2012). The HCV-specific CD4 T cell response in individuals who successfully clear the virus is usually detectable within the first 3 months, peaking around 10 weeks; memory responses can remain detectable many years post-resolution (Bowen and Walker 2005a). Depletion of CD4 T cells in previously HCV-infected chimpanzees has been shown to lead to persistent infection upon repeat inoculation, confirming the critical role of CD4 T cells in controlling HCV infection (Grakoui et al. 2003).

In addition to broad, sustained CD4 T cell responses, CD8 T cell responses to HCV during the acute phase of infection are also required for viral clearance (Bowen and Walker 2005a; Rehermann 2009; Klenerman and Thimme 2012). However, although failure to develop strong acute CTL responses appears to be associated with progression to chronic infection, multi-specific CD8 T cell responses can also be detected in early infection in at least some individuals in whom viral persistence develops (Bowen and Walker 2005a; Kaplan et al. 2007). As observed with the CD4 T cell response, antiviral CD8 T cell responses remain detectable many years later in individuals who clear infection (Bowen and Walker 2005a). An unusual observation in HCV infection has been the delayed onset of interferon-γ (IFN-γ) production by virus-specific CD8 T cells detected early in infection; successful viral clearance can nevertheless ensure, and the significance of this observation thus remains uncertain (Bowen and Walker 2005a). The CD8 T cell response appears to peak later than the CD4 T cell response and continues to increase after falls in transaminases and decreases in viremia to undetectable levels, potentially indicating an ongoing suppressive response. Consistent with this, viremia does recur in some individuals following an apparent phase of viral control (Bowen and Walker 2005a). As observed with CD4 T cells, depletion of CD8 T cells in chimpanzees following an initial HCV infection was observed to be associated with persistence of viral replication until the recovery of detectable HCV-specific CD8 T cell responses (Shoukry et al. 2003).

The mechanisms of T cell control of HCV replication in vivo are incompletely understood. In a number of published studies, the onset of CD8 T cell responses correlated with serum transaminase increases and viral control (Bowen and Walker 2005a), suggesting that cytotoxic mechanisms may play a role in viral clearance. However, HCV infection has also been observed to resolve spontaneously without a significant transaminase increase and may correlate with increases in IFN-γ mRNA within the liver (Thimme et al. 2002), indicating that non-cytopathic control of viral replication may also lead to resolution of infection. Consistent with this hypothesis, in vitro evidence indicates that IFN-γ can inhibit HCV replication (Bowen and Walker 2005a; Jo et al. 2009). In vitro experiments comparing non-cytopathic to cytotoxic mechanism of HCV control have suggested that both pathways may be effective; however, non-cytopathic mechanisms were found to be more efficient, potentially indicating a predominant

role (Jo et al. 2009). However, it should be noted that as transaminase increases are a relatively crude tool in the assessment of hepatocellular injury, the alternative possibility exists that spontaneous resolution of acute hepatitis C without biochemical evidence of liver injury rather reflects cytolytic control of replication in a relatively small number of infected hepatocytes (Bowen and Walker 2005a); although the number of hepatocytes harboring HCV in the acutely infected liver is not known, and is likely highly variable, it may be as low as 5 % (Shoukry et al. 2004).

Adaptive Cellular Immunity to HCV in Chronic Infection

Studies of T cell responses in chronic infection have been complicated by the localization of HCV-specific T cells to the predominant site of infection, the liver. Thus, while a number of studies have detected low-frequency or narrowly focused HCV-specific CD8 T cell responses within the blood during chronic infection, others have isolated virus-specific CD8 T cells from the livers of chronically infected individuals, even after many years of infection (Bowen and Walker 2005a; Klenerman and Thimme 2012). In some individuals, such intrahepatic CD8 T cells can target multiple epitopes (Bowen and Walker 2005a; Klenerman and Thimme 2012). However, HCV-specific CD8 T cells from the livers of chronically infected individuals have also been described to express markers of apoptosis at high frequencies (Radziewicz et al. 2008) and, as will be discussed below, to possess phenotype associated with impaired function.

Studies in the chronic phase of HCV infection using functional methods of identification have demonstrated weak or absent CD4 T cell responses (Shoukry et al. 2004; Bowen and Walker 2005a). Several studies using non-functional methods of identification of virus-specific cells, such as CD25 or CD154 upregulation following stimulation, have suggested that virus-specific CD4 T cells are still present in chronic infection (Bowen and Walker 2005a; Mueller et al. 2010). In contrast, analyses using a limited range of MHC class II tetramers have also indicated that responses are poorly detectable in peripheral blood during chronic infection (Day et al. 2003; Ulsenheimer et al. 2006; Lucas et al. 2007). However, as with CD8 T cell responses, HCV-specific CD4 T cells have been identified in the livers of chronically HCV-infected individuals (Bowen and Walker 2005a), indicating that virus-specific CD4 T cells may also be sequestered to the liver in chronic infection. In some studies, virus-specific CD4 T cells persisting in chronic infection were found to elaborate altered cytokines patterns, including the anti-inflammatory cytokine IL-10 and impaired secretion of IL-2 (Bowen and Walker 2005a). Thus, although it would appear that HCV-specific CD4 T cell responses are relatively difficult to detect during chronic infection, the nature and function of these populations remains to be more fully delineated.

Mechanisms of Immune Evasion by HCV

How HCV establishes persistent infection remains poorly understood. However, as will be discussed below, the virus is postulated to subvert both innate and adaptive immune responses, facilitating its persistence in the majority of infected individuals.

Subversion of the Innate Immune Response by HCV: HCV has been demonstrated to interfere with IFN signaling, a critical component of the innate antiviral response. In in vitro experiments, HCV proteins have been shown to inhibit IFN signaling via the Jak-STAT pathway. The HCV protein NS5A has also been shown to induce IL-8, which inhibits IFN activity in vitro (Bowen et al. 2009). The HCV NS3/NS4A protease has been shown to inhibit production of type I IFN by infected cells, via cleavage of adaptor proteins in the signaling pathways of PAMP receptors. Replicating HCV RNA can be recognized by the intracellular PAMP receptor retinoic-acid-inducible gene I (RIG-I) and toll-like receptor-3 (TLR), a receptor for double-stranded RNA (Gale and Foy 2005). The HCV

protease NS3/NS4A inhibits the activation of interferon regulatory factor-3 (IRF-3), a transcription factor critical in type I IFN production, by cleavage of adaptor proteins in both of these pathways (Gale and Foy 2005; Bowen et al. 2009). However, other hepatotropic viruses that do not establish persistent infection have also been demonstrated to possess similar capacity (Chen et al. 2007; Yang et al. 2007); the extent to which this phenomenon plays a role in the establishment of persistent infection thus remains to be determined.

In addition to effects on intracellular signaling, HCV has also been demonstrated to potentially affect the function of DCs. Reduced numbers of pDCs have been reported in chronic HCV infection, although proportions may be greater than in acute infection. In vitro data suggests that HCV proteins can inhibit pDC function (Bowen et al. 2009; Rehermann 2009). It has been suggested that HCV can infect DCs, although this finding remains controversial (Bowen and Walker 2005a). HCV proteins have also been reported to affect DC function in vitro, as well as to influence antigen presentation by DCs in HCV-infected individuals (Bowen et al. 2009; Rehermann 2009). However, the results of studies of DC function in chronically HCV-infected subjects have been variable (Bowen and Walker 2005a), with no clear consensus as to whether function is impaired. Importantly, the immune defect in chronic HCV infection is virus specific in the absence of advanced liver disease. Therefore, although a role for inhibition of DC function in impaired initiation of adaptive immune responses remains a potential mechanism of HCV persistence, a long-lasting defect in DC function is not consistent with the clinical scenario observed in chronic infection.

HCV has also been shown to inhibit NK cell function via a range of mechanisms. In in vitro studies, the HCV E2 envelope protein was observed to downregulate NK cell function via binding to the tetraspanin CD81. In addition, HCV-derived peptide has been shown to bind to the NK cell inhibitory ligand HLA-E, resulting in impaired NK cell-mediated lysis (Bowen et al. 2009). NK cells isolated from HCV-infected individuals also exhibit reduced capacity to activate DCs (Bowen and Walker 2005a). Galectin-9, which is increased in chronic HCV infection (Mengshol et al. 2010), may also inhibit the function of NK cells (Golden-Mason et al. 2013). However, it remains unclear as to whether NK cells are dysfunctional in vivo during chronic HCV infection (Bowen et al. 2009).

Other Immunomodulatory Activities of HCV Proteins: HCV proteins may have direct effects on T cells. HCV core protein is amongst the best studied and is known to inhibit virus-specific T cell responses in vitro. This protein has been shown to bind to the Clq complement receptor, gC1qR, with subsequent inhibition of T cell proliferative responses, and may mediate immunomodulatory effects via this pathway (Bowen et al. 2009). In addition, the HCV core protein has been shown to impair function of the intrahepatic macrophage, the Kupffer cell (Tu et al. 2010). In vitro cross-linking of CD81 by the HCV E2 protein has been shown to lead to co-stimulation of T cells and may inhibit chemokine secretion and migration (Bowen et al. 2009). However, while such predominantly in vitro data indicates that HCV proteins may affect HCV-specific T cells, given the ubiquitous presence of these proteins, these interactions have the potential to influence all T cell responses. As noted previously, the lack of global immunosuppression in this infection is inconsistent with such a generalized mechanism (Bowen and Walker 2005a).

Impaired Function of HCV-Specific CD8 T Cells: CD8 T cell anergy, or functional silencing, has long been described in chronic viral infection in both animal models and in humans. Available data indicates that this situation can arise in the setting of a defective virus-specific CD4 T cell response (Bowen et al. 2009; Klenerman and Thimme 2012), not unlike that observed in HCV infection evolving toward chronic infection. Consistent with this, early studies of HCV-specific CD8 T cells in chronically infected individuals demonstrated phenotype characteristic of early stages of differentiation (Bowen and Walker 2005a).

Subsequent studies have revealed HCV-specific CD8 T cells to express low levels of CD127 and to upregulate expression of a variety of co-inhibitory markers, including programmed death-1 (PD-1), cytotoxic T lymphocyte antigen-4 (CTLA-4), 2B4, CD160, killer cell lectin-like receptor subfamily G member 1KLRG1, and T cell immunoglobulin domain and mucin domain 3 (Tim-3) (Klenerman and Thimme 2012). Expression of these co-inhibitory receptors is consistent with an exhausted phenotype, which is associated with chronic exposure to antigen. It thus remains unclear whether the observed characteristics of virus-specific CD8 T cells in chronic infection arise due to impaired initial priming, or as a consequence of ongoing exposure to cognate antigen. However, in vitro neutralization studies indicate that HCV-specific cellular immune function can be restored via inhibition of a number of these receptors, either alone or in combination (Klenerman and Thimme 2012). Despite this, a recent trial of monotherapy using a humanized monoclonal antibody against PD-1 in chronically HCV-infected individuals leads to transient reduction in only a minority of subjects (Gardiner et al. 2013), indicating that reversal of virus-specific cellular impairment by such inhibition is likely to require blockade of multiple inhibitory pathways.

Mutational Escape from Cytotoxic T Cell Responses: HCV is a highly mutable virus, as the NS5B RNA polymerase encoded by the HCV genome is error prone and lacks proof-reading capacity, leading to high base substitution rates. As such, it is susceptible to Darwinian selection pressures exerted by the adaptive immune response, which confers replicative advantages to viral subpopulations in which the genome encodes mutations that impair presentation or recognition of epitopes targeted by CD8 T cells. Such viral variants, termed "escape mutations," contribute to viral persistence as the affected CD8 T cell epitopes are no longer encoded by surviving viral populations. CD8 T cell escape mutations have been described as occurring early in HCV infectionm and correlate with the development of viral persistence in both chimpanzees and humans (Bowen and Walker 2005b; Bowen and Walker 2005c; Rehermann 2009; Klenerman and Thimme 2012). Epitope escape from CTL recognition may occur via a variety of mechanisms, including altered proteasomal processing leading to epitope destruction, abrogation of peptide/MHC binding, and altered recognition of variant peptide/MHC complexes by CD8 T cells (Bowen and Walker 2005b; Bowen and Walker 2005c; Rehermann 2009).

Not all epitopes targeted by CD8 T cells undergo mutational escape (Klenerman and Thimme 2012). Absence of escape mutation has been linked to the expression of an exhausted phenotype by CD8 T cells recognizing intact epitopes (Rutebemberwa et al. 2008), suggesting that these mechanisms may contribute to HCV persistence in concert. The parameters that govern the development of escape mutations are incompletely understood, but appear to comprise both viral and immunological factors. The development and persistence of CD8 T cell escape mutations are governed by the associated fitness cost to viral replication (Salloum et al. 2008; Uebelhoer et al. 2008; Dazert et al. 2009), which may impede their development in critical regions of the viral structure (Neumann-Haefelin et al. 2007), or necessitate the evolution of compensatory mutations within the viral genome that counteract effects on viral structure or function precipitated by escape mutations (Uebelhoer et al. 2008). The ability of HCV epitopes to escape CD8 T cell responses is also constrained by the characteristics of the T cell response. Escape mutations have been observed to occur in epitopes targeted by CD8 T cell responses comprised of relatively narrow T cell receptor (TCR) diversity (Meyer-Olson et al. 2004). In addition, the presence of "holes" in the clonal response to HCV-derived epitopes has also been described as favoring the emergence of escape mutations (Wolfl et al. 2008). Available data would also suggest that maintenance of effective CD4 T cell responses is important in protecting against the emergence of CD8 T cell escape mutations (Bowen and Walker 2005b, c).

Although a range of effects on HCV-specific CD4 T cell function have been described following in vitro stimulation with variant peptides

(Bowen and Walker 2005b, c), in contrast to CD8 T cell escape mutations, a similar phenomenon does not occur in epitopes targeted by CD4 T cell responses (Fleming et al. 2010; Fuller et al. 2010). It would thus appear that escape mutations do not play a significant role in the silencing of the virus-specific CD4 T cell response.

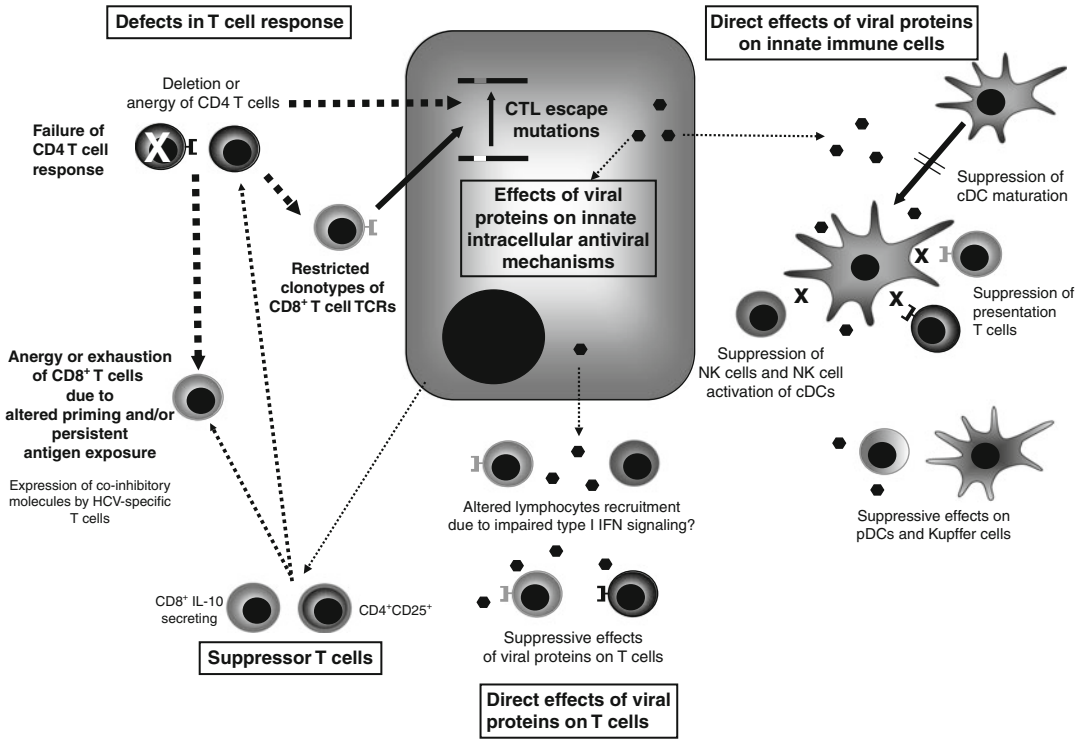
Regulatory T Cells: It has also been postulated that regulatory T cells (▶ Tregs in the Liver) modulate immune responses to HCV, thereby facilitating viral persistence. HCV-specific CD4 T cells secreting cytokines with regulatory effects, such as IL-10 and TGF-β, have been detected in chronically HCV-infected individuals (Bowen et al. 2009). CD4 Treg frequency in the peripheral blood during chronic HCV infection has been reported to be increased in some, but not all, studies (Bowen et al. 2009), while CD4 Tregs have been identified within portal infiltrates (Ward et al. 2007). It has been suggested that galectin-9, the expression of which is increased by Kupffer cells in HCV-infected liver, may mediate expansion of Tregs (Mengshol et al. 2010), although their function in the liver, and hence ability to inhibit the HCV-specific response, may be downregulated by PD-1-dependant mechanisms (Franceschini et al. 2009). In in vitro studies, CD4 Tregs from chronically HCV-infected individuals have been shown to suppress HCV-specific immune responses; however, responses to antigens derived from cytomegalovirus, Epstein-Barr virus, and influenza virus were also reduced (Bowen and Walker 2005a). In addition, similar findings were observed in chimpanzees that cleared HCV infection (Manigold et al. 2006). The role of Tregs in potentiating chronic HCV infection therefore remains unclear, although it may be that more selective effects on the HCV-specific immune response is conferred by increased frequencies of Treg populations within the liver during persistent HCV infection.

In addition to CD4 Tregs, CD8 T cells can also secrete regulatory cytokines with the ability to modulate the antiviral immune response. HCV-specific CD8 T cells that secrete IL-10, a cytokine with suppressive effects on the cell-mediated immune response, have been cloned from the livers of persistently HCV-infected subjects and directly identified within the liver parenchyma (Bowen et al. 2009; Rehermann 2009). Such IL-10 producing HCV-specific CD8 T cells have been demonstrated to suppress in vitro proliferative responses of liver-derived lymphocytes (Bowen et al. 2009). It has been suggested that this population of HCV-specific CD8 T cells may also contribute to viral persistence via impairing the antiviral functions of other virus-specific CD8 T cells.

A wide range of mechanisms have thus been postulated to facilitate evasion of the antiviral responses by HCV and facilitate chronic infection by this pathogen; these are summarized in Fig. 1. Although the level of evidence in support of these potential mechanisms is variable, it is apparent that the hepatitis C virus is able to persist despite the ongoing presence of detectable virus-specific CD8 T cells in many individuals with chronic HCV infection. It is probable that multiple pathways contribute to CD8 T cell failure, including viral escape from selection pressure and functional silencing of virus-specific CD8 T cell responses. Events during the acute phase of infection appear to play a significant role in determining the outcome of infection, pointing toward innate immunity and interactions of HCV with this arm of the immune response as a critical factor in the outcome of HCV infection. In addition, the indispensible role of virus-specific CD4 T cell responses in viral clearance may well be reflected in other phenomena associated with persistent infection, in particular the development of functionally impaired or exhausted CD8 T cell responses and the apparent emergence of CD8 T cell escape mutations in the absence of CD4 T cell help. Further investigations into innate immunity to HCV, the effects of HCV on T cell priming, and the evolution of the HCV-specific immune response will likely clarify the mechanisms underlying HCV persistence.

Pathogenesis of Liver Disease in Chronic Hepatitis C

The hepatitis C virus does not appear to be directly cytopathic. Transgenic expression of



Immune Responses to the Hepatitis C Virus, Fig. 1 Postulated mechanisms by which HCV evades the immune response and establishes persistent infection. Viral evasion of intracellular innate immune pathways may affect the ability of the infected cell to limit viral replication, initiate extracellular innate immune responses, and signal to HCV-specific immune cells. It is likely that impairment of both innate responses and virus-specific CD4 T cell responses is central to viral persistence, while ineffective virus-specific CD8 T cell responses may result from both the development of escape mutations and functional silencing. Modified from Bowen and Walker (Bowen and Walker 2005a)

the HCV polyprotein in mouse livers dose not lead to cytolysis, nor does the virus cause major cytopathic effects in cell culture (Bowen et al. 2009). Nevertheless, replication of HCV can cause endoplasmic reticular stress and oxidative stress (Choi and Ou 2006), which may contribute to hepatocellular injury and associated fibrosis (Tardif et al. 2005). In vitro evidence also suggests that proteins encoded by HCV may contribute to liver injury and fibrosis via a variety of pathways (Choi and Hwang 2006; Spengler and Nattermann 2007).

The contribution of the HCV-specific immune response to liver injury in chronic infection remains unclear. Although HCV-specific CD8 T cells are concentrated within the infected liver in persistent infection, it is thought that they comprise only a minority of the hepatic infiltrate in this condition (Abrignani 1997; Klenerman and Thimme 2012). In addition, studies correlating HCV-specific CD8 T cell responses with markers of hepatocellular injury have been inconsistent (Bowen and Walker 2005a). Nevertheless, this cellular population may play a role in the development of liver disease, mediating hepatocellular injury despite failure to effect viral clearance (Bertolino et al. 2002; Klenerman and Thimme 2012). Reactivation of HCV-related liver disease following withdrawal of immunosuppression and restoration of the host immune response is well documented and often associated with low or undetectable viremia, suggesting immune reconstitution as a cause (Bowen et al. 2009). CD8 T cells from HCV-infected individuals have been shown to mediate autologous hepatotoxicity and bystander killing

of non-antigen-expressing cells (Spengler and Nattermann 2007). Furthermore, Th1-type cytokine mRNA levels have been shown to correlate with the degree of liver fibrosis (Napoli et al. 1996), although the major cellular source of such cytokines has yet to be clarified. Production of the pro-fibrinogenic cytokine TGF-β by HCV-specific T cells has also been hypothesized to play a role in progressive liver injury, although recent in vitro studies have suggested a potential protective effect (Li et al. 2012). Other T cells contained within the immune infiltrate in persistently infected livers have also been suggested as mediators of ongoing injury, including CD161 expressing CD8 T cells via expression of IL-17 (Klenerman and Thimme 2012), and Tregs via production of IL-8 (Langhans et al. 2013). In addition, other cellular populations recruited to the liver during chronic inflammation, in particular macrophages, are also likely to play an important role in mediating hepatocellular injury and ensuing fibrosis (Bowen and Walker 2005a; Dolganiuc et al. 2007).

The pathogenesis of chronic hepatitis and associated fibrosis in chronic HCV infection are as yet not fully delineated. Although viral products may be directly involved in liver injury, persisting antiviral immune responses likely play a central role. However, the relative contributions of antigen-specific and antigen-independent mechanisms to hepatocellular injury in chronic HCV infection remain to be determined.

Conclusion

Despite its relative genetic and structural simplicity, the hepatitis C virus has evolved a remarkable propensity toward persistent infection. It is apparent that components of both the innate and adaptive immune responses are required to mediate viral clearance in the minority of infected individuals who clear HCV, with virus-specific cellular immune responses particularly implicated in resolution of infection. The means by which HCV escapes the immune response have not as yet been fully explained; however, a significant body of evidence now suggests that the virus is able to subvert both the innate and adaptive immune responses. It is hoped that ongoing research will further clarify both the mechanisms of viral clearance and interactions of the virus with the immune system that are central to its persistence, with the ultimate goal of developing a vaccine against this important human pathogen.

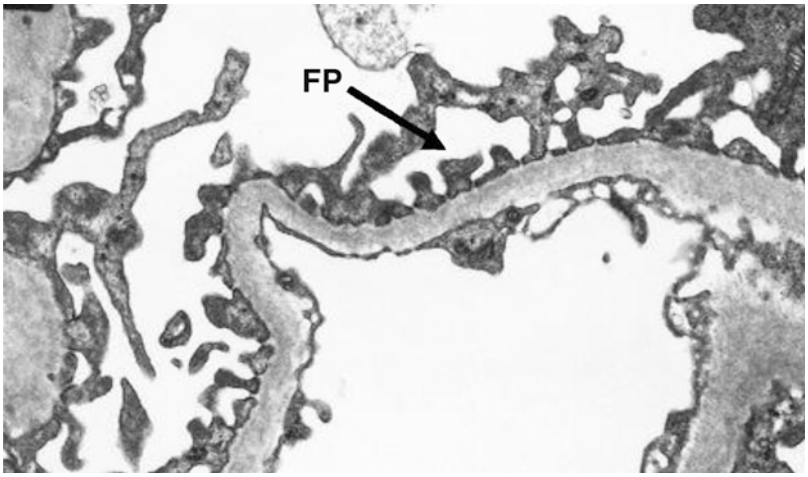
[2]Department of Internal Medicine, Division of Nephrology, The Ohio State University Medical Center, Columbus, OH, USA

Definition

The clinical hallmarks of immune-mediated kidney injury include the appearance of protein and red blood cells in the urine and, in severe cases, impaired kidney function manifested as a rise in serum creatinine or a fall in the glomerular filtration rate.

Perspective

When the immune system attacks the kidney, most commonly the point of attack is the glomerular compartment. The glomeruli are the filtering units of the kidney and in health only allow passage of small molecules such as waste products, water, glucose, and electrolytes. Circulating



Immune System and Kidney, Fig. 1 The Glomerular filtration barrier. An electron-micrograph of the GBM showing the epithelial side with foot processes (FP), slit diaphragms between the foot processes, the thin endothelial layer on the opposite side of the intervening layer of the extracellular matrix material

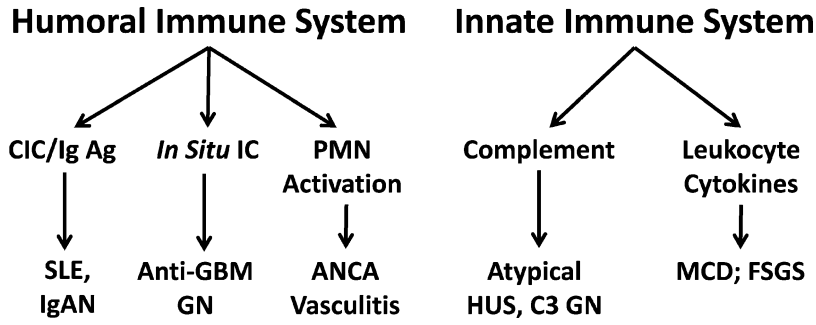
blood cells and serum proteins are largely prevented from crossing the glomerular filtration barrier (GFB). This is made possible because the normal GFB is composed of the glomerular basement membrane (GBM), a unique structure of extracellular matrix material which is sandwiched between a fenestrated endothelial cell layer and the podocytes of the visceral glomerular epithelial cells (Fig. 1). The GFB offers both size and charge selectivity. However, when the GFB is damaged by the immune system, red blood cells, white blood cells, and proteins escape the GFB and pass into the urine. Thus, hematuria and proteinuria are the hallmarks of immune-mediated glomerular injury. In severe cases, hematuria and proteinuria are accompanied by impaired kidney function, clinically manifest as an increased serum creatinine. There are many ways in which the immune system can damage the glomerulus, so hematuria and proteinuria are not specific for any particular type of glomerulonephritis (GN). The precise diagnosis of GN generally requires microscopic examination of kidney tissue, as discussed in the chapter on kidney biopsy (▶ Indications for Biopsy in Autoimmune GN).

The tubulointerstitial compartment of the kidney is also subject to immune-mediated injury. Many of the GNs discussed in this encyclopedia are accompanied by inflammatory or immune damage to the tubulointerstitial space. Chronic damage to the interstitium is associated with chronic kidney disease and predisposes to end-stage kidney failure. Additionally, certain processes not discussed in this section preferentially target the interstitium. An important example is allergic interstitial nephritis. This is essentially an allergic reaction occurring in the kidney's interstitium, often provoked by medications prescribed for other conditions. Allergic interstitial nephritis is important to recognize clinically because it will resolve if the offending agent is removed.

Although multiple components of the immune system are involved in the pathogenesis of most types of GN, these diseases can readily be classified by dominant mechanisms as illustrated in Fig. 2.

Autoantibodies, Immune Complexes, and Glomerulonephritis

Many glomerular diseases are a consequence of autoantibody and immune complex damage. In immune complex diseases, the kidney may be an innocent bystander with circulating immune complexes or immune aggregates initiating damage after depositing in glomeruli. The kidney disease of systemic lupus erythematosus (SLE) represents the prototypical immune complex deposition disease, as discussed in the chapter on lupus nephritis (▶ Lupus Nephritis, Diagnosis and Treatment). Lupus nephritis has several



Immune System and Kidney, Fig. 2 Immune pathways leading to glomerulonephritis. CIC, circulating immune complexes; Ig Ag, Immunoglobulin aggregates; SLE, systemic lupus erythematosus; IgAN, IgA nephropathy; PMN, polymorphonuclear leukocytes; ANCA, anti-neutrophil cytoplasmic antibodies; HUS, hemolytic uremic syndrome; C3 GN, C3 glomerulonephritis; MCD, minimal change disease; FSGS, focal segmental glomerulosclerosis

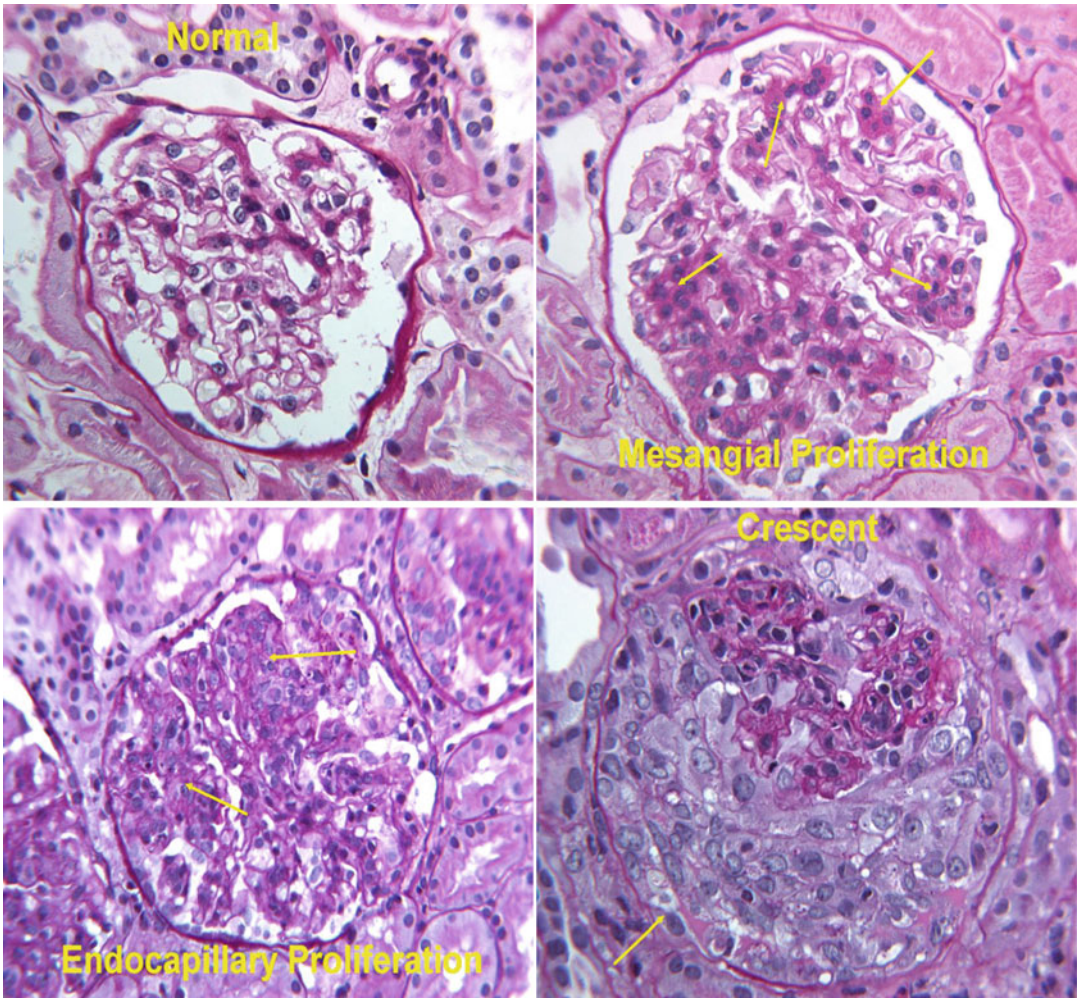
different histologic forms depending on where immune complexes deposit in glomeruli. This is a function of immune complex size, charge, and antigen-antibody affinity. Deposits between the endothelial layer of the GBM and the matrix component (called subendothelial deposits) tend to evoke a very inflammatory response, as they are exposed to circulating immune effector systems such as neutrophils and complement components (Fig. 3). Deposits between the podocytes and the GBM matrix (subepithelial deposits) are somewhat separated from the circulating effectors. These types of deposits do not provoke much inflammation but rather initiate formation of new basement membrane material by intrinsic glomerular cells causing the GBM to become thicker.

In contrast to the pervasive glomerular deposition of immune complexes in lupus nephritis, the immune complex deposition in IgA nephropathy, the most common form of GN in the world, is restricted largely to the glomerular mesangium (Fig. 3). As described in the chapter on IgA nephropathy, these immune aggregates (immune complexes) contain IgA that is antigenic due to aberrant glycosylation of the antibody hinge region (▶ IgA Nephropathy).

Another form of GN in which the immune deposits are restricted to a specific part of the glomerulus is described in the chapter on idiopathic membranous nephropathy. Here, the deposits are subepithelial. In many cases of idiopathic membranous nephropathy the autoantibodies appear to be directed against the podocyte anti-phospholipase A2 receptor. Interestingly, one type of lupus nephritis demonstrates a membranous pattern of immune deposition, but the autoantibodies are not directed against the phospholipase A2 receptor.

In other antibody-mediated GNs, autoantibodies target antigens that are normally expressed by the kidneys. The classic example is anti-GBM disease, in which immune complexes are formed in situ by autoantibodies against exposed neoepitopes in the globular head region of GBM type IV collagen that are usually sequestered. It is not clear how these neoepitopes become exposed. As the chapter on anti-GBM diseases indicates, injury may be restricted to the kidneys or may affect other organs, most commonly the lungs, resulting in a pulmonary hemorrhage-renal syndrome (▶ Anti-Glomerular Basement Membrane Disease).

The theme of antibody-mediated glomerular injury is continued in the chapter on anti-neutrophil cytoplasmic antibody (ANCA)-mediated vasculitis (▶ Vasculitis and the Kidney). These highly inflammatory diseases are often systemic and manifest as pulmonary hemorrhage-renal syndromes. They are characterized by ANCA autoantibodies against neutrophil antigens that activate the neutrophils. But cytokines and the cellular immune system are also actively involved in the pathogenesis of ANCA vasculitis.



Immune System and Kidney, Fig. 3 The glomerular response to mesangial and subendothelial immune complex deposits. A normal glomerulus has an intact Bowman's capsule and open capillary loops. In mesangial immune complex deposition, as may be seen in IgA nephropathy, the *arrows* indicate areas of mesangial proliferation. Endocapillary proliferation, associated with subendothelial immune complex deposition shows no open capillary loops and may be seen in aggressive forms of lupus nephritis. If endocapillary proliferation continues unabated, crescents may form that compress the glomerular capillary network, and breaks of Bowman's capsule (*arrow*) may occur

Thrombotic Microangiopathies

A unique form of glomerular injury, often associated with systemic immunologic disorders is renal thrombotic microangiopathy and is discussed in the chapters covering anti-phospholipid antibody syndrome, scleroderma renal crisis, and TTP/HUS (▶ Scleroderma Renal Crisis). Pathogenic mechanisms include autoantibodies against the endothelium, inability to breakdown von Willebrand factor causing platelet aggregation, and complement dysregulation. These lead to persistent endothelial injury creating an environment that predisposes to microthrombi formation. These microthrombi can obstruct the glomerular capillaries, which causes progressive ischemic kidney injury often associated with hypertension.

The Cellular Immune System

The cellular immune system, possibly through the elaboration of leukocyte cytokines that alter podocyte function and increase glomerular permeability to protein, is thought to play a role in the common childhood GN called minimal change disease (MCD) and the common adult GN known as focal segmental glomerulosclerosis (FSGS) (▶ Spectrum of Minimal Change Disease to Focal Segmental Glomerulosclerosis). However, as pointed out in the chapter on these diseases of the podocyte, mutations of podocyte proteins that affect function of the podocyte filtration barrier are also important and in FSGS, may explain its relative resistance to immunosuppressive therapy.

The Innate Immune System

The innate immune system can impact the kidney in several ways. For many of the antibody-related GNs, complement activation is critical to the pathogenesis of glomerular injury after immune complex deposition. Even in diabetic nephropathy, a major cause of end-stage kidney failure, complement activation, and infiltration of the kidney by immune cells occurs and may be relevant to disease progression (▶ Autoimmunity and Inflammation in Diabetic Nephropathy). Dysregulation of the complement system is also directly involved in certain forms of kidney injury. These defects, either inherited or acquired as described in the chapter on complement, result in uncontrolled complement activation with production of inflammatory products like C5a and the membrane attack complex (▶ Complement Regulation in the Kidney).

Special Circumstances: Kidney Transplantation; Pregnancy

All aspects of the immune system come together in patients who have received a kidney transplant (▶ Impact of Recurrent Autoimmune Diseases in Renal Transplant Outcomes). The chapter on recurrent and relapsing GN in kidney transplant recipients highlights information learned about GN pathogenesis in the setting of pristine glomeruli along with the various forms of immune-mediated organ rejection and how these are addressed clinically.

Pregnancy in patients with immune-mediated kidney diseases is especially challenging. As outlined in the chapter on pregnancy in autoimmune disease, this is an important issue because women during their child-bearing years are often disproportionately affected by autoimmune diseases (▶ Autoimmune Kidney Disease and Pregnancy). Pregnancy may accelerate or activate the underlying autoimmune disease or may accelerate the loss of kidney function in patients with already damaged kidneys from their underlying process. Therapeutic regimens need to be modified to account for fetal well-being. Management of the pregnant patient with autoimmune kidney disease should be undertaken by a multidisciplinary team of physicians, including a high-risk obstetrician, nephrologist, and rheumatologist/immunologist.

Therapy of Immune-Mediated Glomerulonephritis

The therapies of immune-mediated GNs generally involve various combinations of immunosuppressives and corticosteroids (▶ Therapeutic Considerations in Kidney Diseases due to Glomerulonephritis). In some cases, more targeted therapies of specific immune system components have shown promise. Equally important for most forms of proteinuric kidney disease, as discussed in the chapter on kidney protection, control of blood pressure and reduction of proteinuria are crucial ancillary treatments to preserve renal function, especially in cases where immunosuppression does not induce complete remission (▶ Proteinuric Kidney Diseases: Importance of Blood Pressure Control).

In summary, the contributions to this section of the encyclopedia provide a comprehensive picture of how the immune system interacts and injures the kidney, how immune-mediated kidney diseases present clinically, and the therapeutic approaches currently used.

Immune-Mediated Mechanisms of the Metabolic Syndrome

Carey Lumeng
Department of Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI, USA

Synonyms

Adipose tissue; Inflammation; Macrophages; Metabolism; Obesity; Type 2 diabetes

Definition

The origins of metabolic syndrome are closely linked to the activation of proinflammatory innate immune pathways. This entry will review the current state of our understanding about how leukocytes contribute to metabolic diseases associated with obesity.

Metainflammation

The obesity epidemic has resulted in a great need to understand the mechanisms that underlie the development of disease that results from metabolic dysfunction. Metabolic syndrome is defined by a constellation of findings that are the result of maladaptive nutrient regulation. These include dyslipidemia, insulin resistance, hypertension, and central obesity that combine to increase the risk for cardiovascular disease and diabetes. While it has long been recognized that inflammatory markers correlate with metabolic syndrome, the mechanistic contribution of this inflammation to the development of insulin resistance and metabolic disease has been exposed only over the last 10–15 years.

This field of research has revealed common pathways at play in the regulation of nutrient metabolism and immune responses. Both systems are built to achieve a similar end, to maintain homeostasis in an organism in the face of a variety of environmental challenges (e.g., fasting or infection). It has become clear over the years that overlap between metabolic regulation and immune responses may be substantial. Unlocking these commonalities creates opportunities to identify ways to block inflammatory activation associated with obesity and thus uncouple obesity from its negative health effects such as cardiovascular disease and diabetes.

The unique nature of the inflammation associated with metabolic disease has led to the coining of the term "metainflammation" to distinguish obesity-associated inflammation from classical inflammatory response mechanisms. Unique characteristics of metainflammation include the chronic nature of the inflammation, the low-grade inflammatory activation observed, the induction by dietary factors and nutrient composition, and the activation of the inflammatory response in metabolic tissues such as adipose tissue that are not typically thought to have a complex immune network.

Overview of Glucose Metabolism

Metabolic diseases such as type 2 diabetes are the result of the breakdown in the normal homeostatic system that maintains nutrient availability (e.g., circulating glucose) within a very narrow range in times of feeding and fasting. Diabetes results from a breakdown in these systems that lead to an increase in blood glucose levels and a dysregulation of how the body generates and

responds to insulin. Type 1 diabetes is an autoimmune disease that targets pancreatic islets and leads to a loss of insulin production and is not associated with obesity. Type 2 diabetes is strongly associated with visceral adiposity and is the result of a failure of peripheral tissues to respond to insulin and lower blood glucose levels.

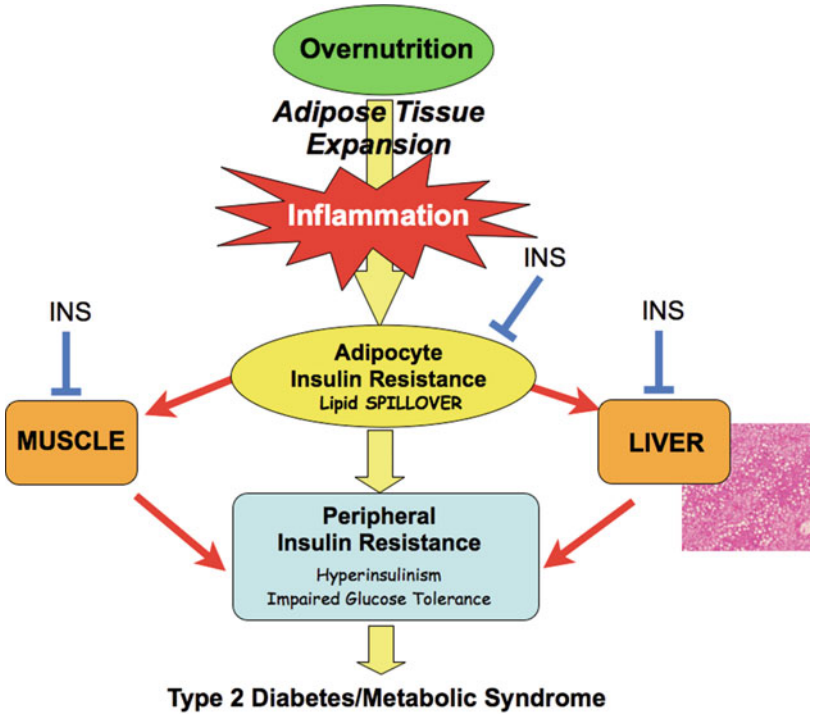
Glucose regulation involves the coordinated function of multiple organs from insulin secreting ß-cells in the pancreas to insulin-responsive tissues that take up glucose from the circulation such as liver, muscle, and adipose tissue. In addition, glucose can be released by the liver, and critical signals from the central nervous system and gastrointestinal system regulate nutrient absorption and utilization. There is evidence that obesity results in proinflammatory activation at multiple control points in this system that combine to limit metabolic flexibility (e.g., how to handle large dietary glucose or fat load).

This review will focus primarily on current understanding of the generation of inflammation in adipose tissue. Adipocytes are the primary energy storage cell in the body that rapidly expand in size and number with nutrient excess. For reasons that are still unclear, adipose tissue hypertrophy is associated with the coordinated activation of inflammatory signals from fat and changes in the function of adipose tissue leukocytes (Fig. 1). The inflammatory signals generated from fat in obesity are diverse and include the production of cytokines such as TNFα, chemokines such as CCL2/MCP1, adipokines such as leptin which can signal to leukocytes, nutrient factors such as saturated free fatty acids, and the suppression of factors with beneficial effects on inflammation such as adiponectin. The net result of adipose tissue inflammation is the impairment of the adipocytes to properly take up, store, and sequester excess nutrients as triglyceride. When this occurs in the face of continued nutrient excess, lipids normally stored in adipose tissue are shunted to other organs not normally designed to handle large lipid loads. Such spillover of lipids contributes to the generation of liver steatosis, lipid droplet accumulation in skeletal muscle, and also the accumulation of lipids in foam cells in atherosclerotic lesions – events that combine to contribute to the morbidities associated with metabolic syndrome. This model has been supported by mouse models which have a profound expansion of adipose tissue in the absence of inflammation that maintains normal glucose homeostasis (Kim et al. 2007b). Overall, this model suggests that by suppressing the inflammatory response to obesity in adipose tissue, adipocyte function can be preserved and the progression towards insulin resistance can be attenuated.

Why is there such overlap between nutrient control and inflammation? Accumulating evidence suggests that many dietary factors associated with obesity can activate the pattern-recognition machinery utilized by the innate immune system to detect pathogens. For example, saturated fatty acids elevated in obesity can bind and activate toll-like receptors TLR4 and TLR2 that lead to NFκB induction (Kim et al. 2007a). Such TLR4 activation can induce the production of intracellular lipids such as ceramides and promote inflammation in multiple tissues (Holland et al. 2011). Fatty acids can also activate the Nod-like receptors and the NLRP3 inflammasome which has been shown to promote insulin resistance through IL-1ß (Vandanmagsar et al. 2011).

Myeloid Cell Contributions to Metabolic Disease

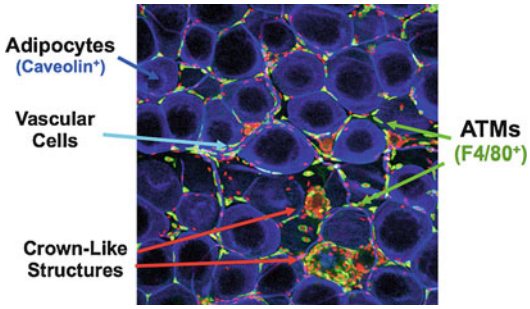
The components of the inflammatory response to obesity were unclear until 2003 when a large population of macrophages were found in adipose tissue in obese patients and rodent models that correlated with inflammation and insulin resistance (Weisberg et al. 2003). This shed light into what is now recognized as an extensive network of leukocytes in adipose tissue that form a large support system of stromal cells for adipocytes (Fig. 2). Adipose tissue macrophages (ATMs) are induced in adipose tissue with obesity and are a main source of inflammatory cytokines such as TNFα. ATM infiltration is more prominent in visceral adipose tissue than



Immune-Mediated Mechanisms of the Metabolic Syndrome, Fig. 1 *Adipose tissue inflammation in the pathogenesis of insulin resistance*. An imbalance between energy uptake and utilization leads to overnutrition. The only tissue designed to store this nutrient excess is adipose tissue which expands via a combination of hypertrophy and hyperplasia. For reasons that are still unclear, this expansion is associated with the triggering of inflammatory signaling cascades as well as an activation of inflammatory leukocytes in fat. Over time, these signals impair the ability of adipocytes to respond to insulin. Such adipocyte insulin resistance leads to increased lipolysis in adipose tissue and the "spillover" of lipids from their normal storage pool in fat to other tissues not normally designed to store lipids. In obesity, tissues such as the liver and skeletal muscle have increased lipid deposition which impairs their ability to properly respond to insulin leading to peripheral insulin resistance seen as impaired glucose tolerance clinically. Over time this puts a stress on the pancreas to produce insulin that can ultimately lead to inadequate insulin production in the fact of insulin resistance which leads to diabetes

in subcutaneous depots, a fact that is important given the associations between visceral adiposity and metabolic syndrome (Aron-Wisnewsky et al. 2009).

An important aspect of ATM biology is the presence of an extensive network of resident macrophages throughout normal adipose tissue development. These resident ATMs (type 2) express surface markers of alternatively activated macrophages (CD206 and CD301) and appear to be dependent upon innate IL-4 production from adipose tissue to provide regulatory functions in fat. With obesity, a distinct ATM population that expresses both F4/80 and CD11c (type 1) are recruited to fat and cluster around dead adipocytes in what are known as crown-like structures (Lumeng et al. 2007a). These ATMs express many classical activation markers and are dependent upon the CCR2/CCL2 chemokine axis for recruitment to adipose tissue in obesity (Weisberg et al. 2005). While these cells express CD11c, it is unclear if these cells have dendritic cell functions. These populational changes in ATMs have led to the model that obesity induces a phenotypic shift in the ATM profile from an M2 to an M1 polarization state. While this is likely an oversimplification of the biology of the system, it has been a useful model from which to frame the problem that has been supported by numerous human and rodent obesity studies.



Immune-Mediated Mechanisms of the Metabolic Syndrome, Fig. 2 *The inflammatory network of adipose tissue*. Confocal microscopy image of visceral adipose tissue from obese mice. C57Bl/6 male mice were fed a high-fat diet (60 % kcal from fat) for 14 weeks prior to imaging. Adipocytes were stained with caveolin (blue). Nuclear stain (PI; red) demonstrates that adipose tissue contains a large number of stromal support cells in direct contact with adipocytes. A dominant population in the fat are F4/80$^+$ adipose tissue macrophages (ATMs; green). These are distributed around adipocytes, along vascular structures, and cluster around dead adipocytes in structures known as crown-like structures

Overall our understanding of the function of ATMs is incomplete. ATMs may play a role in adipose tissue remodeling as experimental ATMs ablation impairs fat angiogenesis and development (Han et al. 2011). There is a coupling between type 1 ATM recruitment and fat cell death. The proinflammatory cytokines made by CD11c$^+$ ATMs contribute to metabolic dysfunction by blocking insulin receptor signaling in adipocytes (Lumeng et al. 2007b). Ablation of CD11c$^+$ ATMs decreased adipose tissue inflammation and led to an improvement in glucose tolerance (Patsouris et al. 2008). Furthermore, there may be a role for adipocytes in the hypoxic response that is associated with fat expansion.

Current models support a model of monocyte trafficking to obese adipose tissue similar to what has been described for atherosclerosis. Obesity induces Ly-6c^{hi} monocytes in the circulation in rodents as well as CD14$^+$CD16$^+$ monocytes in humans (Poitou et al. 2011). Rodent models with attenuation of Ly-6c^{hi} monocytosis have less type 1 CD11c$^+$ ATMs in adipose tissue (Weisberg et al. 2005). This has led to the inference that resident ATMs are derived from Ly-6c^{lo} monocytes, but this has not been directly proven.

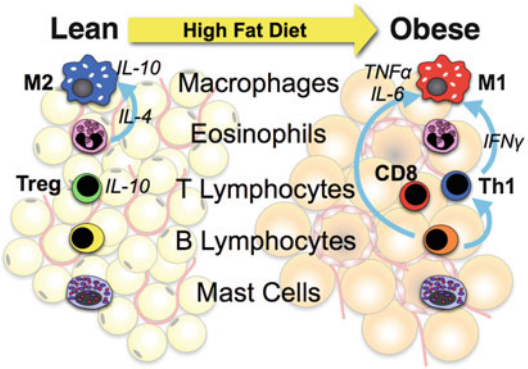
The molecular pathways that contribute to the innate activation of ATMs are varied and include the activation of TLR4, TLR2, and the inflammasome. Obesity induced the activation of NFκB in ATMs specifically which is related to upstream activation signals derived from IKKß as well as noncanonical signaling pathways such as IKKε (Chiang et al. 2009).

Adaptive Immune Responses and Obesity

In mouse models of obesity, ATM induction and activation are most pronounced with prolonged high-fat diet feeding. The possibility that earlier signals derived from adaptive immune responses were suggested by studies investigating the role of adipose tissue lymphocytes in metainflammation (Fig. 3).

CD4$^+$ T cells are found in adipose tissue in smaller quantities than ATMs and undergo similar changes in their profile with diet-induced obesity (Fig. 3). In lean mice and humans, regulatory T cells (Treg) predominate and produce cytokines such as IL-10 which maintain adipocyte insulin sensitivity (Winer et al. 2009). With obesity, fat Tregs decrease in quantity and a population of Th1-skewed conventional T cells (Tconv) are induced (Feuerer et al. 2009). These Tconv secrete IFN-γ which has been shown to contribute to the insulin resistance phenotype induced in obesity (Rocha et al. 2008). The origin of adipose tissue T cells (ATT cells) are not yet established; however, the presence of antigen-specific responses is inferred from evidence that Tconv in fat are clonal and that memory cells are induced with obesity in fat (Yang et al. 2010).

Concurrent with these changes is the induction of adipose tissue CD8$^+$ T cells as well which secrete inflammatory cytokines (Nishimura et al. 2009). This induction appears to be earlier than ATM or CD4$^+$ Tconv in adipose tissue, suggesting that this may be an early initiating event in the cascade of metainflammation. The factors that induce CD8$^+$ cells are not currently known.



Immune-Mediated Mechanisms of the Metabolic Syndrome, Fig. 3 *Leukocyte dynamics in adipose tissue with obesity*. This summarizes the current leukocyte populations identified in adipose tissue and felt to contribute to its function in lean and obese states. Blue lines indicate cross-talk pathways identified between adipose tissue leukocytes to date. Macrophages (ATMs) undergo a populational shift from an M2-dominated state to an M1 state. Eosinophils secrete IL-4 in fat and maintain M2 ATMs in lean mice (Wu et al. 2011). T lymphocytes undergo a populational shift from a Treg dominated to a Th1 and $CD8^+$ T cell-dominated state with obesity. B cells and mast cell also are found in adipose tissue

Finally, recent studies suggest that B cell activation also plays a role in metainflammation (Winer et al. 2011). B cell deficiency was associated with a protection from insulin resistance in rodent models. Evidence suggested that communication between activated B cells and adipose tissue $CD4^+$ T cells may be important for the induction of metainflammation. Surprisingly, an antibody signature was described associated with insulin resistance in humans that further supports a role for adaptive immunity and metainflammation.

Conclusion

To date, almost every leukocyte subtype has been found in adipose tissue, some of which are dynamically changed by obesity, while others are not (Fig. 3). The future challenge is to understand not only how each leukocyte is influenced by nutrient excess but also how these leukocytes communicate and coordinate their responses. Teasing out these connections will take unique approaches given the singular features of metainflammation. Importantly, combining approaches used in the fields of metabolism research and inflammation provides the opportunity to use obesity to tease apart the overlap between metabolic responses and inflammatory signaling. It is the hope that these approaches can benefit the research community while at the same time identifying targets that can be modified to break the link between obesity and disease.

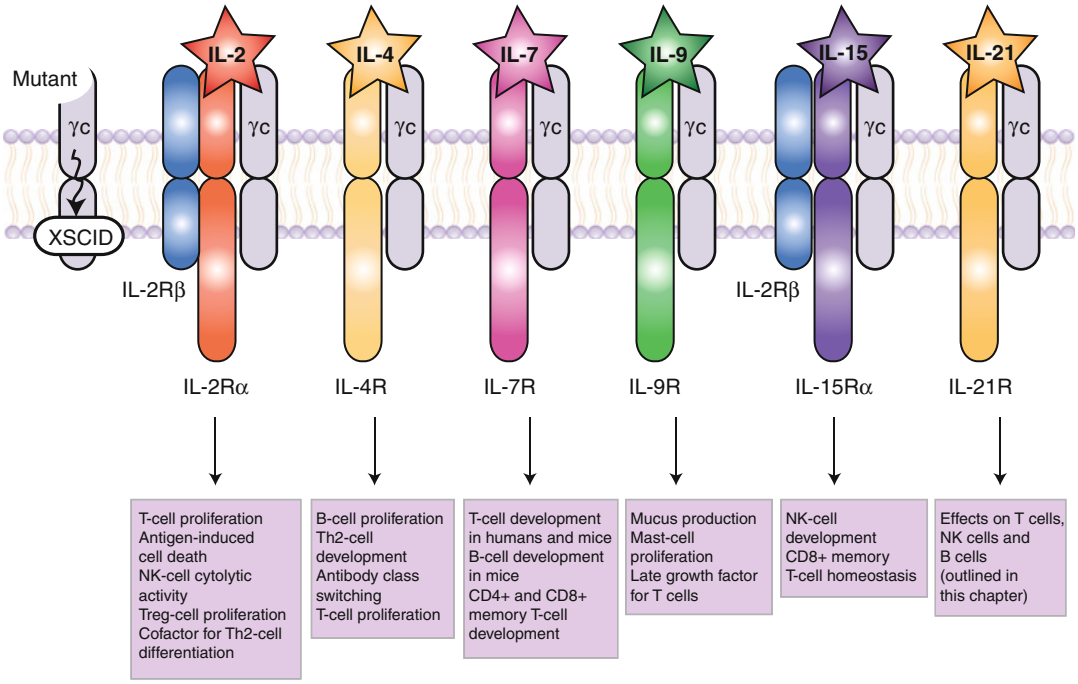
Definition

Interleukin-21 (IL-21) is a cytokine produced by activated $CD4^+$ T cells and NK T cells

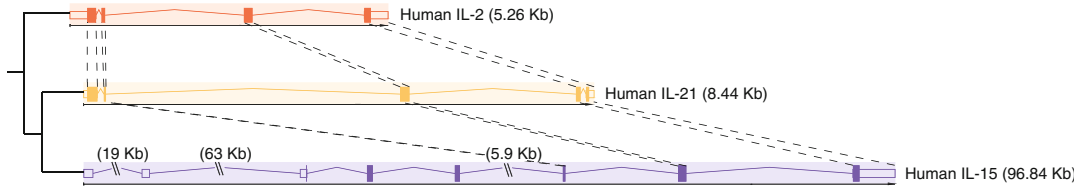


Immunobiology of Interleukin-21, Fig. 1 The common gamma-chain (gc) cytokine receptor family. The IL-21 receptor is a member of a family of receptors that share gc. In addition to gc, each of these receptors has one or more distinctive receptor components. Mutations in gc result in X-linked severe combined immunodeficiency (XSCID); the severity of this disease results from defective signaling through all these receptors (Figure adapted from (Spolski and Leonard 2008))

(Parrish-Novak et al. 2000; Coquet et al. 2007). The IL-21 receptor (IL-21R) is a heterodimeric receptor, which consists of an IL-21-specific IL-21R α-chain and the common γ-chain (CD132) (Asao et al. 2001). Since its discovery over a decade ago, a wide body of literature has provided evidence that IL-21 plays an important role in innate and adaptive immune responses (Leonard and Spolski 2005). This entry focuses on the role of IL-21 in both humoral and cell-mediated adaptive immune responses directed against foreign and self-antigens.

Discovery

In 2000, Ozaki et al. scanned genomic sequences for "virtual" open reading frames (ORFs) and cloned a novel interleukin receptor related to the IL-2Rβ chain. They identified a type 1 cytokine receptor containing typical features, including four conserved Cys residues in the putative extracellular region and the highly conserved Trp-Ser-X-Trp-Ser (WSXWS) cytokine-binding domain (Ozaki et al. 2000). In a parallel study, Parrish-Novak et al. identified an expression tag containing a signal peptide and predicted amphipathic helix as a newly found class 1 cytokine receptor and designated it IL-21R (Parrish-Novak et al. 2000). This gene was also thought to be a signaling subunit, because the intracellular domain included the classic Box 1 and Box 2 motifs, which are important in the signal transduction that is initiated following ligation of cytokine receptors. These characteristics are common to the type 1 cytokine receptor superfamily, which utilize the common γ-chain (γc) as part of the receptor complex as shown in Fig. 1. Located on human chromosome 16p11 downstream of IL-4Rα, the full-length cDNA sequence encodes a 538 amino acid cytokine receptor. IL-21R shows highest identity to IL-2Rβ and IL-4Rα.



Immunobiology of Interleukin-21, Fig. 2 Comparison of the structures of the human IL-21, IL-2, and IL-15 genes. Exons are depicted as *boxes*. Coding regions are *shaded*, and untranslated regions are *open*. The loci are drawn to scale (from Ensembl Genome Browser schematics) except for the large introns in *IL-15*, with the size of each omitted intron as indicated. The tree diagram at the *left* indicates relatedness as measured by alignment of the mature polypeptide sequences (Clustal method, Lasergene software package, DNASTAR) (Figure adapted from (Parrish-Novak et al. 2002))

Using a functional cloning approach, Parrish-Novak et al. identified a ligand for IL-21R, designating it IL-21 (Parrish-Novak et al. 2000). The human *Il21* gene encoded a fully processed mature protein of 133 amino acids (~15,000 MW) and is located on the human chromosome 4q26–27. IL-21 consisted of a four-helix bundle cytokine domain and showed a close relationship to other class I cytokines that also bind the common γ-chain, specifically IL-2 (13.7 % identity) and IL-15 (20 % identity), which have the highest structural and primary sequence similarity to IL-21 (Parrish-Novak et al. 2000) as shown in Fig. 2.

Biological Source of IL-21

IL-21 is produced by $CD4^+$ T cells and NK T cells (Parrish-Novak et al. 2000; Coquet et al. 2007). Once activated, in response to antigen peptide presented in the context of MHC class II molecules on the surface of antigen-presenting cells, $CD4^+$ T cells differentiate into distinct subsets of T helper (Th) cells (e.g., Th_1, Th_2, Th_9, Th_{17}, Tfh). Th cells assist in diverse aspects of adaptive immune responses promoting anti-pathogen activities. NK T cells, in turn, are innate-like T lymphocytes that recognize glycolipid antigens in the context of the CD1 molecule and are thought to influence the adaptive immune response due to their ability to rapidly release cytokines. Interestingly, it has been shown that IL-21 can regulate its own production, in a STAT3-dependent manner (Caprioli et al. 2008). Thus IL-21 production through autocrine amplification can aid $CD4^+$ T cell proliferation and survival (Nurieva et al. 2008; Vogelzang et al. 2008).

Multiple T helper cell subsets have been reported to express IL-21, including T follicular helper (Tfh), Th_{17}, and Th_2 cells (Chtanova et al. 2004; Vogelzang and King 2008), but the Tfh cell subset has been shown to produce the greatest amounts of IL-21 (Chtanova et al. 2004). T_{fh} cells are found in the B cell follicles of secondary lymphoid organs and are important in providing help for the processes of somatic hypermutation and affinity maturation of antibody in B cells during the germinal center (GC) reaction (King 2009). High production of IL-21 by Tfh cells contributes to the T cell help delivered to B cells, as discussed below. Th_2 cells produce cytokines such as IL-4, and Th_2 effector cells are associated with the promotion of IgE and eosinophilic responses against extracellular bacteria, parasites, and toxins in non-lymphoid tissues. By contrast Th_1 cells produce the canonical cytokine IFNγ, assisting macrophages and B cells to clear intracellular pathogens. Th_{17} cells, in turn, produce IL-17, which is involved in the activation, recruitment, and migration of neutrophils, and as such, Th_{17} cells are critical for host defense against extracellular bacteria and fungi. The linear delineation of Th subsets has been recently challenged by information gained from epigenetic studies that provide evidence that Th subsets retain a considerable degree of plasticity (Wei et al. 2009). Plasticity in Th cells that were previously thought to have undergone irreversible lineage commitment emphasizes the

importance of local cellular interactions and other microenvironmental cues in establishing the diversity of Th cell phenotype and function.

IL-21:IL-21R Signaling

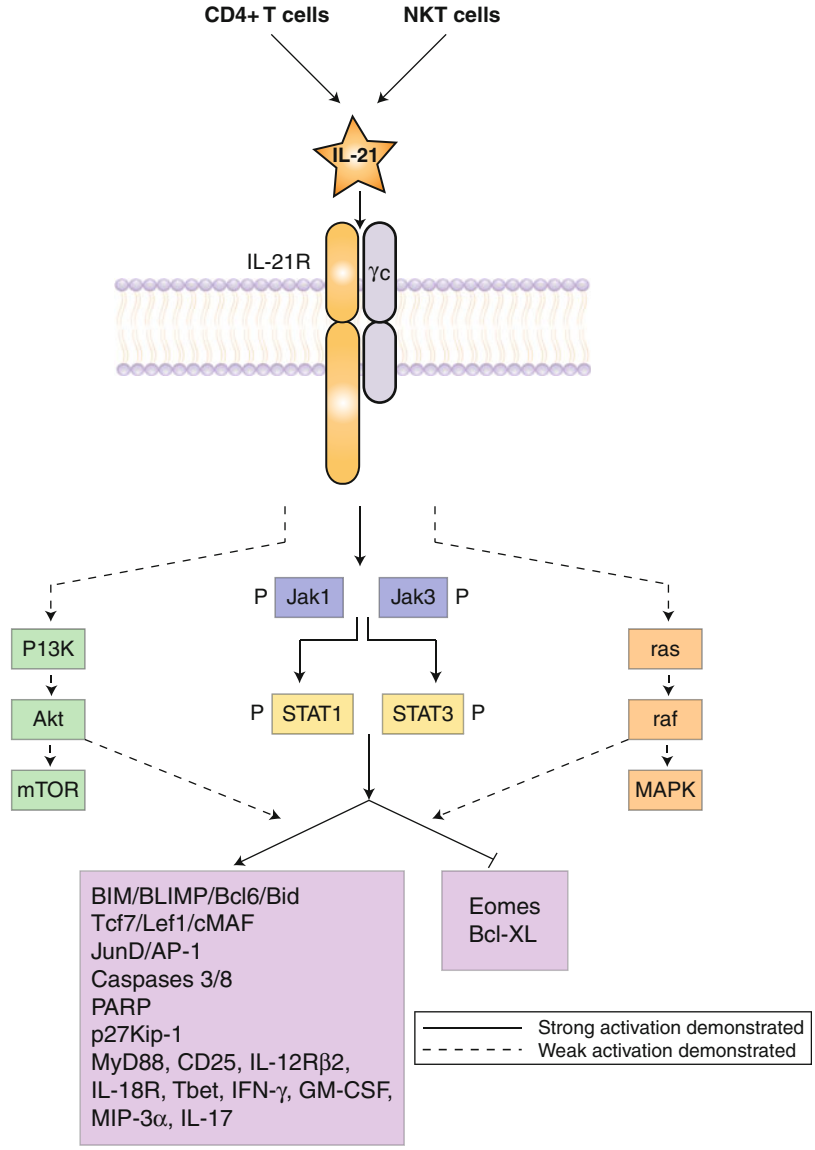
In a series of experiments designed to test the biological properties of the novel cytokine, IL-21 was found to induce proliferative responses in the BaF3, pre-B cell line expressing IL-21R (Parrish-Novak et al. 2000). BaF3 cells, constructed to stably express full-length IL-21R, only initiated a cellular proliferation signal when in contact with its corresponding ligand, IL-21. Conditioned medium from more than 100 primary cells and immortalized cell lines was tested for activity and medium from phorbol myristate acetate (PMA)-/ionomycin-activated human peripheral $CD3^+$ T cells induced proliferation of BaF3/IL-21R cells, but not wild-type BaF3 cells.

IL-21R is expressed on a wide variety of immune cells including B cells, $CD4^+$ and $CD8^+$ T cells, NK cells, dendritic cells, macrophages, and nonimmune cells such as keratinocytes (Ozaki et al. 2000; Parrish-Novak et al. 2000), highlighting the vast influence IL-21 has over a range of cell types. IL-21 acts through signal transduction of its unique receptor chain, IL-21R, in association with (γc), similarly utilized by IL-2, IL-4, IL-7, IL-9, and IL-15, defining it as a member of the IL-2 family of cytokines (Leonard and Spolski 2005). The IL-21R forms a heterodimeric receptor complex with the common gamma-chain and cell lines that lack γc are deficient in IL-21 induced signaling, which can be restored upon reconstitution of γc (Asao et al. 2001). As shown in Fig. 3, binding of IL-21 activates the Janus kinases (JAK)/signal transducer and activator of transcription (STAT) pathway, signaling primarily through STAT1 and STAT3 (Asao et al. 2001; Zeng et al.). The cytoplasmic domain of IL-21R has a membrane-proximal Box 1 motif and six tyrosine residues, implicated as Janus kinase (JAK)-binding sites. The heterodimer IL-21R complex, like IL-15, stimulates activation of JAK1 and JAK3 (Asao et al. 2001). IL-21 has a direct association with JAK 1 since it has been coprecipitated with IL-21R in PHA-activated peripheral blood mononuclear cells (Ozaki et al. 2000). IL-21 activation of JAK3/STAT3 is likely to explain the ability IL-21 to support the survival of both T and B cells during immune responses. STAT3 provides an important counterbalance to STAT5 during the differentiation of T helper cell subsets (Yang et al. 2011). Additionally, phosphatidylinositol-3-kinase (PI3K)-AKT and mitogen-activated protein kinase (MAPK) signaling pathways have been reported to act downstream of IL-21 signaling to influence lymphocyte survival and fate decisions (Zeng et al. 2007).

Role of IL-21 in $CD4^+$ T Cell Immune Responses

Cytokines have an important regulatory role for the homeostasis of hematopoietic progenitor cells (HPCs). HPCs reside in the bone marrow where they undergo proliferation and differentiation to become mature leukocytes and erythrocytes. Upon maturation, leukocytes and erythrocytes are released into the blood to carry out their respective functions. A recent study has described a crucial role for IL-21 in regulating the homeostasis of HPCs (Kaplan et al. 2011). This finding supports earlier observations that mice transgenic for overexpression of IL-21 displayed an increase in hematopoiesis (Ozaki et al. 2006). However, thymic development is normal in mice deficient in IL-21 signaling, suggesting that IL-21 does not play a major role in T cell development or selection (Kasaian et al. 2002; Ozaki et al. 2004). Conversely, evidence supports a role for IL-21 in T cell priming and can costimulate signals delivered through the T cell receptor (TCR). While antigen naïve $CD4^+$ and $CD8^+$ T cells express low levels of IL-21R mRNA, this is markedly upregulated upon T cell receptor (TCR) stimulation (King et al. 2004; Wu et al. 2005).

IL-21 has the ability to influence the differentiation of multiple T helper subsets, including both Th_1 and Th_2 responses. These somewhat diverse outcomes may be attributed to the



Immunobiology of Interleukin-21, Fig. 3 IL-21R signaling pathway. IL-21 signals via the Janus-activated kinase (JAK)/STAT pathway with STAT1 and STAT3 as primary targets. Signaling through the phosphatidylinositol 3-kinase (PI3K) and mitogen-activated protein kinase (MAPK) pathways may also be relevant in certain physiologic or pathologic conditions (Figure adapted from (Davis et al. 2007))

combined effect of IL-21 with other cytokines and signals present in the microenvironment during antigen priming and a broad role for IL-21 in lymphocyte survival as well as differences in the behavior of immune cells in response to IL-21 between in vitro and in vivo conditions (Agnello et al. 2003; Strengell et al. 2004; Pesce et al. 2006; Frohlich et al. 2007).

IL-21 has also been shown to support the generation and/or survival of IL-17A producing (Th_{17}) proinflammatory T helper subset. In vitro studies demonstrated enhanced production of IL-17 in the presence of IL-21, and an ability of IL-21 to substitute for IL-6 in Th_{17} differentiation, which may reflect the ability of both cytokines to activate STAT3. A series of studies indicate a link between IL-21 and the induction and expansion of Th_{17} cells and disease severity in a murine autoimmune model of brain inflammation, experimental autoimmune encephalomyelitis (EAE) (Vogelzang and King 2008). The findings demonstrated a critical role for IL-21 in Th_{17} generation when the key differentiation factor IL-6 was unavailable. By contrast, in the

presence of abundant levels of IL-6, IL-21 was dispensable: *Il21r*$^{-/-}$ mice display normal susceptibility to EAE, shown first by Sonderegger et al. and later confirmed by other groups (Vogelzang and King 2008).

The role IL-21 plays in autoimmune disease may be attributed to its known role in regulating the survival and differentiation of T cells and the generation of antibody-forming B cells (Nurieva et al. 2008; Vogelzang et al. 2008). As discussed below, IL-21 has an important role in the survival and/or differentiation of B cells during the GC reaction. In addition, the autocrine effect of IL-21 on Tfh cell expansion and survival influences the magnitude and output of the GC reaction. GC reactions in models of autoimmunity (Luzina et al. 2001; Vinuesa et al. 2009) may occur in ectopic tertiary lymphoid structures, which have been suggested to provide a site for the generation of self-reactive autoantibodies (Kendall et al. 2007). Interestingly, a novel systemic lupus erythematosus (SLE)-like autoimmune syndrome described in Sanroque mice associates elevated levels of IL-21 with spontaneous germinal center formation and autoimmune pathology (Vinuesa et al. 2005). However, studies from *Il21r*$^{-/-}$ mice indicate that while IL-21 may under normal conditions act to support T_{FH} cells, IL-21-IL-21R interactions are redundant for the generation of T_{FH} cells and GC formation. Similar to Th_{17} generation, other STAT3 signaling cytokines such as IL-6 can act in place of IL-21 for T_{FH} cell generation and survival (Eto et al. 2011). Taken together, studies suggest a contributing role for IL-21 in Tfh cell survival and the persistence of a GC, which is essential for the time-consuming process of somatic hypermutation (SHM) and production of affinity-matured antibodies.

T regulatory cells (Tregs) are critically dependent on IL-2 for their suppressive function and survival. Given that FoxP3 expression is upregulated upon IL-2 signaling through STAT5a/b, it is interesting to find that FoxP3 expression is enhanced in IL-21-deficient mice and IL-21 downregulates FoxP3 expression and inhibits Treg suppressor function (Nurieva et al. 2007). IL-21 has been shown to inhibit TGFβ-driven differentiation of naïve Th cells into Foxp3$^+$ Tregs (Fantini et al. 2007). Additionally, IL-21 was found to be highly effective at overcoming effective at overcoming Treg-mediated suppression of effector T cells by acting directly on the effector population rather than the Tregs (Peluso et al. 2007).

Role of IL-21 in CD8$^+$ T Cell Immune Responses

IL-21 has a profound effect on the expansion of CD8$^+$ T cells (Allard et al. 2007), and while IL-21 is likely to affect both their proliferation and survival, the mechanism by which IL-21 imparts its effects on lymphocytes remains incompletely understood (Vogelzang and King 2008). CD8$^+$ T cell responses to chronic viral infection are sustained in the presence of IL-21. A number of studies have demonstrated a role for IL-21 in supporting chronic, but not acute, responses to viral infections by preventing CD8$^+$ T cell exhaustion (Elsaesser et al. 2009; Frohlich et al. 2009; Yi et al. 2009).

Transgenic overexpression of IL-21 resulted in a predominantly expanded memory-phenotype CD8$^+$ T cell population, as well as increased number of memory-phenotype CD4$^+$ T cells, but, surprisingly, had little effect on B cell numbers (Allard et al. 2007). The expansion of memory-phenotype CD8$^+$ T cells in the presence of excessive IL-21 is likely to reflect both enhanced proliferation and survival. However, CD8$^+$ T cell development appears normal in *Il21r*$^{-/-}$ mice suggesting that while IL-21 can provide a strong survival signal, other factors compensate under homeostatic conditions (Kasaian et al. 2002). Given the essential role of CD8$^+$ T cells in type 1 diabetes (T1D) pathogenesis, it is interesting to note that CD8$^+$ T cells show increased proliferation in NOD mice in response to elevated levels of IL-21 (King et al. 2004; McGuire et al. 2011a, b) and that IL-21 responsiveness by CD8$^+$ T cells was critical for rejection of islet allografts (McGuire et al. 2011b).

In addition to the demonstrated role of IL-21 to costimulate the proliferation of T cells stimulated through the TCR, IL-21 has been shown to

enhance IFNγ production and cytotoxic function of $CD8^+$ effector T cells (Kasaian et al. 2002). IL-21 can also stimulate proliferation and acquisition of cytotoxic effector functions of $CD8^+$ T cells in conjunction with IL-15 and IL-7 (and perhaps IL-2), in both in vitro and in vivo settings (Zeng et al. 2005). The ability of IL-21 to synergize cytokine-mediated proliferation of $CD8^+$ T cells occurs in the absence of overt TCR signaling which suggests that IL-21 may play a cooperative role in antigen-independent expansion. However, these findings have not yet been reproduced with MHC class $I^{-/-}$ cells. Additionally, the activation status of a $CD8^+$ T cell influences its response to IL-21. Combined cytokine effects are more efficient in $CD8^+$ memory T cells; however, these cells are less responsive to IL-21 costimulating antigen dependent proliferation, compared to naïve $CD8^+$ T cells (Liu et al. 2007; Cui et al. 2011).

Role of IL-21 in B Cell Immune Responses

IL-21R is expressed on both immature and mature B cells and further upregulated upon TLR ligand stimulation or antigen binding the B cell receptor (BCR). The seminal paper showing a role for IL-21 in antibody responses showed a significant decrease in IgG1 production in *Il21r*$^{-/-}$ mice following immunization (Ozaki et al. 2002). Mice lacking both IL-4 and IL-21R exhibited a significantly more pronounced phenotype, with dysgammaglobulinemia, characterized by a severely impaired IgG response (Ozaki et al. 2002). The demonstration that IgG production in response to T-dependent antigen is severely compromised in *Il21r*$^{-/-}$*Il4*$^{-/-}$ mice underscores the cooperative nature of IL-21 and IL-4 during the generation of antibody-forming cells (Ozaki et al. 2002). An interesting observation in *Il21r*$^{-/-}$ mice is an increase in the amount of IgE detected in serum following immunization (Ozaki et al. 2002), the dominant isotype produced in allergy and atopy.

Studies utilizing *Il21r*$^{-/-}$ mice have consistently demonstrated that IL-21 has an early role in the survival or differentiation of antibody-forming cells during the GC reaction. However, whether IL-21 predominantly affects the generation of GC B cells, plasma cells, or memory B cells remains controversial. A nonredundant role for IL-21 in the generation of GC and plasma B cells has been demonstrated (King et al. 2010; Linterman et al. 2010; Zotos et al. 2010), whereas other studies have demonstrated that GC B cells do develop and plasma cells can be found in the bone marrow of *Il21r*$^{-/-}$ mice after immunization or infection (Rankin et al. 2011). In addition TLR7 ligation can overcome the requirement for IL-21R signaling in B cells for antibody production following virus infection (Bessa et al. 2010; Rankin et al. 2011). Transgenic expression of IL-21 has been shown to increase the number of IgG1 class-switched B cells and upregulate the germinal centre B cell transcription factor Bcl6 (Ozaki et al. 2004). Excessive levels of IL-21 also lead to preferential differentiation of B cells into plasma cells and Blimp-1 upregulation (Ozaki et al. 2004).

IL-21 has been shown to either assist or hinder B cell responses in vitro, depending on the accompanying activation signals. When paired with the ligation of CD40 in vitro, IL-21 has been shown to increase human B cell proliferation (Parrish-Novak et al. 2000; Good et al. 2006). Conversely, when IL-21 was combined with BCR stimulation or TLR ligands in vitro, B cell responses were reduced. Furthermore, proliferation is inhibited and apoptosis is induced when IL-21 is present in a response against TLR ligands (Leonard and Spolski 2005; Good et al. 2006). Similar to the inconsistent findings on the role of IL-21 in T helper cell differentiation, some of these disparate findings for the effects of IL-21 on B cell behavior may be attributed to the source of antigenic stimulation and the potential for other factors to compensate for IL-21 in vivo.

IL-21 in Chronic Inflammation and Autoimmune Disease

The *Il2*/*Il21* genetic region on chromosome 3 in mice and chromosome 4 in humans has been

identified through genome-wide association studies to be associated with several autoimmune and inflammatory diseases (Hill et al. 2008; Maiti et al. 2010). An association between T1D incidence and the human chromosome 4q27 was initially described, with a subsequent independent case–control cohort confirming this association with patients with T1D and rheumatoid arthritis. Additional autoimmune and inflammatory diseases revealing associations with the *Il2*/*Il21* region include multiple sclerosis, celiac disease, ulcerative colitis, autoimmune thyroid disease (Graves' disease), and systemic sclerosis (Zhernakova et al. 2009). Recent studies have confirmed that the genetic association with lupus within the *Il2*/*Il21* linkage disequilibrium block is localized to IL-21 (Hughes et al. 2011). The gene for IL-21 has also been associated with human T1D (additively to associations with *Il21r*) and other autoimmune diseases including celiac disease, SLE, and a proposed association with multiple sclerosis (Monteleone et al. 2009).

In light of the evidence that IL-21 is redundant for many immune responses, the prominent role of IL-21 in autoimmune diseases remains unexplained. One possibility is that IL-21 can become the dominant voice in autoimmune lesions within non-lymphoid tissue that lay outside the growth factor-rich environment of lymphoid tissue. In this context, IL-21 is known to play an important role in chronic inflammatory lesions (Leonard and Spolski 2005), such as in the pancreas of NOD mice, where responses to elevated levels of IL-21 are associated with spontaneous expansion of T cells, suggestive of ongoing autoreactivity (King et al. 2004). The critical link of T1D disease progression in NOD mice to responsiveness to IL-21 was demonstrated with *Il21r*$^{-/-}$ mice (Datta and Sarvetnick 2008; Sutherland et al. 2009), which were completely protected from disease. A subset of CD4^{+} T cells has been recently described in pancreatic infiltrates of diabetic NOD mice that express the gut-homing chemokine CCR9 and are the major source of IL-21 in the islet lesion (McGuire et al. 2011a). These IL-21-producing CCR9^{+} Th cells were also observed in human lymphoid tissue and were elevated in the peripheral blood of most Sjögren's syndrome patients (McGuire et al. 2011a). The observation of IL-21-producing CCR9^{+} Th cells in the inflamed lesions of both the salivary glands and pancreas suggested a role for IL-21-producing Th cells in directing the regional specification of autoimmune diseases.

Similarly, IL-21 is important in systemic autoimmune diseases; in the BXSB-Yaa mouse strain (Ozaki et al. 2004), a model of lupus neutralizing circulating IL-21 with an IL-21 receptor trap (IL-21R/Fc) delayed disease progression, increasing survival and lowering levels of serum anti-DNA antibodies. Treatment with IL-21R/Fc has effectively reduced disease in numerous murine models of autoimmune disease, including lupus, T1D, EAE, and RA (both collagen-induced arthritis and adjuvant-induced arthritis) (Vogelzang and King 2008; McGuire et al. 2011a).

Following the initial observation of increased IL-21 mRNA in type 1 diabetes-prone NOD mice (King et al. 2004), elevated levels of IL-21 have also been observed in association with human and murine autoimmune diseases and chronic inflammation including rheumatoid arthritis (RA), Crohn's disease, SLE, Sjögren's syndrome (Wang et al. 2007; Vogelzang and King 2008), and autoimmune uveitis (Liu et al. 2009). Elevated IL-21 has also been demonstrated in human inflammatory diseases such as celiac disease, in biopsies of ulcerative colitis patients (Yamamoto-Furusho et al. 2010), and in Crohn's disease, as well as in helicobacter pylori infections, further strengthening the suggestion that elevated levels of IL-21 may play a role in inflammation irrespective of the etiology.

Summary

IL-21 is a pleiotrophic cytokine with an important role in the regulation of the immune system. While the immune system is viewed globally, cytokines generally impart their effects locally – across short distances between cells. The production of IL-21 by CD4^{+} T cells and

the expression of IL-21R on a variety of immune cells indicate that IL-21 is a T helper cytokine that is poised to influence the development and magnitude of immune responses. IL-21 signals through multiple pathways including STAT3/Jak3 and PI3K and is therefore capable of affecting immune cells whose survival and differentiation is influenced by the activation of these pathways, such as B cells and both $CD4^+$ and $CD8^+$ T cells. The contribution of IL-21 to the immune response is influenced by the presence of other cytokine growth factors in the microenvironment that can offer overlapping or synergistic signals to affect cell fate decisions. The observed redundancy for IL-21 during immune responses within secondary lymphoid tissue contrasts with the more prominent influence reported for IL-21 during chronic inflammation within non-lymphoid tissues.

The strong association of elevated amounts of IL-21 with autoimmune and chronic inflammatory disease has led to a considerable number of studies demonstrating that blockade of IL-21-IL-21R interactions can inhibit the development of disease in animal models. The autoimmune and inflammatory diseases shown to be under the control of IL-21 include both organ-specific and systemic diseases that are T cell mediated and B cell mediated. IL-21 remains a promising therapeutic target for treatment of human autoimmune and chronic inflammatory disease as we await the results of ongoing clinical trials.

FHL Familial hemophagocytic lymphohistiocytosis
GIT Gastrointestinal tract
GUT Genito urinary tract
HLH Hemophagocytic lymphohistiocytosis
IBD Inflammatory bowel disease
ICOS Inducible T cell costimulatory
Ig Immunoglobulin
IgAD IgA deficiency
ITP Immune thrombocytopenia
LIP Lymphoid interstitial pneumonia
MGD Midline granulomatous disease
MSH-5 MutS protein homolog 5
NADPH Nicotinamide adenine dinucleotide phosphate
RAG Recombination activating genes
SLAM Signaling lymphocyte-activation molecule
TACI Transmembrane activator and calcium-modulator and cyclophilin ligand interactor
TCR T cell receptor
VZV Varicella-zoster virus
WAS Wiskott-Aldrich syndrome
XLA X-linked agammaglobulinemia
XLP X-linked lymphoproliferative syndrome

Synonyms

Autoimmune disorder; Immune deficiency

Definition

Immunodeficiency is a state in which the immune system's ability to fight infections is compromised due to abnormal function of immune system components.

In autoimmunity the immune system turns against the host's own tissues, cells, or cell components, resulting in prolonged inflammation and subsequent tissue destruction.

Genetic Predisposition to Autoimmunity

Interest in the role immunodeficiency may play in the development of autoimmunity in humans has been revived in recent years. Large-scale genetic association studies, like GWAS (genome-wide association studies) and whole genome sequencing, have highlighted the importance of genetics in the development of autoimmunity. This is confirmed by familial clustering and higher rates of concordance in monozygotic compared to dizygotic twins in patients with autoimmune disorders. Although contribution of the genetic component in each disorder is not equal (e.g., monozygotic twin

concordance is 5 % in systemic sclerosis and 40 % in type 1 diabetes mellitus (T1DM)) it represents a key element in all of them.

A large number of genes have been found to contribute to the development of autoimmune disorders in recent years (Tables 1 and 2). The vast majority of those are genes related to the immune system. Although the effect gene polymorphisms have on the immune system's development and function has not been delineated yet, it is hypothesized that, at least in some cases, these variations may allow for a minor immunodeficiency state to develop (Grammatikos and Tsokos 2012). In contrast to primary immunodeficiency syndromes which are associated with severe single-gene defects and result in outright immune system dysfunction, the widespread single nucleotide polymorphisms and gene variants seen in autoimmune patients seem to result in subtler immune system abnormalities. The cumulative effect of these gene polymorphisms seems to be an immune system with decreased capacity to fight infections.

Infections in Autoimmune Diseases

Patients in most autoimmune disorders experience a higher rate of infections than healthy individuals (Sfriso et al. 2010). Even opportunistic pathogens normally observed in immunocompromised patients (e.g., *Toxoplasma gondii, Pneumocystis carinii*, and *Cryptococcus neoformans*) are encountered in some cases. Although traditional risk factors, like immunosuppressant therapy, certainly contribute, they do not seem to be sufficient to explain this increased susceptibility. The higher frequency of immune system defects in these patients provides a more likely explanation.

Indeed, multiple links between infectious microorganisms and almost all autoimmune disorders have been discovered (Tables 1 and 2). Although what drives this association is still uncertain, it is postulated that a lowered immune system defense level may be allowing for multiple infections to develop and for inflammation to persist. These infections, both at a clinical and a subclinical level, may represent the primary trigger for the development of autoimmunity (Fig. 1). Established examples of autoimmunity that follows infection include rheumatic fever presenting after *Streptococcus pyogenes* infection and Guillain-Barre syndrome after *Campylobacter jejuni*, *HIV*, *CMV*, or *Hemophilus influenza infection.*

A number of pathways exist that can allow a localized inflammation to spread systemically and an immune response against a foreign antigen to turn toward self-antigens (Munz et al. 2009). Among those, epitope spreading, molecular mimicry, bystander, and superantigen activation. Epitope spreading refers to the ability of antigen presenting cells to present multiple antigenic determinants from a single foreign agent's protein and not just the one responsible for their activation, allowing for multiple T cell-specificities to be activated. Superantigens, on the other hand, are antigens that have the inherent property to directly cross-link multiple T cell receptors and activate multiple T cell clones. In bystander activation, it is apoptotic material from host cells presented by antigen presenting cells in the context of inflammation that are believed to allow for autoreactive T cells to develop. Finally, molecular mimicry refers to the process of generation of autoreactive T cell clones owing to sequence similarities of self-antigens with foreign epitopes.

Despite the fact infectious diseases are very common, autoimmunity only develops in a small fraction of the population. Existence of an underlying immune dysregulation in the subgroup of individuals that develop autoimmunity could explain this disparity. Autoimmunity is also commoner than generally thought: although only 3 % of the population is affected by autoimmune diseases, many more are found to harbor autoantibodies without any clinical manifestations.

Apart from genetic predisposition, it seems that environmental influences (e.g., diet or psychology) alter the manifestation of autoimmunity in each patient. Exposure to these factors is thought to begin long before disease development. For instance, a number of reports have been published on the presence of autoantibodies

Immunodeficiency in Autoimmune Diseases, Table 1 Genetic polymorphisms and microorganisms linked to autoimmune disorders

Systemic diseases	Associated genes	Associated infections
▶ Ankylosing spondylitis	HLAB27, NOD2, TNFa, MMP3, TGFβ, IL1	*Enterobacteria, Chlamydia, Shigella, Salmonella, Klebsiella pneumoniae*
Autoimmune cytopenias (anemia, thrombocytopenia, neutropenia)	HLAA2, HLADRB1, FCGR2A, FCGR3A	*Helicobacter pylori, HIV, HCV*
Myasthenia gravis	PTPN22, CTLA4, HLAB8, HLADR3, HLADR1, FCGR2A, FCGR3A, FCGR3B, IL10	*HCV, HSV*
Polyglandular autoimmune syndrome type I	AIRE	*Candida albicans, Rubella*
Rheumatoid arthritis	STAT4, IRF5, UBE2L3, HLADR4, TRAF1, REL, PTPN22, CTLA4, BLK, CCL21, CD40, IL2, PRKCQ, CD28, PDCD1, TNFSF14	*EBV, CMV, HCV, Escherichia Coli, Proteus* sp., *Mycobacteria, Parvovirus B19*
Scleroderma	HLADRB1, HLADQB1, STAT4, TBX21, IRF5, PTPN22, BANK1, BLK, CD247	*EBV, CMV, Parvovirus B19, H. pylori*
Sjögren's syndrome	HLADR3, IRF5, IL10, IL1, MECP2	*EBV, H. Pylori, Coxsackie B3*
Systemic lupus erythematosus	C2,C4A, C4B and C1q deficiencies, FCGR3B, STAT4, TREX1, TLR 7/8, IRAK1, SLC15A4, IFIH1, IRF5, STAT4, STAT1, TYK2, UBE2L3, HLADR2, PD1, PTPN22, PDCD1	*EBV, CMV, Rubella, Parvovirus B19*
Giant cell arteritis/ polymyalgia rheumatica	HLADRB1, RANTES, ICAM1, IL1 RN	*EBV, Chlamydia pneumoniae, Parvovirus B1, HHV*
Granulomatosis with polyangiitis and microscopic polyarteritis	IL10, IL7R, NOTCH1, ITGA2	*EBV, CMV, Toxoplasma, Parvovirus B19, Staphylococcus aureus, Pseudomonas aeruginosa, Haemophilus influenzae*
Organ-specific diseases	Associated genes	Associated infections
Addison's disease (idiopathic)	CIITA, CTLA4, HLADR3, PTPN22, HLADR, HLADQ	
Autoimmune hepatitis	HLAB8, HLAB14, HLADR3, HLADR4, HLADW3, C4 deficiency, CD45	*Measles, HCV, HBV, HSV, VZV, CMV, and EBV*
Autoimmune thyroiditis (Graves' and Hashimoto's disease)	CTLA4, IFIH1, PTPN22, HLADR5, HLADR3	*HCV, HIV, H. pylori, Campylobacter jejuni, Yersinia enterocolitica*
Celiac disease	HLADQ2, HLADQ8, IRF4, UBE2L3, CTLA4, TNFSF14	*HCV, Adenovirus 12, Rotavirus, Human intestinal adenovirus*
IBD (Crohn's disease and Ulcerative colitis)	NOD2, CARD9, IRF5, STAT4, STAT3, JAK2, UBE2L3, TNFSF15, FCGR2A, ORMDL3	*HCV, CMV, H. Pylori, Y. enterocolitica, Mycobacterium avium paratuberculosis, C. difficile*
Multiple sclerosis	CLEC16A, IRF5, IRF8, STAT1, STAT3, TYK2, HLADR2	*EBV, HSV6, Measles, Chlamydophila pneumoniae*
Psoriasis	DEFB4 (high copy number), STAT4, HLAB13, HLAB17, HLACW6	*Group A β-hemolytic streptococcus, HIV, CMV*
Type 1 diabetes	IFIH1, CLEC16A, STAT4, TYK2, CTLA4, PTPN22, HLADQ8, HLADQ2, HLADQ6, CD247	*Enterovirus, Rotavirus, CMV, Mumps, Rubella*

Immunodeficiency in Autoimmune Diseases, Table 2 Genetic polymorphisms linked to autoimmune disorders: role of the encoded proteins

Gene	Full name	Function of encoded protein
AIRE	Autoimmune regulator	Transcription factor responsible for expression of self-antigens in thymus
BANK1	B cell scaffold protein with ankyrin repeats	Involved in BCR-induced calcium mobilization
BLK	B lymphoid tyrosine kinase	Involved in cell proliferation and differentiation
C1q, C2, C4	Complement components of the classical pathway	Involved in protection from bacteria, causing chemotaxis, opsonization, cell lysis, etc.
CARD9	Caspase recruitment domain-containing protein	Involved in TLR-NOD2 signaling
CCL21	Chemokine (C-C motif) ligand 21	Chemokine involved in attracting thymocytes and activated T cells
CD247	CD3ζ chain	Cell signaling molecule involved in TCR signaling
CD28	T-cell-specific surface glycoprotein	Activating surface costimulatory molecule found on T cells
CD40	TNF receptor superfamily member 5	Costimulatory molecule on antigen presenting cells
CD45	Protein tyrosine phosphatase	Different CD45 isoforms expressed by naïve, effector cells, and memory T cells
CIITA	Class II transactivator	Transcriptional coactivator of MHCII genes
CLEC16A	C-type lectin domain family 16 member A	C-type lectin that contains carbohydrate recognition domains
CTLA4	Cytotoxic T lymphocyte antigen 4	Inhibitory cell surface costimulatory molecule found on T cells
DEFB4	Beta-defensin 4	Secreted antimicrobial peptide
FCGR 2A/3A/3B	Immunoglobulin G Fc receptor	Cell surface receptor for antibodies
HLA	Human leukocyte antigen	Cell surface molecule that presents antigens to T cells
ICAM1	Intercellular adhesion molecule 1	Cell surface glycoprotein functioning in lymphocyte tissue transmigration
IFIH1	Interferon-induced helicase	Enzyme that contributes to apoptosis of virally infected cells
IL1	Interleukin 1	Cytokine with role in inflammation, bone remodeling, insulin secretion, etc.
IL1 RN	IL1 receptor antagonist	Inhibits the activities of interleukin 1, alpha (IL1A), and interleukin 1, beta (IL1B)
IL2	Interleukin 2	Necessary for the growth of T cells and the maintenance of T regulatory cells
IL7R	Interleukin 7 receptor	Involved in V(D)J recombination during lymphocyte development
IL10	Interleukin 10	Antiinflammatory cytokine/stimulates B cell maturation and antibody production
IRAK1	Interleukin 1 receptor-associated kinase	Protein kinase that links TLR signaling to TRAF6
IRFs	Interferon regulatory factors	Transcription factors involved in virus-mediated activation of interferon production pathways
ITGA2	Integrin alpha 2	Cell surface protein involved in cell adhesion
JAK2	Janus kinase 2	Involved in transmitting signals from various cytokines, growth hormones, etc.
MECP2	Methyl-CpG-binding protein 2	Binds to methylated DNA/transcriptional repressor and activator
MMP3	Matrix metalloproteinase-3	Involved in the breakdown of extracellular matrix
NOD2	Nucleotide binding and oligomerization domain	Cytoplasmic receptor for peptidoglycans on bacterial cell walls

(*continued*)

Immunodeficiency in Autoimmune Diseases, Table 2 (continued)

Gene	Full name	Function of encoded protein
NOTCH1	Notch homolog 1, translocation-associated	Plays multiple roles in tissue development/induces T cell proliferation
ORMDL3	ORM1-like protein 3	Believed to regulate endoplasmic reticulum-mediated Ca^{+2} signaling
PD1	Programmed death 1	Membrane protein that negatively regulates immune responses
PDCD1	Programmed cell death protein 1	Cell surface protein/plays a role in B cell differentiation
PRKCQ	Protein kinase C theta	Phosphorylates various proteins/important for T cell activation
PTPN22	Protein tyrosine phosphatase, nonreceptor type 22	Protein tyrosine phosphatase that alters the responsiveness of T and B cell receptors
RANTES	Regulated upon activation, normal T cell expressed, and presumably secreted	Chemokine that induces chemotaxis of T cells, ▶ eosinophils, and basophils
REL	v-rel reticuloendotheliosis viral oncogene homolog	Member of the NF-κB family of transcription factors
SLC15A4	Solute carrier family 15, member 4	Transporter of NOD1 ligands in early endosomes
STATs	Signal transducers and activators of transcription	Transcription factors activated in response to cytokines and growth factors
TBX21	T cell specific T-box transcription factor	Transcription factor that regulates Th1/Th2 balance
TGFβ	Transforming growth factor beta	Cytokine involved in regulation of cell cycle, differentiation, and apoptosis
TLRs	Toll-like receptors	Recognize specific components conserved among microorganisms
TNFa	Tumor necrosis factor a	Pleiotropic inflammatory cytokine
TNFSFs	Tumor necrosis factor superfamily ligands	Stimulate the proliferation of T cells/ promote activation of caspases and apoptosis
TRAF1	TNF receptor-associated factor 1	Mediates signal transduction from receptors of the TNFR superfamily
TREX1	Three prime repair exonuclease 1	3–5 exonuclease responsible for proofreading during genome replication
TYK2	Tyrosine kinase 2	Tyrosine kinase implicated in cytokine signaling
UBE2L3	Ubiquitin-conjugating enzyme E2L 3	Degradation of NFκB precursor/suppression of innate immune response(?)
